Hepatitis Viruses: Hepatocellular Carcinoma

34

Ju Dong Yang, Roongruedee Chaiteerakij, and Lewis R. Roberts

1 Introduction

Liver cancer is the fifth most common cancer in men and the Eighth in women. The estimated number of new liver cancer cases worldwide has increased by 70 % between 1990 and 2008. It has been projected that the number will increase by 30 % to one million new cases in 2020. Viral hepatitis is the most common cause of hepatocellular carcinoma (HCC) in the world. Hepatitis B virus (HBV) is the most common etiology of HCC in most Asian and African countries and accounts for more than half of all HCCs in the world. Hepatitis C virus (HCV) infection is the leading cause of chronic liver disease and HCC in most Western countries including the USA. The prevalence of HCV infection has increased and the proportion of patients with liver cirrhosis or HCC from HCV has also increased in the USA over the past several decades. Carcinogenesis is a complex and multistep process involving a sequence of tumor initiation, promotion, and progression over several years. Common molecular mechanisms of HCC occurring in the cirrhotic liver include cell-cycle dysregulation, sustained angiogenesis, apoptosis resistance, and cellular immortalization through reactivation of telomerase reverse transcriptase. In HBV- and HCV-induced hepatocarcinogenesis, the interplay between HBV and HCV, the host immune response to infection, and chronic inflammation in the liver contribute to malignant transformation. HBV and HCV are involved in carcinogenesis directly through induction of genetic mutations and through oncogenic effects of viral proteins. Indirectly, both viruses share some common carcinogenesis pathways, in particular, chronic inflammation, oxidative stress, and tumor suppressor gene *p53* inactivation. The goal of HCC surveillance is to decrease HCC mortality through the early detection of HCC in asymptomatic patients. In real-world practice, the majority of at risk individuals are not under HCC surveillance and HCC is usually detected at a late stage when patients become symptomatic from advanced HCC. There is strong evidence that HCC surveillance increases the early detection of tumors and improves survival in patients with HCC. However, the efficacy of HCC surveillance is still controversial mainly because of the lack of robust level 1 evidence supporting the use of HCC surveillance. Noninvasive diagnosis of HCC in individuals with cirrhosis can be made by contrast-enhanced four phase CT (non-contrast, arterial, portal, and delayed phases) or dynamic contrast MRI. Arterial enhancement and portal venous or delayed phase washout are highly specific characteristic features of HCCs. Percutaneous liver biopsy is indicated when lesions (>1 cm) develop without background liver cirrhosis or dynamic imaging modalities show inconclusive results. The treatment of HCC depends on multiple factors, including the tumor extent, severity of liver dysfunction, performance status of the patient, socioeconomic support, and the availability of different types of treatment. Surgical resection, liver transplantation, and local ablative treatment are potentially curative treatment modalities for patients with early-stage HCC. Transarterial chemoembolization and radioembolization are locoregional treatment modalities applicable for patients with intermediate-stage

HCC. Sorafenib is a targeted systemic treatment that is offered to patients with advanced stage HCC.

2 Historical Background of the Association Between Viral Hepatitis and Hepatocellular Carcinoma

A possible association between hepatitis B virus (HBV) infection and hepatocellular carcinoma (HCC) development was first reported in the 1950s [1]. Subsequently, the association between HBV infection and HCC was supported by several epidemiologic studies in the 1970s, mostly from Africa and Asia [2–6]. A causal relationship between HBV infection and HCC was confirmed by a Taiwanese prospective study showing that HBV-infected patients had a 98.4-fold increased risk for developing HCC compared to individuals without HBV infection [7]. There is also a lower but nevertheless increased risk of HCC associated with chronic HBV carrier status [8]. The relationship between hepatitis C virus (HCV) infection and HCC was first noted in the early 1980s [9, 10]. As HCV (then described as non-A, non-B chronic hepatitis) became endemic in Japan in the late 1940s and early 1950s, the majority of the early evidence of a causal link between HCV and HCC was from studies performed in Japan. Due to the lag time of 20–40 years between the establishment of chronic HCV infection and the development of HCC, a dramatic increase in HCC-related mortality in Japan occurred beginning in the 1970s and most of these HCCs developed in patients with non-A, non-B hepatitis [11]. Subsequent to the identification of the hepatitis C virus in 1990 and the development of specific assays for the infection, among those with chronic non-A, non-B hepatitis, antibody to HCV (anti-HCV) was detected in 94.4 % [10]. Epidemiologic studies from Spain and Italy also reported that 61–75 % of HCC patients were positive for anti-HCV [12–14]. The initial causative role of HCV infection in HCC development was supported by a Japanese study showing that HCV RNA was detected in HCC tissue and the surrounding noncancerous liver tissues of patients with HCC [15]. A meta-analysis of 32 case-control studies published between 1993 and 1997 concluded that chronic HBV-infected patients had 13.7-fold increased risk for HCC compared to individuals without chronic HBV infection, and HCV-infected patients had 11.5-fold increased risk for HCC compared to individuals without HCV infection [16]. This meta-analysis also reported that the risk for HCC increased to 165-fold for those infected with both HBV and HCV, indicating a synergistic interaction of HBV and HCV coinfections on the risk for HCC development [16]. Given the evidence for the association between HBV and HCV infections and HCC risk, both HBV and HCV were classified as human carcinogens by the International Agency for Research on Cancer (IARC) in 1994 [17]. A different meta-analysis found that HBV and HCV infections increase HCC risk by 13.5-fold and 12.2-fold, respectively, while HBV and HCV co-infections additively increase the HCC risk by 51.1-fold [18].

3 Incidence of HCC

Worldwide, liver cancer is the fifth most common cancer in men and the eighth in women [19]. The global incidence of HCC has been rising, from 437,408 cases in 1990 to 782,000 in 2012. HCC cases are projected to increase further to 997,955 new cases by 2020 and 1,251,520 new cases by 2030 [19]. The trends in HCC incidence reflect the temporal and geographical changes in prevalence of risk factors for HCC. The rising incidence is primarily occurring in countries with low and intermediate HCC incidence. In the USA, the annual HCC incidence has been shown to have increased by threefold between 1975 and 2005 (1.5–4.9 cases per 100,000 persons) [20]. Indeed, a study from Olmsted County, Minnesota, has confirmed the increasing trend of HCC incidence, showing that the incidence of HCC increased from 3.5 to 6.9 per 100,000 person years between 1976 and 2008 [21]. In England and Wales, the HCC incidence increased by 46 % between 1971 and 2001 in males (1.8 to 2.7 cases per 100,000 persons) and increased by 8 % in females (0.8 to 0.9 cases per 100,000 persons) [22]. The rising trend in HCC in these countries is mainly attributable to HCV infection. It has been projected that the HCV-related HCC incidence in the USA will peak in 2015–2020 and then gradually decline [23].

In contrast to the rising trends of HCC incidence in low and intermediate prevalence areas, the opposite trends have been observed in high-prevalence countries. For example, the age-standardized HCC incidence in Japan declined steadily between 1995 and 2005 from 41.5 to 24.0 cases per 100,000 persons among men and from 10.8 to 7.3 cases per 100,000 persons among women [24]. These declines are attributed to the marked reduction in the incidence of HCV infection after implementation of a nationwide primary prevention program [24]. Similarly, a gradual decline in HCC incidence has also been observed in Taiwan where HBV is the major cause of HCC. Within 10 years after initiation of a nationwide vaccination program, the HCC incidence in children aged 6–14 years had decreased dramatically from 0.76 per 100,000 in the period from 1982 to 1986 to 0.36 per 100,000 in the period from 1990 to 1994 [25].

The overall incidence of HCC rises sharply after age of 40 and increases with age in both genders [19]. The incidence peaks at age 70 and then declines [20]. The age distribution of HCC varies worldwide. Several factors, including gender, age at HBV or HCV infection, and coexistence of other risk factors, account for the global variations in the peak age of

onset. The peak age of onset in Africa, another region where HBV is a major cause of HCC, is generally younger than in other parts of the world, suggesting that viral, genetic, environmental, or other risk factors may modify the risk for HCC development. For example, the peak age of onset in Mali is 40 years [26].

4 Geographical Variation of HBV and HCV-Induced HCC

Although HCC develops in all regions around the world, substantial global variation of HCC incidence is observed (Fig. 34.1). Over 85 % of HCC cases occur in East and Southeast Asia and in Middle and Western Africa, whereas the incidence is much lower in Europe (with the exception of South Europe), South America, North America, Australia, and New Zealand [19]. The variation in geographical distribution of HCC is explained by the prevalence of specific risk factors, in particular, chronic HBV and HCV infections. A strong correlation between HCC incidence and prevalence of chronic HBV and HCV infections has been reported (Fig. 34.1). It was estimated that 75–80 % of HCC cases worldwide are associated with either chronic HBV (50–55 %) or HCV (10–25 %) infection, while the global prevalences of HBV and HCV are about 6 and 3 %, respectively [27]. Most countries in Asia, except for Japan, Pakistan, and Mongolia, have a higher proportion of HBV-related HCC than HCV-related HCC. HBsAg seropositivity among HCC patients was 27–64 % in India, 53 % in Taiwan, 52–66 % in Turkey, 58–60 % in Thailand, 59–67 % in China, 62–82 % in Korea, and 61–93 % in Vietnam, whereas anti-HCV positivity was approximately 2 % in Vietnam, 5–15 % in Korea, 3–10 % in China, 4–53 % in India, 19–29 % in Turkey, 28 % in Taiwan, and 5–10 % in Thailand among HCC patients in these countries [28]. By contrast, only 18 % of HCC cases in Japan and approximately 30 % of HCC cases in Pakistan and Mongolia were positive for HBsAg. Japan had the highest proportion of HCC cases positive for anti-HCV (68 %) and anti-HCV positivity of HCC patients was 45 % in Pakistan and 40 % in Mongolia. Of the Asian countries, HBV and HCV coinfection was most commonly found in Mongolia (25 %) [28]. Similar to Asian countries, most countries in Africa have a much higher prevalence of HBV-related HCC cases than HCV-related cases. HBsAg positivity in HCC cases was approximately 65 % in Mozambique, 60 % in the Gambia, 45 % in South Africa, and 42 % in other African countries. The only exception is Egypt where the proportion of HCC cases with HBsAg+ was only 10 %. Egypt had the highest proportion of HCC cases with anti-HCV+

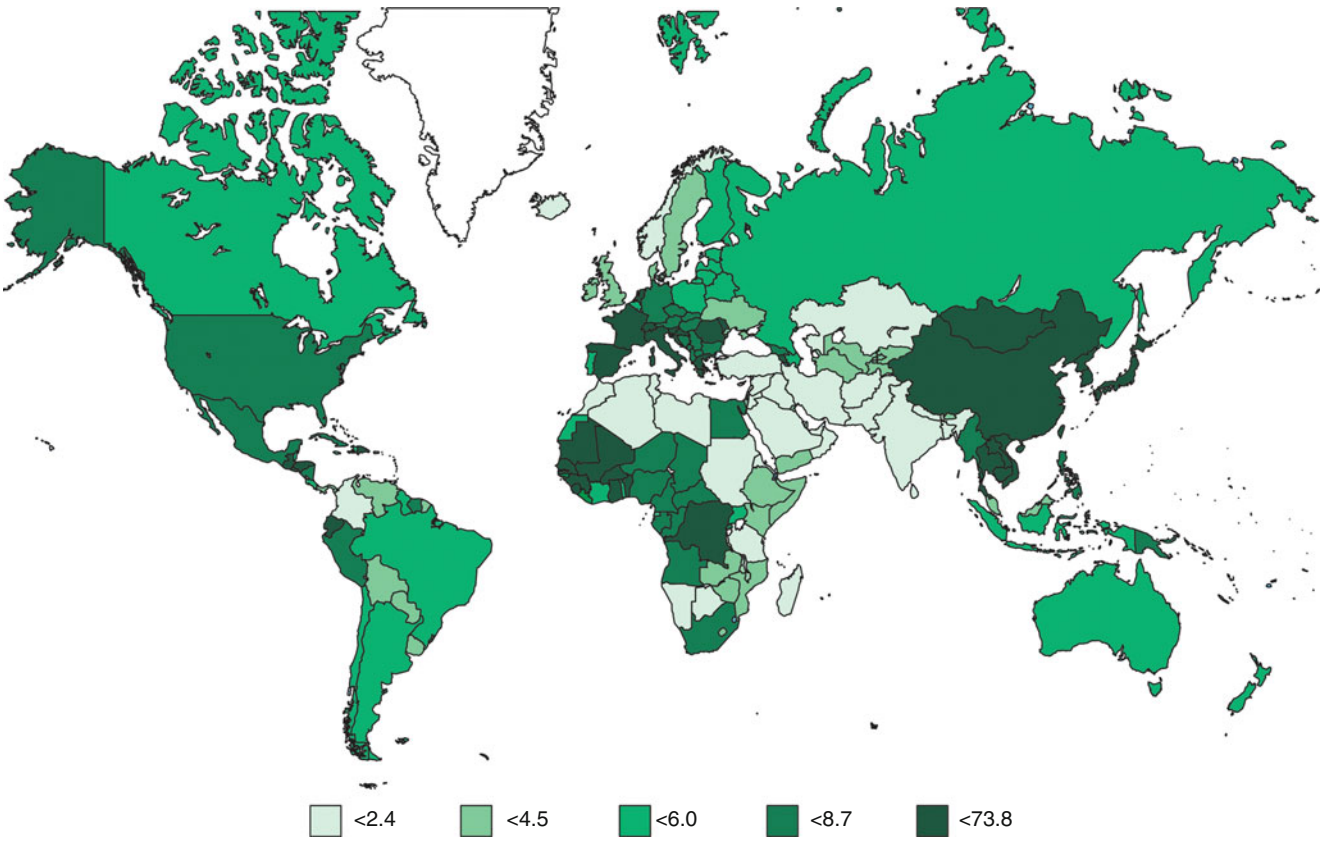

Fig. 34.1 (**a**–**c**) Worldwide incidence of HCC and prevalence of HBV and HCV

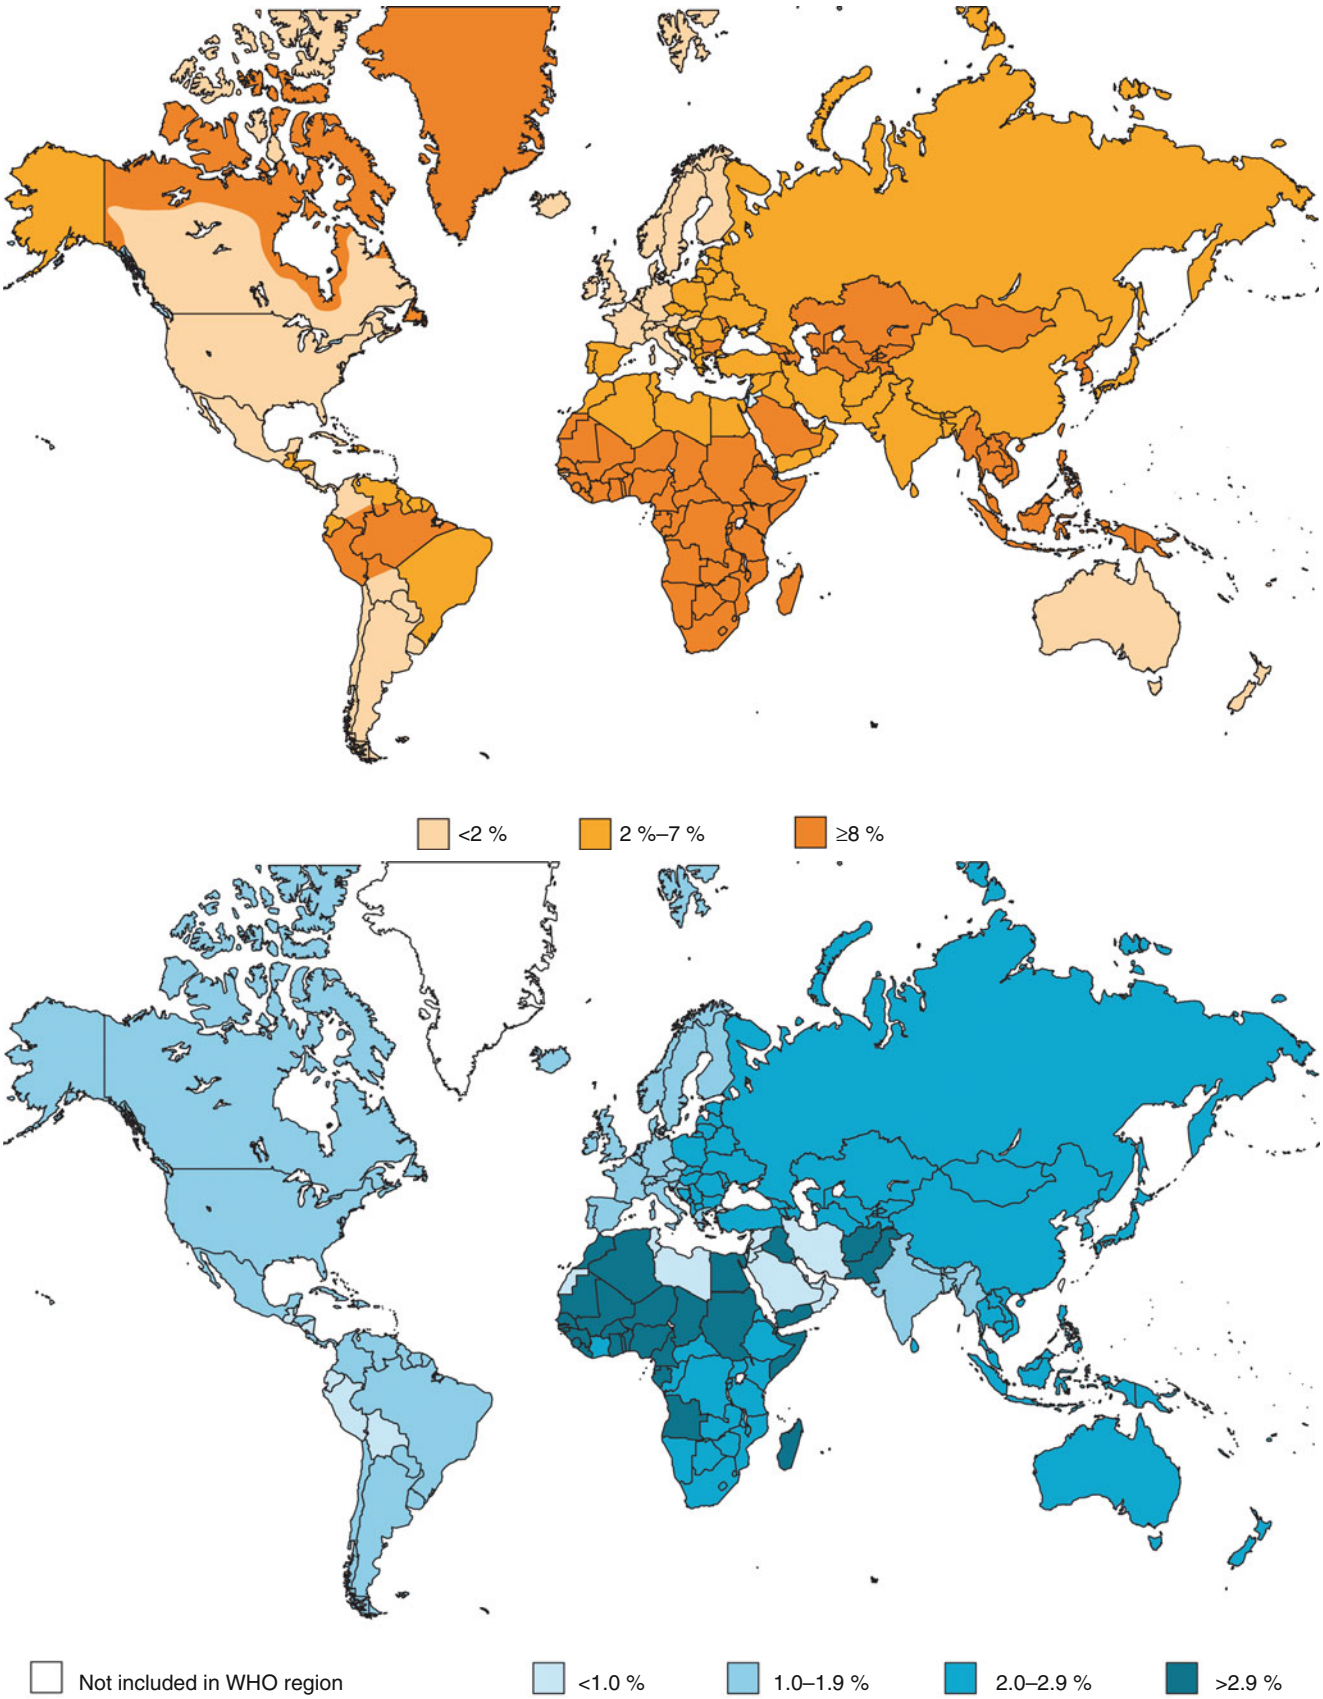

Fig. 34.1 (continued)

(69 %), whereas all other African countries reported a proportion of 5–25 % of HCC cases with anti-HCV+ [28]. The initial spread of HCV infection in Japan was thought to be due to mass treatment campaigns for endemic *Schistosoma japonicum* beginning in the 1920s [29]. Similarly, the high prevalence of HCV-associated HCC in Egypt is thought to be related to the iatrogenic transmission of HCV in that population during mass treatment campaigns for endemic *Schistosoma mansoni* [30].

Contrary to Asian and African countries, in most European countries except for Greece, the proportion of HCC patients with positive anti-HCV is greater than those with positive HBsAg. Anti-HCV positivity in HCC patients was 48 % in Spain, 43 % in Italy, 36 % in Austria, and 25 % in Belgium and the *UK*, while the proportion with positive HBsAg+ was approximately 10–20 % in these countries. In Greece, the proportion of HCC patients positive for HBsAg and anti-HCV was 56 and 16 %, respectively [28]. In Germany, the proportion of anti-HCV-positive cases (25 %) was close to that of HBsAg-positive cases (22 %). It is important to note that the proportions of HCC cases negative for both HBsAg and anti-HCV among European countries were relatively higher compared to the proportions in Asian countries (35 % in India and 5–25 % in all other Asian countries) and in Africa (less than 30 %). Strikingly, in Sweden 82 % of HCC cases were seronegative for HBsAg and anti-HCV, in contrast to the proportion that was seronegative for both viruses in other European countries (32–52 %) [28]. The high proportion of HCC cases seronegative for both viruses reflects the fact that risk factors other than chronic HBV or HCV infection, particularly alcohol use and increasingly fatty liver disease, are of substantial importance in contributing to HCC development in Europe. The proportion of HCC cases with positive HBsAg or anti-HCV varies greatly among countries in North, Middle, and South America. In the USA, HCV accounts for 30–50 % and HBV accounts for 5–15 % of HCCs. In Brazil, 40 % of HCC cases were seronegative for both HBV and HCV viruses and 37 and 18 % of HCC cases were positive for HBsAg and anti-HCV, respectively. In Peru and Mexico, 44 % of cases had positive HBsAg, 20 % of cases had positive anti-HCV, and 30 % of cases were seronegative for both HBV and HCV viruses [28].

5 Mortality

In 2012, an estimated 746,000 worldwide deaths were due to liver cancer [19]. Liver cancer was the second leading cause of cancer-related death in males, the sixth cause of cancer death in females, and the second most common cause of death from cancer overall [19]. Liver cancer is considered to be the second most lethal cancer, after pancreatic cancer, which had the highest mortality to incidence ratio of 0.96 [19]. The mortality to incidence ratio of HCC was 0.98 in 1990 and remained high at 0.95 in 2012 (Fig. 34.2) [31]. It has been predicted that the number of liver cancer deaths will increase to 929,368 in the year 2020 and to 1,175,804 in 2030 [19]. The 5-year survival rate for liver cancer worldwide is estimated at 15 % [32]. There are substantial geographical, regional, and local variations in HCC survival, in large part related to access to surveillance and therapy. Although the number of liver cancer deaths has been increasing due to the increasing incidence of HCC, the overall survival in patients with HCC appears to have improved over time. A study from Olmsted County, Minnesota, showed that overall survival in patients with HCC has improved over the past three decades, with an increasing proportion of patients receiving curative treatment over time and improvement in survival from a median survival time of 3 month in 1976 to 9 months in 2008 ($P = 0.01$) [21].

6 Etiology of HCC

6.1 Hepatitis B and Hepatitis C Viruses

HBV and HCV infections are the most common causes of HCC in the world. Alcohol is the next most common etiology of HCC. Due to the rising epidemic of obesity and metabolic syndrome, NAFLD (nonalcoholic fatty liver disease) is now recognized as one of the four major etiologies of HCC [33].

Variations in incidence of HCC in different racial and ethnic populations are generally related to the underlying prevalence of the major risk factors in these populations. In the USA, Blacks and Hispanics have a 2.5 and 2.0 times higher incidence compared to Whites, respectively [34]. In addition to the different risks of HCC, the clinical features and presentation also differ among different races. Caucasian carriers of HBsAg tend to develop HCC at an older age in a background of underlying liver cirrhosis, while Asians and Africans tend to develop HCC at a relatively early age with less cirrhotic change of the liver [23]. This difference may be explained by the difference in age at which HBV infection is acquired in the different populations as well as genetic variations of host and HBV genotype between the different races. It is well known that persistent HBV replication is associated with increased risk of HCC [35, 36]. HBV genotype C is the most prevalent genotype in Asians and known to be associated with the presence of hepatitis B virus e antigen (HBeAg), a decreased rate of spontaneous HBeAg clearance, higher rates of HBeAg reversion after HBeAg clearance, and an increased risk of HCC independent of HBV DNA levels [37–40]. Several publications from Asian countries have identified male sex, older age, elevated serum alanine aminotransferase (ALT), positive HBeAg status, elevated serum

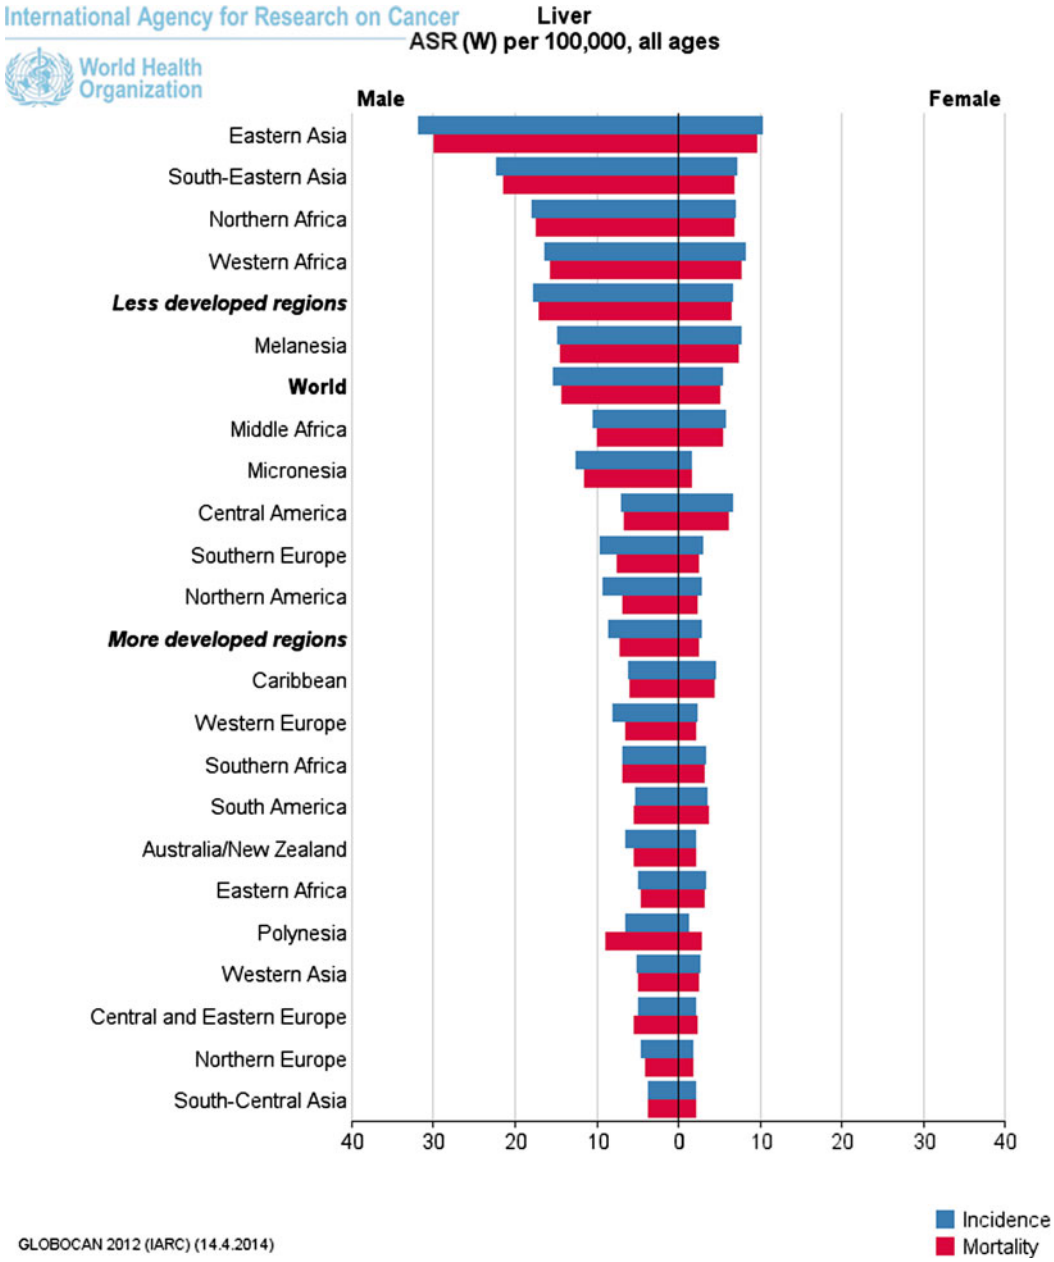

Fig. 34.2 Worldwide incidence and mortality of HCC in males and females

HBV DNA level, and HBV genotype C as independent predictors of HCC development [41, 42]. The risk for HCC can also be affected by long-term changes in serum levels of HBV DNA or ALT. A study from Taiwan showed that persistently high HBV DNA levels (1,000,000–10,000,000 copies/mL) are associated with a substantially increased risk of HCC, with a hazard ratio (HR) of 16.8 (CI, 7.3–38.4) compared to controls. The ALT level was also significantly associated with HCC risk [43].

Hepatitis C is the leading cause of chronic liver disease and HCC in most Western countries including the USA [21, 44]. The prevalence of HCV and the proportion of patients with liver cirrhosis or HCC induced by HCV in the USA have also increased over the past several decades [45]. A population-based study in Olmsted County, Minnesota, showed that HCV is the main driver of the increasing incidence of HCC, accounting for 45 % of HCCs between 2001 and 2008 [21]. Individuals with positive anti-HCV have a 28-fold increased risk of HCC compared to individuals with negative anti-HCV [46]. In Taiwan, a population-based study showed cumulative lifetime (age 30–75 years) incidences of HCC for men and women with positive anti-HCV were 23.73 and 16.71 %, compared to lifetime incidences for HBsAg-positive individuals of 27.38 and 7.99 % for men and women, respectively. HCV and HBV coinfection increases the risk of HCC; the cumulative lifetime

incidences of HCC in dually infected men and women were 38.35 and 27.40 %, respectively [47].

HCV transmission by blood transfusion was common in the USA and other highly developed countries prior to the introduction of screening; the risk of HCV transmission from a blood transfusion has been negligible in the USA since the implementation of donor blood screening for HCV in 1990 [48, 49]. More recently, the most common route of transmission has been by percutaneous exposure to blood via illegal intravenous or intranasal drug use and via high-risk sexual behaviors [50, 51]. Transmission of HCV among injection drug users (IDUs) remains problematic, as suggested by a report that the prevalence among them in England and Wales rose from 47 % in 1998 to 53 % in 2006 [51]. Iatrogenic transmission is not uncommon as a route of HCV transmission, even in more developed parts of the world. In a study from Spain, hospital admission was the most common risk factor preceding the diagnosis of acute HCV infection, which usually progresses to chronic HCV infection [52]. Although mother to infant vertical transmission is rare, a high HCV titer in the mother is known to increase the frequency of HCV transmission [53, 54].

6.2 Alcoholic Liver Disease

Alcoholic liver disease is the second most common risk factor for HCC in the USA [55]. Although alcohol intake is known to increase the risk for HCC, the threshold dose and the minimal duration of use associated with risk of HCC are not well established [56]. The risk of developing HCC appears to be lower in patients with alcoholic cirrhosis compared to patients with cirrhosis from other etiologies; in a recent Danish nationwide cohort study, the 5-year cumulative HCC risk for the alcoholic group was only 1.0 % (95 % CI, 0.8–1.3 %) [57]. It is known that females are more susceptible than males to liver injury from alcohol intake due to differences in alcohol metabolism [58]. One quarter of alcoholic patients in the USA have HCV infection [59]. Not surprisingly then, coexisting viral hepatitis and alcohol intake appears to increase the risk of HCC [56, 60]. A population-based study from Olmsted County, Minnesota, has shown that HCV patients with significant alcohol intake develop HCC at an earlier age compared to those without significant alcohol consumption [21]. Secular trends in per capita alcohol consumption in different countries or regions may therefore have significant impact on trends in HCC incidence.

6.3 Obesity-Related Nonalcoholic Steatohepatitis

Obesity-related nonalcoholic steatohepatitis (NASH), or nonalcoholic fatty liver disease (NAFLD), is emerging as an important new risk factor for HCC in many developed countries [61, 62]. Obesity has been associated with a significantly increased risk of mortality from HCC [63]. A study using the US Scientific Registry of Transplant Recipients for primary adult liver transplant recipients between 2001 and 2009 showed that NAFLD was the third most common indication for liver transplantation in the USA and is on a trajectory to become the most common indication. A US referral center study showed that NAFLD is the third most common cause of HCC [33]. Importantly, there is substantial and increasing evidence suggesting that NAFLD can lead to the development of HCC in the absence of established cirrhosis [64, 65]. The annual incidence rate of HCC in patients with NASH cirrhosis was reported to be 2.6 % [66]. Diabetes has been shown to be associated with a two- to threefold increased risk of HCC in multiple cohort and case-control studies [67]. A more recent large cohort study showed that well-controlled diabetes (HgbA1C <7 %) in patients is associated with a 44 % reduction in the risk of developing HCC compared to poorly controlled diabetes (HgbA1C >7 %) [68]. It is not clear however whether diabetes has a direct carcinogenic effect in the liver or whether it indirectly increases the risk of HCC by promoting hepatic inflammation and fibrosis. Metformin and statin drugs have been shown to be associated with a decreased risk of HCC, and metformin treatment was independently associated with an 80 % decrease in HCC occurrence in a cohort of patients with HCV-induced cirrhosis [69, 70]. A more recent meta-analysis which included approximately 105,495 patients with type 2 diabetes showed that metformin was associated with an estimated 62 % reduction in the risk of liver cancer among patients with type 2 diabetes ($P<0.001$) [71]. Fish oil also appears to be protective against the development of HCC. A Japanese population-based prospective cohort study of 90,296 subjects showed that consumption of n-3 polyunsaturated fatty acid (PUFA)-rich fish and individual n-3 PUFAs was associated with a 30–40 % risk reduction of HCC, in a dose-dependent manner. These inverse associations were similar irrespective of HCV or HBV status [72]. Statin use was associated with a 26 % decrease in risk of HCC in a matched case-control study nested within a cohort of VA patients with diabetes [73]. On the other hand, insulin treatment for diabetes has been shown to be associated with an increased risk of HCC [70, 74]. Based on the available evidence, no definitive statement can be made about the contribution lipid derangement (fatty liver) on the risk of HCC due to viral hepatitis.

6.4 Aflatoxin

Aflatoxin B is a mycotoxin which is a frequent food contaminant in sub-Saharan Africa and Eastern Asia and is a

well-known risk factor for HCC [75]. Aflatoxin B has a synergistic effect with HBV in HCC development by inducing p53 mutations (most commonly a G-to-T transversion in codon 249) and activating oncogenic pathways [76].

6.5 Other Cofactors

A positive family history of liver cancer increases the risk of HCC by two- to threefold independent of viral hepatitis [77]. Males are at two to four times greater risk for HCC than females. The male predilection varies around the world and is usually higher in high-incidence areas [19]. The sex discrepancy in HCC incidence is explained by two factors, namely, the difference in rates of exposure to known risk factors and sex hormone-related effects. Males are more likely to be exposed to hepatocarcinogens, in particular, viral hepatitis infection, alcohol, and smoking. Testosterone may also increase HCC risk by promoting hepatocyte proliferation and malignant transformation via induction of the androgen signaling pathway [78], whereas estrogenic hormones have a protective effect against HCC by suppressing the release of interleukin-6 from Kupffer cells in the liver [79]. Interleukin-6, a proinflammatory cytokine, inhibits apoptosis of HCC cells. In addition, male and female sex hormones have opposing effects on HBV replication, that is, testosterone increases HBsAg gene expression, whereas estrogen suppresses HBV replication [80–82].

7 Contribution of HBV and HCV Infection to Mechanisms of Hepatocarcinogenesis

Chronic liver inflammation, commonly induced by chronic viral hepatitis B or C infection, alcohol, or fatty liver disease, is a major driver of liver fibrogenesis and carcinogenesis. Hepatitis viruses, alcohol, fat, and other hepatotoxic agents induce acute liver cell injury and death [83]. Liver cell death induces inflammation and the production of cytokines and growth factors essential for regeneration of liver cells [84]. This leads to restoration of the normal cytology and architecture of the liver. Liver cell death as well as the cytokines produced in response to liver injury also produce reactive oxygen species which trigger tissue regeneration and repair. In the setting of chronic liver inflammation induced by chronic viral hepatitis B and/or C infection, repeated cycles of tissue injury, regeneration, and repair lead to telomere shortening, exhaustion of the capacity for liver regeneration, and eventually to hepatocellular senescence. Concurrently, the persistent liver inflammation induces stellate cell activation and liver fibrogenesis, contributing to architectural distortion of the liver tissue [85]. Within this context of exhausted liver regeneration, some hepatocytes escape from senescence through activation of the telomerase enzyme or alternative mechanisms, leading to cellular immortalization [86]. It appears that generation of a genotoxic inflammatory tumor microenvironment with a high concentration of reactive oxygen species leads to the accumulation of genetic alterations in immortalized hepatocytes, as well as to epigenetic alterations in DNA methylation, histone modification, and noncoding RNA expression that contribute to the development of the tumor phenotype [87]. The combination of oncogenic alterations, including oncogene-activating gene mutations, gene amplification, and increases in oncogene expression, as well as tumor suppressor inactivation by mutation, genetic loss, or epigenetic mechanisms, results in dysregulation of the cell cycle, the establishment of a proliferating mass of tumor cells, and consequent effects on angiogenesis, immune escape, and the tumor microenvironment that leads to overt malignancy [83, 88]. HBV and HCV contribute to HCC carcinogenesis through several mechanisms, in particular, the oncogenic effects of viral HBx and HCV core proteins [89]. The accumulation of pre-S1 and pre-S2 mutant HBsAg in the endoplasmic reticulum and the interaction between the HCV core protein and hepatocyte mitochondria trigger the generation of reactive oxygen species, a key pathogenic mechanism in hepatocarcinogenesis [90, 91]. HBx protein dysregulates the TSC1/mTOR signaling pathway through IKKβ activation resulting in hepatocyte proliferation [92]. HCV core protein promotes cell proliferation through activation of the Wnt/beta-catenin pathway, and NS5A nonstructural protein promotes hepatocyte proliferation through activation of the PI3K/Akt pathway [93, 94]. Concurrently, hepatocyte cell death is inhibited through the suppression of the p53-induced apoptosis pathway by NS5A [95]. HBV core and HCV E2 also interfere with TNF-related apoptosis-inducing ligand (TRAIL)-induced apoptosis and tumor necrosis factor alpha (TNF-α)-mediated apoptosis [96, 97]. The HBx and HCV core protein can induce telomerase reverse transcriptase (TERT) and telomerase activity, leading to hepatocyte immortalization [98, 99]. Additionally, tumor angiogenesis is stimulated through HBx and HCV core protein-induced vascular endothelial growth factor (VEGF) activation [100, 101]. The HBx protein also enhances HCC invasion and metastasis by increasing the activity of matrix metalloproteinases, protease enzymes important for cancer cell migration and metastasis [101].

During the last few years, next-generation sequencing (NGS) technologies have been applied to elucidate additional details of the pathogenesis of HCC and have begun to provide a comprehensive genomic landscape of HCC. Many novel genetic alterations and pathways that potentially contribute to the pathogenesis of HBV- and HCV-induced HCC have been identified. Unlike noncancerous liver tissue in which HBV integrations take place in multiple

locations in the human genome, HBV integrations have been confirmed to occur commonly within or upstream of the telomerase reverse transcriptase gene *TERT* in HCC tissues [102]. A number of mutations in chromatin-remodeling family genes, in particular *ARID1A* and *ARID2*, have been identified in up to 50 % of HCC tumor tissues, suggesting that the chromatin-remodeling pathway could potentially be an important pathway in HBV- and HCV-related HCC [102, 103]. There is evidence that *ARID2* functions as tumor suppressor gene in HCC and that *ARID1A* may be a driver of HCC metastasis [103, 104]. *IRF2*, a gene involving in cell growth regulation, was found to function as a tumor suppressor by regulating the P53 pathway, one of the most important pathways in hepatocarcinogenesis [105]. A potential role of the oxidative stress pathway in HCC development has also been revealed. Mutations of the *NFE2L2* gene which encodes *NRF2*, a transcription factor regulating expression of antioxidant enzyme-coding genes, have been identified. *NFE2L2* has been shown to be significantly associated with mutations of *CTNNB1* in the Wnt/beta-catenin pathway, another major pathway in hepatocarcinogenesis [105]. Novel mutations in several genes regulating cell proliferation and cell survival, such as the cell adhesion molecule gene *VCAM1*, have also been indentified in HBV-related HCC [103]. The patterns of nucleotide substitutions of HBV-induced HCC and HCV-induced HCC are different, for example, C:G>A:T and T:A>A:T transversions are common patterns in HBV-related HCC whereas G:C>T:A transversion is a common pattern in HCV-related HCC [103, 105]. These results point to differences in the underlying etiologic mechanisms of HCC and will hopefully result in advances in individualized prevention and therapy of HCC.

8 Prevention

The most effective means of controlling HCC is primary or secondary prevention of chronic HBV and HCV infections, since chronic viral hepatitis and the resultant liver cirrhosis are the major causes of HCC. These control measures are covered in greater detail in Chaps. 32 and 33. As the majority of HBV and HCV infections are transmitted through direct blood exposure, avoidance of high-risk behaviors through public education and social awareness is a key approach to primary prevention of viral hepatitis-induced HCC. Iatrogenic transmission is a not uncommon route of hepatitis virus transmission. There are well-recognized risks of HBV and HCV transmission in dialysis units, endoscopy units, and other health-care settings. Therefore, it is critical to recognize and prevent transmission of hepatitis virus in health-care and para-health-care settings by implementing infection control measures such as screening blood products for the two viruses, use of disposable needles and procedure supplies, and thorough sterilization of surgical instruments. It is also important to avoid modifiable risk factors for HCC such as heavy alcohol use, diabetes mellitus, obesity, and smoking, particularly in patients with chronic viral hepatitis, as these factors can increase the risk of HCC in a synergistic manner [60, 106–108]. Global HBV vaccination has reduced the burden of HCC. HBV vaccination was introduced in 1984 and universal HBV vaccination had been implemented in 86 % of WHO member states by 2006 [23]. In countries with a high coverage of the population, HBV vaccination has resulted in dramatic decreases in the incidence of HBV infection and HCC development [109]. In contrast to HBV vaccination, there is currently no effective HCV vaccination available, due in part to difficulties related to the high mutation rate of HCV during viral replication.

Effective antiviral treatment has been shown to decrease the risk for HCC in patients with viral hepatitis. Lamivudine treatment decreases progression from cirrhosis to HCC in chronic HBV patients, and this preventive effect has also been seen in patients without liver cirrhosis [110–112]. Antiviral treatment for HCV which results in sustained virologic response decreases the risk of progression to HCC; in contrast, patients who do not achieve a sustained response continue to have a high risk of progression to HCC [113–115]. However, newer antiviral drugs appear to offer greater promise of a cure for HCV infection (Chap. 33). The role of antiviral treatment in patients with HCV cirrhosis is controversial [113–118]. The US HALT–C study examined the effect of interferon on the risk of HCC development. This trial included 1,048 patients with chronic hepatitis C and advanced fibrosis who did not have a sustained virologic response (SVR) to therapy. Participants were randomly assigned to groups given a half dose of peginterferon or no treatment (controls) for 3.5 years and followed up for a median of 6.1 (maximum, 8.7) years. After 7 years of follow-up, the cumulative incidences of HCC in treated and control patients with cirrhosis were 7.8 and 24.2 %, respectively (HR: 0.45); in treated and control patients with fibrosis but not cirrhosis (Ishak fibrosis stages 5 and 6), incidences were 8.3 and 6.8 %, respectively (HR, 1.44), suggesting that peginterferon treatment is effective in lowering the risk of HCC in patients with cirrhosis but not in patients without cirrhosis [119]. A similar European study showed a conflicting result. Patients with chronic hepatitis C with compensated liver cirrhosis who had failed to respond to interferon-alpha plus ribavirin were randomized to treatment with peginterferon alfa-2b or no treatment. Although the progression of liver cirrhosis was significantly slower for patients who received peginterferon alfa-2b compared with controls (HR, 1.56), there was no difference in the risk of HCC between patients received peginterferon alfa-2b and those receiving no treatment [120]. Evidence for a role of interferon treatment in preventing recurrence after liver

resection has been controversial. Although most previous studies suggest there is an effect of interferon in reducing the risk of HCC recurrence, a randomized controlled trial showed no difference in the risk of recurrence between groups who received 53 weeks of adjuvant IFNα-2b treatment and observation alone ($p=0.83$). In fact, adjuvant IFNα-2b treatment was associated with a significantly higher incidence of hematologic complications, including leucopenia and thrombocytopenia.

9 Surveillance for HCC

The goal of HCC surveillance is to decrease HCC mortality through the early detection of HCC in asymptomatic patients. In real-world practice, the majority of patients are not under HCC surveillance and HCCs tend to be detected at a late stage when patients become symptomatic from advanced HCC [33]. A population-based study using data from the Surveillance, Epidemiology, and End Results (SEER)—Medicare database—showed that only 17 % of cirrhotic patients are under regular HCC surveillance 3 years before diagnosis of HCC [121]. Similarly, of 13,000 patients with HCV-induced cirrhosis seen at 128 VA health-care facilities, only 12 % received routine HCC surveillance [122]. A more recent retrospective study with 156 cirrhotic patients identified from outpatient gastroenterology and primary care practices showed that patients with NASH cirrhosis were less likely to be under surveillance than patients with cirrhosis from other etiologies and were less likely to receive gastroenterology referral [123].

The prognosis of patients with HCC is dictated by the initial stage at diagnosis of HCC. Long-term overall survival or disease-free survival is possible only in patients who present with early-stage HCC which is amenable to potentially curative treatments, typically liver transplantation or surgical resection. There is substantial evidence that HCC surveillance increases the early detection of tumors and improves the survival of patients with HCC [124, 125]. Admittedly, this observation may in part be due to lead-time or length-time biases. However, the use of HCC surveillance is still controversial primarily because of the lack of robust level 1 evidence from randomized trials supporting the use of HCC surveillance. Thus far, two randomized controlled trials have investigated the efficacy of surveillance in reducing HCC mortality. Both studies were in cohorts of HBV patients from China. One randomized controlled trial was performed with 5,581 HBV patients [126]. This study used serum alpha-fetoprotein (AFP) as the primary tool for surveillance and showed that surveillance increased the detection of early-stage tumor but did not affect overall survival and liver cancer mortality. The second study of 19,000 HBV-positive individuals showed a positive effect of HCC surveillance on HCC mortality [127]. Although there was a high dropout rate of study participants, individuals under biannual surveillance with serum AFP and abdominal ultrasound (US) had a 37 % decreased risk of mortality from HCC than individuals not under surveillance. Unfortunately, no randomized controlled trials have investigated the efficacy of HCC surveillance in patients with etiologies other than HBV.

Table 34.1 Candidates for HCC surveillance

Cirrhosis	Non-cirrhotic HBV carrier
HBV cirrhosis	Asian men >40 years old
HCV cirrhosis	Asian women >50 years old
Alcoholic cirrhosis	Family history of HCC
Nonalcoholic steatohepatitis	Africans >20 years old
Primary biliary cirrhosis	
Other cause of cirrhosis	

Currently, based on studies showing an annual risk of HCC greater than 1.5 % per year, the American Association for the Study of Liver Diseases (AASLD) recommends that patients with cirrhosis, regardless of etiology, should be under HCC surveillance [128]. In addition, it is recommended that high-risk hepatitis B carriers (i.e., with annual HCC incidence >0.2 %) including Asian males aged over 40, Asian females aged over 50, Africans aged over 20, those with high viral load or elevated transaminases, and patients with a family history of HCC should enter HCC surveillance (Table 34.1) [128]. Surveillance should be performed every 6 months; this interval is based on how fast HCC tumors grow rather than the degree of HCC risk in each individual patient. In addition, it has been shown that a program of surveillance every 6 months can result in better clinical outcomes compared to surveillance every 12 months [129].

Abdominal US and serum AFP are the most commonly used tests for HCC surveillance in clinical practice. Although abdominal US is highly dependent upon operator experience and delineation of tumor nodules can be challenging in patients with obesity and nodular liver, abdominal US has been shown to have a sensitivity over 60 % and specificity over 90 % as a screening test for HCC [124]. These estimates may not be achieved in routine practice [130]. CT and MRI are not routinely used for HCC surveillance due to their high cost and the risks of repeated exposure to radiation (for CT) and contrast (for both modalities). These modalities are sometimes used as screening tests in patients listed for liver transplantation for whom the cost- and risk-benefit ratios may be in favor of their use. The use of serum AFP for HCC surveillance is controversial because of the poor sensitivity of AFP testing for early-stage disease; however, some proponents argue that AFP is still of value in patients for whom high-quality US evaluation cannot be obtained due to obese patient habitus or a lack of experienced ultrasonographers.

10 Diagnosis of HCC

The majority of HCCs can be diagnosed without biopsy of the tumor as HCC is a highly vascular tumor and has the specific radiologic finding of arterial enhancement and venous phase washout on contrast CT or MRI. The AASLD recommends a systematic approach for evaluating suspicious nodules found by surveillance US of patients at risk for HCC [128]. If the nodule is smaller than 1 cm, then follow-up with a repeat US every 3 months is recommended. If there is no change in the size of the lesion, US should be repeated every 3 months for up to 2 years without further investigation with CT or MRI. This is because most small nodules are noncancerous and small subcentimeter HCCs usually have not acquired the typical features of hypervascularity with venous washout, making a conclusive diagnosis by cross-sectional imaging difficult. If the nodule remains the same or regresses, it can be presumed that the nodule was not an HCC and regular 6 months surveillance can be reinstituted. If the nodule is larger than 1 cm on initial observation or becomes larger than 1 cm during follow-up, then further workup using contrast-enhanced four phase CT (non-contrast, arterial, portal, and delayed phase) or dynamic MRI is used for the confirmatory diagnosis of HCC (Fig. 34.3). If either MRI or CT shows the characteristic features of arterial enhancement and portal venous or delayed phase washout, then the diagnosis of HCC is confirmed (Fig. 34.4). If the initial cross-sectional imaging study – CT or MRI – shows inconclusive features, then the other test should be performed next to determine if it will reveal characteristic features of HCC. If the second imaging study shows characteristic features, then HCC is diagnosed. If not, percutaneous liver biopsy may be performed.

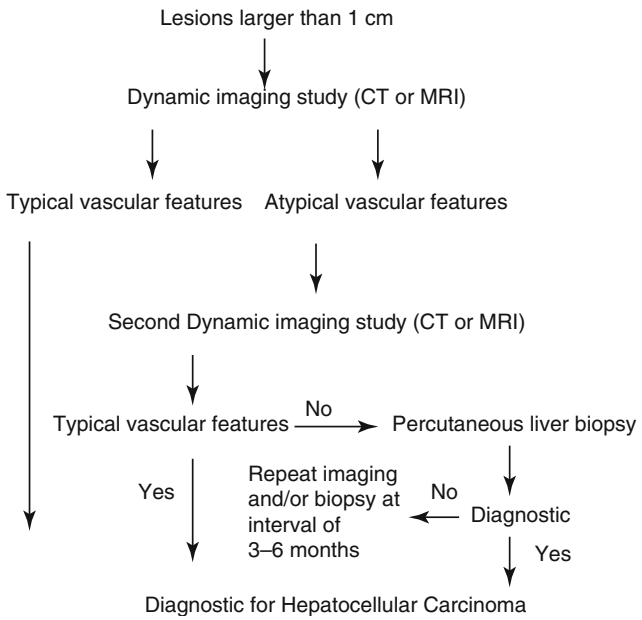

Fig. 34.3 Diagnostic algorithm of HCC

Percutaneous liver biopsy is indicated when lesions (>1 cm) develop without background liver cirrhosis or dynamic imaging modalities show inconclusive results. Since percutaneous needle biopsy is susceptible to sampling error with an up to 10 % false-negative rate for the biopsy of small HCCs, a negative result does not rule out HCC and close follow-up is required at 3- to 6-month intervals until the nodules disappear or acquire the typical radiologic features of HCC [131]. Percutaneous biopsy should be used with caution, particularly in patients who are eligible for curative treatment such as surgical resection or liver transplantation because of the 2–3 % risk of needle track seeding [132]. In the USA, since the United Network for Organ Sharing (UNOS) does not apply, Model for End-Stage Liver Disease (MELD) points are not assigned to patients with HCC until the masses reach at least 2 cm in size; in patients who are otherwise eligible for treatment with liver transplantation, many centers will follow >1 cm nodules with serial imaging until they reach 2 cm in size.

While the serum AFP is no longer used as a diagnostic criterion for HCC in the current AASLD practice guideline, levels of 400–500 or greater have 98 % or higher specificity for the diagnosis of HCC, similar to the specificity of the combination of arterial enhancement and venous washout by CT or MRI for the diagnosis of HCC; it may therefore have utility in selected settings.

11 Treatment of HCC

Treatment of HCC depends on multiple factors including extent of tumor, severity of liver dysfunction, performance status of the patient, socioeconomic support, and the local availability of different types of treatment. Surgical resection, liver transplant, and local ablative treatment are potentially curative treatment modalities that can be offered to patients with early-stage HCC (Fig. 34.5). Transarterial chemoembolization and radioembolization are locoregional treatment modalities that are used in patients with intermediate-stage HCC. Sorafenib is a targeted systemic multikinase inhibitor that shows limited effectiveness in patients with advanced stage HCC (Fig. 34.5).

11.1 Surgical Resection

Surgical resection can be curative for HCC in patients with well-preserved liver function and limited tumor extent. Candidates for surgical resection should be carefully

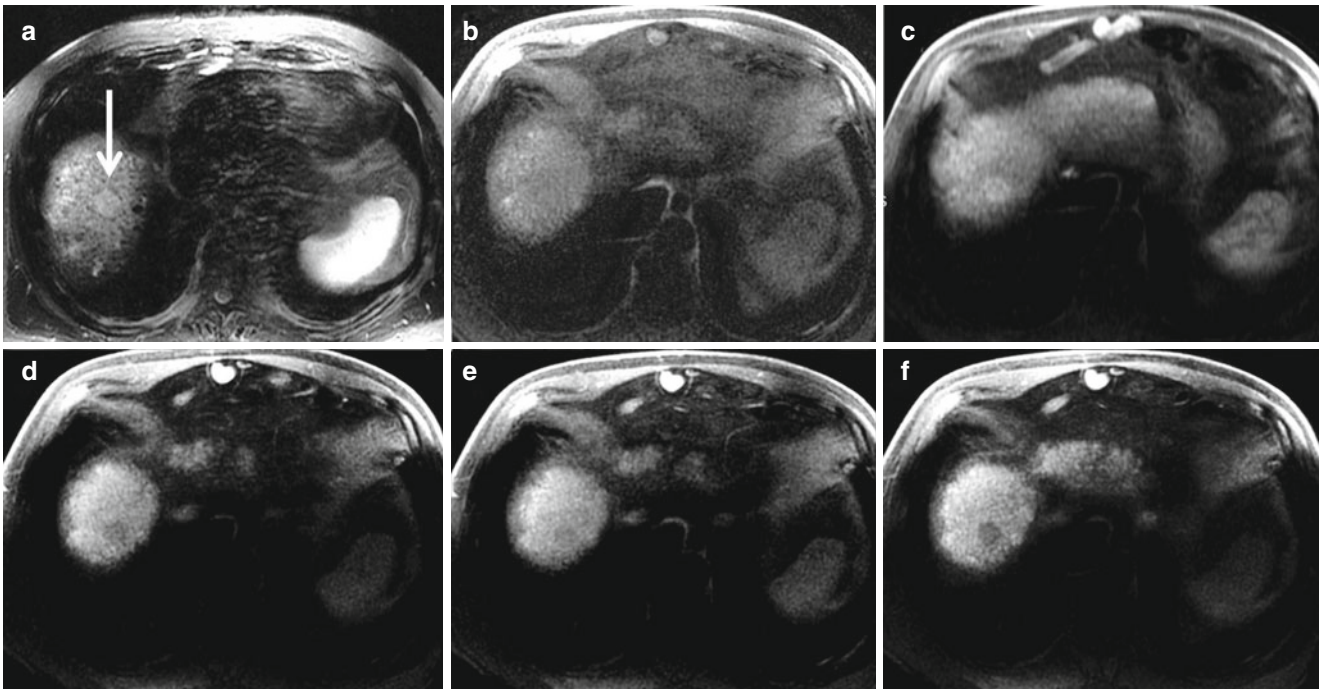

Fig. 34.4 Radiologic characteristics of HCC. HCC in a 67-year-old male with chronic hepatitis C. MRI study performed with intravenous Gd-EOB-DTPA (Eovist). HCC (*arrow*) is hyperintense on axial T2-weighted image (**a**), barely visible on pre-contrast T1-weighted image (**b**) shows hyperenhancement in arterial phase (**c**) and washout in portal venous (**d**) and delayed (**e**) phases. No uptake of contrast in the 20-min hepatocyte phase (**f**)

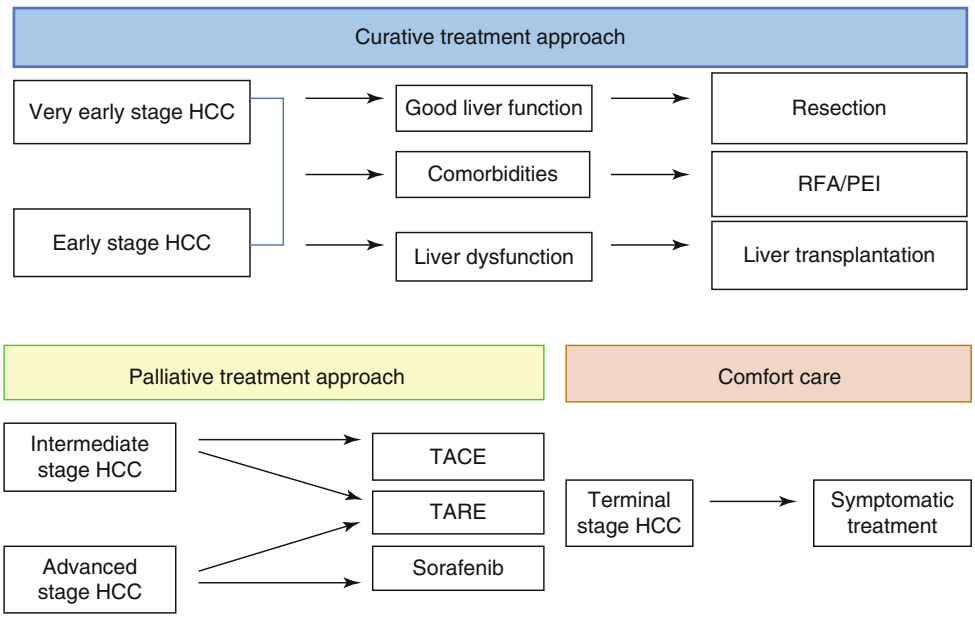

Fig. 34.5 Treatment recommendation according to a modified BCLC staging classification. *RFA* radiofrequency ablation, *PEI* percutaneous ethanol injection, *TACE* transarterial chemoembolization, *TARE* transarterial radioembolization

selected after thorough evaluation of underlying liver function and tumor extent as there is a risk of tumor recurrence and also of postoperative hepatic decompensation. In patients who develop HCC in the context of cirrhosis, the remaining liver continues to be at risk of development of cancer after surgical resection either because of the development of new HCCs in the cirrhotic liver or because of growth of micrometastasis from the previously resected HCC that was not visible in the initial imaging. The risk of recurrence after resection of HCC exceeds 70 % at 5 years [133]. Hepatic reserve is assessed by the indocyanine green retention test in some Asian countries and signs of clinically significant portal hypertension (thrombocytopenia, splenomegaly, varices) and bilirubin in Western countries [134].

A MELD score of 8 or less also reflects well-preserved liver function and is a strong predictor of both low perioperative mortality and long-term survival [135]. Dynamic multiphase CT or MRI is used for anatomic delineation of tumor extent. Surgical resection is typically not recommended for HCCs with associated vascular invasion or tumor metastasis, although it is performed in patients with macrovascular invasion in some Asian countries. Although large tumor size and number are associated with a high risk of recurrence after surgical resection, they should not preclude surgical resection in patients with resectable tumors and reasonable hepatic reserve [136]. A study using hospital discharge data from the Nationwide Inpatient Sample in the USA reported that the use of surgical resection has been decreasing over the past 15 years, whereas the use of liver transplant and radiofrequency ablation has increased in the USA [137].

11.2 Orthotopic Liver Transplantation

Orthotopic liver transplantation (OLT) is the most effective treatment for HCC. OLT completely removes the HCC and the rest of the benign liver and results in the best clinical outcomes. An increasing proportion of HCC patients in the USA receive OLT for HCC treatment [137]. The highly resource intensive nature of OLT and the requirement for long-term medical and social support are the main downsides of this treatment approach. There are significant racial disparities in likelihood of receiving liver transplant; African American and Pacific Islanders were about 40 % less likely to undergo OLT than Whites [138]. OLT is a preferred treatment modality in patients with early-stage HCC who are not good candidates for liver resection. A single center study in the USA showed that OLT is more commonly used in HCC patients with HCV, whereas surgical resection was more common in HCC patients with HBV. This difference was attributed to the smaller tumor extent and worse liver function in the HCV cohort versus the HBV cohort [139]. As the availability of organs is very limited, strict criteria exist for selection of candidates for OLT. The Milan criteria (a single tumor 5 cm or less in diameter or up to three lesions with the largest no more than 3 cm in diameter) are generally used to select candidates with HCC for OLT. Patients transplanted for HCC who meet these criteria achieve long-term survival that is similar to that of patients receiving OLT for non-HCC indications [140]. As some patients who are beyond Milan criteria can benefit from OLT, more liberal selection criteria have been proposed as expanded selection criteria for OLT, including the University of California San Francisco (UCSF) criteria [141, 142]. These criteria are yet to be universally implemented by UNOS. For HCCs that are initially beyond UNOS criteria, a downstaging strategy using local or locoregional therapy to reduce the tumor size and number to meet the Milan criteria, followed by subsequent transplantation, has shown encouraging results and is used in several institutions [143, 144]. A meta-analysis which included 720 patients who underwent transplantation following downstaging after initial presentation with disease outside the Milan criteria showed that absolute and disease-free survival rates in patients transplanted following downstaging are comparable to those in patients within the Milan criteria [145].

11.3 Living-Donor Liver Transplantation

Living-donor liver transplantation (LDLT) has been developed mostly in Asian countries and successfully replicated worldwide to address the lack of donor liver availability, despite significant morbidity and some mortality risk to donors [146]. LDLT may be an effective treatment modality in an environment of deceased donor liver shortage considering the current strict eligibility for listing and significant dropout rate from tumor progression or death while on the waiting list for OLT [147].

11.4 Percutaneous Ablation

Percutaneous ablation has been used more frequently in the USA over the past 15 years as it is less invasive than surgical treatment but results in similar clinical outcomes in selected patients. It is a potentially curative treatment for small tumors in patients who are not eligible for liver transplantation or resection due to comorbidities, liver dysfunction, or limited surgical resources. Percutaneous ethanol injection (PEI) has an excellent treatment effect for small tumors as complete necrosis is achieved in most HCCs smaller than 2 cm [148]. Currently, radiofrequency ablation (RFA) is now more frequently used than PEI. Randomized clinical trials have shown that complete tumor necrosis (96 % in RFA vs. 88 % in PEI), 3-year recurrence free survival (34–49 % in RFA vs. 12–43 % in PEI), and overall survival (62–78 % in RFA vs. 36–72 % in PEI) are significantly higher in patients with RFA than PEI [149]. Studies including two randomized control trials showed that RFA has similar efficacy to surgical resection in the treatment of early-stage HCCs with a lower complication rate and cost [150–153]. A study using a Markov model showed that RFA is as effective as surgical resection in treatment of small HCCs. A retrospective comparative study showed that RFA is superior to surgical resection in HCC less than 2 cm in terms of overall survival (72 % vs. 62 % for 5-year overall survival, $p<0.05$) and treatment complications (19 % vs. 51 %, $p<0.01$) [154].

11.5 Transarterial Chemoembolization

Transarterial chemoembolization (TACE) is the most commonly used treatment modality in patients with HCC [33]. TACE delivers a chemotherapeutic agent via the hepatic artery branches into the tumors while embolizing the tumor vasculature. TACE is primarily indicated in patients with unresectable HCC without portal vascular invasion or extrahepatic metastasis. Although patients with unresectable multifocal HCC have a poor long-term prognosis, TACE has been shown to improve overall survival in the intermediate time frame, when compared to supportive management (2-year overall survival of 31–63 % and 11–27 % in the TACE and control groups, respectively) in two randomized controlled trials [155, 156]. It was shown that patients who responded to the treatment have longer overall survival than patients who did not respond [157]. Although TACE was traditionally considered contraindicated in patients with portal vein invasion, one retrospective cohort study with 125 patients with HCC and main portal vein invasion showed that TACE improved the overall survival. The multivariate analysis showed that treatment with TACE with a hazard ratio of 0.26 ($P<.001$) and Child-Pugh class A status with a hazard ratio of 0.55 ($P=.004$) were independent predictive factors of a favorable outcome [158].

TACE is an alternative treatment option in patients with early-stage HCC when ablative treatment cannot be safely performed due to the tumor location. TACE is also frequently used for downsizing HCC tumors or as a bridging treatment prior to liver transplantation [143, 159]. Drug-eluting bead TACE is a newer technique that uses beads loaded with doxorubicin that are designed to gradually release the chemotherapeutic agent into the tumor, resulting in effective delivery of a high concentration of chemotherapeutic agent into the tumor while minimizing systemic release. This technique appears to be as effective as or superior to traditional TACE in terms of efficacy and safety [160]. As with TACE, patients with poor liver function or portal vein invasion should not be routinely treated with this treatment modality due to the high risk of acute liver decompensation [161]. One small randomized controlled trial showed that the combination of TACE and RFA was superior to RFA alone in patients with solitary HCC. The rates of local tumor progression at the end of the third year in the RFA and TACE-RFA groups were 39 and 6 %, respectively ($P=.012$) [162]. This result awaits further validation in larger groups of the patients. Combination TACE-RFA was also shown to be as effective as surgical resection in terms of overall survival in one retrospective study [163].

11.6 Transarterial Radioembolization

Transarterial radioembolization (TARE) with Y90-impregnated glass microspheres (TheraSphere®) or resin beads (SirSphere®) has been increasingly used for patients with unresectable multifocal HCC, including HCC with portal vein invasion. TARE appears to achieve equivalent survival outcomes with acceptable safety and improved tolerability as compared to TACE [164, 165]. A single center study in the USA analyzed 245 patients treated with TARE ($N=123$) and TACE ($N=122$) and showed that TARE resulted in a longer time to progression of HCC (13 vs. 8 months, $p<0.05$) with comparable overall survival (21 vs. 17 months, $p=0.23$) [166]. A number of multicenter cohort studies also support these findings [167].

11.7 Conventional Chemotherapeutics

Most HCCs are resistant to conventional chemotherapeutic agents. Moreover, HCC patients usually have poor tolerance to systemic chemotherapy due to hepatotoxicity and bone marrow suppression. Several molecular pathways have been implicated in liver carcinogenesis including receptor tyrosine kinases, Wnt/β-catenin, ubiquitin-proteasome, epigenetic promoter methylation and histone acetylation, PI3Kinase/AKT/MTOR, pro-angiogenic molecules, and telomerase [168]. Targeted therapies against these pathways are under active investigation. Sorafenib, an oral multikinase inhibitor that targets the Raf kinase, VEGFR, and PDGFR signaling pathways, is approved for the treatment of advanced HCC. In a phase 3 randomized placebo-controlled trial of 602 patients with advanced HCC, overall survival was 10.7 months in the sorafenib group compared with 7.9 months in the placebo group, with an acceptable side effect profiles [169]. Sorafenib was also shown to improve survival in a phase 3 randomized control trial performed in Asian Pacific countries where HBV was the dominant etiology. Overall survival was 6.5 months in the sorafenib group compared with 4.2 months in the placebo group ($p=0.01$) [170]. The most common side effects are diarrhea, fatigue, and hand-foot syndrome, and side effects appear to be more common in patients with advanced cirrhosis [171]. Recent results suggest that patients with amplification of the FGF3/FGF4 locus on chromosome 11, those with lung metastases, and those with more poorly differentiated tumors are more likely to respond to sorafenib [172]. Immunotherapy against glypican 3, a heparan sulfate proteoglycan that is overexpressed in HCCs, has been reported to be effective in improving overall survival in phase 1 clinical trials [173]. Combinations of sorafenib and other targeted agents or locoregional treatment are under active investigation.

12 Unresolved Problems

The disease burden of HCC is increasing worldwide. Since viral hepatitis is the major etiology of HCC, improved prevention and treatment of viral hepatitis should decrease the incidence of HCC. This can be achieved by increasing

HBV vaccination rates, through improved awareness of viral hepatitis by patient education in order to minimize high-risk behaviors, such as needle sharing, and through health-care provider education to minimize iatrogenic transmission. It is also critical to screen high-risk individuals and identify those who have already contracted chronic HBV or HCV infection. There is still a major gap in implementation of HBV and HCV screening, and the majority of patients are diagnosed with viral hepatitis after they develop complications related to liver cirrhosis, when the opportunity to decrease the risk of HCC has largely been lost. Patients with cirrhosis should be enrolled in surveillance programs for the early diagnosis of HCC, since the diagnosis of HCC at an early stage makes them eligible for potentially curative treatments that can result in long-term survival. Unfortunately, the majority of patients are diagnosed with HCC at an advanced stage. The optimal screening strategy for HCC is still controversial. The serum AFP clearly has limitations as a screening test for HCC due to its relatively poor sensitivity for the detection of early-stage disease when used in a single measurement. The repeated assessment of AFP and other markers in the context of a surveillance program by practitioners experienced in recognition of the patterns of nonspecific elevation of AFP can partially offset the concerns about the high rate of false-positive AFP elevations. However, there is clearly a major unmet need to identify sensitive, specific, and inexpensive biomarkers of early HCC. The development of sorafenib as a treatment for advanced HCC was a major landmark in therapy of HCC. However, sorafenib improves overall survival by 2–3 months and is therefore of only moderate efficacy as a single agent. Well-designed clinical trials testing the combination of sorafenib with other targeted treatments, with locoregional treatments, or in patients at high risk of recurrence after surgery or local ablation are needed. There is also the need to develop additional targeted treatments, virotherapy, and immunotherapy approaches to broaden the repertoire of therapeutic choices. Ideally, the development of these approaches will be paired with the identification of key molecular signatures predicting response to specific therapies. Recent major advances in antiviral and anticancer therapeutics and molecular and genetic analyses are very encouraging and give hope for substantial future improvements in the prevention and treatment of HCC.

Human Herpesviruses: Cytomegalovirus

35

Robert F. Pass

1 Introduction

Human cytomegalovirus, hereafter referred to simply as CMV, is a member of the Herpesviridae, sharing physical and biological properties of this virus family. CMV produces a chronic infection in its human host, with prolonged viral shedding after initial infection and indefinite persistence thereafter in a latent state with perhaps continued low-level replication. Immunosuppression leads to reactivation of latent virus and loss of immune control of replication. Although other members of the Herpesviridae are occasionally transmitted vertically, transmission of CMV from the mother to the newborn or even prenatally is common. It occurs through multiple mechanisms and plays a key role in the epidemiology of CMV infection and in maintaining the prevalence of CMV infection in a population. Cytomegalovirus infection is prevalent in all human populations though the age at acquisition of the virus varies largely due to differences in child rearing and reproductive behavior.

The medical and public health significance of CMV infection is due to the fact that it is the most common cause of congenital infection in developed countries and is a common opportunistic infection in immunocompromised patients. Congenital CMV infection is probably the most common infectious cause of central nervous system (CNS) impairment among children in the United States. It is a leading cause of sensorineural hearing loss and an important cause of mental retardation and cerebral palsy. Cytomegalovirus infection has been particularly troublesome in transplant patients because it can be transmitted with the graft or with blood products and it is reactivated by immunosuppressive medications that are necessary to prevent rejection of the graft. Cytomegalovirus infection is ubiquitous among adults with HIV infection and prior to the advent of highly active antiretroviral treatment (HAART). CMV was a frequent cause of vision loss due to retinitis and damage to multiple organ systems. In addition, CMV is suspected of contributing to the development of chronic vascular disease, autoimmune disease, and immune senescence. Although antiviral treatment is available for CMV infections, it is not completely effective. Prevention of congenital CMV infection through vaccination is an important public health goal, and multiple vaccines are in development.

2 Historical Background

The clinical and histopathologic findings of cytomegalic inclusion disease were recognized for decades prior to the recovery of cytomegalovirus from human tissue in 1955. In 1904, there were two reports describing histopathologic changes consistent with CMV cytopathology (intranuclear inclusion surrounded by a clear zone – the "owl's eye" appearance) in tissues from newborns, although at that time syphilis and parasitic infection were considered likely etiologies [1, 2]. Over the years others described similar histopathologic findings in the salivary glands, lungs, liver, and kidneys from infants and children. The term cytomegaly was used initially in 1921 [3]. It was suggested that the cytopathology seen in some stillbirths was associated with a prenatal insult and that this cytopathology was similar to that seen with varicella zoster and herpes genitalis infection [3, 4]. Subsequently, the cytopathology associated with the fatal prenatal infection was noted in the salivary glands of infants who had died from other causes, suggesting that it could be due to a common agent [5]. In 1950, the term "generalized cytomegalic inclusion disease" was first used to describe infants with multiorgan involvement; diagnosis of this condition by premortem detection of cytomegalic cells in the urine of affected newborns was reported in 1952 [6, 7]. Tissue culture isolation of human CMV occurred in the mid-1950s in three laboratories roughly simultaneously.

Weller reviewed the history of the initial tissue culture isolation of human CMV [8]. The first reported isolation and propagation of a cytopathic agent from a fatal case of cytomegalic inclusion disease was in 1956 from the laboratory of Margaret Smith [9]. At about the same time, investigators in the Weller laboratory inoculated specimens from a newborn with hepatosplenomegaly, intracranial calcification, and chorioretinitis into tissue culture derived from the embryonic skin and muscle and noted the development of cytopathic changes now considered characteristic of CMV; they concluded that they had isolated the etiologic agent of cytomegalic inclusion disease [10]. In the Rowe laboratory, an agent isolated from the adenoids of children produced cytopathology that was not as expected for adenovirus but was similar to the cytopathic agent isolated by the Smith and Weller laboratories. Rowe et al. developed an antibody assay and determined that the majority of adults had antibody to this agent [11]. The isolation and propagation of CMV opened the door for the development of serological and other diagnostic methods as well as in vitro study of the virus. In less than 10 years from the reported isolation of CMV from humans, seroconversion to CMV was associated with a heterophile-negative mononucleosis, cytomegalic inclusions were reported in the lungs of immunosuppressed adults, and the initial case reports of CMV disease in renal transplant patients were described in a report that anticipated the finding that the transplanted kidney would be a source of infection [12–14]. Early studies of bone marrow transplantation as an experimental treatment for aplastic anemia and acute leukemia in the late 1960s and early 1970s found that CMV was an important cause of interstitial pneumonia that was often fatal [15, 16]. Approximately a decade later cytomegalovirus was recognized as an important opportunistic pathogen in the initial reports of acquired immunodeficiency in homosexual men [17, 18].

3 Methodology

3.1 Mortality

Multisystem disease at birth is evident in approximately 5–10 % of congenital CMV infections; it is occasionally fatal. A recent study used data from US death certificates to estimate mortality due to congenital CMV infection [19]. Death certificates contain basic demographic information and can list up to 20 causes or contributors (identified by ICD-9 or ICD-10 codes). During the study interval from 1990 through 2006, 777 congenital CMV-related deaths were identified; 557 (71.7 %) occurred in infants <1 year of age, 0.11 % of the total deaths among US infants. The annual number of deaths from congenital CMV infection varied from 36 to 56, and there was no trend in either direction during the study interval. Demographic breakdown of CMV-related deaths and adjusted mortality rates are shown in Table 35.1. The mortality rates by race and region roughly parallel overall CMV seroprevalence and congenital CMV infection rates documented in other sources. However, this study was limited by (1) errors in death certificates, both in failing to include congenital CMV infection and in incorrectly concluding that CMV contributed to death, (2) the omission of fetuses that die prior to being recorded as a live birth, and (3) possible failure to diagnose congenital CMV infection.

In the past, CMV infection was an important cause of mortality among bone marrow (stem cell) transplant patients. Antiviral prophylactic and treatment regimens have reduced CMV mortality dramatically in both stem cell and solid organ transplant patients. Similarly, CMV was a frequent opportunistic infection among terminal AIDS patients with very low CD4+ T-cell counts. Where effective antiretroviral therapy has been employed, it has prevented loss of immune function and made CMV disease and mortality uncommon.

Table 35.1 Deaths related to congenital CMV infection and age-adjusted mortality based on data from US death certificates, 1999–2006

Variable		Congenital CMV-related deaths, *n* (%)	Mortality rate[a] (95 % CI[b])
All		777 (100 %)	0.16 (0.15, 0.17)
Sex	Male	340 (43.8 %)	0.15 (0.13, 0.16)
	Female	437 (56.2 %)	0.18 (0.16, 0.19)
Race/ethnicity	Asian	15 (1.9 %)	0.08 (0.04, 0.12)
	African American	199 (25.6 %)	0.27 (0.23, 0.31)
	Hispanic	123 (15.8 %)	0.14 (0.11, 0.16)
	Native American	15 (1.9 %)	0.34 (0.17, 0.51)
	White	425 (54.7 %)	0.14 (0.13, 0.16)
Region	Northeast	82 (10.6 %)	0.10 (0.10, 0.12)
	West	186 (23.9 %)	0.16 (0.14, 0.19)
	Midwest	183 (23.6 %)	0.17 (0.15, 0.19)
	South	326 (42.0 %)	0.19 (0.17, 0.21)

[a]Age-adjusted mortality per one million person-years
[b]Confidence interval

Fatal CMV disease in a normal host is extraordinarily rare; there are no data upon which to base an estimate of mortality rate. It is possible, however, that CMV influences overall mortality. Studies in older Latinos and in older adults with stable cardiovascular disease have associated CMV antibody level with mortality [20, 21]. Whether CMV infection influences cardiovascular and all-cause mortality was investigated in a representative sample of the US population from the National Health and Nutrition Examination Survey (NHANES) III, 1988–1994, and its linked mortality file, which matched participants with the US National Death Index [22]. After adjusting first for demographic factors (age, gender, race/ethnicity, country of origin, level of education), then for clinical factors (smoking, body mass index, and diabetes), and finally for serum C-reactive protein level, CMV seropositivity remained significantly associated with all-cause mortality (hazard ratio = 1.19, 95 % confidence interval 1.01–1.41). After adjusting for multiple confounders, there was not a statistically significant association between cardiovascular death and CMV seropositivity. These intriguing findings merit further study.

3.2 Morbidity

Because CMV infection and disease are reportable in only a few states, there are no data from public health reports that can be used to provide a population-based estimate of morbidity. Aside from disease in immunocompromised patients, the most important morbidity from CMV infection involves cognitive, motor, and sensory impairments that occur in children with congenital infection; and they are usually not recognized in infancy. Since approximately 90 % of newborns with congenital CMV infection lack signs or symptoms at birth, an accurate estimate of morbidity will require surveillance based on virological screening of newborns. Current estimates of morbidity due to congenital CMV infection and in immunocompromised patients are based on rates from convenience samples.

Although only a minority of infants with congenital CMV infection manifest it clinically, all newborns with congenital CMV infection shed virus in the urine and saliva. Morbidity from congenital CMV infection can be divided into clinical and laboratory abnormalities in the newborn and subsequent central nervous system (CNS) impairments. Neither the abnormalities in the newborn nor their sequelae are specific for CMV; similar morbidity occurs with other infections or diseases. Detection of congenital CMV infection requires screening newborns for the presence of the virus in body fluids. In an analysis of 15 studies (including 117,986 newborns with at least 800 in each study), virological methods detected congenital CMV infection at rates ranging from 0.3 to 1.3 %; the overall rate was 0.7 % of live births [23]. Clinical evidence of disease (symptomatic congenital infection) was present in 12.7 % of the 117,986 newborns with congenital infection [23]. It was estimated that CNS sequelae occurred in 40–58 % of infants who were symptomatic at birth and in 13.5 % of those who had no evidence of disease at birth [23]. The authors estimated that for every 1,000 cases of congenital CMV infection, there would be 5 deaths and 168–188 children with permanent sequelae; it was acknowledged that this could be an underestimate because some studies in their analysis did not provide adequate follow-up assessment of cognitive and vision function. Assuming 4,000,000 US births per year with a 0.7 % congenital CMV infection rate, there are approximately 28,000 newborns with congenital CMV infection born each year. Among those, approximately 140 deaths would occur and 5,000 children would develop permanent sequelae due to CMV infection.

3.3 Serological Methods

Cytomegalovirus infection results in production of IgG antibody to CMV which persists indefinitely; detection of IgG antibody to CMV identifies subjects who have ever had CMV infection and is the basis for seroprevalence studies. Commercially available, automated methods for detection of CMV antibody can distinguish CMV-infected from uninfected persons with a high degree of accuracy and are used to screen blood and organ or tissue donors as well as transplant recipients. Incident CMV infection is usually identified by serological methods including seroconversion from CMV IgG antibody negative to positive. Antibody isotype and avidity can be used to identify recent CMV infection in someone who tests positive for IgG antibody to CMV. After initial (primary) CMV infection, IgM antibody to CMV and low-avidity IgG antibody will be present in serum for around two to 9 months. These methods are now being used in the evaluation of women suspected of having acquired CMV during pregnancy. Serological methods are also useful in evaluating non-immunocompromised patients with mononucleosis-like illness or other symptoms that are compatible with primary CMV infection. Among immunocompromised patients, serological results are not as useful. Although screening for CMV infection prior to organ transplantation or immunosuppression can identify those at risk for primary infection or reactivation after transplantation, serum antibody measurements in immunocompromised patients are not helpful in determining whether or not CMV is causing disease; quantification of CMV viremia is preferred for this determination. Serological methods are not appropriate for diagnosis or surveillance for congenital CMV infection; virus detection by culture or polymerase chain reaction is more accurate.

3.4 Detection of Virus

Viral detection is the most reliable method for diagnosis of congenital CMV infection and for screening newborns (surveillance) for congenital CMV infection. Detection of CMV in body fluids of a newborn is proof of congenital CMV infection, and failure to detect CMV is proof that congenital infection is not present. In most other clinical settings, the presence or absence of CMV in body fluids cannot be as unambiguously interpreted. Cytomegalovirus is shed in body fluids for months to years after initial infection and shedding can recur intermittently afterward. Beyond the newborn period, shedding of CMV in body fluids signifies CMV infection but cannot reliably predict when that infection occurred unless the subject was known to be CMV antibody negative prior to and near the time that viral shedding was found. The presence of viremia is more likely to be associated with recent than past infection in an immunocompetent subject, but viremia can persist for months after primary infection.

Historically detection of CMV was based on tissue culture isolation of virus, a method that involves inoculation of clinical samples onto monolayers of human fibroblasts, careful maintenance of the tissue, with regular observation for 4 or more weeks, and identification of CMV by its characteristic focal cytopathic effect. Tissue culture methods were modified to achieve more rapid results, using monoclonal antibody to immediate early viral proteins to identify CMV in tissue culture (on coverslips in small vials or in 96-well plates) within 24–48 h of inoculation [24, 25]. Polymerase chain reaction (PCR) methods for detection of CMV DNA have a number of advantages over tissue culture-based methods. They are more rapid, making it possible to have results in hours rather than days; PCR is also more sensitive and more amendable to automation than tissue culture methods and can give quantitative results as genome equivalents per unit of sample (volume, number of cells, or mg of DNA). In immunocompromised patients, shedding of CMV in body fluids does not reliably correlate with the presence of disease due to CMV infection. The quantity of virus (or viral DNA) in the blood is more likely to correlate with CMV disease; however, the quantity of virus that is likely to be associated with CMV disease differs for different types of immunocompromised patients (solid organ transplant recipients, stem cell transplant patients, AIDS patients).

4 Biological Characteristics of Human Cytomegalovirus

Human cytomegalovirus is a large, double-stranded DNA virus with physical similarities to other members of the family *Herpesviridae*. CMV is approximately 200–300 nm in diameter with a lipid bilayer envelope through which project spikes of a number of virus-encoded glycoproteins. The envelope surrounds an amorphous tegument; within the tegument is a capsid of 162 capsomeres which contains the double-stranded DNA. The CMV genome is composed of 236,000 base pairs with 167 protein-encoding genes [26]. Reiterated terminal and internal base pair sequences divide the genome into unique long (U_L) and unique short (U_S) regions; specific genes and gene products are identified by their position in the U_L or U_S regions.

The sequence of events that unfold as virus gains entry to the host cell, activates its regulatory programs, copies its DNA, directs assembly of progeny virions, and releases these to the extracellular environment has been the subject of much study. A detailed review of that literature is recommended for the interested reader [27]. Cytomegalovirus attachment and entry are mediated by fusion of specific envelope glycoproteins with cell surface receptors including heparan sulfate, integrins, and platelet-derived growth factor. Cytomegalovirus can also enter cells via an endocytic pathway which is dependent on proteins encoded by the UL128, UL130, and UL131 gene complex. Replication of CMV involves stepwise transcription of genes as occurs with other herpesviruses; immediate early proteins appear within seconds of viral attachment and entry and serve a regulatory role, initiating replication. The delayed early proteins regulate viral DNA replication. Viral DNA replication, protein synthesis, and assembly of nonenveloped particles take place within the nucleus. The late phase of replication involves the synthesis of structural proteins, virion assembly, and release from the cell. The cytomegalovirus envelope appears to be acquired sequentially from the nuclear membrane and endosomal membranes in the cytoplasm and during transport through the Golgi apparatus and egress through the cell surface. The typical cytoplasmic inclusion seen in CMV-infected cells represents the accumulation of nucleocapsids and dense bodies (enveloped tegument without nucleocapsid or DNA) in the Golgi complex. Table 35.2 lists a small number of notable human CMV genes and gene products from a published list that includes information on function for over 100 gene products [27].

5 Descriptive Epidemiology

5.1 Demographics and Prevalence of Infection

Seroepidemiological studies of CMV prevalence have been performed on convenience samples from many different populations and ethnic groups from developed and developing countries. These studies show that CMV infection is endemic in every human population that has been studied,

Table 35.2 Human CMV genes and gene products, selected from a comprehensive published list which includes over 100 genes with assigned functions [27]

Gene	Product location or gene family	Product and function
UL32	Tegument	pp150, nucleocapsid stabilization
UL48	Tegument	Intracellular capsid transport
UL50, UL53	Tegument	Capsid egress from nucleus
UL52	Core	DNA incorporation into nucleocapsids
UL54	Core	DNA polymerase (target of ganciclovir and foscarnet)
UL55	Envelope glycoprotein	gB, multimeric forms, mediates entry
UL73	Envelope glycoprotein	gN, complexes with gM for envelopment
UL75	Envelope glycoprotein	gH, complexes with gL, role in entry when gH-gL complexes with gO or UL128-131A
UL83	Tegument	pp65, abundant tegument protein; suppresses interferon response
UL86	Capsid	Major capsid protein
UL97	Core	Viral protein kinase (phosphorylates ganciclovir)
UL100	Envelope glycoprotein	gM, complexes with gN
UL115	Envelope glycoprotein	gL, complexes with gH
UL123	Regulatory	Major immediate early protein; enhances transcription
UL128, UL130, UL131A	Envelope glycoproteins	pUL128, pUL130, and pUL131A couple with gH-gL to form pentameric complex for endocytic entry into endothelial and epithelial cells

Table 35.3 Prevalence of cytomegalovirus (CMV) infection among women of childbearing age

Study location, date	Population	*N*	% prevalence
Ankara, Turkey [28]	Women 15–49 years	745	99
Cotonou, Benin [29]	Pregnant women	211	97
Seoul, South Korea [30]	Prenatal clinic	575	96
Sendai, Japan [31]	Prenatal clinic	10,218	95
Sao Paulo, Brazil [32]	Pregnant women, middle SES[a]	427	67

though there are wide variations in age-related prevalence. Representative data from Europe, North and South America, Africa, and Asia is shown for women of childbearing age in Table 35.3. The prevalence of CMV infection in women of childbearing age is of great interest because of the public health importance of congenital infection. Studies of age-specific prevalence show dramatic differences between populations. For example, in upper- and middle-income groups from the United States and Europe, it is common for CMV acquisition to be delayed until adult years. In contrast, in developing countries prevalence is near 100 % during childhood and prior to sexual maturity. In the United States and Europe, the prevalence of HCMV infection is greater in the lower socioeconomic strata, among nonwhites, women, and immigrants from developing countries [36–38]. Child-rearing practices, particularly breastfeeding and group care of children, can have a major effect on CMV prevalence. In populations where the majority of mothers are CMV antibody positive and nurse their infants, infection rates of 50 % or more in the first year of life have been reported [39]. Group care of young children increases CMV prevalence [40]. Whether children acquire CMV from a maternal source or from other young children, they shed virus for years and will infect other children and susceptible adults. Among teenagers and young adults, sexual contact is an important source of CMV infection; indicators of sexual activity including the number of sex partners and presence of sexually transmitted diseases due to agents such as chlamydia have been associated with higher rates of CMV infection [41–44]. Customs that influence age at onset of sexual activity and sexual mores probably account for differences between populations in CMV infection rates in adolescents and young adults. Studies from developed countries report that prevalence of CMV infection is around 7–10 % higher in women than in men from the same population [38, 45]. Although CMV infection rates are higher in nonwhites than in whites, racial differ-

[b]Confidence interval

ences probably reflect differences in exposure related to child rearing, social customs, and crowding. Seasonal variation in occurrence of CMV infection has not been recognized, and epidemics have not been described; but there are reports of very high endemic infection rates in institutional populations such as day-care centers [40].

Although the majority of published studies of CMV prevalence are based on seroepidemiological study of convenience samples, two reports from the United States provide prevalence data from population-based samples. The National Health and Nutrition Examination Survey (NHANES III, 1988–1994) provided demographic data and sera from a randomly selected sample of the US population (≥6 years of age) [38]. Results summarized as age-adjusted seroprevalence are shown in Table 35.4. The overall prevalence of CMV infection was 58.9 %. Prevalence of CMV was higher in females (63.5 %) compared with males (54.1 %). Prevalence was also higher in non-Hispanic blacks (75.8 %) and Mexican Americans (81.7 %) than in non-Hispanic whites (51.2 %). Prevalence estimates increased from 36 % for the 6–11-year age group to 91 % for subjects ≥80 years of age. Factors associated with higher prevalence of CMV infection after multivariate analysis were fewer years of education, residence in the South, larger family size, foreign birth, and health insurance from a nonprivate source. NHANES data (including CMV antibody data) collected during three successive 2-year intervals between 1999 and 2004 were combined into NHANES 1999–2004, and findings were compared with those of NHANES III (1988–1994) [46]. Differences in CMV seroprevalence in the earlier and later periods were not significant. Age-related CMV prevalence estimates by sex, ethnicity, and race from NHANES 1999–2004 are shown in Fig. 35.1.

5.2 Incidence and Mechanisms of Transmission

Cytomegalovirus is acquired by contact with human body fluids that contain the virus. Knowledge of the mechanisms for transmission of CMV is based on deduction from epidemiological studies. The quantity of virus required to initiate infection is unknown. A small challenge study reported inoculation of five healthy CMV-seropositive men subcutaneously with 1×10^3 plaque forming units of a low-passage CMV strain from a newborn with congenital infection; the virus was recovered from only two subjects [47]. One of these subjects had fever, malaise, adenopathy, lymphocytosis, and abnormal liver function tests; the other subjects had milder symptoms and all symptoms cleared by 9 weeks post inoculation. There are no reported challenge studies examining other routes or sites of inoculation or in seronegative subjects. With naturally acquired infection, CMV is present in multiple body fluids for months or longer. Persons with past CMV infection shed virus in the urine, saliva, or genital secretions from time to time. The spread of CMV has been consistently associated with activities that lead to direct contact with body fluids of another person – intimate contact,

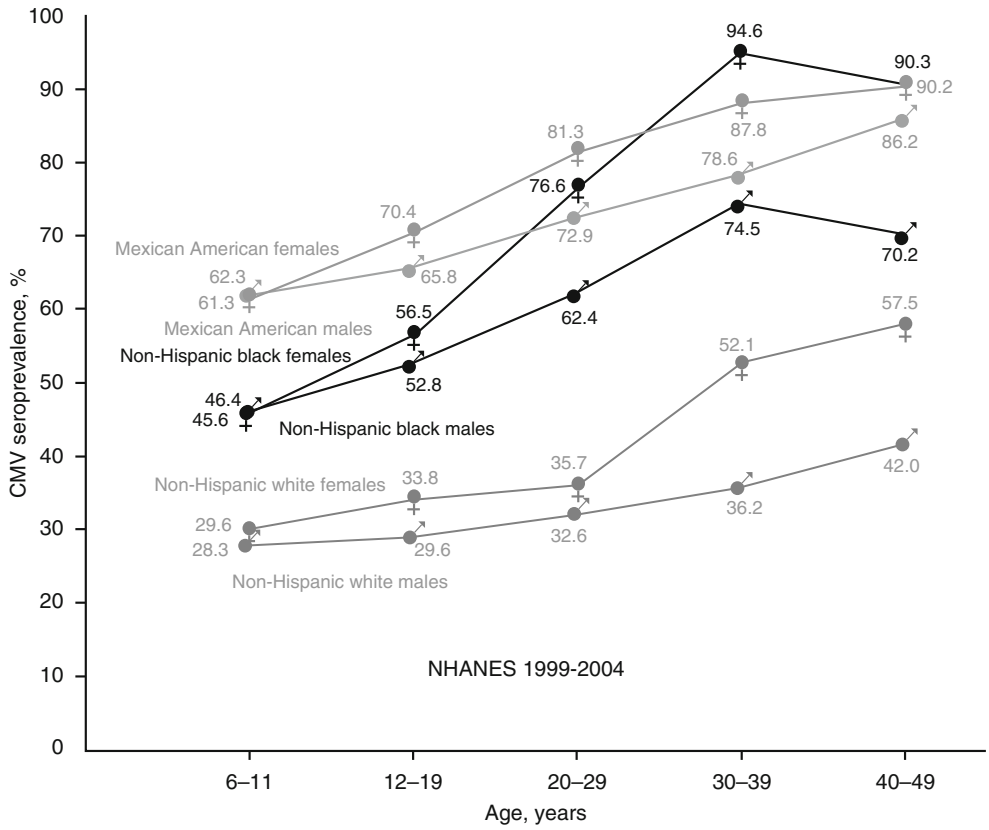

Fig. 35.1 Multivariate adjusted CMV seroprevalence by age group for the United States, based on the National Health and Nutrition Examination Survey (NHANES), 1999–2004. Results are stratified by age, sex, and race/ethnicity. Numbers adjacent to circles are prevalence. Male and female data are shown by their respective icons, ♂ and ♀. For the youngest age group, *circles* were plotted slightly above or below true values in order to separate male and female results (Reproduced with permission from Bate et al. [46])

Table 35.5 Incident CMV infection rates from follow-up of seronegative adults not selected for expected increased risk of infection

Study	Population	Sex	Age, mean years (range)	Race, % nonwhite	*N*[a]	CMV infections	Annualized rate, %/year
Birmingham, AL, USA, 1978–1984 [49]	Pregnant women, upper/middle income	Female	25.4	9.4 %	4,692	77	2.5
	Pregnant women, low income	Female	21.3[b]	89 %	507	19	6.8
Minneapolis, MN, USA, 1986[c] [50]	Nurses, nursing students, blood donors	F:M ≈ 3:1[c]	25.8 (18–59)[c]	<2 %	519	16	1.8
Birmingham, AL, USA, 1993–1998 [51]	Multigravida pregnant women, low income	Female	23.8	83 %	604	142	5.9
Giessen, Germany, 1992–2002 [45]	Blood donors	Female	(18–60)	Not given	6,018	88	0.65
	Blood donors	Male	(18–60)	Not given	7,142	67	0.45

Studies that followed 500 or more seronegative subjects and provided annualized infection rates are included

[a]*N* is the number of CMV-seronegative subjects followed

[b]This is the mean age for 4,078 low-income women screened; the mean age for the seronegative subjects was not given

[c]This study did not provide interval dates for data collection; it was published in 1986. The sex ratio and age listed are for the 943 subjects screened for antibody to CMV; specific data for the seronegative subjects followed was not given

child care, parturition, breastfeeding, blood transfusion, and organ transplantation. Rates for incident CMV infection in young adults are of interest because they can inform estimation of risk of acquiring CMV during pregnancy. Table 35.5 lists cohort studies that have followed 500 or more seronegative subjects, measured infection rates by repeated testing for antibody to CMV, and expressed results as an annualized rate. The study of blood donors from Germany reported higher seroprevalence and incidence of CMV infection in women compared with men [45]. Prevalence data from NHANES III were used to estimate CMV incidence for the US population between 12 and 49 years of age [48]. The overall incidence for seronegative persons in this age range was 1.6 per 100 person-years. The incidence was lower

Table 35.6 Reported high rates of CMV infection among adolescents and adults

Study	Exposure	Rate, %/year
Mothers [52]	Premature infant with transfusion-acquired CMV	47
Parents [53]	Child in group day care	21
	Child attends day care and is shedding CMV	30
Day-care workers, Iowa [54]	Caregiver for preschool-aged children	7.9
Day-care workers, Richmond, VA [55]	Caregiver for preschool-aged children	11
Day-care workers, Toronto [56]	Caregiver for preschool-aged children	12.5
Day-care workers, Birmingham, AL [57]	Caregiver for preschool-aged children	20
Adolescents, aged 12–15 years, Cincinnati, OH [58]	Urban adolescent clinic	13.8
Women, Seattle, WA [59]	Clients of sexually transmitted disease clinic	37

among males (1.5) than females (1.8); it was lower among non-Hispanic whites (1.4) and higher among non-Hispanic blacks (5.7) and Mexican Americans (5.1).

Table 35.6 lists situations in which exposure to CMV is expected and high incidence rates have been reported. Young children or infants who have acquired CMV from a maternal source, from other children, or even from blood transfusions in a hospital newborn nursery shed virus in the saliva and urine for years. Care of young children involves changing diapers and wiping up drool and respiratory secretions; unless great care is taken, contact with body fluids will be a daily occurrence. High rates of CMV infection have been reported in parents of premature babies who acquired CMV from blood transfusion and in parents of children who acquired infection in day-care centers – Table 35.6 [52, 53]. Group care of preschool-aged children can lead to very high rates of child-to-child transmission of CMV. The author has studied day-care centers in which every child in a classroom for 2-year-olds was shedding CMV in the saliva or urine. Not surprisingly high rates of CMV infection have been reported in child-care workers as shown in Table 35.6 [54–57]. In addition, DNA fingerprinting of virus has provided strong evidence for child-to-child transmission in day-care centers as well as child-to-parent and child-to-day-care worker transmission [58, 59]. Cytomegalovirus is present in the saliva, cervicovaginal secretions, and semen in adolescents and adults, especially those with recent primary CMV infection, and high rates of infection have been reported in adolescents and in relation to sexual activity [44, 60, 61].

5.3 Mother-to-Child Transmission of CMV

Mother-to-child transmission of CMV is important medically because of congenital infection with its attendant risk for disability due to central nervous system damage. However, transplacental transmission of CMV is a relatively uncommon event compared with transmission during birth or via breast milk. Although the latter two routes of transmission are not important causes of morbidity (with the possible exception of infection of VLBW premature newborns), they are of tremendous importance epidemiologically.

5.3.1 Intrapartum CMV Transmission

When CMV is present in the cervix or vagina at the time of delivery, the infection rate in newborns delivered vaginally is ~50 % [62]. Newborns infected during birth begin to shed virus in the urine and saliva at around 3–6 weeks of age. In full-term newborns these CMV infections rarely produce any signs of illness and are not associated with cognitive impairment [63]. In VLBW premature newborns, intrapartum CMV infection and breast milk-acquired infection have been implicated as causes of acute systemic illness characterized by a sepsis-like condition with worsening respiratory status and hematologic abnormalities similar to those seen in congenital infection [64, 65]. The occurrence of intrapartum CMV infection is dependent on maternal shedding of CMV in the genital tract. Around 10 % of CMV antibody-positive young women have CMV in the vagina or cervix by virus culture; rates near 30 % have been observed late in pregnancy [35]. In addition, genital tract shedding of CMV is more common among young women and is uncommon in women over 30 years of age [66]. Most studies on genital tract shedding employed virus culture for detection of CMV. Genital tract CMV shedding rates are higher when PCR is used for virus detection; rates of ~20–25 % have been reported in nonpregnant women [67, 68]. The impact of intrapartum transmission on CMV epidemiology depends on the seroprevalence of CMV among women and on maternal age at delivery. In populations in which nearly all mothers are CMV antibody positive, 10–15 % of newborns could acquire the virus during birth. In the United States, the intrapartum infection rate for newborns is probably less than 5 %.

5.3.2 Mother-to-Child Transmission of CMV Through Breast Milk

Cytomegalovirus can be detected in breast milk from around 95 % of CMV-seropositive mothers [69–71]. Colostrum usually has very low levels or no CMV; virus is commonly present in milk collected at weeks 2–12 of lactation [72]. Studies performed in healthy, term newborns prior to the advent of

Table 35.7 Rates of congenital CMV infection from 8 large studies that screened newborns using virus culture or PCR to detect CMV in the saliva or urine

Study	SES	Method	*N*	Congenital infections
Malmo, Sweden 1977–1986 [77]		Urine, VC	16,474	76 (0.46 %)
Birmingham, USA, 1978–1984 [49]	Middle/upper	Urine, VC	8,545	47 (0.55 %)
Canada [78]		Urine, VC	15,212	64 (0.42 %)
London, 1979–1982 [79]		Saliva, VC	14,200	42 (0.30 %)
Birmingham, USA, 1980–1990 [80]	Lower	Urine, VC	17,163	215 (1.25 %)
Sapporo, Japan, 1977–2002 [81]		Urine, VC	11,938	37 (0.30 %)
Sao Paulo, Brazil, 2003–2007 [82]	Lower	Urine or saliva, PCR	8,047	87 (1.08 %)
Eight US cities, 2008–2009 [75]	Mixed	Saliva, PCR, and rapid VC	34,989	177 (0.51 %)

VC virus culture

PCR showed that transmission of CMV through milk was clearly more likely if the milk was positive by virus culture; around 50 % of infants fed with milk that is positive by virus culture acquire CMV. In populations with high rates of both maternal seroprevalence and breastfeeding, the majority of infants acquire CMV during the first year of life [39]. Infants who acquire CMV will shed virus in body fluids for years and will transmit CMV to their peers as well as their caregivers.

5.3.3 Epidemiology of Congenital CMV Infection

Congenital CMV infection is defined by isolation of virus from body fluids collected within 3 weeks of birth. Newborn screening for virus is required to obtain accurate estimates of congenital infection rates. Screening for IgM antibody to CMV or other serological methods are not as sensitive or specific for diagnosis of congenital infection. Clinical identification of cases cannot be used because more than 90 % of newborns with congenital CMV infection will have no detectable abnormalities by physical examination. Testing urine or saliva by PCR or virus culture is the preferred approach to screening [73–75]. Screening of newborn blood or dried blood spots by PCR has received considerable study but does not appear to be as sensitive when used to screen for congenital infection as testing urine or saliva [76]. Congenital CMV infection rates from studies that screened urine or saliva from large numbers of newborns by virus culture or PCR are shown in Table 35.7; rates of congenital CMV infection ranged from 3 to 12.5 per 1,000 live births. Higher rates, around 20–40/1,000, have been reported from smaller studies in Africa and Brazil and in groups of mothers thought to be at increased risk for CMV transmission [83–86]. Congenital CMV infection rates are higher in developing countries and in low-income groups in developed countries. Other maternal characteristics associated with increased risk of congenital CMV infection include younger age, single marital status, and nonwhite race [80, 87].

Although it may seem counterintuitive that congenital infection rates would be higher in locations where rates of maternal immunity to CMV are highest, this finding is due to congenital infections in babies born to mothers who were immune prior to conception. When congenital CMV infection occurs in a mother known to be immune prior to pregnancy, the maternal infection has been referred to as a *recurrent* infection to distinguish it from primary infection. The occurrence of congenital CMV infection in offspring of immune mothers was first reported based on proven congenital infection in consecutive births to the same mother. In the 1970s, congenital infections were reported in a cohort of mothers who were known to have shed virus or to be CMV antibody positive prior to pregnancy [83]. In a more recent cohort study, congenital CMV infection occurred in 28/2,857 (1.0 %) babies born to mothers who were known to be CMV antibody positive at the time of a previous birth, an average of approximately 4 years earlier [51]. Appreciable congenital CMV infection rates (1–3.9 %) have been observed in populations in which the maternal seroprevalence was so high (95–100 %) that one could only conclude that recurrent maternal infections were the source [30, 84–86]. Other studies reported the lack of maternal IgM antibody to CMV and presence of high-avidity IgG antibody as evidence of past infection in a significant proportion of mothers of newborns with congenital CMV infection, evidence that maternal infection occurred prior to the current pregnancy [77, 82]. In low-income populations and in developing countries, in which almost all women acquire CMV prior to reproductive age, most congenital CMV infections occur in women who are immune prior to conception. In contrast, in middle/upper-income populations in the United States and some European countries, congenital infection rates in women known to be CMV antibody positive prior to pregnancy are very low, from 0.14 to 0.24 %, and most congenital CMV infections are the result of primary maternal infection during pregnancy [49, 88–92]. The occurrence of congenital CMV infection in babies born to immune mothers probably reflects reinfection; a role for reactivation or persistent infection cannot be ruled out [93, 94].

The rate of primary maternal infection during pregnancy varies from 0.7 to 4.1 % [35]. Primary infections are more common in younger mothers and in those from a lower socioeconomic

level. The rate of fetal infection with primary maternal infection during pregnancy is approximately 20–75 % [35, 92, 95]. The rate of transplacental transmission is lower when maternal infection occurs in the first trimester, and it increases with increasing gestational age, as has been observed with rubella virus and other causes of congenital infection. Symptomatic congenital infection and CNS sequelae are more likely to occur with first-trimester maternal infection [49, 96–98].

6 Pathogenesis and Immunity

CMV damages tissues by causing cell death, but it can also block host cell death programs temporarily as progeny virions are being produced. The host inflammatory/immune response may also contribute to tissue damage. Damage at the cellular level can directly affect organ function by loss of cells as occurs in the central nervous system or inner ear in congenital infection. Infection of vascular endothelial cells can lead to focal necrosis and organ dysfunction as occurs with retinitis in AIDS patients or in newborns with congenital infection. Key themes in understanding the biology of human CMV infection include its ability to infect vascular endothelium and multiple cell types in many different organ systems, the importance of cell-mediated immunity in controlling its replication and preventing disease, its elaborate mechanisms for evading host innate and adaptive immune responses, its ability to co-opt host cell-signaling pathways and cytokine systems, and its ability to establish latency and persist in the host indefinitely. Infection is probably established by inoculation of virus onto a mucosal surface or into the circulatory system (transfusion, organ transplantation, fetal infection). A plausible sequence of events would include local replication at the site of inoculation followed by viremic spread to other tissues and organs throughout the body. CMV can be found in many different organs and tissues including the salivary glands, kidneys, lung, liver, adrenal glands, vascular endothelium, endometrium, intestinal epithelium, bone marrow, retina, brain, and inner ear. Around 2–4 weeks after exposure, the replication at multiple sites likely leads to a secondary viremia, which is followed by the initial signs of disease in immunocompromised patients or the rare healthy host who develops an illness with primary CMV infection. Although the normal host immune response to CMV is nearly always sufficient to prevent disease, it does not eradicate virus. It takes months for the immune system to control viremia and even longer to terminate viral shedding in body fluids.

6.1 Humoral Immune Response

From studies in transfusion and transplant patients with primary CMV infection, it was found that IgG and IgM antibody to CMV appear 4–6 weeks after exposure. Serum IgG antibody to CMV persists indefinitely after primary infection. Antibodies to multiple CMV proteins are found in human sera after infection. Specific envelope glycoproteins, notably gB, the gH/gL/gO complex, the gM/gN complex, and a pentameric complex of gH/gL/pUL128/pUL130/pUL131A, are the principal targets of neutralizing antibody [99, 100]. Although experience in immunocompromised patients demonstrates that humoral immune response to CMV cannot control ongoing viral replication or prevent disease when cell-mediated immunity is profoundly impaired, there is no question that humoral immunity plays an important role in preventing CMV infection and disease. In transplant patients and newborns with breast milk- or transfusion-acquired infection, cytomegalovirus disease is much more significant among those who were CMV antibody negative prior to infection [101, 102]. Follow-up of seropositive and seronegative young mothers showed that the congenital infection rate in subsequent offspring was reduced by two-thirds among those who were initially antibody positive [103]. A randomized, placebo-controlled trial of a CMV gB vaccine which induces high levels of antibody showed modest efficacy in preventing CMV infection in seronegative young women and CMV disease in seronegative solid organ transplant recipients [104, 105]. In addition, prophylaxis of seronegative recipients of kidneys from seropositive donors with high-titer CMV immune globulin reduced the frequency and severity of CMV disease. There is also substantial evidence from studies in experimental animals that antibody alone can prevent CMV disease.

6.2 Cell-Mediated Immunity

The risk of human CMV disease and the severity of disease increase with impairment of cell-mediated immunity. Cytomegalovirus-specific T lymphocytes appear in the peripheral blood shortly after initial infection in the normal host and remain detectable indefinitely afterward. Cytotoxic T lymphocytes (CTLs) target a number of viral proteins; the tegument protein pp65 (UL83) and the immediate early transcription activator IE1 (UL123) are major targets of CTL [106–108]. Among transplant patients, CMV disease is most likely to occur during the time of greatest immunosuppression and among patients who have received the most potent T-lymphocyte immunosuppressive regimens. Impaired CMV-specific CTLs and CD4+ T-lymphocyte responses have been linked to CMV disease in solid organ and hematopoietic stem cell transplant (HSCT) patients and in AIDS patients with very low CD4+ T-lymphocyte numbers [109, 110]. The administration of autologous CMV-specific CTLs propagated and stimulated by antigen in vitro has been used to control CMV infection [111, 112]. CMV DNA encodes multiple genes with products related to inhibition or modulation of

natural killer (NK) cell responses, evidence that NK cell function is a key component of host defense against CMV [113–115]. There is also evidence that NK cells play a role in preventing CMV reactivation and disease in solid organ transplant patients, and severe infection due to CMV was reported in an adolescent who lacked NK cells [116, 117].

6.3 CMV Evasion of Host Defense Mechanisms

Like many other viruses, CMV has evolved means of modifying or escaping host defenses or using host cell-signaling mechanisms in ways that should promote viral replication and spread within the host and within the community. More than 25 CMV gene products (excluding those that influence the cell cycle or cell tropism) have the potential for these functions, including interference at multiple steps with MHC-I-dependent processing and presentation of antigen, with interferon induction and activity and with NK cell function [27, 118]. In addition CMV encodes host chemokine homologs (IL-10 and CXC), chemokine receptors, multiple genes that inhibit apoptosis, and chemokines that influence leukocyte migration in ways that could facilitate dissemination of virus within the host [27]. The result of all of this viral genomic focus on the host immune and inflammatory systems could well explain why CMV replication and viral shedding in body fluids continue well after antiviral antibody and cell-mediated immune responses are present. However, understanding of how viral functions interact with host defense mechanisms at the level of the whole organism to produce disease or persistent infection is limited.

6.4 Latency

Latency is a characteristic feature of herpesvirus infection. In the broadest terms, it is characterized by the absence of any evidence of viral replication and the persistence of the entire viral genome in host cells. Understanding of CMV latency is incomplete. Review of the molecular and cellular basis for latency is beyond the scope of this discussion but has been reviewed in detail [119]. The latent state is also characterized by limited viral gene expression, with the latency-associated transcripts presumably playing a regulatory role related to maintaining latency and the capability to be reactivated to productive infection in response to specific stimuli. The cellular localization of latent virus may depend on specific cellular functions that allow persistence of viral DNA but restrict viral replication. The leading candidates for the site of latency are myeloid stem cells and bone marrow progenitor cells where CMV DNA and latency-associated transcripts have been found. At the cellular level, it appears that reactivation to productive infection occurs with further differentiation of these cells or in response to inflammatory cytokines or allogeneic tissue. The molecular and cellular evidence for latency is compelling, but in a human with past CMV infection, it is not clear whether the lack of evidence of active infection (viral shedding in body fluids or viremia) is due to latency or persistent infection below the level of detection in limited cell populations such as the intestinal or salivary gland epithelium. It is clear that CMV-seropositive patients will consistently develop reactivation to the point of easy detectability during immune impairment due to drugs or HIV infection or in response to inflammation or allogeneic transplant.

7 Patterns of Host Response

7.1 CMV Infection in the Normal Host

Primary cytomegalovirus infection in healthy adults is clinically apparent in only around 10 % of subjects, and this estimate is based on cohort studies that used interviews to ascertain symptoms near the time of seroconversion. An even smaller proportion of adults with primary CMV infection seek medical attention for illness. Studies of seronegative pregnant women who seroconverted to CMV reported that less than 10 % had an illness suggestive of CMV infection during the interval of seroconversion [49, 120]. A study of 148 blood donors that seroconverted to CMV found evidence of recent infection (CMV DNA in blood) in 13. One of the 13 had clinical and laboratory findings indicative of a mononucleosis-like syndrome. In addition, myalgia was reported by 4/13 donors with primary CMV infection compared with 0/13 in a control group [121]. Symptomatic primary CMV infection in children appears to be distinctly uncommon; two studies in day-care centers where acquisition of CMV infection was common were unable to associate onset of CMV infection with illness [122, 123]. Primary CMV infection is recognized as a cause of a heterophile-negative mononucleosis that cannot be distinguished clinically from the much more common mononucleosis due to Epstein-Barr virus infection. CMV mononucleosis is characterized by fever for up to 2 weeks or longer, pharyngitis, lymphadenopathy, hepatomegaly, and splenomegaly; chills, sweats, abdominal pain, and weight loss have also been reported [124–126]. A study of patients who were referred for laboratory testing because of clinical suspicion of CMV infection and had serological evidence of primary CMV infection (CMV IgM antibody and low-avidity IgG antibody) reported that the average duration of symptoms was 7.8 weeks [127]. Children who have symptoms with primary CMV infection are less likely than adults to have fever and are more likely to have splenomegaly [128]. Rare clinical

manifestations or complications of primary CMV infection include encephalitis, transverse myelitis, Guillain-Barré syndrome, uveitis, hemolytic anemia, thrombocytopenia, vascular thrombosis, myocarditis, and colitis. Severe systemic illness with multiorgan involvement due to CMV infection has been reported [129, 130]. Unusually severe CMV infection in a presumably normal host should prompt careful investigation of the immune system including testing for HIV infection, lymphocyte subsets, and if possible T-lymphocyte and NK cell function.

Primary CMV infection in the normal host is characterized by viremia and prolonged viral shedding in the urine, saliva, and genital fluids [131–133]. Viremia (detected by PCR) is present for weeks to months, and shedding of virus in body fluids can persist for months to over a year. Viral shedding persists even longer in children; those who acquire CMV during the first year of life can shed virus in the urine or saliva continuously for years [134, 135]. Active CMV infection (virus in the blood and body fluids) persists in the presence of antibody to the virus and CMV-specific T-lymphocyte responses.

7.2 Congenital CMV Infection

As previously noted, only around 10 % of newborns with congenital CMV infection have associated clinical abnormalities at birth. The most common abnormalities noted in children with congenital CMV infection are shown in Table 35.8, adapted from Istas et al. [136]. All newborns with any of these abnormalities should be tested for congenital CMV infection unless another diagnosis has been firmly established. Microcephaly, hepatomegaly, splenomegaly, petechiae, and chorioretinitis in a newborn are suggestive of congenital CMV infection. However, accurate diagnosis requires detection of CMV in body fluids to distinguish it from other causes of congenital infection with similar clinical findings. Jaundice, hyperbilirubinemia, petechiae, thrombocytopenia, hepatomegaly, and splenomegaly usually clear spontaneously within weeks of birth [137]. Neurological abnormalities, chorioretinitis, and abnormalities on newborn brain imaging are predictive of subsequent cognitive, motor, and sensory sequelae which occur in around 40–60 % of newborns with symptomatic congenital CMV infection [23, 137–139]. Newborns with congenital CMV infection who have no clinical abnormalities at birth (asymptomatic) do much better; around 7–25 % will have sequelae with sensorineural hearing loss being the most common disability [23, 140–142]. The impact of CNS damage from congenital CMV infection on cognitive, sensory, and motor development can take years to be fully recognized. In addition, hearing loss in congenital CMV infection is often progressive or has onset after the newborn period.

Table 35.8 Clinical findings in 258 infants with congenital CMV infection who were symptomatic at birth, from data reported to the US National Congenital CMV Disease Registry, 1990–1993

Clinical feature	% patients
Non-neurological abnormalities	
Petechiae or purpura	54
Small for gestational age	47
Hepatosplenomegaly	40
Jaundice at birth	38
Hemolytic anemia	11
Pneumonia	8
Neurological abnormalities	
One or more of the following	68
Intracranial calcifications	37
Microcephaly	36
Unexplained abnormality	27
Hearing impairment	25
Chorioretinitis	11
Seizures	11
Neonatal death	9
Laboratory abnormalities	
Platelet count $\leq$75,000/mm^3	48
Direct bilirubin $\geq$3 mg/dL	36
Alanine aminotransferase level >100 U/L	23

Modified from reference Istas et al. [136]

7.3 Postnatal CMV Infection in Newborns

CMV is commonly spread from mother to newborn during birth or by breast milk; these infections are not associated with illness unless they occur in VLBW premature newborns, and even for these patients, there is disagreement as to the clinical impact of CMV infection. Clinical findings similar to those associated with symptomatic congenital CMV infection have been observed in VLBW newborns in temporal association with the onset of CMV infection acquired from the mother's milk or from blood transfusion. Morbidity from transfusion-acquired CMV infection in newborns occurs almost exclusively in those who are CMV seronegative and are VLBW, <1,200 g at birth [101]. It is now common practice to provide the blood for newborns that is from CMV-seronegative donors or that has been filtered to remove CMV. Breast milk-acquired CMV infection does not cause illness in the term, immunocompetent newborn. VLBW premature newborns have lower levels of maternal CMV IgG and may lose serum antibody to CMV within a few weeks of birth. In addition they are more vulnerable because of comorbidities and immunologic immaturity. Significant illness due to transmission of CMV from the mother's milk to VLBW premature newborns has been described [65, 143]. In these infants, onset of CMV infection was associated with worsening of respiratory symptoms, a sepsis-like illness, and thrombocytopenia. Although there has been concern that CMV infection in

VLBW newborns could cause the same sort of sequelae and disability seen in congenital CMV infection, results from different centers are not in agreement on this important point with some reporting no evidence of long-term sequelae and others reporting increased risk for CNS impairments [144–146]. A recent study with 8 years of follow-up reported normal cognitive and motor function for former CMV-infected VLBW premature newborns and a well-matched, uninfected control group. However, cognitive and motor function were slightly better in the uninfected children and differences were statistically significant [147]. With investigators differing on the frequency and importance of morbidity due to CMV from the mother's milk in premature newborns, it is understandable that there is no consensus on whether steps such as pasteurization or freezing to inactivate CMV should be taken to prevent transmission. However, the fact that CMV is frequently transmitted to newborns through the mother's milk and could cause disease should serve as a caution to those who provide banked human milk to premature newborns.

7.4 CMV Infection in Immunocompromised Hosts

Cytomegalovirus infection is one of the most common and persistent opportunistic infections to produce disease in immunocompromised patients. Impaired immunity, especially T-lymphocyte function, leads to reactivation of CMV and active viral infection and with substantial immune impairment, CMV disease. For patients who encounter CMV for the first time while immunocompromised, the risk of CMV disease is greater. This fact is particularly relevant to transplant patients for whom the transplanted organ or tissue or blood transfusions could be the source of a primary CMV infection. The manifestations of and risk factors for CMV disease as well as diagnostic methods and approaches to treatment vary according to the clinical setting and can be quite different for transplant patients compared with AIDS patients.

7.4.1 CMV Disease in Solid Organ Transplant Patients

Cytomegalovirus infection defined by the presence of virus in body fluids or conversion from CMV antibody negative to positive occurs commonly after immunosuppression and transplantation; the infection rate depends largely on the proportion of patients who were CMV seropositive pretransplant, the CMV status of donors, and the intensity of the immunosuppressive regimen. The transplanted organ, blood products, and reactivation of endogenous latent virus are sources of CMV. Cytomegalovirus disease occurs in a variable proportion of CMV-infected transplant patients; reviews by leading experts provide detailed discussion of diagnosis, prevention, and treatment of CMV disease in solid organ transplant recipients [148–151]. Cytomegalovirus disease is common among seronegative recipients of organs from seropositive donors, but severe disease can also occur in solid organ transplant recipients who are CMV seropositive pretransplant and profoundly immunosuppressed by chemotherapy aimed at preventing rejection of the graft. Cytomegalovirus disease increases the length of hospitalization and significantly increases the cost of organ transplantation [152–155].

Viremia and viral shedding in the urine and other body fluids usually occur about 4–6 weeks after transplantation. Signs of CMV disease may accompany onset of viremia and usually occur within the first 12 weeks after transplantation. Common clinical and laboratory signs at the onset of CMV disease are often referred to as *CMV syndrome* and include fever, malaise, arthralgia, rash, leukopenia, and elevation of hepatic transaminases. More severely affected patients (those with primary infection and/or more profound immunosuppression) could have pneumonitis, retinitis, or gastrointestinal ulceration. Cytomegalovirus infection in solid organ transplant patients has also been associated with coinfection by other opportunistic pathogens, notably *Pneumocystis carinii*, *Aspergillus*, and other fungi, and antiviral prophylaxis aimed at preventing CMV disease has reduced the rate of secondary bacterial and candida infections [156, 157]. Cytomegalovirus infection in solid organ transplant patients has also been linked to inflammation or rejection of the donor organ – graft rejection or glomerular injury in renal transplant patients, hepatitis in liver transplant patients, pneumonitis in lung or heart-lung transplants, and coronary artery restenosis in heart transplants.

7.4.2 CMV Disease in Hematopoietic Stem Cell Transplantation

Prior to the use of antivirals to prevent and treat CMV infection, CMV was a major cause of mortality in HSCT patients largely due to its association with pneumonitis in patients with graft-versus-host disease. In the early days of bone marrow transplantation, CMV pneumonia (often in association with graft-versus-host disease) occurred in 20–40 % of HSCT recipients and had a mortality of around 85 % [158]. A study from Sweden found that CMV disease rates in HSCT patients fell to 2.2 % and mortality to 0 following implementation of effective antivirals [159]. Sources of CMV infection for HSCT patients include donor cells, blood products, and reactivation of their own latent virus. Blood products are of particular concern because transfusions of blood and platelets are often needed prior to engraftment of the transplanted stem cells. The clinical manifestations of CMV infection in HSCT patients include the CMV syndrome at the onset of infection which may resolve without further problems. Pneumonitis and gastrointestinal disease (esophagitis, gastritis, colitis) are the most common manifestations of more serious CMV

disease; encephalitis, retinitis, and hepatitis have also been attributed to CMV. The risk of opportunistic infections is also increased in HSCT patients with CMV infection. Graft-versus-host disease is one of the factors associated with severe CMV disease; other clinical variables associated with CMV disease in HSCT patients are transplantation of stem cells from a CMV-positive donor to a CMV-seronegative recipient, donor-recipient histoincompatibility, myeloablative conditioning regimens, and immunosuppressive regimens which produce lymphocyte depletion or profound T-lymphocyte functional impairment (high-dose steroids, mycophenolate mofetil, T-cell depletion, anti-CD52, and antithymocyte globulin) [160, 161].

Although the use of antivirals has reduced the rate of CMV disease in the first 90–120 days after HSCT transplant, a significant proportion of patients develop CMV disease within a few months after antiviral prophylaxis or treatment is discontinued. A report from a major US HSCT center revealed that among patients who received either prophylactic or preemptive antiviral therapy for CMV in the first 100 days post transplant, 17.8 % experienced late-onset CMV disease at an average of 5.5 months after transplant [162]. Patients with late-onset CMV disease had increased mortality, 46 %, and CMV disease recurred in 38 % of survivors. Late-onset CMV disease in HSCT patients is widely recognized as a persistent problem for which there is not yet an ideal solution. Prolongation of antiviral treatment is an option though it raises concern for development of antiviral resistance.

7.4.3 CMV Infection in Acquired Immunodeficiency Syndrome

Prior to the use of HAART, CMV disease was common among adult AIDS patients, especially those with CD4 cell counts of less than 50/mm^3. The widespread use of HAART has reduced the proportion of HIV-infected patients with profound immune impairment and dramatically reduced the occurrence of CMV disease in them. Retinitis is the most common manifestation of CMV disease in adults with AIDS; without antiviral treatment, CMV retinitis progresses to blindness [163]. Other manifestations of CMV disease in AIDS patients include gastrointestinal inflammation and ulceration involving any part or multiple sites of the digestive tract. Less common effects of CMV include encephalitis, peripheral neuropathy, polyradiculoneuritis, pneumonitis, hepatitis, adrenalitis, pancreatitis, and sialoadenitis [164, 165].

Cytomegalovirus disease is much less common in children with AIDS in developed countries but has similar manifestations when it occurs. Prior to the control of HIV infection with antiretroviral drugs, coinfection with CMV was associated with more rapid progression to AIDS in some studies in children [166, 167]. Similar to experience in adults, the use of HAART in HIV-infected children in the United States made CMV disease distinctly uncommon; data from the Perinatal AIDS Collaborative Transmission Study showed a more than tenfold reduction in nonocular CMV disease and a similar dramatic reduction in retinitis in the era of HAART compared with pre-HAART [168]. Congenital CMV infection is a potential complication of maternal HIV/AIDS. One would intuitively expect congenital infection rates to be higher among babies born to HIV-infected mothers. However, a Brazilian study of HIV-infected mothers who did not have advanced HIV infection found the rate of congenital CMV infection in their babies (2.7 %) was similar to that in babies born to mothers without HIV infection (2.9 %) [169]. Evidence from other studies suggests that maternal HIV infection does increase the risk of congenital CMV infection. A study from Spain reported an overall congenital CMV infection rate of 4.6 % in infants of HIV-infected mothers; the rate was 9.2 % prior to 1997 compared with 1.3 % afterward, and the rate was higher in mothers who did not receive zidovudine during pregnancy [170]. A report from the French Perinatal Cohort indicated that the rate of congenital CMV infection in HIV-1-uninfected infants born to HIV-1-infected mothers decreased from 3.5 % in the pre-HAART era to 1.2 % in the post-HAART era [171].

8 Treatment and Prevention

8.1 Antiviral Agents

Antivirals licensed for systemic use in the United States for treatment of CMV infection are ganciclovir, valganciclovir, foscarnet, and cidofovir. The mechanisms of action and clinical use of these antivirals have been reviewed [172]. Ganciclovir, a synthetic analog of deoxyguanosine, interferes with viral DNA replication after intracellular phosphorylation by preventing incorporation of deoxyguanosine triphosphate into viral DNA [172]. Ganciclovir has been the most widely used antiviral for CMV, but it is poorly absorbed from the gastrointestinal tract and requires intravenous administration. Valganciclovir, a valyl ester of ganciclovir, with much better oral bioavailability, is converted to ganciclovir after absorption and is often used in situations where prolonged administration of drug for treatment or prevention is necessary. Pharmacokinetic studies have established dosages for valganciclovir which will achieve systemic ganciclovir levels similar to those achieved with IV administration [173]. Foscarnet is also used to treat and prevent CMV infections in immunocompromised hosts. It is preferred in some centers in transplant patients for preemptive therapy in order to avoid the marrow-suppressive effects of ganciclovir because it is less likely to be associated with neutropenia due to bone marrow suppression [174]. Foscarnet is also used when antiviral resistance to ganciclovir is a concern and at

times in combination with ganciclovir. Cidofovir has been used primarily to treat CMV retinitis in AIDS patients. Cytomegalovirus resistance to ganciclovir is associated with prolonged antiviral use and treatment failure [175]. Antiviral resistance has been reported with each of the antivirals that are licensed for CMV treatment or prevention; a review that covers the epidemiology, molecular basis, diagnosis, and management of CMV antiviral resistance is recommended for the interested reader [176].

8.2 Antiviral Treatment of CMV Disease

Cytomegalovirus disease in immunocompetent hosts does not merit antiviral treatment; the expected outcome, with rare exceptions, is spontaneous recovery. Although no antiviral is currently licensed for treatment of symptomatic congenital CMV infection, ganciclovir has been shown to decrease the risk of progression of hearing loss and improve developmental outcome when given to newborns with severe symptomatic congenital CMV infection intravenously for 6 weeks [177, 178]. The use of ganciclovir to treat these newborns has been endorsed by the Committee on Infectious Diseases of the American Academy of Pediatrics; the use in less severely affected newborns was not recommended [179]. The majority of newborns with congenital CMV infection have no clinical abnormalities at birth and will not have any sequelae of infection. Whether antiviral treatment will reduce the risk of hearing loss or other sequelae in newborns with congenital CMV infection who have no abnormalities at birth is not known. The use of valganciclovir orally in the place of IV ganciclovir for treatment of congenital CMV infection is currently being investigated [180].

Antivirals are used for treatment of CMV disease defined by clinical and laboratory abnormalities in immunocompromised patients. When the patient treated for CMV disease is expected to remain profoundly immunocompromised, treatment of the acute illness is often followed by maintenance antiviral therapy over an extended period of time. In addition to treatment of the established disease, antivirals are used in transplant patients to prevent disease. Prophylactic administration of antiviral, usually ganciclovir, from the time of transplant for several months is used in situations in which the perceived risk of CMV disease is high enough to counterbalance the potential toxicity of the antiviral or the risk of antiviral resistance, for example, in CMV-negative recipients of a solid organ transplant from a CMV-seropositive donor. In centers in which there is laboratory capability for rapid and frequent measure of the quantity of CMV in the blood, a preemptive approach to prevention is often used. Preemptive strategies are based on frequent laboratory monitoring of the quantity of CMV in the blood (likely using quantitative real-time PCR) with administration of antiviral triggered by detection of a quantity of CMV DNA in the blood associated with a significant risk of disease. Reviews of CMV disease in solid organ and HSCT patients by experts and consensus guidelines sponsored by professional organizations consider the evidence for antiviral strategies and provide recommendations on antiviral use in transplant patients [150, 151, 160, 181–183]. There are similar guidelines for HIV/AIDS patients, though the effective use of antiretroviral agents to control HIV infection and prevent development of immune impairment has dramatically reduced the occurrence of retinitis and other manifestations of CMV disease [167, 184].

8.3 Prevention of Maternal and Congenital CMV Infection

Prevention of CMV infection in pregnant women was recently reviewed [185]. The two most important sources of maternal CMV infection are contact with young children and sexual contact. Because CMV infection in the normal host is almost always clinically silent and shedding of CMV in body fluids can continue for months to years after initial infection, control efforts must be based on the assumption that the saliva, urine, or other body fluids from anyone are a potential source of CMV. Aside from transfusion and organ transplantation, it is rare for the circumstances of CMV exposure to be identified in time for postexposure prophylaxis to be considered. There is currently no role for postexposure prophylaxis with immune globulin or antivirals as there are no data on their efficacy or safety. Hand washing and careful attention to hygiene are recommended to prevent CMV infection in pregnant women. The Centers for Disease Control and Prevention has made specific recommendations for prevention of CMV infection for pregnant women and persons who care for infants and children which are aimed at interrupting exposure to body fluids, shown in Fig. 35.2. Some prenatal care providers screen pregnant women for antibody to CMV during pregnancy though this practice is uncommon in the United States. Such screening could be used to identify those with serological evidence of primary infection (CMV IgM antibody positive with low-avidity CMV IgG antibody) for counseling and prenatal diagnosis. In addition it would be possible to target women who were seronegative with information aimed at decreasing their risk of infection. Studies in pregnant women demonstrated that rates of CMV infection could be reduced by intensive efforts to educate seronegative women on risks and consequences of CMV infection during pregnancy and on recommended methods for prevention [186, 187]. Screening of pregnant women for CMV infection or susceptibility has not been recommended by obstetric organizations [188–191]. Screening of pregnant women for CMV will merit further consideration when it is clear that accurate tests for primary CMV infection are widely available, evidence for the

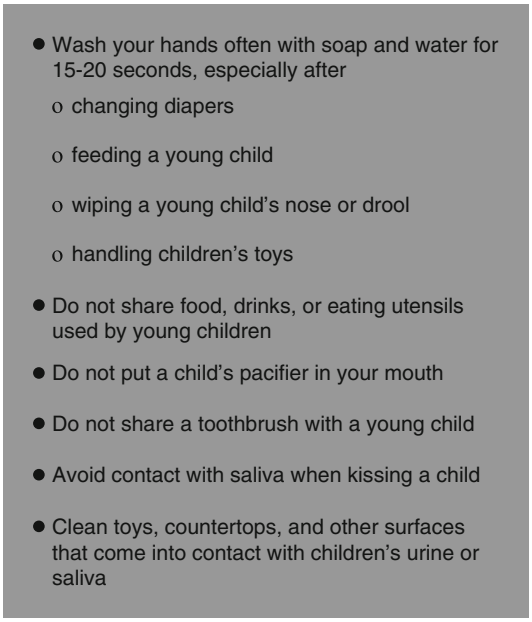

Fig. 35.2 Centers for Disease Control and Prevention of the United States Public Health Service recommendations for pregnant women to decrease risk of maternal and congenital CMV infection [32]

effectiveness of prevention measures is stronger, and interventions other than termination of pregnancy if fetal infection is found are available. The American College of Obstetricians and Gynecologists does recommend counseling women with young children or those who work with young children on the use of gloves and rigorous hand washing after contact with diapers or respiratory secretions [188].

Passive immunization with CMV immune globulin preparations has been studied for prevention and treatment of fetal CMV infection. In 2005, a study of CMV immune globulin in women with primary infection early in pregnancy reported a fetal infection rate of 16 % in women who received serial injections of CMV immune globulin compared with 40 % in those who chose no treatment [192]. A retrospective study reported higher frequency of adverse outcome 16/37 (43 %) for infants of women with primary CMV infection early in gestation during years when CMV immune globulin was not being used, compared with infants of women enrolled in later years who were given a single treatment of 200 Units per kilogram of CMV immune globulin 4/31 (13 %) [193]. A randomized, placebo-controlled, observer-blind clinical trial found no statistically differences between CMV immune globulin recipients and placebo recipients in the rate of fetal infection or the clinical outcome of congenital infection [194]. In addition there was not a significant difference in neutralizing antibody or antibody avidity between women who transmitted virus to the fetus and those who did not. A large, randomized, placebo-controlled, phase 3 clinical trial of CMV immune globulin for prevention of congenital infection through treatment of women with primary gestational CMV infection is enrolling subjects [195].

8.4 Prevention of Healthcare-Acquired CMV Infections

Cytomegalovirus infections that occur as a result of hospitalization or as a complication of medical care can cause significant morbidity in organ transplant recipients, VLBW newborns, pregnant women, patients with congenital and acquired immunodeficiencies, and patients receiving immunosuppressive medications. Cross infection from healthcare worker to patient or from patient to patient through fomites or healthcare workers is rare, probably because it is prevented by hygiene practices that are a routine part of hospital care. For hospitalized patients known to have CMV infection, standard precautions are recommended. Transmission of CMV in the healthcare setting is a potential complication of blood transfusions, assisted reproductive technology, transplantation of organs or tissue, and provision of banked human milk to premature newborns. The latter two have been discussed in Sects. 8.4 and 8.3, respectively.

8.4.1 Prevention of Transfusion-Acquired CMV Infection

Transmission of CMV through blood transfusion is prevented by limiting vulnerable patients to transfusion with the blood from donors who have never been CMV infected (CMV IgG negative) or by filtering the blood through commercially available cotton wool filters, which remove white blood cells and have been shown to reduce the risk of transfusion-transmitted CMV infection [196]. Selection of seronegative donors is more effective for preventing transfusion-acquired CMV infection and disease in HSCT patients than is leukoreduction [197]. A meta-analysis of studies that compared selection of seronegative donor blood to leukoreduction concluded that the former was associated with a 58 % reduction in risk of CMV infection [198]. However, a survey of the American Association of Blood Bank physicians in 2010 found that 65 % of respondents considered leukoreduction and selection of CMV-negative donors to be equally effective for prevention of CMV infection [199]. Practices differ among institutions as to which approach is used and whether blood products from CMV-seronegative donors are provided to specific high-risk groups of patients.

8.4.2 Prevention of CMV Transmission Through Assisted Reproductive Technology

It is common to find CMV in the semen, though published rates vary widely depending on the population studied and

method used for viral detection. Using cell culture, CMV was found in the semen of 3/54 (5.6 %) young adults in North Carolina [200]. A study in HIV-uninfected subjects in Paris reported detection of CMV by cell culture in the semen from 7/111 (6.3 %) of male partners of women with human papillomavirus infection [201]. A study of 635 cryopreserved semen samples from 231 donors in France found that 1.57 % overall were culture or PCR positive as were 3.3 % of CMV-seropositive donors [202]. A study in an infertility clinic in Crete reported 50/172 (29 %) semen samples were positive for CMV by PCR [203]. A study of couples from an in vitro fertilization program in Texas reported 25 % of 53 semen samples positive for CMV by PCR; none of 568 oocytes and embryos not suitable for cryopreservation were positive for CMV [204]. There is justifiable concern over the possibility for transmission of CMV to recipients of donor sperm, especially to CMV-seronegative recipients, because they could potentially develop a primary CMV infection at the time of conception. It was estimated from CMV seroprevalence in recipients and donors in an infertility clinic in France that the risk of insemination of a CMV-seronegative woman by the semen from a CMV-seropositive donor would be 21 % if there was no matching of seronegative women with the semen from seronegative donors [205]. In the United States, the Food and Drug Administration (FDA) regulates transplantation of human cells and tissue, including the semen and oocytes, and requires establishments that transfer human cells to follow written protocols to prevent transmission of infections [206]. The FDA also lists commercial antibody assays that have been cleared for screening for IgG and IgM antibody to CMV [207]. The American Society for Reproductive Medicine has published guidelines for assisted reproductive technology aimed at preventing transmission of CMV and other infectious agents. The guidelines recommend screening of recipient women and semen donors for CMV IgG and IgM antibody and state that the semen from CMV-seropositive donors should be restricted to seropositive recipients [208].

8.4.3 Prevention of Transmission of CMV from Patients to Healthcare Workers

Transmission of CMV from patients to healthcare workers is very unlikely if standard hospital hygiene and infection control practices are followed. The rates of incident CMV infection among healthcare workers with patient contact do not appear to be different from those among adults of similar age [50, 209]. It is important to recognize that most patients who have CMV in body fluids will not be identified, especially in pediatric wards, because acquisition of CMV is a normal childhood occurrence and CMV-infected children shed virus for years. Therefore, rather than singling out patients known to have CMV infection for special precautions or restricting pregnant healthcare workers from caring for them, healthcare workers should consider all patients as potential sources of CMV. The Hospital Infection Control Practices Advisory Committee of the CDC has recommended standard precautions, the same precautions used for of all hospitalized patients, for patients with CMV infection [210]. Screening healthcare workers for CMV antibody was not recommended.

8.5 Cytomegalovirus Vaccine

An expert panel assembled by the Institute of Medicine concluded that the development of a vaccine to prevent congenital CMV infection should be a top priority for the United States for the twenty-first century [211]. The first clinical trial with a CMV vaccine was conducted in the early 1970s, and there have been numerous clinical trials with a small number of different CMV vaccine platforms in the intervening 40 years. Immunization with the Towne CMV vaccine, a live virus vaccine attenuated by serial in vitro passage, reduced the severity of disease due to primary CMV infection in seronegative renal transplants who received kidneys from seropositive donors [212]. However, it did not prevent infection in transplant patients or in parents whose children had acquired CMV in day-care centers [213]. A randomized, placebo-controlled, phase 2 clinical trial with a subunit vaccine composed of recombinant CMV envelope glycoprotein B with MF59 adjuvant showed 50 % efficacy for prevention of CMV infection in seronegative young mothers, the first evidence for vaccine prevention of CMV infection [104]. A randomized clinical trial with the same vaccine in solid organ transplant patients showed that vaccine recipients were less likely to develop viremia or require preemptive antivirals than placebo recipients [105]. A more recent clinical trial with a plasmid DNA vaccine showed that immunization of HSCT patients could reduce the frequency and magnitude of viremia, a surrogate marker for CMV disease [214]. A number of novel CMV vaccines are now in development [215]. Although there is optimism about the development of a CMV vaccine that can prevent maternal or congenital infection and reduce disease burden in immunocompromised patients, no phase 3 clinical trials are yet underway, and any prediction of when a licensed vaccine will be available would be speculative.

9 Unresolved Problems

The importance of CMV as a fetal and neonatal pathogen causing morbidity, mortality, and disability is well established as is the role of CMV as an opportunistic infection in

immunocompromised patients, especially transplant recipients. The knowledge of routes of transmission of CMV and the use of antiviral drugs have contributed to prevention and treatment of CMV disease in these patient groups. Although substantial effort and expense are currently devoted to preventing and treating CMV disease, it remains a major problem for immunocompromised and especially transplant patients. Antiviral treatment of newborns with congenital CMV infection appears to have a very modest effect on outcome, and prevention of congenital infection is more of a hope than a reality. The biggest unresolved problem in control of CMV infection is the development of vaccines that can prevent fetal infection and CMV disease in immunocompromised patients.

There is growing interest in a possible role for CMV infection as a cause of a wide variety of chronic diseases. It has been linked to all-cause mortality and proposed as a factor in immune senescence, an explanatory term for the decreased ability of the aged to combat infections [22, 216]. Immune senescence is characterized by reduced numbers of naïve T lymphocytes, decreased diversity of naïve T-lymphocyte receptor repertoire, and decreased diversity and function of CD4+ and CD8+ T cells [217]. Biological evidence suggesting a role for CMV in immune senescence comes from studies documenting the broad immunogenicity of CMV proteins and the remarkable domination of T-lymphocyte responses in CMV-seropositive subjects with around 10 % of CD4+ and CD8+ memory cells committed to CMV, a level of immunodominance not seen with other infections [218]. Cytomegalovirus infection has been associated with decreased immunogenicity of influenza vaccine in subjects aged greater than 60 years, in whom an increase in late-differentiated CD4+ T cells was also associated with decreased immune response [219]. It has been hypothesized that the preoccupation of the immune system with CMV diminishes its ability to deal with other infections as a result of accumulation of terminally differentiated T lymphocytes specific for CMV and increased levels of inflammatory cytokines [220].

CMV has also attracted interest as a possible factor in development of chronic vascular and autoimmune disease. The virus infects vascular endothelial cells and induces angiogenesis; abnormal neovascularization promoted by CMV infection has been proposed as a mechanism for induction of atherosclerosis [221, 222]. The association between CMV infection and coronary restenosis in cardiac transplant recipients and accelerated graft rejection in other solid organ transplant patients is well established. Furthermore, a study in non-immunocompromised adults reported an association between the presence of serum IgG antibody to CMV and impaired in vivo response to endothelium-dependent vasodilators [223]. However, two large seroepidemiological studies failed to confirm an association between CMV infection and atherosclerotic diseases [224, 225]. Although Guillain-Barré syndrome, immune thrombocytopenia, and autoimmune hemolytic anemia are generally accepted as rare complications of primary CMV infection, the association between CMV and other autoimmune diseases is more controversial. A role for human CMV infection has been proposed in the onset or progression of systemic lupus erythematosus, systemic sclerosis, and type 1 diabetes [226–230]. It will be challenging to sort out what role CMV infection plays in these and other specific chronic diseases. Inflammation and immunosuppression used to treat autoimmune diseases can trigger reactivation of human CMV, and the virus encodes a number of genes which reflect its complex interaction with the host inflammatory system. The associations with autoimmune diseases could be due to epidemiological, pathogenic, or host genetic features that are not fully understood at this time [228, 231]. If it becomes clear that CMV plays an etiologic or even facilitating role in atherosclerosis or autoimmune disease, the current view of CMV as a major problem for the fetus and immunocompromised persons and a relatively benign, silent commensal for others would be radically changed. It would then be necessary to intensify vaccine development and to formulate strategies aimed at preventing CMV infection in everyone rather than at preventing disease in vulnerable groups.

Human Herpesviruses: Herpes Simplex Virus Types 1 and 2

36

Christine Johnston, Rhoda Ashley Morrow, and Lawrence R. Stanberry

1 Introduction

The term *herpes* has been used in medicine for at least twenty-five centuries [1]. The word έρπης, from the verb έρπειυ (to creep), was used by the ancient Greeks to describe spreading cutaneous lesions of varied etiology [2]. The "herpetic eruptions which appear about the mouth at the crisis of simple fever" were first described around 100 AD by a Roman physician, Herodotus. About 1,600 years later, herpes of the genital tract was first reported by a French physician, Astruc. By the nineteenth century, the generally accepted use of the term *herpes* was restricted to certain diseases associated with vesicular eruptions. Early in the nineteenth century, Willan and Bateman first suggested that herpes labialis, herpes genitalis, and herpes zoster could be differentiated from each other based on clinical features [1]. By the latter part of that century, a recognition of cytopathological differences permitted discrimination between infections of the pox and the herpes groups. In the early part of the twentieth century, epidemiologic and experimental studies further supported the distinction between herpes zoster and oral or genital herpes. The studies of Gruter and other European workers showed that specimens obtained from zoster lesions could not be transmitted to the rabbit cornea, in contrast to those obtained from the other two herpetic conditions. Around 1920, a German physician, Lipschutz, maintained that, although biologically related, orolabial herpes and genital herpes were etiologically different.

Over the ensuing 40 years, the experimental host range of herpes simplex viruses was widened to include other laboratory animals, chick embryos, and ultimately cell cultures. The clinical spectrum of HSV infections was expanded to include gingivostomatitis, encephalitis, meningitis, Kaposi's varicelliform eruption, and neonatal disease. Data also accumulated to show that HSV infections could recur in the presence of demonstrable levels of serum antibodies.

In the early 1960s, Schneweis [3] in Germany and Plummer [4] in England reported antigenic differences among HSV strains. By 1967, Nahmias and Dowdle [2] in the United States had demonstrated that the large majority of genital and newborn infections are caused by HSV-2 and that most nongenital infections are caused by HSV-1, relating these clinical findings to the usual mode of transmission of the two virus types. By the 1970s, strain differences of the two HSV types were illuminated at the molecular level by restriction endonuclease analysis of their viral DNAs [5]. In more recent times, the use of type-specific serologic tests and polymerase chain reaction (PCR) methods has allowed for the rapid detection and accurate typing of HSV infection.

2 Description of Agent

Herpes simplex viruses belong to the Herpesviridae family, a collection of more than 300 DNA viruses that infect a wide range of species from fungi to man [6, 7]. The other human herpesviruses are cytomegalovirus (CMV), varicella zoster virus (VZV), Epstein–Barr virus (EBV), and human herpesviruses 6A (HHV-6A), 6B (HHV-6B), 7 (HHV-7), and 8 (HHV-8). All of these viruses have the capacity to persist in their natural host, either in neural cells, e.g., HSV and VZV, or in nonneural cells, e.g., CMV, EBV, HHV-6, HHV-7, and HHV-8. The sequence and positional relationships of multiple genes suggest that the human herpesviruses were derived

from a common ancestral herpesvirus that existed, perhaps, 400 million years ago [8]. The high prevalence in primitive societies of antibodies to the nonsexually transmitted human herpesviruses, in contrast to the low prevalence of antibodies to nonpersistent viruses [9], emphasizes the survival advantage conveyed by viral persistence and supports the notion of an early origin of the herpesvirus family. HSV-1 and HSV-2 are closely related alpha herpesviruses that share about 50 % nucleic acid homology and 83 % amino acid sequence identity indicating these two viruses evolved from a common ancestor [7]. Based on amino acid sequence analysis, it has been estimated that the two viruses diverged between 8 and 10 million years ago [10, 11]. It has been hypothesized that divergence occurred as a consequence of bipedalism, the acquisition of continual sexual attractiveness by the ancestral human, face-to-face mating, and increased microbiological separation of the respective sites of infection [9, 11]. It is also possible that HSV-1 is more closely related to the ancestral herpesvirus and that HSV-2 represents recent evolution of the family.

Despite an early observation [12] that HSV-1 is more likely to be associated with a nongenital infection and that HSV-2 has a predilection for genital infection, both HSV-1 and HSV-2 can cause oral and genital primary infections. However, the viruses do differ in their propensity to cause recurrent infections, with recurrent oral and ocular infections more likely to be due to HSV-1 and recurrent genital infections more likely to be caused by HSV-2 [12, 13]. It has been proposed that the two viruses evolved in part to facilitate reactivation from the distinct sensory ganglia: HSV-1 from trigeminal ganglia and HSV-2 from sacral ganglia. Animal model studies using chimeric mutant viruses suggest that the unique latency-associated transcript (LAT) regions of the two viruses may confer the anatomic site-specific reactivation profile [14]. There are some other interesting biological differences between HSV-1 and HSV-2 including differences in susceptibility to some antiviral agents [15], differences in lability to temperature (HSV-2 is more labile at 39 °C than HSV-1), and the apparent ability of fever to trigger recurrent fever blisters (labial herpes) but not genital herpes.

Herpes simplex viruses consist of four major morphological components: a centrally located core surrounded by three concentric structures—the capsid, the tegument, and the envelope (Fig. 36.1).

The core contains DNA coiled around proteins arranged in the form of a barbell. The icosahedral capsid contains 162 capsomeres and measures around 100 nm. Between the capsid and the envelope is the tegument, composed of fibrillar material. The envelope, derived from nuclear and, occasionally, other cell membranes, confers a diameter of 150–200 nm on the complete virus particle. The lipid composition of the envelope makes the virus particularly susceptible to ether and other lipid solvents. Herpes simplex viruses are labile outside the host, losing infectivity within minutes to hours [17, 18]. Virus infectivity is lost more quickly at extremes of temperature and pH and with exposure to ultraviolet and ionizing radiation or surface active agents such as nonoxynol-9 [19].

The HSV-1 virion contains a linear double-stranded DNA molecule of 152 kilobase pairs (kbp). The genome of HSV-2 is slightly larger at 155 kbp. About half of the HSV-1 and HSV-2 DNA sequences are homologous, and they share approximately 83 % amino acid sequence identity. Ongoing work is defining the biological roles of the 74 viral genes encoded by each virus. In addition to encoding proteins required for viral replication, the viruses encode several proteins and microRNAs (miRNAs) that facilitate immune evasion [20, 21]. HSV-1 and HSV-2 have a wide in vitro and in vivo host range, being able to infect a wide variety of cell types of human or animal origin as well as numerous types of experimental animals, ranging from mice to monkeys [22–26]. HSV-1 infection does not protect against HSV-2, but it may decrease the risk of symptomatic seroconversion [27].

HSV-1 encodes for at least 11 glycoproteins, of which gB, gD, gH, gK, and gL are essential for productive infection in cell culture [28, 29]. HSV gG is type-specific, and gE and gI can act as a receptor for the Fc portion of IgG. HSV gB, gD, and the heterodimer gH/gL are involved in viral entry into the cell [30].

3 Laboratory Methodology Involved in Epidemiologic Analysis

3.1 Serology

Development of radioimmunoassay-based gel methods [31], then, more convenient Western blot methods, allowed accurate discrimination of antibodies to HSV-1 from those directed against HSV-2 antigenic targets [32, 33]. Because HSV-1 typically is acquired early in life, later acquisition of HSV-2 induces anamnestic responses to type-common epitopes, effectively masking the type-specific HSV-2 response in tests based on the relative strength of neutralization or binding of serum antibodies to crude HSV-1 or HSV-2 antigen mixtures. Studies of patients who were seroconverting to HSV-1 or to HSV-2 showed that the Western blot ("HSV-WB") was uniquely able to overcome the anamnestic response to detect type-specific antibody production in those with prior HSV-1 infection [32, 34]. HSV-WB remains the gold standard test for confirming the presence of HSV-2 antibodies [35].

Two other reference tests, the immunodot enzyme assay (IEA) developed at Emory University [33] and the gG-2 monoclonal antibody blocking assay developed by the Central Public Health Laboratory (CPHL) in London

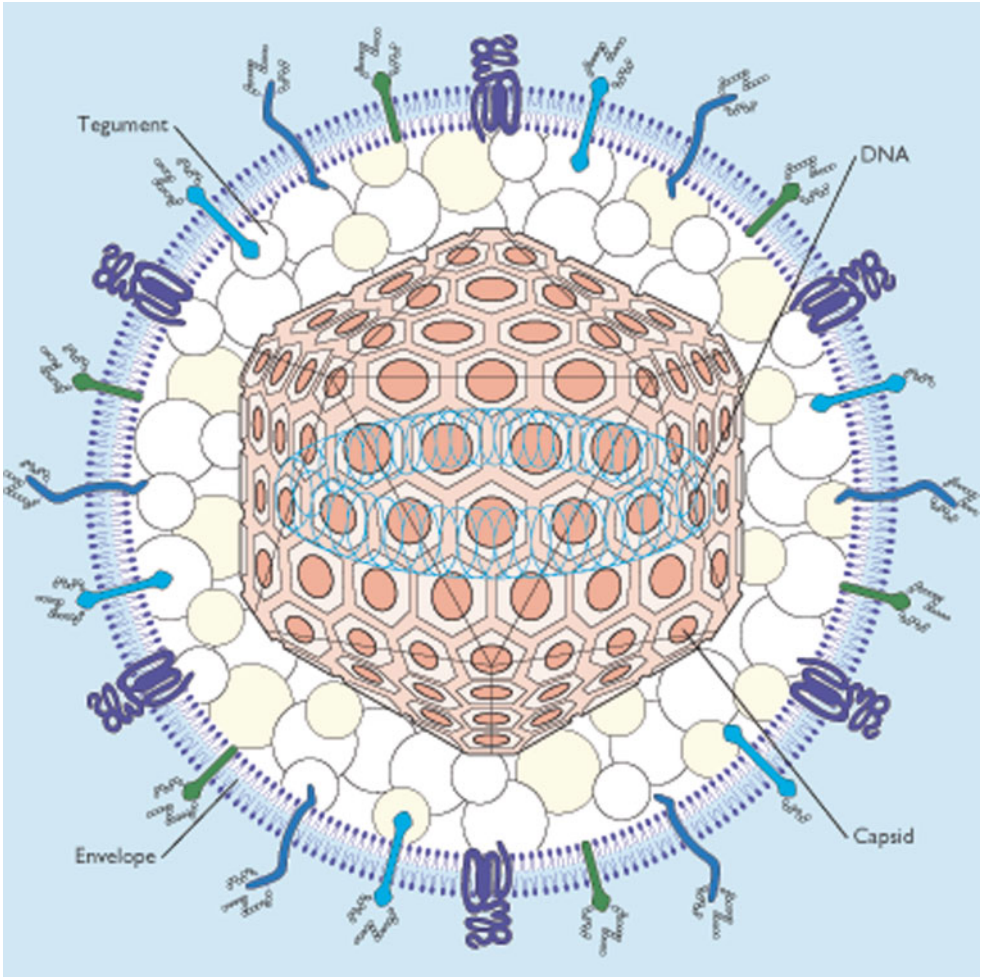

Fig. 36.1 Schematic of HSV virion (Adapted from Johnston et al. [16])

[36, 37], were extensively validated against HSV-WB in populations with well-characterized, virologically defined infections. The IEA has played a key role in tracking the prevalence of HSV-2 over time in the United States [38–41]. The CPHL test has been used to determine HSV-2 prevalence in European countries [42].

In the 1990s, HSV-WB was used to characterize the performance of tests based on a single type-specific glycoprotein, gG-1 from HSV-1 and gG-2 from HSV-2, for detecting antibodies to HSV-1 and HSV-2, respectively. Most gG-based tests have simpler, enzyme immunoassay formats, and a number of these EIAs are now available commercially (Table 36.1). The HerpeSelect HSV-2 IgG EIA from Focus Technologies is the most widely used, FDA-approved, commercial type-specific serology in the United States for diagnostic testing, with results calculated as an index value. The test operates well in the high positive range (index value >3.0), but care must be taken in interpreting low-positive results, due to possible antibody cross-reactivity with HSV-1 resulting in a false-positive result. In one large study, only 35 % of low-positive results were confirmed as positive by HSV-WB [43]. The EIAs developed by Alere, EUROIMMUN, and Trinity are all FDA approved but have had limited published performance data [44, 45].

At least one commercial EIA (from Focus Technologies) can be successfully applied to antibodies eluted from dried blood spots, a potential advantage for seroprevalence studies in areas without serum storage or laboratory testing capacities [46]. Other gG-based tests such as the "Biokit HSV-2 Rapid Assay" use membrane and lateral flow technologies to provide near-patient or "point of care" testing outside of laboratory settings [47]. While commercially available, the relatively high cost of the Biokit rapid assays has outweighed its potential value in determining seroprevalence of HSV-2 in underserved areas of the world. However, the Biokit rapid assay has been useful in some settings as an alternative to limited-availability reference tests to confirm the results of EIA-positive tests in serum samples [43, 48].

Within 10 years of the development of type-specific serologic tests for HSV, commercial and reference tests became critical research tools for the descriptive epidemiology of genital HSV-2 in populations around the world, revealing HSV-2 prevalence that varied widely by region, gender, and age [49]. The CPHL monoclonal antibody blocking test was

Table 36.1 Examples of HSV type-specific serology tests

Test format	Examples	Advantages	Limitations for seroepidemiologic studies
Enzyme immunoassay, FDA approved	HerpeSelect IgG ELISA (Focus) HSV Captia (Trinity) EUROIMMUN Alere/Wampole	Commercially available	Population-specific performance issues of some tests
Enzyme immunoassay	Kalon HSV-2 EIA	Commercially available Better specificity in African populations than other EIAs	Lower sensitivity than other EIAs for early seroconversion
Membrane rapid assays	Biokit HSV-2 rapid assay	Near-patient format Commercially available Possible utility as confirmatory assay	More expensive per test than EIA
Western blot	HSV Western blot (University of Washington, USA)	Validated against clinical and virologic criteria	No commercial formats, limited availability
Reference tests	Immunodot enzyme assay (IEA) (Emory and CDC,USA) gG monoclonal antibody inhibition assay (CPHL, UK)	Validated against clinical and virologic criteria or UW HSV Western blot	No commercial formats, limited availability
High-throughput tests	Bio-Rad HSV IgG	Multiplexed, FDA approved	Limited availability

used to demonstrate the low specificity of most commercial enzyme immunoassays in sera from sites in Africa [45]. There is now an extensive literature using either the CPHL test or the HSV-WB as gold standards that document poor specificity of the Focus Technologies HSV-2 EIA in sera from sub-Saharan Africa [50, 51] and the Republic of South Africa [48]. A selective, further loss of specificity reported in the HIV-positive subpopulations in these areas was not replicated in a large study in Kampala, Uganda [52]. To a lesser extent, the EIA from Kalon and the rapid assay from Biokit also exhibit lower specificity than in North American populations [52–54]. The combinations of tests and changing cutoffs for positive results may mitigate the specificity problems [48, 51, 54], but until the underlying cause is discovered and serologic assays are developed to overcome the problem, seroepidemiologic outcomes for HSV-2 should take into account the method used and any confirmatory testing used in the study.

The availability of accurate type-specific serology also led to a modification in the definition of genital herpes to recognize the high proportion of patients who become infected without recognizable symptoms. The understanding that genital herpes is often unrecognized by clinicians based on clinical presentation alone [55, 56] led to recommendations for laboratory testing, in general, and for type-specific serology, specifically, in high-risk populations [57]. It is not recommended to use HSV IgM testing to diagnose HSV. While IgM can be more sensitive than IgG for individuals who are seroconverting to HSV, IgM is also produced in many individuals during the course of recurrent shedding episodes. Thus, even type-specific IgM is a poor marker of first-episode HSV infection [58]. Avidity tests have been developed to discriminate between first and subsequent HSV-2 episodes, but these tests have not been adapted for widespread commercial use [59].

Because no serologic assay has yet been described that can discriminate between HSV-1 antibodies elicited by oral versus genital infection and because the most widely used commercial HSV-1 type-specific serology tests may lack sensitivity [60, 61], current estimates of genital HSV-1 prevalence may be conservative.

3.2 Virus Detection Methods

Direct observation of virus in patient or subject samples provides strong causal inference of symptom etiology. Methods that have been well described for HSV diagnosis include those that detect type-common or type-specific HSV antigens, viral culture, or various viral nucleic acid detection techniques. Each approach has advantages and limitations as applied to studies intended to define the role of HSV in clinical syndromes or conditions for transmission of the virus (Table 36.2). DNA amplification methods such as polymerase chain reaction (PCR) and viral culture share the advantage of amplifying the target virus or nucleic acid before detection and are, therefore, far more sensitive than antigen detection methods.

Early studies of HSV shedding and transmission were generated using viral culture-based methods [56]. Since HSV viability depends on collection and transport methods, use of viral culture may underestimate presence of virus [62, 63]. Once a specimen arrives in the laboratory, cell culture isolation methods can markedly affect the ability to detect HSV by its characteristic effects on cell morphology or cytopathic effect (CPE). Choice of host cells and length of time that cul-

Table 36.2 Advantages and limitations of HSV-specific detection methods as used for epidemiology studies

Method	Advantages	Limitations
Antigen detection	Can simultaneously detect and type as HSV-1 or HSV-2 Inexpensive, fast to perform (2–4 h) Less vulnerable to virus degradation than culture	Lack of sensitivity
Viral isolation in cell culture	Virus is amplified via several replication rounds before detection More sensitive than antigen detection	Virus may lose viability in transport Recognizing CPE is subjective and requires training for expertise Requires antigen detection to definitively identify CPE as being due to HSV Slow to perform (3–10 days)
Modified viral dulture	Faster than culture (16–48 h) Some viral amplification provided greater sensitivity Less expensive than culture Objective endpoint allows readout by less experienced personnel	Viable virus required Less sensitive than standard culture
ELVIS™ HSV ID	Faster than culture (24 h), more sensitive than other modified culture methods Objective, colorimetric readout	Binding virus required Less sensitive than some culture techniques Much less sensitive than PCR
DNA amplification and detection (PCR)	Most sensitive of all testing methods Not vulnerable to loss of virus viability if samples collected into extraction buffer Rapid (2–4 h) Objective readout	Older methods vulnerable to contamination May be more expensive Current lab-based methods differ from lab to lab Limited commercial kit availability

tures are held for observation are the major factors that affect the rate of positivity across laboratories. Modified culture methods that provide a short (16–48 h) amplification period in culture followed by "blind" detection of viral antigen before CPE is seen can increase sensitivity and allow simultaneous typing of isolates. A second, well-characterized, modified viral culture method, "ELVIS™ HSV ID," uses genetically modified host cells in which an HSV structural protein induces expression of an enzyme reporter gene [64].

Studies since the late 1990s have depended on nucleic acid amplification methods because of their proven superiority in sensitivity over all other methods and high specificity [65]. Closed systems such as the LightCycler (Roche Diagnostics) [66] and TaqMan (Applied Biosystems Inc.) [67] methods greatly reduced the contamination of specimens with resulting amplicons or with exogenous DNA from other sources in the laboratory, making PCR both reliable and sensitive for the detection of low levels of virus in specimens. Commercial reagents have been available for HSV PCR, but most major labs have developed their own PCR tests, making comparisons of studies based on PCR difficult. Recently, the US Food and Drug Administration (FDA) approved an alternative test, BD ProbeTec HSV Q^x, an automated system that amplifies and simultaneously detects type-specific regions of the glycoprotein G gene [68]. Because the primers and probes for PCR tests can be selected to target only HSV sequences, the test has inherently high specificity and has been used to good effect to demonstrate that HSV is a predominant (although often not the sole) pathogen present in genital ulcers in the United States [69], Europe [70], and Africa [71].

PCR is now the accepted method to diagnose neonatal herpes [72] and HSV encephalitis from cerebrospinal fluid specimens [73]. Its increased sensitivity has been instrumental in revealing HSV shedding and localization patterns after infection, and it is now the method of choice for defining epidemiologic patterns of oral, ocular, and genital shedding.

4 Descriptive Epidemiology

4.1 Seroepidemiology

Since the realization of antigenic differences in HSV-1 and HSV-2 in the 1960s [4] and the development of serologic assays to differentiate between HSV-1 and HSV-2 as discussed above, seroepidemiology studies have revealed distinct patterns of incidence and prevalence of HSV-1 and HSV-2.

4.1.1 HSV-1 Incidence

HSV-1 is typically acquired during childhood through nonsexual contact via infected oral secretions [74]. While few studies have measured seroincident HSV-1 infection directly, incidence can be inferred more indirectly through serial cross-sectional studies. The 1999–2002 US National Health and Nutrition Examination Survey (NHANES) found that HSV-1 seroprevalence in children increased from 26.3 % in 6–7-year-olds to 36.1 % in 12–13-year-olds, suggesting rapid acquisition during the childhood years [61].

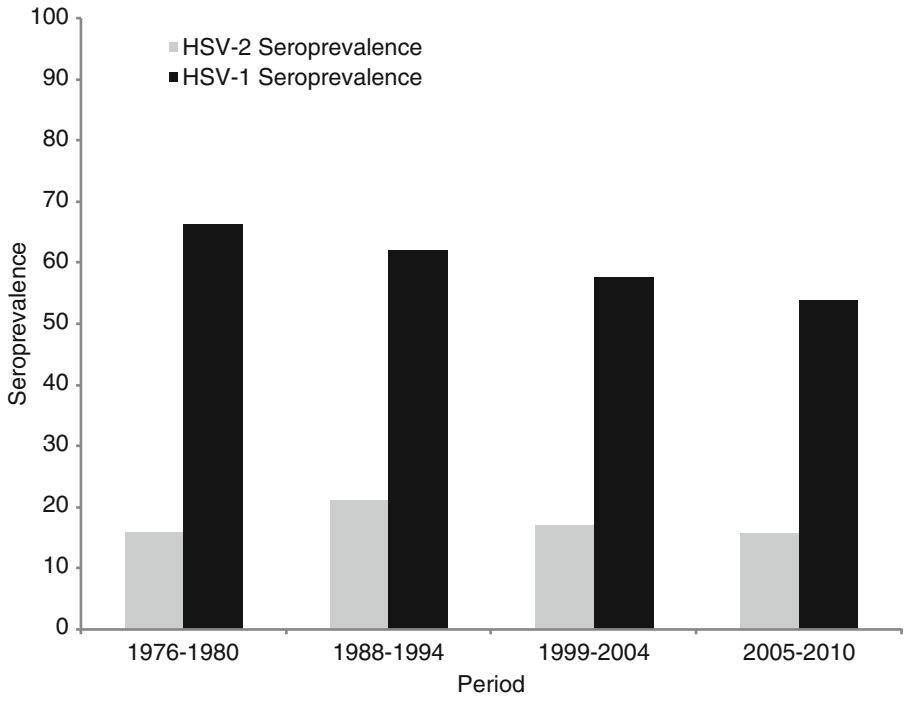

Fig. 36.2 Age-adjusted seroprevalence HSV-1 and HSV-2 in the United States, NHANES Data 1976-2008 [39]

4.1.2 HSV-1 Prevalence

HSV-1 seroprevalence is highest in developing countries, where it reaches nearly 100 % and increases with age [49]. In the United States, HSV-1 seroprevalence has been declining over the past three decades, with 2005–2010 NHANES revealing that 53.9 % of persons ages 14–49 are HSV-1-seropositive, a 6.8 % decline since 1999–2004 (Fig. 36.2) [39, 75].

The largest decline in seroprevalence was found in persons ages 14–19, from 46 to 39 %, a relative decrease of 14.7 % [39]. In parallel with the declining HSV-1 seroprevalence in adolescents, sexual acquisition of HSV-1 is becoming more common, and HSV-1 has surpassed HSV-2 as the leading cause of first-episode genital herpes in women <25 years of age and men who have sex with men [76–79]. HSV-1 seropositivity is significantly associated with increasing age, birth outside of the United States, and poverty [39, 61]. Rates of HSV-1 seropositivity are nearly twofold higher in non-Hispanic blacks and Mexican Americans as compared to non-Hispanic whites.

4.1.3 HSV-2 Incidence

HSV-2 is most often acquired after initiation of sexual activity, through intimate genital contact. In the United States, prospective studies performed in family planning clinics and STD clinics have shown an incidence of 7.8 and 11.7 per 100 person-years, respectively [80, 81]. Similarly, US military populations have an HSV-2 incidence of 6.2 per 100 person-years [82]. In adolescent women (ages 12–15) initiating sexual activity in the United States, the HSV-2 incidence was 4.4 per 100 person-years [83]. Again, incidence has been estimated indirectly in settings with high HSV-2 seroprevalence, such as sub-Saharan Africa, where seroprevalence rates increase markedly during adolescence, from 7.3 % in 15-year-olds to 33.5 % at 24 years of age in women [84]. Similar increases are seen in men, from 3.1 % at age 15 to 14.4 % at age 24 [84], with up to 43 % of uncircumcised men infected by age 24 in some populations [85]. As of 2003, 536 million people aged 15–49 were estimated to be infected with HSV-2 worldwide, with incidence of 23.6 million per year (Table 36.3) [86].

4.1.4 HSV-2 Seroprevalence

HSV-2 seroprevalence is twofold higher in women compared to men and increases with age and the number of lifetime sexual partners, reaching nearly 100 % in cohorts of female sex workers [49, 86]. Country-specific HSV-2 seroprevalence has been estimated using random sampling and population-based surveys in antenatal clinics and in high-risk populations such as HIV-seropositive persons, commercial sex workers, and persons attending STD clinics [49]. The most comprehensive review of global HSV seroprevalence was performed by Smith et al. [49]. HSV-2 seroprevalence is highest in sub-Saharan Africa, with >80 % of men and women ≥35 years of age infected [49]. In Central and South America, seroprevalence in women ranges from 33 % at ages 25–29 to 45–50 % at age 40–50. Seroprevalence is 4–40 % in Europe, with highest prevalence in Greenland (74 % of women age 25–39) and Scandinavia (15–35 % among women age 25–35). Data from the Middle East and

Table 36.3 Global seroprevalence and seroincidence of HSV-2 infection in men and women, by region, in 2003 [86]

	Seroprevalence (in millions)			Seroincidence (in thousands)

Adapted from Looker et al. [86]

Table 36.4 Epidemiology of clinical manifestations of HSV infection

	Incidence/prevalence	Population affected
Genital ulcer disease	50–80 % due to HSV-2 (prevalence)	Sexually active persons
Gingivostomatitis	Not available	Children
HSV encephalitis	2.2 cases/million PY	Children, sixth decade of life
Ocular HSV	11.8/100,000 PY	Mean age 43
Neonatal HSV	4–31.3/100,000 PY	Neonates
Eczema herpeticum	~6/100,000 pediatric hospital admissions	Children, median age 1
Herpetic whitlow	2.4/100,000 PY	20 % in children, 41 % in young adults

North Africa are limited, but in antenatal and obstetrics clinics, seroprevalence ranges from 0 % in Syria to 12 % in Bangladesh to 32 % in Egypt [87]. In Northeast India, women in antenatal clinics had an overall seroprevalence of 8.7 %, although this varied from 2.7 to 15 % depending on the region [88]. In Asia, seroprevalence is lowest in Japan and the Philippines, with estimates at 7–9 %. Women in antenatal clinics in Australia had seroprevalence ranging from 4.3 % in 15–19-year-olds to 20 % in >35-year-old. In all populations studied, HSV-2 seroprevalence was higher in commercial sex workers and STI clinic attendees than the general population [49].

In the United States, the 2005–2008 NHANES showed that 16.2 % of persons age 14–49 were HSV-2 seropositive (Fig. 36.2) [89]. In the 1988–1994 NHANES, there was an increase in HSV-2 seroprevalence to 21.9 % [38]; in the most recent survey, this trend seems to have reversed and seroprevalence rates have stabilized [39]. As with HSV-1, race is associated with seroprevalence; non-Hispanic blacks have rates three- to fourfold higher than non-Hispanic whites or Mexican Americans [89]. Most people with HSV-2 infection have not been previously diagnosed; in the NHANES, 81.1 % of people were not aware of their infection [89]. HSV-2 seroprevalence rates are higher in STD clinic populations, with overall rates of 40 % in the United States [90]. HSV-2 seroprevalence is also higher in HIV-infected persons, with 50–90 % seroprevalence in this population [84, 91–95].

5 Patterns of Host Response: Clinical Manifestations and Epidemiology of HSV Infections

Most people with HSV infection are asymptomatic or have mild disease that is undiagnosed [39]. Therefore, persons who present to clinical care represent a minority of those infected. However, HSV causes a wide range of manifestations on mucosal surfaces and skin and in the central nervous system (Table 36.4).

5.1 Genital Infections

HSV is the leading cause of genital ulcer disease (GUD) worldwide. Studies using PCR in the United States [96], Africa [71, 97–99], and Asia [100] show that 50–80 % of genital ulcers are due to HSV. The predominance of HSV-2 has increased as the etiologic agent of GUD appears to have increased over time. For instance, in a South African mining community, HSV-2 prevalence in genital ulcers increased

from 17 % in 1993 to 36 % in 1998 [101] and in Botswana from 23 % in 1993 to 58 % in 2002; over the same period, *Haemophilus ducreyi* declined from 25 % in 1993 to 1 % in 2002 [97]. In response to this epidemiologic shift, antiviral therapy (acyclovir) is now included in the World Health Organization (WHO) recommendations for syndromic management of genital ulcer disease [102]. Genital herpes has also been an increasing cause of visits to physician offices in the United States over the last four decades, with 232,000 clinic visits in 2010, up from 17,000 in 1970 and 57,000 in 1980 [103].

5.1.1 Primary Genital Infection

HSV primary infection is defined as acquisition of virus in the absence of antibody to either HSV-1 or HSV-2. In a large series of 209 persons with laboratory-documented primary genital herpes, the most recent sexual contact was 5.8 (range 1–45) days prior to symptoms [104]. Patients typically develop discrete vesicles or pustules on genital skin and mucosal surfaces, which ulcerate and coalesce to form painful wet ulcers. Genital symptoms and viral shedding are greatest during this wet ulcer stage. As the skin reepithelializes, a dry crust forms, viral shedding ceases, and the lesions resolve. Symptoms last a median of 19 days during primary infection in the absence of antiviral therapy [104]. Primary genital HSV may cause significant local signs and symptoms, including severe bilateral ulcerations, cervicitis or proctitis, dysuria or urinary retention, vaginal or urethral discharge, and lymphadenopathy [104]. In addition, ~25 % of persons with symptomatic primary infection have evidence of HSV viremia [105], and this may be associated with more systemic symptoms such as fever and myalgias. Up to 1/3 of women develop signs of aseptic meningitis during primary symptomatic genital infection [104]. Primary genital HSV-1 infection may be associated with more lesions and longer duration than primary genital HSV-2 [104].

5.1.2 First-Episode Infection

First-episode genital HSV is defined as the first recognized clinical outbreak of genital HSV, and it may occur either in the absence of HSV antibody (primary) or in the presence of antibody to HSV-1 or HSV-2 (non-primary). Symptoms of non-primary HSV are less severe than primary HSV, possibly due to the presence of neutralizing antibody [104] or acquired immunity. The differentiation between first-episode and recurrent disease has implications for patient management, as higher doses of antiviral agents and longer duration of therapy are required to treat first episode.

5.1.3 Recurrent Genital Infection

Clinical recurrences of genital HSV recurrences are very heterogeneous: some patients may have monthly genital recurrences, while others may never have a recognized recurrence after their first episode. In a large series of 457 patients with laboratory-documented symptomatic primary genital HSV-2 diagnosed before suppressive antiviral therapy was widely used, the median number of recurrences during the first year after primary genital infection was 4; 20 % of patients had more than 10 recurrences [12]. After the first 2 years of infection, the median number of recurrences decreased to 2 episodes/year [106], although some people continued to have much more frequent recurrences. In contrast, HSV-1 genital recurrence is less frequent, with a median of 1.3 recurrences the first year after symptomatic primary and 0.7 recurrences/year in the second year [107]. Recurrent genital HSV infection may have a prodrome of neuralgia, tingling, or itching prior to the appearance of genital vesicles/pustules or ulcers in 60 % of patients. Symptoms during recurrent infection are generally localized to the genital tract and are more mild than first episode, although they are more severe in women, lasting a mean of 6 days, as compared to men (mean 3 days) [104].

5.1.4 Other Genital Symptoms

HSV is the most common cause of gram stain-negative proctitis in men who have sex with men (MSM) [108] and causes about 25 % of cases of proctitis overall in this population [109]. HSV proctitis may present with fever; severe, burning rectal pain and tenesmus; perianal ulcerations; and urinary retention [109]. HSV is shed from the cervix in most women with first-episode genital herpes; the cervix may have ulcerative lesions or may be diffusely friable [104].

5.1.5 Subclinical Acquisition and Infections

The placebo or control arms of randomized clinical trials of HSV vaccines and antiviral agents have provided the opportunity to prospectively evaluate the epidemiology of HSV acquisition. In one vaccine study that evaluated 2,393 high-risk persons, only 57 (37 %) of 155 new HSV-2 infections were symptomatic; the remaining 98 (63 %) persons had subclinical seroconversion [27]. Other prospective studies reported similar findings [110]. In the control arm of the Herpevac trial, which tested a glycoprotein D2 subunit vaccine in HSV-1-/HSV-2-seronegative women, the incidence of HSV-2 was 1.1/100 person-years; 63 % of seroconversions were subclinical [111]. The HSV-1 incidence was 2.5/100 person-years and 74 % of seroconversions were subclinical.

5.1.6 Genital Herpes in the Immunocompromised Host

Severe genital HSV may be found in immunocompromised persons. Chronic genital ulcerations due to HSV-2 were one of the first recognized manifestations of AIDS [112] and remain an AIDS-defining condition. Persons with advanced HIV infection have frequent HSV recurrences; the risk is greatest for those with CD4 count <100 cells/mm not on

highly active antiretroviral therapy [113]. Atypical presentations such as hypertrophic lesion may occur in immunosuppressed patients [114–118]. In addition, persons undergoing solid organ or stem cell transplantation are at increased risk for recurrent HSV. Immunocompromised persons may develop acyclovir-resistant herpes [119, 120], a rare occurrence in immunocompetent hosts [121]. Continuous anti-HSV suppressive therapy prevents both HSV recurrences and acyclovir resistance in immunocompromised hosts [122].

5.2 Oral Infections

Similar to genital disease, oral HSV may be classified as primary and recurrent disease. In contrast, however, oral disease is caused almost exclusively by HSV-1, with few case reports of HSV-2 causing oral disease.

5.2.1 Gingivostomatitis

This typically occurs in young children and is due to primary acquisition of HSV-1. Children present with fever, severe labial and oral ulcerations, and pharyngitis or esophagitis, with difficulty eating due to pain [123]. Lesions last for a mean of 12 days, with persistent viral shedding for a mean of 7 days [123]. Similar to primary genital HSV-2 infection, 34 % of patients with symptomatic primary gingivostomatitis are viremic [124].

5.2.2 Recurrent Oral Infections

Oral HSV recurrences, often called "cold sores" or "fever blisters," present as a single labial ulceration, most often involving the lower lip. Risk factors for recurrence include fever, illness, and exposure to sunlight [125, 126]. Although the recurrence rate of oral HSV-1 is not well defined, in one prospective study of 12 persons after primary concurrent oropharyngeal and genital HSV-1, orolabial recurrences occurred in 42 % of persons, with a recurrence rate of 0.12 recurrences/month [13]. Similar recurrence rates were reported in persons with a history of symptomatic oral HSV-1 [125].

5.3 Neurologic Infections

5.3.1 Encephalitis

Herpes simplex encephalitis (HSE) is a significant cause of HSV-related morbidity and mortality. HSV-1 is the leading cause of sporadic viral encephalitis worldwide, causing a third of viral encephalitis in the California encephalitis project [127]. In a prospective study from England, 38 (19 %) of 203 patients with encephalitis had HSV infection [128]. There is a bimodal age distribution, with 1/3 of cases occurring in children >6 months and <18 years of age and half of cases occurring in adults over age 50 [129]. Encephalitis may occur during primary infection but occurs during reactivation in about 2/3 of cases [130]. In a retrospective study conducted over 12 years in Sweden, 236 cases of laboratory-confirmed HSV-1 encephalitis were diagnosed, for an incidence of 2.2 cases per million persons per year [131]. Similar findings have been described in the United States [132]. HSV encephalitis was equally distributed in men and women [131]. Despite antiviral therapy, the 1-year mortality was 14 % [131]. Patients may present with febrile confusion and focal neurologic signs. Cerebral spinal fluid (CSF) typically shows a pleocytosis, consisting predominantly of lymphocytes; it may be hemorrhagic, with slightly decreased glucose and markedly increased protein. Brain imaging typically reveals temporal lobe involvement, sometimes with hemorrhage requiring craniotomy. Seizures and neuropsychiatric sequelae occur in nearly a quarter of patients after recovery from acute encephalitis [131]. A significant advance in the field is the ability to accurately diagnose HSV encephalitis with HSV PCR from cerebrospinal fluid, a faster and less invasive approach than viral culture from brain biopsy material [133]. HSV-2 may also cause encephalitis but this is less common. Intravenous acyclovir is the gold standard therapy for HSE. Without therapy, mortality is 70 % [132]. HSV may also cause ascending myelitis [134, 135], although this is rare.

5.3.2 Meningitis

HSV may cause recurrent aseptic meningitis ("Mollaret's meningitis"), with fever, headache, and stiff neck. This is commonly caused by HSV-2 and may or may not be accompanied by a genital herpes outbreak [136]. In a series of 40 persons with HSV-2 meningitis, almost half had confirmed or suspected neurologic recurrence during a 1-year follow-up [137]. A recent trial of suppressive valacyclovir 500 mg BID did not prevent recurrences [138]. Higher doses of oral antiviral therapy may be required to suppress recurrences of Mollaret's meningitis.

5.3.3 Possible Role in Alzheimer's Dementia

HSV-1 has long been hypothesized to have a pathogenic role in the development of Alzheimer's dementia (AD) [139], based on the following evidence for biological plausibility: (1) the frontal and temporal lobes and hippocampus are affected in AD and HSV-1 encephalitis [140]; (2) HSV-1 is a risk factor for developing AD in persons with apolipoprotein E ε4 (APOE4) isoform [141, 142], and this allele is associated with symptomatic oral HSV-1 lesions [143] with transgenic mouse models showing that APOE4 mice have significantly higher number of HSV1 genomes in brain tissue as compared to APOE3 mice, suggesting an interaction between HSV-1 and APOE4 [144]; and (3) in neuronal cell culture, HSV-1 infection causes β-amyloid

[145] and amyloid precursor protein accumulation [146] as well as tau phosphorylation [147], hallmarks of the pathogenic changes of AD. In Vero cells, HSV-1-induced β-amyloid and abnormally phosphorylated tau protein accumulation is reduced in the presence of antiviral agents such as acyclovir [148]. HSV-1 DNA has been found in brain tissue from persons with AD [141] and in amyloid plaques [149], but it has also been found in normal age-matched controls [141]. Further research will be required to determine whether HSV-1 infection contributes to the pathogenesis of AD.

5.4 Ocular Infections

HSV-1 and HSV-2 can cause keratitis, blepharitis, conjunctivitis, iridocyclitis, or retinitis [150]. Herpetic keratitis is the leading cause of corneal blindness in the developed world [151]. HSV infection produces corneal ulcerations that may be recurrent and can lead to scarring and neovascularization. In a longitudinal study conducted in Rochester, Minnesota, the incidence of ocular HSV was 8.4/100,000 person-years [151]. In this series, the first episode most commonly involved the superficial cornea (63 %) or lids and conjunctiva (54 %); the deep cornea was involved in only 6 % of patients [151]. The Moorfields hospital in London has followed 108 patients with primary HSV ocular disease over a period of 2–15 years; of these 32 % had recurrent disease [152]. Nearly half of these had 2–5 recurrences, and 11 % had more than 6 recurrences. In the Rochester series and others, the recurrence rates increase with the years of follow-up [151]. Most recurrences involved the conjunctiva or eyelid; few had corneal involvement [152]. HSV-1 and HSV-2 may also cause acute retinal necrosis, which can lead to vision loss. Acute retinal necrosis may occur years after neonatal herpes [153].

5.5 Neonatal Infections

Exposure to either HSV-1 or HSV-2 during labor and delivery can lead to severe infection in the neonate [73]. Although neonatal herpes is not a reportable disease [154], several studies have provided estimates of incidence in the United States and Canada. Using inpatient hospital admission data, the incidence of neonatal HSV in the United States is 9.6 cases/100,000 live births [155]. Incidence estimates using population-based methods and hospital discharge records [156, 157] or ICD-9 codes [158, 159] involving a number of cities in the United States range from 4 to 13.3 cases/100,000 live births [160]. A prospective, active-surveillance study in Canada showed similar rates, with 5.9 cases/100,000 live births [161]. In this study, 40 % of women had no history of genital HSV and only 2 % of cases had intrapartum lesions noted [161]. Rates up to 31.3/100,000 have been found in prospective studies at research centers with active surveillance [162]. Maternal acquisition of HSV near the time of delivery is associated with higher risk of neonatal herpes [163]. In the largest study of risk factors for HSV transmission to the neonate, the detection of HSV from the genital tract at the time of delivery and first-episode genital herpes near delivery were significant risk factors for transmission [162]. In addition, HSV-1 infection, HSV isolation from the cervix, the use of invasive monitoring, maternal age <21 years, and delivery before 38 weeks were associated with neonatal herpes [162]. Women who have genital ulcers at the time of delivery have a markedly reduced risk of transmission if delivered by cesarean section [162]. However, C-section is not recommended for HSV-2-seropositive women who do not have ulcers or prodrome at the time of delivery [164]. In women who are HSV-2 positive with a history of genital herpes, suppressive antiviral therapy is recommended from week 36 to delivery [164]. This practice decreases the risk of genital herpes recurrences requiring cesarean section [165, 166], reduces viral shedding [166–168] at the time of delivery, and presumably decreases the risk of HSV transmission, although this has not been demonstrated in clinical trials [166, 167]. Of note, cases of neonatal HSV have been described even in babies whose mothers received suppressive therapy [169]. While 85 % of neonatal HSV transmission occurs during the peripartum period, HSV can be transmitted in the postnatal period (10 %) or in utero (estimated 5 %) [72].

Neonatal HSV is classified into three types: (1) skin, eye, and mucous membrane (SEM) accounts for 45 % of infection; (2) CNS disease accounts for 30 % of infection; and (3) disseminated disease accounts for 25 % of infection [170]. Patients with SEM or disseminated disease present at 10–12 days of life, and those with CNS disease present at 16–19 days of life [72, 170]. Infants typically present with skin vesicles, although up to 40 % of patients with disseminated or CNS disease may not have any vesicles present [170]. Lethargy and fever occur in ~50 % of patients with CNS or disseminated disease, seizures occur in nearly 60 % of patients with CNS disease, and pneumonia and DIC occur in nearly 40 % of patients with disseminated disease [170]. SEM disease is associated with minimal morbidity and mortality. Although antiviral therapy has reduced morbidity and mortality due to CNS or disseminated disease, even with a 21-day course of high-dose IV acyclovir (60 mg/kg/day) [171], there is 30 % mortality with disseminated disease [170]. A 6-month course of suppressive oral acyclovir appears to be safe and may result in improved neurodevelopmental scores in patients with neonatal herpes [172]. HSV viral type does not affect neonatal herpes morbidity or mortality.

5.6 Cutaneous HSV Infections

HSV-1 or HSV-2 can cause a variety of syndromes involving the skin.

5.6.1 Eczema Herpeticum (Kaposi's Varicelliform Eruption)

Eczema herpeticum is a rare complication of childhood atopic dermatitis, occurring in 3–6 % of patients [173]. It is a vesicular rash that starts within areas of eczema but can spread to involve normal skin. A prospective Canadian study identified 79 cases of eczema herpeticum between the years of 2000 and 2009. The mean age of patients was 4.3 years, one-third of patients were <1-year-old, and nearly 10 % had recurrent infection [174]. Fever or bacterial infection occurred in over half of the patients, and keratoconjunctivitis occurred in 10 %. A retrospective study in the United States described 1,331 children hospitalized with eczema herpeticum, accounting for approximately 6 in 100,000 admissions. The median age in this study was 1 year (range 1–4). Prompt initiation of acyclovir was associated with decreased hospital length of stay [175].

5.6.2 Herpetic Whitlow

Recurrent digital vesicles/ulcers occur after autoinoculation, often in children. Occupational HSV acquisition can occur in persons who have frequent contact with oral mucous membranes, for instance, nurses [176], dentists/dental hygienists [177], or anesthesiologists. In the largest series describing 79 cases, the incidence was 2.4 cases per 100,000 persons, with 20 % of cases in children <10 years of age and 41 % in young adults aged 21–30 [178]. All cases in children were HSV-1. Recurrent episodes have been described with both HSV-1 and HSV-2 infections. Although herpetic whitlow usually involves the fingers, rare cases of toe involvement have been described [179, 180].

5.6.3 Herpes Gladiatorum (HG)

Outbreaks of HSV-1 have been described during wrestling events [181], likely due to contact of abraded skin with HSV-1 from infected oral secretions. The face, neck, and arms are the most commonly affected areas. An estimated 17 % of 330 participants in a 28-day camp acquired HG, which likely underestimated the transmission rate, as the HSV serostatus of participants was unknown [182]. Some authors advise the empiric use of valacyclovir prophylaxis for wrestlers' events, although the efficacy and cost-effectiveness of this approach are unknown.

5.6.4 Herpes-Associated Erythema Multiforme (HAEM)

HSV is the most common infectious trigger of erythema multiforme. Oral and skin lesions are caused by a cell-mediated response to HSV. Patients with HAEM have HSV detected in CD34+ cells in blood and in skin biopsies by PCR [183]. Some patients may also have recurrent EM [184].

Disseminated HSV Infections. Rarely, HSV may cause disseminated disease in adults resulting in fulminant hepatitis, sometimes requiring liver transplantation [185], pneumonia [186], and high levels of viremia. Cases have been described in pregnant women [187, 188], immunocompromised hosts [189–191], or healthy, immunocompetent adults [192–195]. Intravenous acyclovir should be used in cases of proven or suspected disseminated HSV.

6 Pathogenesis

The pathophysiology of primary mucocutaneous HSV infection is schematically represented in Fig. 36.3.

In the susceptible host, primary infection begins when HSV is transmitted to mucosal or cutaneous surfaces generally in the oral cavity or genital tract and occasionally other cutaneous sites. HSV entry into cells is a complex process involving attachment and membrane fusion. At least five glycoproteins are involved in the process, gC, gB, gD, and the heterodimer gH/gL [197]. Two viral glycoproteins, gB and gC, are responsible for attachment of the virion to cell surface proteoglycans [198]. Following attachment the virion envelope glycoprotein gD binds to specific cell surface receptors, including the herpesvirus entry mediator (HVEM) on fibroblasts and ocular cells; nectin-1 on neurons, keratinocytes, and epithelial cells; and 3-O-sulfotransferease-modified heparan sulfate. Subsequent interactions with gB and gH/gL trigger fusion events that lead to entry [199]. During the fusion process, the viral envelope is lost, the capsid and associated tegument enter the cytoplasm, and the capsid travels along microtubules via the dynein and kinesin motors using retrograde transport to the cell nucleus [200]. In the neuronal nucleus, the viral DNA either enters a latent state or is replicated to generate progeny virions. Subsequent reactivation of latently infected neurons also results in viral replication and generation of progeny virions. Genome replication, capsid assembly, and genome encapsidation appear to occur in the nucleus with subsequent transport to the cytoplasm for envelopment and posttranslational modification of envelope glycoproteins. The enveloped virions are moved along the microtubules via a kinesin motor-driven anterograde transport process to the nerve endings where they are released into the extracellular milieu. Viral replication occurs in epithelial cells at the portal of entry, but HSV also rapidly enters the nerve endings and moves via axoplasmic transport processes to the nucleus of the neurons located within the sensory ganglia [196, 201, 202]. Animal studies have shown that, following replication in ganglion

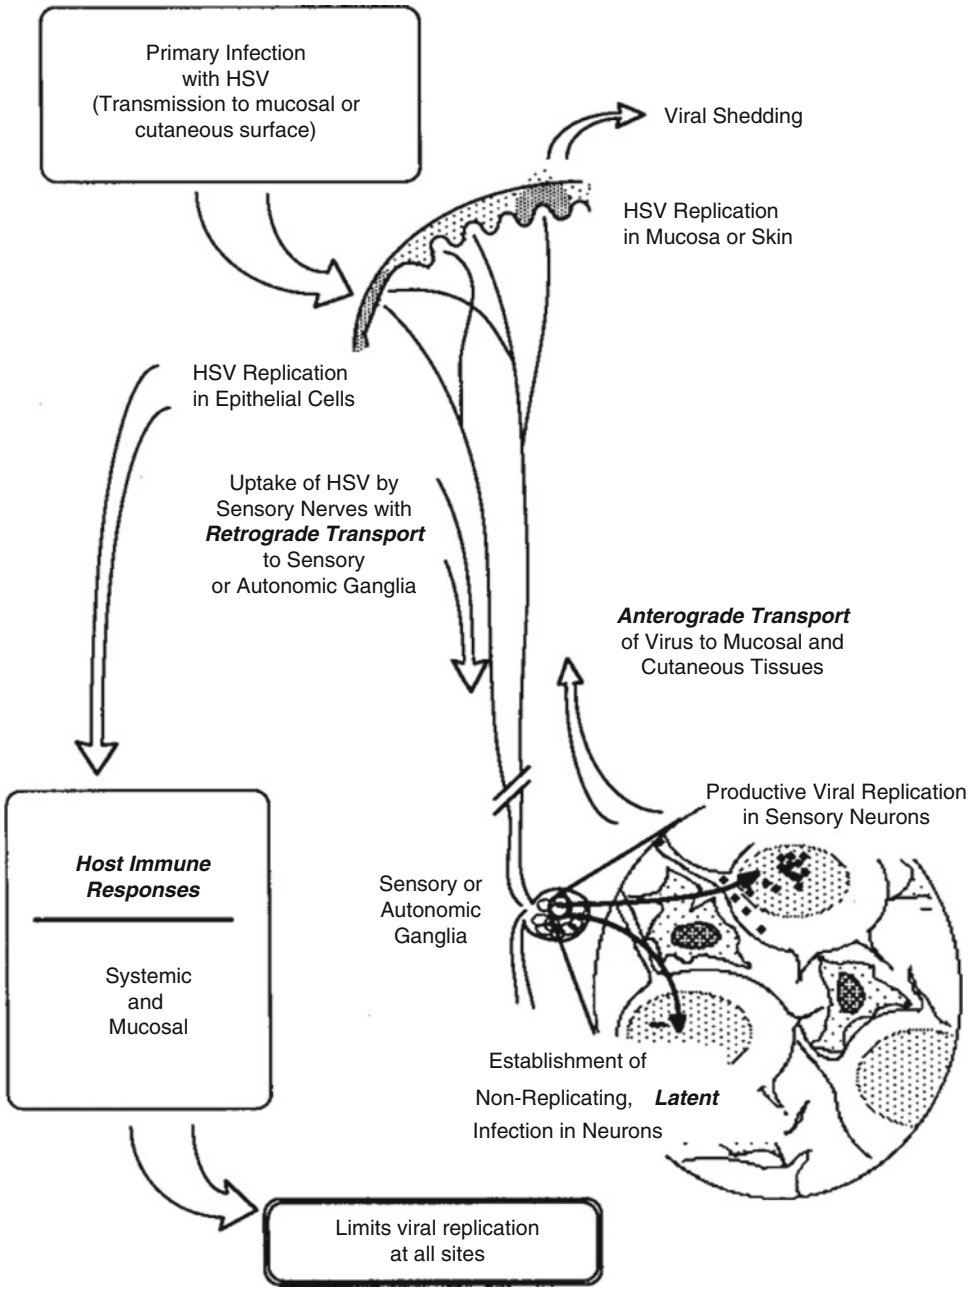

Fig. 36.3 Schematic representation of the pathogenesis of primary mucocutaneous herpes simplex virus infection (Adapted from Stanberry [196])

cells, virus is transported through unmyelinated C-type sensory nerve fibers back to mucosal and cutaneous sites where further replication produces the characteristic vesicles of primary mucocutaneous HSV infection [203, 204]. The intraneuronal spread and amplification of virus at the level of the ganglia appear necessary for the development of clinically apparent mucocutaneous HSV infection [196]. The distinction between the individual who experiences subclinical primary infection and the patient who suffers severe symptomatic disease probably relates to the extent to which virus replicates in sensory ganglia and spreads to multiple mucocutaneous locations. The pathogenesis of recurrent mucocutaneous HSV infection is schematically presented in Fig. 36.4. The current paradigm is that superinfection by a second strain of HSV-2 is uncommon [205, 206], although it has been described [207–209].

HSV has evolved a novel survival strategy; it is able to persist within the sensory neurons in a nonreplicating state throughout the life of the host. The establishment, maintenance, and reactivation of the latent infection involve IFNγ and granzyme B secretion by CD8+ T cells and viral factors including the latency-associated transcript (LAT), viral miRNAs, and immediate early proteins [210, 211]. In humans and some experimental animal models,

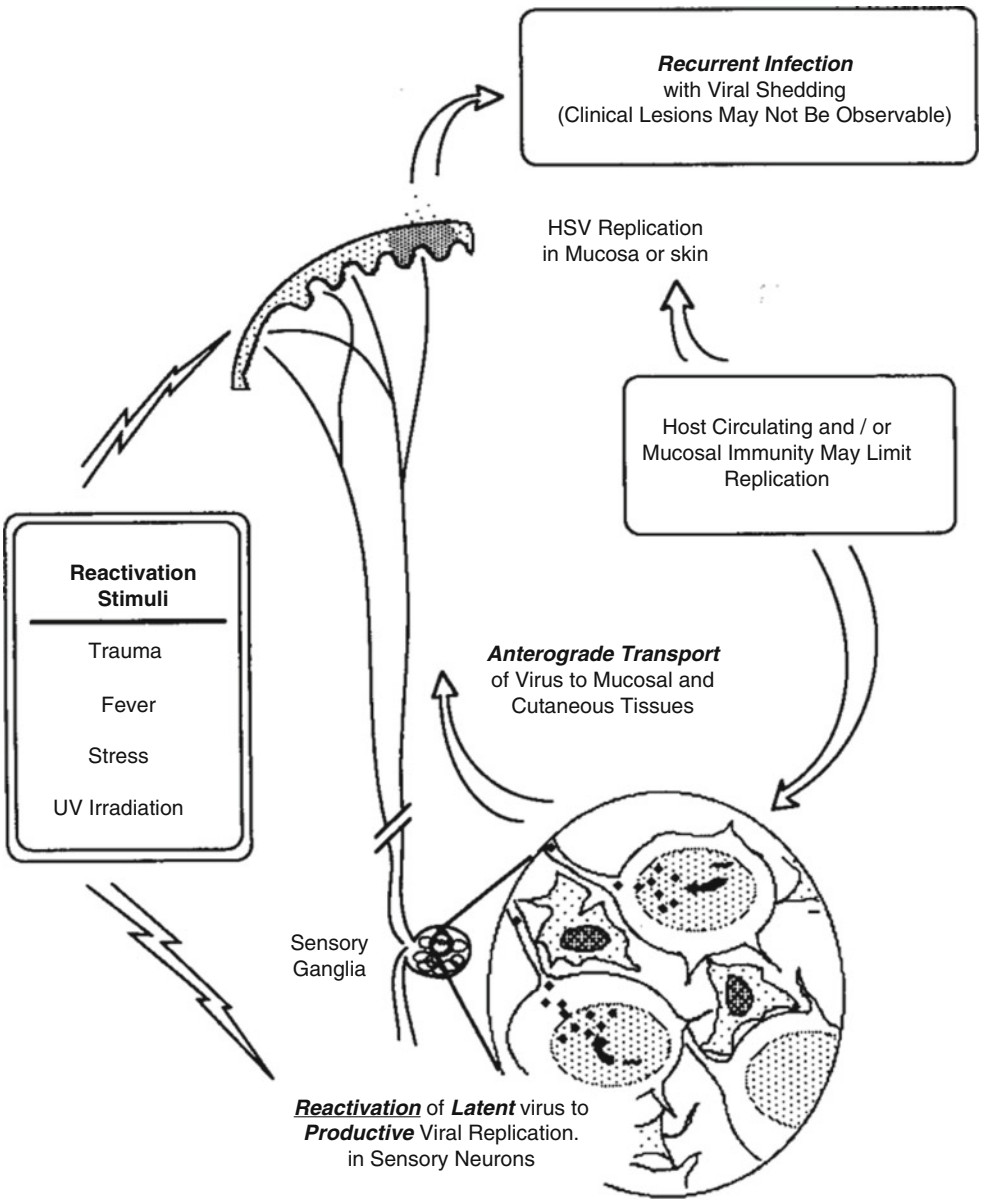

Fig. 36.4 Schematic representation of the pathogenesis of recurrent mucocutaneous herpes simplex virus infection (Adapted from Stanberry [196])

the nonreplicating latent virus can periodically reactivate to a replication-competent state, resulting in the production of infectious virions. Stimuli such as ultraviolet radiation, trauma, or stress may trigger the reaction process. Following reactivation, virus is transported via selected sensory neurons back to the periphery where further replication in epithelial cells results in recurrent mucocutaneous symptoms or subclinical viral shedding. It was previously believed that reactivation events are infrequent or rare and that virus was transmitted only in the presence of oral or genital lesions. However, studies that have used daily sampling of oral and genital secretions for HSV culture or PCR have shown that HSV is often detected on mucosal surfaces and skin ("shed") in the absence of symptoms [56, 212]. Clinical and virologic phenotypes of HSV infection are driven by interactions between anatomic site of infection (trigeminal or sacral ganglia) and the type of HSV [13]. HSV-1 appears to have better tropism for the trigeminal ganglia, leading to increased shedding and reactivation from the oral mucosa, while HSV-2 establishes a more robust infection in the sacral ganglia. Disrupting the HSV-2 LAT [213] or replacing the HSV-2 LAT with HSV-1 LAT in the guinea pig model leads to less frequent genital recurrences, suggesting that tropism may be due to individual type-specific proteins [14, 214].

HSV infections of the central nervous system (encephalitis) and of the eye have special pathogenic mechanisms by which virus causes disease [215, 216]. Brain and mouth isolates taken concurrently in patients with herpes encephalitis have been found to be identical in some patients but dif-

ferent by restriction enzyme analysis in others. These data suggest that persons previously infected with HSV-1 can develop a central nervous system herpetic infection from their old strain or from a newly acquired HSV-1 infection. Additionally, serologic data demonstrating concomitant primary oral and central nervous system infection support the concept that herpes encephalitis outside the newborn period can be a primary infection [217]. In the case of HSV infection of the posterior segment of the eye, it is recognized that, in large part, an immunopathologic process produces the retinal injury [215].

Unlike HSV infections in adults, neonatal herpes is rarely asymptomatic. Animal model studies suggest that the pathogenesis of infection may be different for SEM, CNS, and disseminated disease [218, 219]. Factors that probably influence the extent and severity of neonatal disease include the portal of virus entry, viral inoculum, neurovirulence of the virus strain, immunocompetence of the neonate, and perhaps genetic determinants of susceptibility to HSV infection. For neonatal infection the portals of entry may include the umbilical cord, the eye, the oral and nasal orifices, and the skin if damaged by trauma or scalp electrode placement. If host and viral factors restrict HSV replication to the site of inoculation, the infant may develop infection limited to the skin, eye, or mouth. Encephalitis without evidence of disseminated disease probably results from intraneuronal spread of virus from mucosal sites in the eye, nose, or mouth to sites within the central nervous system. Disseminated infection with multiple organ involvement including the brain is probably due to hematogenous spread, viremia having been documented to occur in some cases of neonatal infection [220, 221]. As with other HSV infections, neonatal herpes results in the establishment of a latent infection that may be reactivated to cause recurrent cutaneous infections and likely affects the long-term developmental outcomes of the infected infants [172, 222].

Host immune responses, particularly cellular responses, are important in limiting HSV infection. Patients with immature or compromised immune function generally have more severe HSV infections. These patient populations include newborns; severely malnourished children; those with measles or HIV infection; those with severe burns; those receiving immunosuppressive therapy; patients with cancers; persons with selected immune deficiencies, such as the Wiskott–Aldrich syndrome; and rarely pregnant women [223–228]. While viremia does not appear to play an important role in the pathogenesis of infection in the normal host, in the immunocompromised patient, including the newborn, virus may disseminate to internal organs via hematogenous spread or extend to contiguous tissues due to swallowing or aspiration of contaminated secretions resulting in esophagitis, tracheitis, or pneumonia [186, 220, 228, 229].

7 Immunity

With primary infection, innate and adaptive immune responses develop in a coordinated fashion to control viral replication and promote healing [202]. Despite these responses, HSV establishes a lifelong latent infection in the sensory ganglia and can subsequently reactivate to cause symptomatic or subclinical recurrent infections [230]. In mucosal tissues innate responses prompt the production of antimicrobial factors such as β-defensins and trigger toll-like receptor (TLR) activation, which promotes inflammatory cytokine production with subsequent natural killer cell activation and maturation of dendritic cells [231]. Germline mutations that impair innate immune responses have demonstrated that innate immunity is critical in the control of HSV infections [232].

In individuals with primary HSV infection, IgG, IgA, and IgM antibodies can be detected within 1–3 weeks by a variety of assays [233–237]. Reactivation of latent infection with subsequent symptomatic and subclinical recurrences can result in anamnestic IgG as well as IgM responses. The role of antibodies in the control of HSV infections is unclear. Some animal studies suggest that B cells and antibodies are not essential for resolution of HSV infection [238, 239], while others suggest they may be important in protecting against infection [240]. A study in newborns suggested that high levels of maternally derived HSV neutralizing antibody could protect the infant from neonatal herpes infection [241]. It is worth noting that patients who lack the ability to produce antibodies are able to control HSV infections, suggesting at the very least that effective control of HSV infections can be mediated through non-antibody mechanisms.

The discussion of assays best suited for epidemiologic studies and the challenges of distinguishing HSV type 1 and HSV type 2 antibodies is presented in Sect. 3.

CD4 and CD8 T cells play critical roles in the control of primary, latent, and recurrent HSV infection [202, 242]. Animals lacking CD4 and/or CD8 cells are diminished in their ability to limit HSV replication in epithelial and neural tissues [243]. Likewise, patients with impaired T-cell immunity can have more severe and prolonged clinical disease, greater likelihood of hematogenous dissemination with visceral organ involvement, and more frequent recurrent infections [220, 244–247].

There is some evidence to suggest that host immunogenetics and differential immune responses can influence infection phenotype. For example, infected individuals with CD4 T cells reactive to glycoprotein B peptides HSV1:$gB_{166–180}$ and HSV1:$gB_{666–680}$ were found only in asymptomatic subjects, while those with CD4 T cells reactive to the epitope HSV1:$gB_{661–675}$ were found only in symptomatic subjects [248]. With regard to recurrence phenotype, lower levels of IgG1 and IgG3 antibodies that mediate antibody-dependent

cellular cytotoxicity were found in subjects who experienced recurrent infections, suggesting these antibodies play a role in controlling recurrences [249]. Most HSV-1-infected patients do not develop central nervous system infection; however, herpes encephalitis does develop in individuals with toll-like receptor 3 deficiency [250].

8 Transmission

HSV is transmitted through intimate contact with infected oral or genital secretions, during exchange of saliva, sexual contact, or during labor and delivery (neonatal

HSV) [251]. HSV is most frequently transmitted during periods in which virus is detected on mucosal surfaces in the absence of signs or symptoms of HSV (subclinical viral shedding).

8.1 HSV Genital Shedding

It is well established that both HSV-1 and HSV-2 can be shed from genital and perigenital sites.

8.1.1 HSV-2 Genital Shedding

Studies of daily self-collected genital swabs for HSV culture and PCR in association with recording of daily symptoms and lesions have allowed for characterization of the frequency, patterns, and symptoms associated with genital HSV shedding [56, 212, 252, 253]. HSV-2 genital shedding rates are highest during the first year after first-episode genital herpes [56, 212, 254], with HSV detected by HSV PCR on 34 % of days [254]. HSV shedding rates decline to ~20 % of days 1 year after first-episode genital herpes (Fig. 36.5).

Shedding is persistent over time, with shedding rates of 17 % in persons ≥10 years post first-episode infection [254] (Table 36.5). Persons with asymptomatic genital HSV-2 shed less frequently than those with symptomatic disease, with virus detected on 10 % of days (Fig. 36.5) [253]. Men and women shed HSV from the genital tract at similar rates [252]. Genital HSV-2 shedding is associated with symptomatic genital infection, number of recurrences per year, and white race [253]. In a cohort of 27 women with recurrent HSV-2 infection, 100 % shed when followed over a 100-day period, suggesting that most people shed virus [255].

Episodes of shedding are clustered together and last a median of 3 days, with longer shedding episodes in the presence of a lesion, lasting a mean of 6.8 days (Fig. 36.6) [56, 256].

However, shedding occurs most frequently in the absence of genital symptoms or lesions ("subclinical shedding") [56, 253]. Subclinical shedding occurs more frequently in persons with a history of symptomatic as compared to asymptomatic infection (13.1 % of days vs. 8.8 % of days) [253]. Importantly, HSV can be transmitted during periods of subclinical shedding [257]. HIV-infected persons shed more frequently that HIV-negative men [258] and women [244], with increased risk of shedding in those with lower CD4 counts.

Intensive genital and oral shedding studies have provided insight into the pathogenesis of HSV infection. Collection of oral and genital swabs every 6 h has shown that most HSV reactivations are of very short duration, with 60 % of shedding episodes cleared within 12 h [259, 260]. Shedding

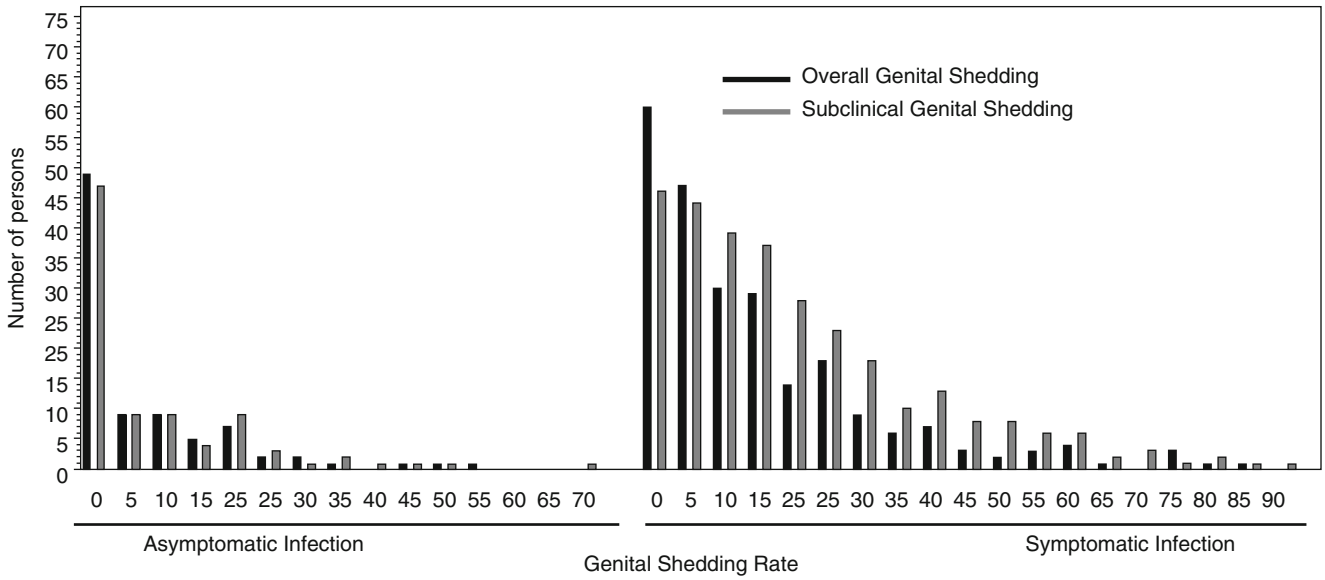

Fig. 36.5 Distribution of genital HSV-2 shedding rates among 88 persons with asymptomatic infection and 410 person with symptomatic infection (Adapted from Tronstein et al. [253])

Table 36.5 Overall shedding rates measured by PCR, by site and HSV type, and by time after primary infection, where available

	HSV-1 (%)	HSV-2 (%)
Oral	33.3	1.3
Genital, overall	N/A	20
Genital, <1 year after 1st episode	2[a]	33.6
Genital, 1–9 years after 1st episode	<1[a]	20.6
Genital, >10 years after 1st episode	N/A	16.7
Genital, asymptomatic	N/A	10

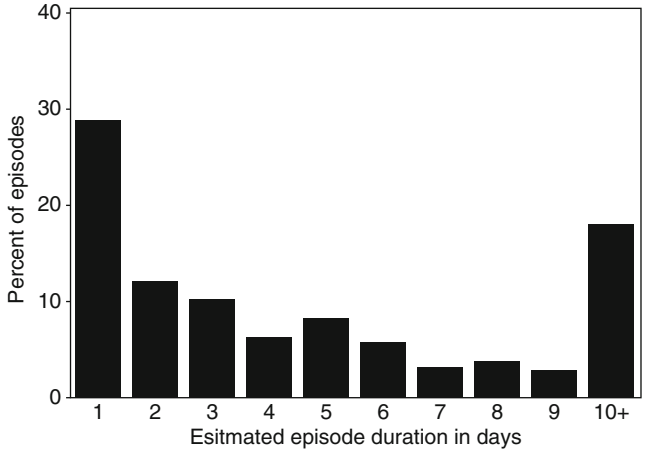

Fig. 36.6 Duration of 1695 genital HSV shedding episodes identified by PCR (Adapted from Schiffer et al. [256], p. 557)

does not follow a circadian pattern, with episodes occurring at equal rates throughout a 24-h period. These studies have also revealed that HSV reactivations are more frequent than previously appreciated and suggest rapid clearance of HSV, perhaps via a resident immune response in the oral and genital mucosa [260]. Mathematical models predict that HSV is produced at a rate of 50 particles/day from the ganglia to produce observed shedding patterns [261] and that increased quantity of CD8+ T cells limits the length and symptoms of reactivations [262]. In addition, genital HSV shedding may involve the bilateral genital tract, particularly in the setting of a genital lesion [263, 264].

8.1.2 HSV-1 Genital Shedding

There are few data characterizing genital HSV-1 shedding rates after first-episode genital HSV-1 infection, and these studies have used HSV culture [56]. For 14 women with symptomatic genital HSV-1 infection, genital HSV was detected on 1.9 % of days; subclinical shedding was detected <1 % of days sampled. Further studies with more participants with both symptomatic and asymptomatic genital HSV-1 infection and using PCR will be necessary for a more definitive description of genital HSV-1 shedding patterns.

8.2 HSV Oral and Ocular Shedding

8.2.1 HSV-1 Oral and Ocular Shedding

HSV-1 oral and ocular shedding was studied in 50 asymptomatic persons over a 30-day period. HSV was detected from 37.5 % of oral swabs and 33.5 % of ocular samples [265]. Only one participant did not shed HSV-1 from the eye or saliva during the follow-up period. In a review of published HSV-1 oral shedding studies, 6 % of people were shedding HSV when sampled with a single specimen [266]. HSV-1 was detected in 31.9 % of participants sampled more than 5 times per week; the overall rate of shedding was 33.3 % of samples in persons who collected at least 3 specimens.

8.2.2 HSV-2 Oral Shedding

In a study of HIV-negative men, the oral HSV-2 genital shedding rate measured by PCR was 1.3 % of days [267]. Oral shedding was always asymptomatic and was often concurrent with genital HSV-2 shedding or lesions [267]. The rate of oral HSV-2 shedding was higher in HIV-infected men than in HIV-negative men.

8.3 Genital HSV Transmission in Sexual Relationships

Prospective studies of HSV-2-discordant couples have demonstrated that 70 % of HSV-2 transmissions occur in the absence of symptoms in the source partner [257]. A study of 199 persons with newly acquired, laboratory-documented genital herpes showed that the median duration of the sexual relationship was 3.5 months, with a median of 40 sexual acts prior to transmission [268], suggesting rapid transmission in new sexual partnerships.

9 Treatment and Prevention

9.1 Treatment

Three oral antiviral agents are available to treat HSV infections. Acyclovir, valacyclovir (prodrug of acyclovir), and famciclovir (prodrug of penciclovir) are guanosine nucleoside analogues that require initial phosphorylation by the HSV-encoded thymidine kinase, followed by phosphorylation by cellular kinases [269]. The nucleotide triphosphates are preferentially incorporated by viral DNA polymerase into the growing DNA chain, resulting in chain termination [269]. These drugs are inactive in uninfected cells and have an excellent safety profile, including well-documented safety in pregnant women [270, 271]. These oral antiviral drugs are used to treat genital and labial herpes either at the time of a recurrence (episodic therapy) or daily to prevent recurrences

(suppressive therapy). Episodic therapy is recommended for first-episode and recurrent genital herpes and should be started at the first sign of a clinical recurrence [57]. The use of oral antiviral drugs during first-episode or recurrent genital herpes decreases the duration of lesions, symptoms, and viral shedding [272–274]. High-dose, single-day oral regimens of valacyclovir and famciclovir can be used episodically for oral or genital HSV recurrences [275]. Suppressive therapy prevents recurrences of genital HSV-2 [276–279], decreases the frequency and titer of HSV shedding from anogenital sites [110, 212, 280], and improves quality of life [281]. In HSV-2-discordant couples, daily suppressive therapy for the infected partner also reduces the risk of genital HSV-2 transmission [110]. However, breakthrough shedding and lesions can occur on suppressive therapy, even when high doses are used [282]. Suppressive therapy can also be used to prevent oral HSV recurrences [283]. Dosages and schedules for the oral antivirals were reviewed by Cernik and colleagues [284], and recommendations for treatment of genital herpes are available from the US Centers for Disease Control and Prevention (CDC) [57].

Intravenous acyclovir achieves high levels of CNS penetration and is the treatment of choice for CNS disease [132], neonatal HSV [171], disseminated HSV infection, and severe primary genital infection [285]. Ocular drops of acyclovir, vidarabine, trifluridine, or ganciclovir may be used for HSV keratitis [286]. Foscarnet is available for acyclovir-resistant herpes [287]. Helicase-primase drugs [288] and microbicides [289] are in early development, as are other novel antiviral delivery methods, such as vaginal acyclovir rings [290].

9.2 Prevention

9.2.1 Vaccine Strategies

The optimal intervention for prevention of HSV infection and disease would be a preventive or therapeutic HSV vaccine, a tool that thus far has eluded scientists [242]. Most HSV vaccines tested in humans have been based on glycoprotein targets on the surface of the HSV virion. Several vaccines have been efficacious in mouse and guinea pig models but have failed to prevent infection or disease in human trials [242]. One promising exception was an HSV-2 glycoprotein D (gD-2) subunit vaccine with alum and 3-O-deacylated monophosphoryl lipid A adjuvant tested in persons with high-risk sexual behavior and in HSV-2-discordant couples [291]. Overall, the vaccine was not effective, but in a subgroup analysis of HSV-1-/HSV-2-seronegative women, the vaccine was ~75 % effective [291]. A more recent, larger trial involving ~8,300 HSV-1-/HSV-2-seronegative women disappointingly showed that this vaccine did not protect against HSV acquisition, despite stimulation of robust neutralizing antibody [292]. We do not know immune correlates of protection against HSV, and we will likely need to understand more about the effective immune response against HSV before we will be successful in creating an effective vaccine [242]. Recent studies from the mouse model have suggested that systemic vaccination to stimulate memory T-cell responses ("prime") followed by local recruitment of T cells through application of topical genital agents ("pull") approach to stimulate resident memory T-cell responses in the genital tract may be an effective immunization strategy [293]. Live-attenuated [294], replication-competent [295], and replication-incompetent vaccine constructs have also been effective in animal models [296, 297] but will require further testing in humans. Future HSV vaccine development will require consideration of whether a vaccine needs to protect against both HSV-1 and HSV-2.

9.2.2 Available Prevention Strategies

There are four available strategies for the prevention of genital HSV transmission; however, no strategy is 100 % effective. In heterosexual HSV-2-discordant couples, daily suppressive antiviral therapy for the infected partner decreases HSV-2 transmission by nearly 50 % [110]. Consistent condom use decreases the risk of transmission by ~30 %, with similar efficacy for men and women [298]; condoms are likely less effective for HSV-2 than other sexually transmitted infections because areas of viral shedding may not be covered by the condom. In a time to event study, disclosure of HSV serostatus to sexual partners decreased time to HSV-2 acquisition in susceptible partners [268]. Randomized trials of male circumcision for prevention of HIV acquisition have demonstrated that circumcised men have a 25 % lower risk of acquiring HSV-2 and a lower risk of GUD than uncircumcised men [299, 300]. However, circumcision status does not affect the risk of HSV-2 transmission to female partner [301].

10 Unresolved Epidemiologic Issues

Whether and who to screen for HSV-2 infection has been a contentious issue. While some experts advocate screening individuals in STD clinics, persons with high-risk sexual practices, or women in the prenatal setting to identify those at risk of transmitting neonatal HSV [302], screening is currently not recommended by the US Preventive Services Task Force [303], due to concerns about false-positive tests in populations with low prevalence, cost-effectiveness, lack of proven interventions to improve health outcomes, and potential harm in learning that one is HSV-2 seropositive. Despite concerns about psychological effects of screening for herpes, studies have shown that there is no longstanding harm to HSV-2 screening and diagnosis in asymptomatic persons [304].

Neonatal HSV is reportable in only 9 US states, and even in these states, there is no clear case definition for reporting disease [160]. The resulting inability to determine the true incidence and morbidity/mortality of disease has led to a call for the CDC to institute national reporting, but this has not been implemented, to date [154].

Despite improved understanding of viral pathogenesis and host immune responses and the availability of effective antiviral agents for HSV, the patterns of occurrence of HSV infection have changed little in recent years, and the epidemiology of the highly evolved, ubiquitous herpes simplex virus is likely to remain substantially unaltered, without an effective vaccine.

Acknowledgment The authors would like to acknowledge and thank Drs. Andre J. Nahmias and Daniel M. Jorgensen for their contributions to the previous versions of this chapter.

Human Herpesviruses: Human Herpesvirus 6

37

Mary T. Caserta† and Caroline Breese Hall†

1 Introduction

Over the last quarter of a century since its discovery, human herpesvirus 6 (HHV-6) has been recognized as the most rapidly and ubiquitously acquired virus known to infect humans. During this period HHV-6 has been primarily known as the "roseola virus," but recent advances in technology have markedly expanded the spectrum of its mein to include diseases associated with both primary infection and reactivation. In addition, new data on HHV-6 transmission, its integration into human chromosomes, its latency, and congenital infections have added to our understanding and to the conundrums of its epidemiologic and biologic behavior.

2 Historical Background

The techniques developed for the in vitro cultivation of human peripheral blood mononuclear cells (PBMCs) led not only to the discovery of human retroviruses but also to the identification of HHV-6. The new virus was detected within the peripheral blood lymphocytes of adults with lymphoproliferative diseases and/or AIDS in 1986 [91]. Based upon preliminary cell typing experiments, the virus was initially called human B-lymphotropic virus (HBLV). Further characterization of the virus and its proclivity to infect CD4+ T lymphocytes resulted in its being renamed the sixth member of the human herpesvirus family. Two years later when this same virus was detected by Yamanishi and colleagues [116] in the lymphocytes of four infants with roseola, a whole new spectrum of its potential disease associations and clinical importance were evoked, and these continue to be explored.

For over 200 years roseola-like illnesses have been described among young children under multiple sobriquets, including exanthem subitum, rash rose of infants, and most prophetically, sixth disease. The specific disease now recognized as roseola was first separated from other exanthematous illnesses by Zahorsky with his description of 15 cases in 1910 [127]. The first prospective study by Breese [17] 30 years later provided the descriptive epidemiology of roseola, which was confirmed as a manifestation of infection with HHV-6 a half century later.

3 Methods for Epidemiologic Analysis

Initially serologic surveys were the primary means of describing the epidemiology of HHV-6 infection, particularly its acquisition and duration. These studies demonstrated the ubiquity of infection with HHV-6 by detecting high rates of antibody in all populations examined [26, 42, 115]. New molecular techniques for detection and determining viral state have further defined its epidemiologic patterns according to age, presence in body sites, replicative state, and new or reactivated infection [20, 33, 67, 111] (see section Diagnosis, Table 37.1).

4 Biologic Characteristics Affecting the Epidemiologic Pattern

The viral structure of HHV-6 is typical of herpesviruses and includes a 160–162 kb linear double-stranded DNA genome contained within a nucleocapsid with icosahedral symmetry [16]. A tegument composed of proteins and RNA surrounds the nucleocapsid which is in turn enclosed in a lipid envelope embedded with viral glycoproteins, together forming the

Table 37.1 Diagnosis of HHV-6 infections

		Type of infection diagnosed				
Assay[a]	Specimen	Acute primary	Recent active	Past/latent	Reactivated	Comments
Serology[b]						
Antibody titers	Serum/plasma					
IgG titers		+	+	+	±	Sensitive. Seroconversion indicative of primary infection
						HHV-6A and HHV-6B not differentiated
						Limited HHV-6 and HHV-7 cross-reactivity depending on assay used
						Results not available during acute illness as requires testing of 2 or more serial specimens
						Single specimen, if antibody negative, DNA positive, suggests early, primary infection
						Maternal antibody may be present <6 months of age and confuse results
IgM titers		+	+			Not detected in all primary infections
						May be detected in small percent of normal individuals and in some reactivated infections
Avidity titers		+	+	+		Single specimen testing indicates acute infection within 6 weeks (low avidity) or >6 weeks (high avidity)
DNA/RNA detection						
DNA PCR	Mononuclear cells in blood and other specimens	+	+	+	+	DNA detection may indicate acute and/or past infection, requires serology and/or RT-PCR for clarification
						Differentiates HHV-6A and HHV-6B
	Serum/plasma or whole blood	+			+	Lysis of peripheral blood mononuclear cells can produce appreciable proportion of false-positive results[a] [2, 20]
Real-time DNA PCR	Serum/plasma or whole blood	+			+	Quantitative, very sensitive, costly
						Lysis of peripheral blood mononuclear cells can produce appreciable proportion of false-positive results[a] [2, 20]
RNA PCR						
RT-PCR	Mononuclear cells	+			+	Very sensitive, semiquantitative
						Differentiates HHV-6A and HHV-6B, costly
Real-time RT-PCR	Mononuclear cells	+			+	Very sensitive, quantitative, costly
Viral growth	Mononuclear cells of blood and other specimens	+			+	Available only in research laboratories
						HHV-6A and HHV-6B can be differentiated
						Results usually not available during acute illness
Viral antigen detection	Blood, secretions	+			+	Suggests active replication, semiquantitative
						Differentiates HHV-6A and HHV-6B
						Sensitivity and specificity variable

[a]CI-HHV-6 may confound interpretation of diagnostic tests; see text on Congenital Infections

[b]Multiple serologic tests are available including immunofluorescent assays (IFA), neutralizing antibody assays, enzyme immunoassays (EIA), immunoblots, anticomplement assays [33, 111, 122]

fully mature ~200 nm virion particle [26]. Additionally, the overall genome organization of HHV-6 is similar to other herpesviruses with a large, central unique region (U) of approximately142–145 kb size bounded on both ends by identical direct repeat (DR) elements of 8–13 kb [30, 39, 55]. The unique region of the genome also contains three

intermediate repeat elements [26]. Based upon an identified tropism for lymphocytes, HHV-6 was initially thought to be a γ herpesvirus similar to Epstein-Barr virus (EBV). However, studies of the genomic structure combined with sequencing data suggested that the unique region of HHV-6 was similar to human cytomegalovirus (CMV) and is colinear with human herpesvirus 7 (HHV-7). This led to HHV-6 being classified along with CMV and HHV-7 into the *Betaherpesvirinae* subfamily [26, 79]. Further reports have confirmed that HHV-6A and HHV-6B are is most closely related to HHV-7, and these viruses share the genus *Roseolovirus* [16].

The genome of HHV-6 is predicted to contain 115–119 open reading frames (ORFs) coding for approximately 97 unique genes [30, 39, 55], including seven conserved gene blocks shared by all human herpesviruses and found in a similar alignment in HHV-6, HHV-7, and CMV [16, 26]. HHV-6 also encodes a set of beta genes found exclusively in HHV-6, HHV-7, and CMV, as well as several unique genes not found in other herpesviruses [26].

Two species of HHV-6 have been identified, HHV-6A and HHV-6B, based upon differences in genome coding content, epidemiology, and cell tropism [38]. Prototypic isolates of both HHV-6A and HHV-6B have been completely sequenced with an overall nucleotide sequence identity between them of 90 %. The most conserved regions of the HHV-6 genome are found in open reading frames U2 through U85 [30, 55]. Recent studies have confirmed stable genetic differences between HHV-6A and B, adding credence to the move to separate them into two distinct species [33]. Further diversity in HHV-6 isolates was initially suggested by finding that HHV-6B could be subdivided into two subgroups with 96 % sequence identity between the groups based upon a region of an immediate early gene [23]. However, subsequent analyses of the regions encoding two major HHV-6 glycoproteins, gB and gH, have demonstrated that single isolates may contain regions characteristic of both subgroups, and thus, this distinction is not uniform [3].

Recent reports have highlighted the importance of the direct repeat (DR) segments of the HHV-6 genome in the virus life cycle. Cleavage and packaging motifs as well as imperfect and perfect human telomere repeat sequences (TAACCC) are present in the DR regions [75]. Preliminary studies have suggested that the perfect telomere repeat segments (TRS) of the virus mediate integration of the entire HHV-6 genome into the telomeres of human chromosomes in a subset of the population [8]. Multiple chromosomes have been shown to harbor integrated HHV-6, usually one site per person, and always at the telomere, suggesting that the telomere provides the specificity for integration [76]. Although the exact mechanism has not been fully elucidated, integration is postulated to occur via homologous recombination and may be facilitated by the U94 protein of HHV-6 [7]. U94 is unique to HHV-6 but shares homology with the adeno-associated virus 2 (AAV-2) Rep 68/78 gene [107, 108] and has been demonstrated to play a role in HHV-6 latency [90]. Viral integration into the host telomere has also been described in animal herpesviruses, specifically Marek's disease virus (MDV), a pathogen of chickens that is associated with the development of T-cell lymphomas [33]. Whether chromosomally integrated HHV-6 (ciHHV-6) causes any human diseases is currently unknown. Furthermore, yet to be determined is whether ciHHV-6 virus can replicate in vivo and produce infectious viral particles, as has been demonstrated in vitro and in MDV [8].

Infection with HHV-6 is followed by latency or persistence of the virus for the life of the host. Primary lytic infection with HHV-6 principally occurs in mature CD4+ T cells in vivo and is associated with characteristic cytopathic effects and cell lysis in vitro [101]. Monocytes and macrophages have been demonstrated to be the predominant cell types harboring latent HHV-6 in the peripheral blood [60] with more recent data suggesting that CD34+ stem cells may also be a site of viral latency and a reservoir for reactivation [6, 57]. Although all isolates of HHV-6 can be propagated in vitro in primary cord blood mononuclear cells, HHV-6A and HHV-6B can be distinguished in part by their differential growth in established cell lines [27, 28]. Santoro and colleagues determined that the human complement regulatory protein CD46 is a receptor for HHV-6 and co-immunoprecipitates with glycoprotein H (gH) of the virus [92, 93]. During infections with HHV-6A, the complex of gH/gL/gQ1/gQ2 glycoproteins was found to be the viral ligand for CD46, but not for HHV-6B with CD134 recently identified as a specific receptor for HHV-6B, perhaps helping to explain the differences in tropism between HHV-6A and HHV-6B [73, 104]. The presence of CD46 on all nucleated cells of the body may also help to explain the finding that HHV-6 can infect many cell types including fibroblasts, epithelial cells, endothelial cells, astrocytes, oligodendrocytes, microglia, dendritic cells, and natural killer cells [5, 19, 22, 27, 31, 66, 68, 95]. These in vitro findings correlate with the ability to detect HHV-6 DNA in saliva, cervical swab samples, peripheral blood mononuclear cells, and brain tissue in clinical specimens and suggest these sites harbor HHV-6 in a latent or persistent state following primary infection.

5 Descriptive Epidemiology

Serosurveys have demonstrated that infection with HHV-6 is ubiquitous and occurs quite rapidly after the fall in maternal antibody at 4–7 months of age [126]. Essentially all children are seropositive by 2–3 years of age with the peak time of acquisition of primary HHV-6 infection at a median 8 months of age (Fig. 37.1) [48]. In general, no seasonal pattern of

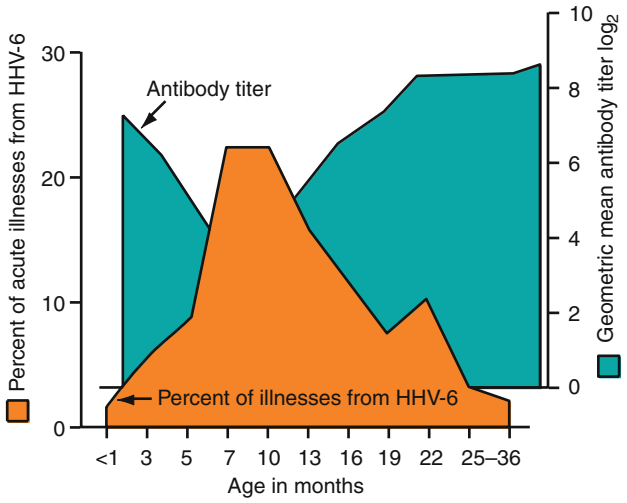

Fig. 37.1 Changes in HHV-6 antibody titers and percent of illness due to primary infection by age Used with permission from Hall [43]

roseola has been identified, and most cases are sporadic with rare outbreaks reported [83].

HHV-6B is responsible for 97–100 % of primary infections in North America, Europe, and Japan [29]. However, HHV-6A has been reported recently to cause the majority of primary infections in one region of sub-Saharan Africa [12, 13]. The significant cross-reactivity between HHV-6A and HHV-6B in standard serologic assays has confounded broader study of the epidemiology of the two species. HHV-6 A and HHV-6B specific immunoblot assays have been developed, but determining their validity has been hampered by the lack of available sera from individuals with only HHV-6A infection [50, 105]. The frequency of infection with HHV-6A is unclear, but currently HHV-6A has not been definitively associated with recognized clinical findings, and HHV-6A DNA is not readily detectable in PBMC or saliva in adults from North America or Europe [36, 45]. These data are in contrast to the relative frequency of HHV-6A and HHV-6B noted in studies of ciHHV-6 in the United States in which HHV-6A is identified in approximately 33 % of cases [47]. The variations in the detection of HHV-6A and HHV-6 B DNA may relate to differences in tissue tropism, mode or age of acquisition, or the geographic location of the population. The complete understanding of HHV-6A awaits further study.

6 Mechanisms and Routes of Transmission

Information on the transmission of HHV-6 has been limited by the typical absence of contact with similar clinical cases by the affected individual and, second, by the lack of a feasible animal model. In 1941 Breese [17] unsuccessfully attempted to recover a filterable virus from the secretions of infants during the preeruptive febrile phase using multiple means of inoculation to infect a variety of animal models and tissue cultures. No other laboratory investigations of transmission occurred until Kempe and coworkers in 1950 [59] demonstrated that the sera and secretions obtained during the febrile phase of a child with roseola contained an infectious agent that could transmit the clinical disease after an incubation period of 10 days in humans and when transmitted to monkeys produced a characteristic febrile illness after about 5 days. Further investigations to determine the definitive incubation period of HHV-6 have not been done.

6.1 Horizontal Postnatal Transmission of HHV-6B

HHV-6B is assumed to be acquired from the secretions of asymptomatic close contacts based on the observations of the rapid acquisition of infection in the first months of life and the lack of exposure to clinically similar cases [48]. Although the data are limited [24, 109], children who acquired HHV-6 prior to their first birthday have been reported as being more likely to practice saliva-sharing behaviors [89]. HHV-6 DNA may be detected in saliva, but in contrast to HHV-7, infectious virus rarely is identified [15, 16]. HHV-6 DNA has also recently been identified in 60 % of nasal mucous specimens from healthy volunteers suggesting that respiratory droplet transmission may also be possible [49].

6.2 Perinatal HHV-6 Infections

Primary infection has been documented in the perinatal period which suggests that horizontal transmission may also occur at or shortly after birth [18, 48]. HHV-6 DNA has been detected in 3.3–10 % of cervical swab samples in nonpregnant women [21, 63] and in 7.5–25.5 % of cervical swab specimens of pregnant women [21, 71, 84]. HHV-6 DNA has not been detected in breast milk [32].

6.3 Congenital HHV-6 Infections

Congenitally acquired HHV-6 infections have been shown to occur by the detection of HHV-6 DNA in cord blood [24, 44]. Although the prior assumption was that all HHV-6 congenital infections were due to transplacental infection from maternal viral reactivations or reinfections, similar to that of CMV, HHV-6 intrauterine infections have been shown to result from either transplacental passage or from the unique mechanism of germline passage of the chromosomally integrated genome of HHV-6 [21, 25, 47]. However, the great majority (86 %) of

congenital infections appear to be caused by chromosomal integration [47]. In all cases of ciHHV-6, the viral genome is integrated into the telomeres of human chromosomes, as described above [7]. Both HHV-6A and HHV-6B have been shown to be integrated, and ciHHV-6 has been estimated to be present in 0.2–1 % of populations from Japan, the United Kingdom, and the United States [65, 85, 103].

A recent report suggests that mothers with ciHHV-6 also may pass their integrated virus via a transplacental mechanism [46]. In this study, children with congenital HHV-6 infection not due to chromosomal integration and their parents were examined. None of the fathers had ciHHV-6, but all of the mothers had ciHHV-6, and the mother's species type was the same as that identified from her infant. These findings suggest that ciHHV-6 may replicate and raise the possibility that nearly all transplacental congenital infections could be from replicating maternal ciHHV-6.

6.4 Diagnosis of ciHHV-6 Passed by the Germline

Because ciHHV-6 is in germline cells, each nucleated cell will contain one or more ciHHV-6 genomic copies. Thus, the diagnosis of ciHHV-6 is presumed if HHV-6 DNA is (1) consistently detected in all nucleated cells and (2) in cells of different lineages, such as white blood cells and hair follicles and (3) viral loads are persistently high (≥1 genomic copy/cell or about one million HHV-6 DNA copies per ml blood) [113].

7 Pathogenesis and Immunity

Primary infection with HHV-6 induces a coordinated immune response from the host. In the first 2 weeks of infection, enhanced natural killer (NK) cell activity is detected in children with roseola along with elevated serum levels of interferon (IFN)-α, IFN-γ, interleukin (IL)-2, IL-4, and monocyte chemotactic protein (MCP)-1 [61, 100, 123]. Concurrently, IgM and IgG antibody responses to primary HHV-6 infection are produced with viral-specific neutralizing antibodies identified within 1 week which are temporally associated with clearance of the virus [11, 98, 119]. The IgM response is nonspecific and lasts approximately 1–2 months, while specific IgG antibodies are maintained with the levels declining in later adulthood [120, 126]. HHV-6 infection also induces T-cell proliferation with viral-specific CD4+ T-cell epitopes mapped to regions of abundant virion proteins [78]. Evidence for the importance of both antibody- and cell-mediated responses to HHV-6 is found in the generally apparent protective effect of maternal antibody in the newborn period and the recognition that disease associated with HHV-6 reactivation occurs most commonly in immunocompromised hosts with T-cell deficits, secondary to either medications or disease.

In addition to the host response to infection, HHV-6 interacts with the immune system in important ways suggesting that the virus has acquired several strategies for immune evasion. Following infection, HHV-6 induces downregulation of the T-cell receptor (TCR)/CD3 complex in PBMCs via inhibition of receptor recycling [99]. MHC class I molecules are also diverted from the cell surface during HHV-6 infection [37, 52], while CD4 transcription is upregulated [34, 69]. HHV-6 also can infect antigen-presenting dendritic cells, but the functional impact of infection is unclear [14, 96, 102]. In addition to the typical cell lysis which follows infection [40, 54, 118], HHV-6 infection induces apoptosis of T cells, primarily naïve and central memory CD4+ and CD8+ cells. The HHV-6 genome encodes two homologs of β-chemokine receptors [56, 72] as well as a protein, identified as a CCR-2 chemokine agonist [70, 132], that can induce monocytic cell migration. These myriad interactions with the immune system are postulated to enhance viral replication in infected cells, recruit susceptible cells to the site of infection, or circumvent the host immune response to infection.

Despite the rapidly increasing knowledge of the basic biology of HHV-6, how the infection induces disease remains unclear. Early reports found that the duration of symptoms in primary infection was associated with the degree and persistence of viremia suggesting that the virus has direct effects on the host [9]. HHV-6 DNA also has been detected in most, but not all, of cerebrospinal fluid (CSF) samples of patients with encephalitis, implying either direct viral pathogenesis or possibly an immune-mediated process [4, 53, 124]. However, proving HHV-6 to be the direct cause of disease based solely upon the detection of HHV-6 DNA is confounded by its known capacity for latency or persistence in the central nervous system (CNS) and by the knowledge that viral DNA can be detected in asymptomatic individuals with ciHHV-6 [77]. Further studies and diagnostic methods are needed to clarify the pathogenesis of HHV-6.

8 Patterns of Host Response

8.1 Clinical Features of HHV-6 Infection

8.1.1 Primary Infection

Manifestations of primary HHV-6 infection are variable and may show geographic differences. In Japan, initial disease is primarily roseola (exanthem subitum), whereas in the United States the clinical findings are nonspecific or have findings suggesting other illnesses [10, 41].

Roseola typically presents with the abrupt onset of fever which usually reaches 39–41°C and lasts 3–5 days, and with defervescence the rash appears. It is usually maculopapular

Fig. 37.2 The rash of roseola in a child with primary HHV-6 infection (Used with permission from Hall [43]

and varies in intensity of color and number of lesions. The trunk tends to be most involved, but the back of the neck, forehead, and extremities may also be affected (Fig. 37.2).

In the United States, the initial presentation in about 30 % of primary illnesses is a highly febrile disease without localized findings (Fig. 37.3) [48]. Only about 20 % of children later develop a rash and are diagnosed with roseola. Approximately 10 % of children with proven HHV-6 infection are diagnosed at presentation with presumed bacterial sepsis, and about one-half are initially diagnosed with a febrile respiratory or gastrointestinal illness. Otitis media is frequently diagnosed, based primarily on tympanic membrane erythema. Whatever the initial diagnosis, however, the most characteristic findings of primary illness are the abruptness and height of fever (average 40 °C), the development of postoccipital lymphadenopathy, and the decline in the white

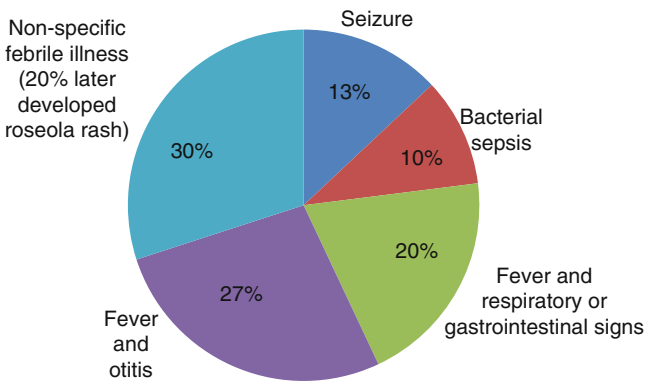

Fig. 37.3 Diagnosis at presentation of 354 US children with proven primary HHV-6 infection (Used with permission from Hall [43])

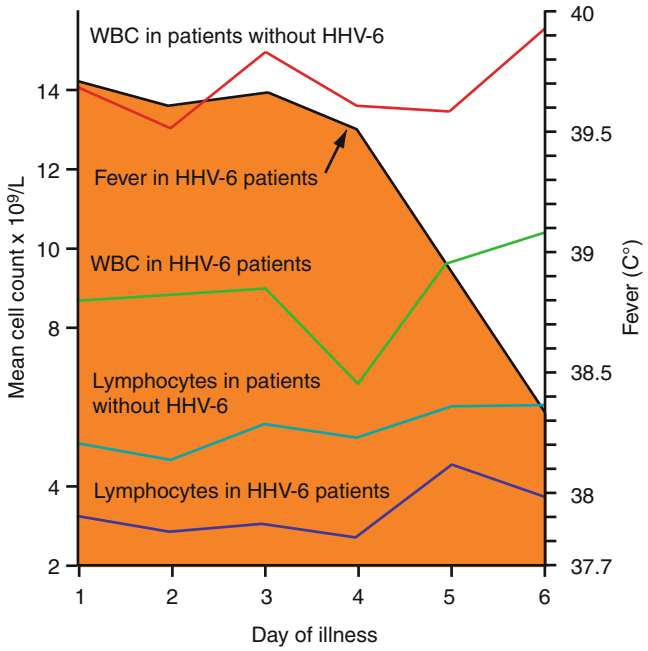

Fig. 37.4 Fever and hematological parameters in children with proven primary HHV-6 infection (Used with permission from Hall [43])

blood cell count after 2–3 days, which is subsequently followed by a rise in the proportion of lymphocytes (Fig. 37.4) [17, 87].

Of note is that the great majority of primary HHV-6 infections appear to be symptomatic but self-limited and the usual outcome is complete recovery. Asymptomatic infection has been estimated to occur in only about 5 % of primary infections [131].

Seizures, occurring in 13 % of children with primary HHV-6 infection, are the most common complication and sometimes have features that are atypical for classical febrile seizures including higher frequencies of partial seizures, prolonged and repeated seizures, and postictal paralysis [97]. Among young children identified as having primary infection with HHV-6 or HHV-7 and suspected to have encephalitis, status epilepticus was the most common presentation [112]. A recent nationwide Japanese survey estimated that the annual rate of encephalitis or encephalopathy complicating exanthem subitum (roseola) was 6 per 100,000 cases of roseola [125]. A little over half of these children developed significant neurologic sequelae, which were associated with abnormal findings on computed tomography (CT) during the acute phase of illness [125]. CSF findings in children with primary HHV-6 infection and encephalitis or encephalopathy are usually normal or show only mild elevations in cell counts or protein [58]. Additionally, the viral load in the CSF has been found to be less than 100 copies per milliliter in a small number of children with encephalitis complicating primary HHV-6 infection, and CSF concentrations of IL-6 have been shown to be significantly elevated compared to controls, suggesting that inflammatory cytokines may have a role in the pathogenesis of HHV-6 disease [53, 58].

8.1.2 Congenital HHV-6 Infections

No specific clinical findings currently are associated with congenital HHV-6 infection [44]. Most infants with congenital HHV-6 infection are asymptomatic and do not have findings which are clinically different from those of controls without congenital HHV-6 infection. Unknown, however, is whether subsequent developmental effects will occur.

8.1.3 HHV-6 Reactivation

In addition to the association between primary HHV-6 infection and seizures noted above, studies also have suggested a link between reactivated or persistent HHV-6 infection of the CNS and chronic seizure disorders that develop later in childhood or beyond. Best described is medial temporal lobe epilepsy (MTLE), which may follow prolonged febrile seizures or status epilepticus and is associated with mesial temporal sclerosis [106]. HHV-6 DNA has been identified in the hippocampus and lateral temporal lobes of a significantly greater number of brain samples from patients undergoing surgery for MTLE, and with higher viral loads, compared to samples from subjects with other types of epilepsy [31, 35]. HHV-6 protein was also identified in the affected areas by immunohistochemistry, suggesting active viral replication. Furthermore, the possible connection between HHV-6 and epilepsy is strengthened by preliminary data suggesting that HHV-6 infection interferes with a glutamate transporter protein in the CNS which may be a possible mechanism for the induction of seizures [35].

Reactivation of HHV-6 has been repeatedly demonstrated among immunocompromised hosts, especially among patients undergoing hematopoietic stem cell transplant (HSCT). Prospective studies have demonstrated reactivation of HHV-6 in the peripheral blood of 35–65 % of patients, most often from 14 to 28 days after transplantation [80, 81, 114, 121]. HHV-6 reactivation in HSCT is consistently associated with fever and rash and sometimes with CNS disorders [121, 129]. In particular, a specific syndrome of posttransplant acute limbic encephalitis (PALE) has been identified and characterized by altered mental status, insomnia, amnesia, and seizures, with temporal lobe disease evident on imaging [51, 110]. This syndrome occurs in approximately 1–4 % of patients, usually associated with the detection of HHV-6B, and higher viral loads in plasma than that observed in patients without CNS disease [74, 81, 82, 128]. Additionally, umbilical cord blood transplantation appears to confer a significantly higher risk for these complications than other types of HSCT and is associated with high mortality and long-term morbidity [51, 74]. HHV-6 reactiva-

tion has also been implicated in many but not all studies as causing delayed engraftment of platelets and neutrophils, graft failure, graft-versus-host disease, and myelosuppression in patients following HSCT [26].

Among patients with solid organ transplantation, the rate of HHV-6 reactivation varies from 20 to 55 % [62]. However, disease has been noted in only about 1 % [88]. Described consequences of HHV-6 reactivation include fever, rash, hepatitis, colitis, encephalitis, renal dysfunction, and graft rejection [62, 88]. Nonetheless, the specific impact of HHV-6 reactivation on solid organ transplantation is not yet clear. Routine monitoring for HHV-6 reactivation during transplant is not recommended nor is antiviral prophylaxis [88].

Little information exists on the role of ciHHV-6 among transplant recipients. Preliminary studies have suggested that patients with ciHHV-6 who have liver transplants have significantly higher rates of bacterial infections than those without ciHHV-6 [64]. Further evidence to determine whether the chromosomal integration of HHV-6 adversely affects the outcome of solid organ transplantation will require study of many more patients with ciHHV-6.

Among the immunocompetent adult population, an association between HHV-6 and multiple sclerosis has been suggested, but this link remains controversial [117]. HHV-6 reactivation also has been observed among patients with the drug-induced hypersensitivity syndrome, also known as drug rash with eosinophilia and systemic symptoms (DIHS/DRESS). However, if and how HHV-6 contributes to the pathophysiology of DIHS/DRESS is unclear [1].

8.1.4 Laboratory Diagnosis

Multiple serologic and molecular assays have been developed to detect and characterize infection with HHV-6 (Table 37.1).

Many of these tests are difficult to perform reliably and not available outside of research laboratories. Polymerase chain reaction (PCR) is readily available and has been used to identify the presence of the HHV-6 genome in multiple body fluids and tissues. The identification of HHV-6 DNA in plasma or other cell-free fluids by qualitative PCR was initially thought to be a reliable marker for active viral replication, due to either primary or reactivated infection [94]. However, recent data suggest that the detection of HHV-6 DNA in plasma is only 84 % specific compared to viral isolation [20]. Additionally, essentially all plasma samples from individuals with ciHHV-6 have detectable HHV-6 DNA in every sample which further confounds the interpretation of plasma results. Quantitative PCR and reverse transcription PCR can be used in addition to standard qualitative DNA detection assays to help discriminate between latent virus, actively replicating virus, and ciHHV-6 [20, 85].

9 Prevention and Control

HHV-6 infection is ubiquitous among humans, rapidly acquired in infancy or early childhood, and present for the life of the host. Despite the substantial gains in our understanding of HHV-6, many gaps remain, and the full clinical impact of infection has yet to be characterized completely. These limitations have prohibited significant progress toward the prevention of infection with HHV-6. Additionally, in view of the recent recognition that the complete viral genome is integrated into human chromosomes and can be passed vertically from parent to child in approximately 1 % of infants, complete prevention is unlikely to be possible.

Efforts at controlling disease manifestations due to primary HHV-6 infection or reactivation also remain preliminary. The antiviral drugs, ganciclovir, foscarnet, and cidofovir, have all been shown to have in vitro activity against HHV-6. They have been used either alone or in combination among small numbers of patients with presumed HHV-6 disease, but their effect on decreasing viral replication has been variable [26, 33, 130]. However, no drug has been studied in controlled clinical trials with clinically relevant endpoints, and none is currently licensed for the treatment or prevention of HHV-6 infection or disease.

10 Unresolved Problems

Although HHV-6 infection has been associated with several different clinically distinct diseases, the full extent of the pathology induced by infection or reactivation of the virus is still unknown. Because HHV-6 infects essentially the entire population and induces lifelong latency or persistence, a major challenge is determining when disease is due to the direct or indirect effects of the virus versus when the viral DNA is detected but not involved in disease pathogenesis. Significant steps needed to understand HHV-6 infection include deciphering the extent and timing of infection with HHV-6A, its clinical manifestations compared to those of HHV-6B infection, and whether an interaction between the two exists.

The recognition of ciHHV-6 has significantly increased our recent understanding of HHV-6's pathophysiology, and much of the prior information on HHV-6 needs to be reevaluated in light of the potential effects of ciHHV-6. The recently described role of ciHHV-6 in congenital infections has been particularly revealing but has simultaneously engendered an intriguing list of further questions. Does ciHHV-6 have the ability to replicate and create fully mature viral particles? Does ciHHV-6 cause disease, and, if so, what is the pathogenesis? Could ciHHV-6 interfere with normal cell development by disrupting the human genome or by producing viral genetic elements or proteins even in the absence of fully mature virions? [86] Among individuals with ciHHV-6 does

disease subsequently develop after birth and in different tissues than those usually seen with typical primary HHV-6 infection? Does a difference exist between infection due to chromosomal integration and infection from HHV-6 acquired postnatally that can be explained by differences in biology, immunity, or tolerance to one or both? The coming chapters in the biography of HHV-6 will be intriguing and important.

Epstein-Barr Virus (EBV): Infectious Mononucleosis and Other Non-malignant EBV-Associated Diseases

38

Karen F. Macsween and Ingólfur Johannessen

1 Introduction

Epstein-Barr virus (EBV), a member of the human gammaherpesvirus subfamily, was discovered in African lymphoma cell lines by Epstein, Barr and Achong in 1964 following the initial description by Burkitt, a British surgeon working in Africa, of an endemic malignant tumour affecting the jaw of children in Uganda [1–3]. Thus, EBV was the first candidate human tumour virus to be identified. The malignancy, affecting African children (Burkitt's lymphoma, BL), is now known to be of B lymphocyte origin, and EBV is considered to be an essential cofactor in the outgrowth of the endemic form of the tumour. Furthermore, EBV is the causative agent of infectious mononucleosis (IM) [4, 5], and the virus is aetiologically associated with a variety of epithelial and lymphoid lesions in the immunocompetent and immunosuppressed host, although its role in some tumours is not yet entirely clear [6] (see Table 38.1).

Of lymphoid malignancies, EBV is found in 96 % of endemic (African) BL (eBL; reviewed in [15]). In Europe and the USA, around 20 % of sporadic BL (sBL) is associated with EBV (reviewed in [16]) as well as approximately 50 % of Hodgkin's lymphoma (HL) (reviewed in [17]), and around 90 % of non-HL (NHL) arising in organ transplant recipients (post-transplant lymphoproliferative disease, PTLD; reviewed in [18]). Additionally, EBV is found in subsets of T/natural killer (NK) cell lymphomas (reviewed in [19]). Furthermore, EBV is detected in almost 100 % of undifferentiated (non-keratinised) and 30–100 % of differentiated (keratinised) nasopharyngeal carcinoma (NPC) as well as up to 10 % of gastric carcinomas (reviewed in [20]).

2 Historical Background

The discovery by Peyton Rous at the Rockefeller Institute for Medical Research (later, the Rockefeller University) in New York City in 1911 of a cell-free transmissible agent that caused sarcoma in chickens (later identified as a retrovirus – the Rous sarcoma virus) was a watershed in the understanding of tumour development since it was the first oncovirus to be described [21]. Also, it provided evidence for the role pathogens might play not only in animal but also human tumour development.

Anthony Epstein (knighted in 1991), a British doctor working in pathology at the Middlesex Hospital Medical School in London (UK) in the early 1960s, had carried out research on Rous sarcoma virus and acquired expertise in electron microscopy (EM) under the supervision of George Palade (awarded the Nobel Prize in Physiology and Medicine in 1974 for innovations in EM and cell fractionation) at the Rockefeller Institute. By chance, Epstein noticed a poster at the Middlesex Hospital in early 1961 that advertised an open lecture on Wednesday 22 March in the Hospital's Courtauld Lecture Theatre on the most common childhood cancer in tropical Africa given by Denis Burkitt who was then working in Uganda. At the lecture, the first one Burkitt gave in the UK on what is now known as BL, Epstein assessed that the tumour epidemiology presented (high incidence in a geographical belt with high temperature and rainfall) was consistent with a viral cause of disease that was carried by an arthropod vector. Following his first encounter with a child with BL in 1957, and realising how common the tumour was in African children, Burkitt had embarked on a detailed mapping project that showed the high BL incidence area to overlap with that of holoendemic malaria [1, 22, 23].

Burkitt's presentation at the Middlesex Hospital was the beginning of collaborative links with Epstein that included Burkitt sending BL biopsy material by a then recent direct jet route from Kampala to London. However, despite application of cell culture and EM expertise over the ensuing nearly 3 years, the Epstein laboratory could not detect virus in the

biopsy material or following its inoculation in vitro and in vivo. Equally, attempts to expand the biopsy material were unsuccessful. The situation changed on Friday 5 December 1963 when a biopsy arrived at the Middlesex Hospital after considerable delay due to the Kampala flight having been diverted to Manchester as a result of dense fog in London. The sample appeared cloudy, which was taken as indication of bacterial contamination, but Epstein decided to view the sample under light microscopy prior to the specimen being discarded. To his surprise, instead of bacteria, he observed free-floating, viable tumour cells that had detached themselves from the main biopsy and appeared to be growing as a cell suspension. Their appearance reminded him of the first successful in vitro cultures of murine lymphoid cells (using free-floating cell suspension rather than solid tumour fragment) that he had seen on a prior visit the same year to Yale University Medical School. As a result, Epstein decided that Friday in December of 1963 to attempt expanding BL biopsy material by suspension culture of the free-floating tumour cells of the newly arrived biopsy, the 26th one to arrive in his laboratory from Burkitt. And it worked – following in vitro culture in the London laboratory, this BL biopsy gave rise to the first BL-derived continuous cell line (still growing today) referred to then as 'Epstein-Barr 1' ('EB-1'; Yvonne Barr and Bert Achong had then joined the Epstein group as research assistants).

Once sufficient cellular material had been generated, Epstein undertook the first EM study of EB-1 on 24 February 1964, which revealed virus particles with the characteristic morphology of herpesviruses [2, 24, 25]. Subsequent collaboration from 1965 onward with Gertrude and Werner Henle in Philadelphia on EB-1 (and EB-2) demonstrated that the newly discovered herpesvirus was distinct from the then known human herpesviruses CMV, HSV and VZV [26] and became known in the Henle laboratory as the 'Epstein-Barr virus' (or 'EBV'). It was also in the Henle laboratory that the causative link between EBV and IM was established in 1967 when one of their research technicians manifest symptoms and signs of the disease (then of unknown aetiology) in August that year and her blood was shown by her colleagues in the Henle group to seroconvert to EBV seropositive status [5].

3 Biology

EBV is a large enveloped gamma-herpesvirus (around 120 nm in diameter) which contains a 172 kbp linear dsDNA genome within an icosahedral capsid consisting of 162 capsomeres [2, 27, 28]. Overall, the EBV genome has coding potential for about 70 proteins. The virus infects B cells in vitro and in vivo [29, 30]. In vitro, latent infection involves expression of latent viral genes without production of virus and is compatible with host cell growth, whereas expression of lytic genes in productive/lytic infection results in host cell death and release of infectious virus (virions).

The *Eco*RI and *Bam*HI genome restriction fragments have been cloned and restriction maps constructed [31–33]. The complete DNA sequence of the laboratory EBV B95-8 strain has been determined [34]. Open reading frames (ORF) are assigned a four-letter and number acronym based on the restriction fragment where transcription begins; for example, the BCRF1 ORF refers to the first [1] rightward ORF of the *Bam*HI C fragment [34].

3.1 In Vitro EBV Infection

EBV preferentially infects B lymphocytes in vitro through attachment of the major viral envelope glycoprotein gp350/220 to the B cell surface cluster designation (CD) 21 molecule (the EBV receptor), which is the complement receptor (CR) 2 that binds the C3d component of complement [35, 36]. Entry also involves binding to a cell surface co-receptor, the human leukocyte antigen (HLA) class 2 molecules, by a second virus envelope glycoprotein (gp), gp42, that complexes with virus-derived gp25 (gL) and gp85 (gH) mediating fusion of virus envelope with target cell membranes [37–41].

Whilst CD21 is the main receptor for EBV, deletion mutants lacking gp350 may still infect B cells suggesting alternative means of virus entry (e.g. through cell-to-cell contact) into B (and epithelial) cells [42, 43]. Although EBV has been shown to infect epithelial cells in vitro and in vivo [44–46], whether a CD21 homologue is normally present on epithelial cells (HLA class 2 molecules are absent), and the role of epithelial cells in EBV infection, is still unclear. Alternative (CD21-independent) modes of EBV entry into epithelial cells have been proposed since oropharyngeal epithelium in vivo may be one source of infectious virus in saliva. In an in vitro model of human polarised tongue and pharyngeal cells, EBV can enter epithelial cells by (1) direct cell-to-cell contact of apical cell membranes with EBV-infected lymphocytes, (2) interaction between the (lytic) virus envelope BMRF2 gp and β1 (or α5β1) integrins at basolateral membrane sites and (3) direct virus spread across lateral membranes [39, 46, 47]. In this model, virus egress occurred from apical and basolateral membranes. Recent evidence of EBV infection of polarised epithelial cells by transfer infection from memory B cells adds support to the model [48].

The EBV genome is divided into a unique short (US) and unique long (UL) sequence region by up to 12 tandemly reiterated 3 kbp internal direct repeats (IR1). Tandem repeat segments are contained in the unique regions with three of them (all in UL) referred to as IR2, 3 and 4. The linear genome is flanked at either end by reiterated 500 bp terminal direct repeats (TR). Following entry into target B cells, covalent linkage of the TR segments gives rise to a covalently closed circular (ccc) episome (or plasmid) in the nucleus of the latently infected cell, which is where the virus replicates [49, 50]. In each host cell, only 1 genome forms a ccc episome despite many becoming cell associated during B cell infection [51] indicating cellular or viral exclusion mechanisms [52], and redundant linear genomes are lost. Multiple identical copies persist in the latently infected cell as a result of amplification by cellular DNA polymerase [53]. The number of TR involved in formation of the ccc episome is characteristic of any circularisation event, and progeny cells retain the same episome thereby giving rise to a clonal virus population – a feature that has been used to assess clonality of the virus in tumours [54]. During latency, the episomes are replicated once every cell cycle in synchrony with host cell DNA and equal partitioning to progeny cells (for a review, see [55]).

In vitro, 1–10 % of the infected B cell pool is 'immortalised' by EBV giving rise to continually proliferating B lymphoblastoid cell lines (BLCL) [56, 57]. In contrast to B cells, EBV infection of epithelial cells in vitro is difficult and does not result in full latent gene expression or lytic infection. Therefore, BLCL serve as the main in vitro model of EBV infection, latency and oncogenesis. Similar to antigen-stimulated B lymphocytes, BLCL express the B cell activation markers CD23, CD30, CD39 and CD70 as well as the cell adhesion molecules (CAMs) lymphocyte function-associated antigen (LFA)-1 (or CD11a/18), LFA-3 (or CD58) and intercellular adhesion molecule (ICAM)-1 (or CD54) [55, 58]. In contrast, these markers are virtually absent on resting B lymphocytes.

BLCL express all EBV latent proteins which constitute only 10 of a possible 70 viral-encoded proteins [34]: six EBV nuclear antigens (EBNA-leader protein (LP), 1, 2, 3a, 3b and 3c) that constitute the EBNA complex, three latent membrane proteins (LMP1, 2a and 2b) and possibly one (or more) protein of the BARF0 open reading frame from the *Bam*HI A region of the virus genome (BART transcripts; for an overview of EBV latent transcripts, see Table 38.2 and [59]. Several EBV-encoded microRNAs (miRNA) have been described [60] that are clustered in two regions of the genome (BART and BHRF1) and are thought to function as host and viral gene regulators (as well as having anti-apoptotic effect), which, unlike proteins, do not elicit an immune response [61]. Additionally, two small non-polyadenylated (and, thus, non-coding) EBV-encoded RNAs (EBER1 and 2) are abundantly expressed during latency. Analysis of virus deletion mutants in the BLCL model has shown that of the latent virus proteins, only EBNA1, 2, 3a, 3c and LMP1 are essential for in vitro immortalisation, whereas EBNA-3b, LMP2a, 2b and EBERs are not (see Table 38.2). Whilst EBNA-LP deletion mutants have a reduced in vitro immortalising capacity in B cells compared with wild-type EBV, the role of BART transcripts in immortalisation remains unclear. The expression of the latent genes is tightly regulated by methylation of the gene promoters [62] in order to allow EBV to persist within the host without eradication by the host immune response. EBV DNA becomes CpG methylated slowly with time in latently infected B cells [63], and extensive DNA methylation is associated with transcription repression [64]. Such dinucleotide methylation is considered to explain BZLF1-mediated activation of latent cells to lytic cycle (see below; [65]).

Latent viral infection has been defined as latency 1, 2 or 3 based on EBV promoter usage and latent gene expression (see [59]). Latency 3 (EBNA expression driven by Wp/Cp in fragments *Bam*HI W and C, respectively; observed in BLCL and most PTLD) is characterised by transcription of all the EBNAs together with the three LMP proteins. In contrast, latency 1 (EBNA expression driven by Q promoter in fragment *Bam*HI Q; seen in EBV-associated BL and early passage BL cell lines) involves the transcription of EBNA1 only. Latency 2 (EBNA expression driven by Qp; detected in EBV-associated HL and NPC) entails EBNA1 expression together with a variable expression of the LMP proteins. EBERs and BARTs are expressed in all forms of latency [55]. However, since viral gene expression found in clinical samples does not always conform to the above latency types, this text uses an alternative scheme that refers to persistent

Table 38.2 EBV latent transcripts and their functions

ORF	Protein	Mol.wt (kDa)	Cellular site	Function	Required for immortalisation?
BKRF1	EBNA1	65–97	Nucleus	Episome maintenance; transcriptional transactivator	Yes
BWRF1	EBNA-LP	20–130	Nucleus	Promotes in vitro immortalisation; co-operates with EBNA2 in facilitating entry into cell cycle	Uncertain
BYRF1	EBNA2	75–105	Nucleus	Viral oncogene; transactivates cellular (e.g. CD21, CD23) and viral (e.g. LMP1 and 2) gene expression	Yes
BLRF3/BERF1	EBNA3a	130–195	Nucleus	Remains uncertain	Yes
BERF2a/b	EBNA3b	145–160	Nucleus	Regulation of cellular gene expression (e.g. CD40)	No
BERF3/4	EBNA3c	130–195	Nucleus	DNA binding protein; regulates viral (e.g. LMP1) and cellular (e.g. CD23) expression	Yes
BNLF1	LMP1	58–63	Membrane	Viral oncogene; acts as a constitutively expressed TNF receptor; upregulates cellular genes (e.g. *bcl*-2 and IL6) and activates cellular pathways (e.g. NF-κB); mimics CD40 function	Yes
BARF1/BNRF1	LMP2a	54	Membrane	Acts as a constitutively activated BCR homologue; prevents entry into lytic cycle	No
BNRF1	LMP2b	40	Membrane	Remains unclear	No
BCRF1	EBER1,2	–	Nucleus/cytoplasm	Confer resistance to apoptosis; induce IL10 production	No
BARF0	BARTs	–	Cytoplasm	Remains unclear	Not known

BCR B cell receptor, *IL* interleukin, *kDa* kilo ($\times 10^3$) Dalton, *Mol.wt* molecular weight, *NF* nuclear factor, *ORF* open reading frame, *TNF* tumour necrosis factor

infection as either 'unrestricted' or 'restricted'. The former expression pattern refers to a latency 3-type infection, whereas the latter refers to any other more restricted profile.

Lytic EBV infection involves productive viral DNA replication, expression of most virus genes, release of infectious virus and host cell death. The majority of EBV-encoded proteins are expressed during lytic infection although only a small number of BLCL cells enter lytic cycle at any given time. Since herpesviruses do not encode an RNA polymerase, EBV utilises host cell RNA polymerase II for transcription of its viral messenger RNA (mRNA). The immediate early (IE) viral proteins BRLF1 and BZLF1 initiate the lytic cycle, which is characterised by the sequential expression of early antigen (EA) complex, viral capsid antigen (VCA) complex and membrane antigen (MA) complex proteins. Each complex consists of several proteins (reviewed in [55]). The early (IE and EA) lytic proteins are operationally differentiated from the late (VCA and MA) lytic antigens by the persistent expression of the former, but not the latter, in the presence of viral DNA synthesis inhibitors. During lytic infection, EBV also expresses a human interleukin (IL) 10 homologue (viral IL10, or vIL10). Furthermore, EBNA1, LMP1, 2a, 2b and EBERs continue to be transcribed.

3.2 In Vivo EBV Infection

Following primary infection, EBV persists in vivo in a latent form at a fairly constant level in approximately 1–10 per 10^6 circulating B cells [66–68]. Around 90 % of seropositive virus carriers (cumulative results when assayed on several occasions) give rise to BLCL in vitro when (1) their peripheral blood leukocytes (PBLs) are cultured in the presence of the immunosuppressant cyclosporine-A (Cy-A), or (2) their throat washings are cocultured with susceptible EBV-negative cord blood mononuclear cells [69]. Circulating EBV-infected B cells are antigen-selected small, CD19+ve, CD23-ve, CD27+ve, CD80-ve, surface immunoglobulin (sIg) M+ve, sIgD-ve and resting memory B cells [56, 57, 66, 67, 70, 71].

Opinion is divided as to whether infection of epithelial cells occurs prior to infection of B cells, or whether infection of B cells occurs directly via the large surface area of the tonsillar crypts where a specialised discontinuous epithelium exists [72–74]. Early work found EBV-infected epithelial cells in IM [75, 76], a finding refuted by later studies [77–79], which may reflect differences in methodology. It is possible that a transient infection of epithelial cells occurs as a prelude to infection of B cells; this would occur prior to the onset of IM symptoms and could therefore be missed in studies involving tonsils excised in acute IM. In situ hybridisation (ISH) studies of tonsils removed during IM suggest that interindividual transmission of EBV occurred via the transfer of EBV-infected lymphocytes [77]. Recent evidence suggests, however, that EBV infection of epithelial cells may have a pivotal role in such transmission [80].

Based on coding sequence differences of EBNA2, 3a, 3b, 3c and EBERs, EBV is of two types referred to as 'type 1' and 'type 2' (or 'type A' and 'type B') [81]. The EBNA2 proteins derived from both types share only 56 % of

amino acids and have differing functional capabilities with type 2 being less capable of transforming B lymphocytes in vitro [82, 83]. Although both virus types have a worldwide distribution, Caucasian and Oriental populations are predominantly infected with type 1 virus, whereas type 2 virus is frequently found in African populations [84, 85]. Immunocompromised hosts may (more often than immunocompetent individuals) harbour both types simultaneously [86, 87], and infection with type 2 has been associated with high-risk sexual behaviour in HIV-infected and uninfected men [88]. In contrast, HIV-infected haemophiliac males have a prevalence of type 2 infection that is closer to that of the general population [89]. Amongst HIV-seropositive populations, type 2 EBV is over-represented in EBV-associated malignancies that arise in the context of HIV-induced immunosuppression [90].

EBV gene expression (transcriptional) patterns displayed by PBLs from healthy virus carriers have been analysed by reverse transcriptase polymerase chain reaction (RT-PCR) amplification of whole cell, or enriched B cell, population RNA extracts. Using such an approach, LMP2a transcription has been reported in vivo as has EBNA1, LMP2a and EBERs expression without detectable lytic BZLF1 transcripts [91, 92]. Similarly, EBNA1 and LMP2a expression have been described as well as EBNA1 and LMP1 only [93, 94]. In contrast, a further study detected lytic BZLF1 and BALF2 transcripts in 72 and 16 %, respectively, of enriched peripheral blood B cell extracts from virus carriers [95].

Taken together, the only consistently expressed latent virus gene in peripheral blood of healthy virus carriers is LMP2a ('latency programme'). Furthermore, cells showing full viral latent gene expression ('growth programme') have never been observed in peripheral blood in healthy virus carriers although such an expression profile has been detected during IM [92]. Thus, the LMP2a-only 'latency programme' has been proposed as the mechanism of in vivo latency with LMP2a providing the EBV-infected memory B cell with survival signals similar to those that maintain the long-term memory B cell pool [66]. In line with this is an observation that LMP2a inhibits the switch from latency to lytic infection in EBV-infected B cells in vitro [96]. According to current thinking, LMP2a and LMP1 provide infected B cells with B cell receptor (BCR: sIg) and CD40 co-stimulatory signals, respectively, and thereby mimic both survival signals required to maintain the infected B cell pool [97–104].

3.3 A Model of EBV Persistence

The EBV expression profile of tonsils from healthy EBV carriers has been examined in detail. The research group demonstrated latently infected naïve B cells in tonsils, and their presence was associated with viral replication [66]. Furthermore, in contrast to the studies above on peripheral blood, the same research group showed full latent viral gene expression (including EBNA2; 'growth programme') in purified naïve (sIgD+ve) tonsillar B cells [105]. These cells were activated CD80+ve (B7.1+ve) lymphocytes. Based on their findings, the research group suggested that infectious virus is restricted to regions of the tonsil that harbour only naïve B cells (e.g. the mantle zone). Latently infected memory B cells from the periphery could extravasate in the tonsillar marginal zones and reactivate EBV in response to signals in the mantle zone. The EBV-infected naïve B cells would either be killed by virus-specific T lymphocytes or differentiate within the tonsil to become resting memory B cells that would then leave the tonsil to circulate in peripheral blood whilst virus gene expression became restricted [102].

A model of EBV persistence in vivo has been proposed based on the observation that EBV persists in resting memory B lymphocytes that do not express any viral proteins [66, 106–111] and that this situation arises despite the virus's clear ability to drive proliferation of its host cells. Further support for the pivotal role of B cells in both primary and persistent infection comes from a study demonstrating that patients lacking Bruton's tyrosine kinase and, therefore, suffering from X-linked agammaglobulinaemia and the absence of functional B cells cannot be infected by EBV [112]. In the model of virus persistence, it is proposed that EBV promotes formation of long-lived virus-infected memory B cells using normal pathways of B cell response to antigen [113]. The oral lymphoepithelium of the tonsil (tonsillar crypts; part of Waldeyer's ring) is exposed to environmental antigens that are sampled by naïve B lymphocytes [73, 114]. When encountering specific antigen, naïve B lymphocytes are activated via their BCR and migrate as blast cells into tonsillar follicles to produce germinal centres where B cell maturation occurs [115]. Differentiation (involving antigen-specific T helper (Th) cells) entails rounds of proliferation associated with isotype switching and mutation of Ig genes followed by competitive selection for B cells that bind the antigen most avidly and their release as long-lived antigen-specific memory B cells. Non-selected B cells die by apoptosis. Paralleling this scenario, EBV expresses all of its growth-promoting latent antigens ('growth programme') following primary virus infection of naïve B cells in tonsillar epithelium [105]. Thus, the virus promotes B cell activation, blast formation, proliferation and formation of tonsillar follicles without specific antigen-mediated BCR triggering. In the tonsillar follicle, the transcription programme changes to the more restricted 'default programme' (EBNA1, LMP1 and 2 only; [107]). At this stage, LMP2 drives Ig isotype switching [116, 117], whilst LMP1 promotes Ig gene mutation and downregulates *bcl*-6 expression thereby retaining memory B cells in the germinal centre [116, 118, 119]. Therefore, the importance of the 'default programme' may be to offer

virus-infected B cells a selective advantage in the germinal centre [113]. For an overview of this model of EBV persistence, see [111].

Once they leave the germinal centre, latently infected B cells switch off virus protein expression ('latency programme') and are maintained as normal memory B cells [108]. EBV-infected memory B cells are thought to express virus proteins only rarely in the peripheral circulation [108]. Whilst the numbers of such virus-infected cells can form over half of the memory B cell pool during the acute stages of IM [70], a steady state of approximately 1–10 EBV-infected cells per 10^6 circulating memory B cells is detected within a year of IM reflecting a dynamic balance between cell proliferation and cell loss through lytic infection [108, 120]. However, the role of either EBV reinfection of B cells or direct virus infection of memory B cells, in maintenance of the virus-infected B cell pool is unclear [121]. Equally, short-term EBV persistence in the absence of a germinal centre reaction and a typical B cell memory pool has been demonstrated in X-linked hyper-IgM syndrome patients who (due to a mutation in the CD40 ligand gene) do not harbour such cells [122].

Virus reactivation in mucosal sites leads to virus transmission. As a result of antigen-mediated BCR triggering and homing of antibody-producing memory B cells to mucosal sites, an infected memory B cell activates EBV to lytic infection [114, 123, 124]. Studies in vitro and in vivo have demonstrated such a link between B cell differentiation and lytic infection [124, 125]. In the tonsil, this results in egress of infectious virus into saliva. The importance in transmission of reactivation of virus in genital sites is still unclear although virus is detected in samples from the male and female genitourinary tract suggesting the possibility of sexual transmission [126–128].

The above model of persistent infection centres on memory B cells as the site of EBV persistence, but oropharyngeal epithelium may support virus replication and amplify virus in the oropharynx and, by extension, play a central role in transmission [80, 112, 129, 130]. However, epithelial cells are not considered to support persistent EBV infection.

4 Laboratory Diagnosis

From an early stage, IM was known to be associated with an absolute lymphocytosis and atypical lymphocytes [131, 132] (Fig. 38.1). Recognised in 1932 by Paul and Bunnell, production of heterophile antibodies that cross-react with animal antigens, particularly agglutinins to sheep erythrocytes, was used for laboratory confirmation of IM [133]. In 1937, Davidsohn refined the Paul-Bunnell test with the use of guinea pig kidney antigen, which improved specificity, by removing Forssman antibodies (animal erythrocyte agglutinins in human serum not related to acute EBV infection) [134]. The approach forms the basis of the rapid heterophile ('monospot') test with subsequent amendments [133–135] (see also Public Health England (PHE) and US Centres for Disease Control and Prevention (CDC) websites). The heterophile test has a sensitivity of around 85 % and specificity of around 94 % for IM in a patient with symptoms of mononucleosis [136].

An absolute lymphocytosis is typical but not always present in IM, and many EBV-induced IM cases will have a normal total lymphocyte count; lymphopenia is rarely present, but atypical lymphocytes are usually present although the proportion of such cells will comprise ≥10 % of the total lymphocyte count in only around a fifth of IM cases [137]. However, the finding of ≥10 % atypical lymphocytes in peripheral blood of patients with mononucleosis has 75 % sensitivity and 92 % specificity for IM [138]. Mild thrombocytopenia is common but neutropenia less so [139, 140]. Elevations of one or more liver function tests, including bilirubin, alkaline phosphatase and aminotransferases, occur in around 80 % of IM cases, whilst clinical jaundice is apparent in up to 5 % of patients [141, 142]. Hyperbilirubinaemia may result from impaired hepatic clearance and/or increased destruction of red blood cells as a result of haemolysis. Jaundice is more common in older patients and is a frequent accompaniment of patients that succumb to rare fulminant infection [143, 144].

EBV-driven IM is confirmed in 20–25 % of patients where it is clinically suspected, and laboratory investigations are instigated with the remainder having 'IM-like' illnesses that are a heterogeneous group and may include drug reactions and/or infections by other herpesviruses (CMV, HHV-6, HSV), other viral agents (adenovirus, HIV, hepatitis viruses, influenza, parvovirus B19, rubella), bacteria (streptococci), parasites (toxoplasmosis) or other causes [145–147]. There is overlap in the clinical presentation and haematological features of acute EBV infection and these conditions, although the likelihood of any individual feature being present varies according to the diagnosis.

Common clinical features of patients with IM, CMV mononucleosis and acute toxoplasmosis comprise fever, sore throat, enlarged lymph nodes and splenomegaly [142]. However, CMV mononucleosis is primarily characterised by prolonged fever, lymphocytosis, atypical lymphocytes and abnormal liver function tests. Sore throat and cervical lymphadenopathy are not characteristic of CMV, but they do occur in a third and one-fifth of cases, respectively [142, 148, 149]. Similarly, acute toxoplasmosis is primarily characterised by the presence of lymphadenopathy and the absence of hepatomegaly, with sore throat, fever and splenomegaly occurring only occasionally.

Reminiscent of EBV-induced IM, other acute infections (e.g. CMV, HIV, HBV and toxoplasmosis) may present with atypical lymphocytes in the blood and severe perturbations

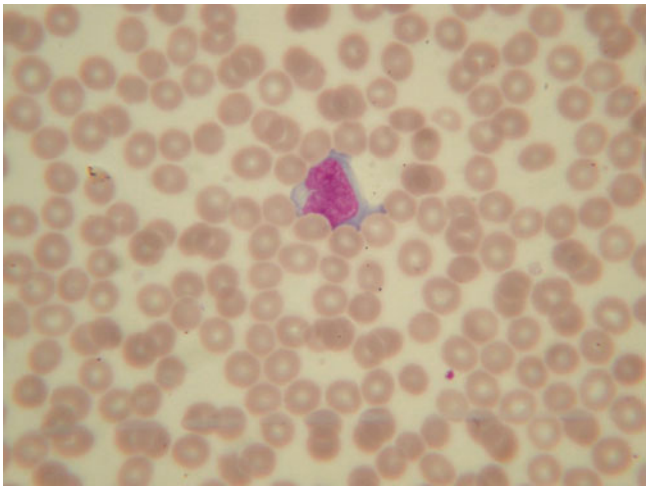

Fig. 38.1 Peripheral blood film in IM showing atypical lymphocyte (Photograph provided by Dr R Jones, St John's Hospital, Livingston, UK)

of lymphocyte subsets with inversion of the normal CD4:CD8 ratio [150–153].

4.1 Serology

Our knowledge of the host's immune response to primary EBV infection is modelled on IM (see Odumade et al. [154]). IgA, IgM and IgG antibodies to VCA are usually detected by the onset of IM together with IgG antibodies to EA and MA [155]. A range of (mostly IgM) heterophile and autoantibodies also appear transiently. During convalescence, IgG antibodies to EBNA1 arise, whilst IgA and IgM antibodies to VCA as well as IgG antibodies to EA (and heterophile antibodies) decline to undetectable levels [156]. There is a dichotomous antibody response to the nuclear antigens, with those against EBNA2 and 3 being formed early and those against EBNA1 being delayed. IM is rare in the first year of life – presumably as a result of protective maternal antibodies being transferred to the neonate in utero – and children uncommonly show typical symptoms of IM ([157]; for a review of IM, see [136]).

Current EBV serological tests assess host antibody responses to VCA, EA and/or EBNA by immunofluorescent (IFA) or enzyme immunosorbent assays (EIA). In the UK, test algorithms have been standardised by PHE (formerly, the Health Protection Agency, HPA) for use in diagnostic clinical laboratories as UK Standards for Microbiology Investigations (UK SMI; see the PHE website). For serological diagnosis of primary EBV infection, the SMI algorithm (endorsed by the UK Clinical Virology Network, or UKCVN: association of all UK clinical virology laboratories) is contained in UK SMI V26: 'Epstein-Barr Virus Serology' (issue 4, 2012). SMI V26 requires an initial test panel of either (1) VCA IgM and IgG followed by EBNA IgG if either test is reactive or (2) EBNA IgG on its own followed by the other two tests if a negative EBNA result is obtained. Furthermore, EBV IgG avidity testing may aid discerning between primary infection and past acquisition of virus [158, 159]. The approach highlights the role of EBNA IgG in determining past infection but recognises that such antibodies may also arise soon after acquisition of EBV.

For each assay platform, EBV serostatus can be assigned based on the results of VCA IgM, VCA (or VCA/EA) IgG and EBNA IgG as follows: 'no serological evidence of infection', 'early acute infection' (VCA IgM+ve), 'recent acute infection' (VCA IgM+ve, VCA IgG+ve) or 'past infection' (EBNA IgG+ve).

Historically, IFA has been considered the 'gold standard' for EBV serological assessments. However, IFA contains an element of observer subjectivity as well as falling prey at times to non-specific IF reactivity. As a result, IFA is rapidly being replaced in UK clinical virology laboratories with a more automated EIA approaches that do not require as much assay-specific expertise for interpretation as well as lending themselves to the high throughput and short turnaround times necessary in the hospital setting. Recent assessment of 3 EBV-specific IgM EIAs on such automated platforms found assay sensitivity to be 84–89 % [160], although sole reliance on EBV IgM may result in up to 8 % of IM patients being missed at first presentation [161].

The serological profile of primary EBV infection in organ graft recipients often differs from that seen in healthy immunocompetent individuals. Specifically, IgM antibody responses to VCA and/or heterophile antibodies are not always detected [162]. Furthermore, immunocompromised EBV carriers often have a 'reactivated' serological profile characterised by raised levels of IgG antibodies to VCA and EA but not to EBNA [163]. Also, in seropositive patients, suppressed EBV-specific cytotoxic T lymphocytes (CTL) activity is associated with increased oropharyngeal virus shedding and raised numbers of circulating EBV+ve B cells [164, 165].

4.2 Other Techniques

Propagation of EBV in vitro, from saliva or throat washings, as BLCL, is generally not offered in clinical laboratories. Tissue sections (e.g. biopsy material) can be probed for EBERs using ISH techniques or immunostained for various EBV proteins. These techniques and, in particular, nucleic acid amplification tests (NAATs; e.g. PCR) for EBV DNA have a role in determining active EBV infection in the immunocompetent host but are especially important in the diagnosis of EBV-associated disease in the immunocompromised host.

PCR analysis of EBV DNA viral load (VL) in the blood allows detection of EBV DNAemia which may be of use in

assessing active EBV infection during IM as well as in other EBV-associated diseases such as in pre-emptive management algorithms with a view to prevent progression to PTLD [166–169]. DNAemia is generally short lived following presentation of clinical symptoms of IM although EBV DNA assessments may aid early diagnosis of IM ([170]; for a review of the clinical utility of EBV PCR in the clinical setting, see [171]). In the UK, SMI guidance highlights the use of EBV PCR in the context of VCA IgM+ve, VCA IgG-ve and EBNA IgG-ve results in the setting of IM-like disease in order to exclude a false IgM result and address inconclusive serological results.

EBV PCR analysis is also recommended when assessing primary acquisition of virus, or reactivation of past infection, in immunocompetent and immunocompromised hosts. In the latter, serology may be unreliable (see above). Further guidance is available from the British Transplantation Society (BTS) [172] for EBV PCR testing post organ transplantation which does not recommend routine EBV DNAemia surveillance of adult transplant recipients by PCR with the exception of stem cell graft recipients. Conversely, routine surveillance is recommended to aid in pre-emptive identification of primary EBV infection in seronegative paediatric transplant recipients since that setting constitutes high risk of PTLD. Currently, routine EBV VL measurements aimed at monitoring response of PTLD to therapy are not recommended. There is as yet no clear consensus between UK clinical virology laboratories as to the clinical utility of EBV PCR in the diagnosis and management of EBV-associated disease (including IM). Thus, the use of EBV PCR varies somewhat between individual UK laboratories although rapid advances in NAAT technology will influence future use of the assays. Until recently, the lack of an international EBV standard for VL determinations compounded interpretation of PCR assay results and hindered comparison between clinical laboratories. The first such WHO international standard has now become available from the UK National Institute for Biological Standards and Control (NIBSC; see their website) which should aid such assessments. Equally, interpretation depends on type of samples analysed although plasma is generally accepted as being a suitable specimen for EBV PCR – but some centres prefer whole blood. Furthermore, it is clear that a single VL assessment cannot be used to predict the likelihood of PTLD since lesions may arise in patients with unremarkable VL [173, 174], and serial sampling is indicated. A rapid increase in VL in serial samples obtained following transplantation may indicate increased risk of PTLD development [167], and prompt reduction in immunosuppression may be indicated in such circumstances [175]. However, the role of EBV VL measurements in assessing treatment response to PTLD therapy, and in predicting risk of PTLD relapse, is still somewhat unclear since studies have not shown clear and consistent correlation between EBV VL and clinical course in solid organ transplantation [176, 177].

4.3 Challenges in Laboratory Diagnosis of IM

The typical findings of VCA IgM+ve, VCA IgG+ve and EBNA IgG-ve results together with a positive heterophile antibody ('monospot') test are not found in every case of EBV-induced IM. VCA IgM and IgG antibodies are usually present at the onset of symptoms/signs, but one or both may be delayed in arising [145, 146, 178]. Rarely, VCA IgM antibodies are not detected at outset of IM which may reflect low titre and screening dilution used [179]. Equally, high-titre IgM may give rise to a prozone effect although modern automated EIA platforms have in-built dilution steps to prevent such false-negative readings. Antibodies to EBNA are usually absent in the acute phase of IM (developing in convalescence), but may occasionally be detected during the first week of illness [146, 180]. Amongst patients with VCA IgM+ve IM, 85–96 % will have a positive heterophile antibody test using horse erythrocytes [145, 146, 179] although up to 25 % of IM patients may show negative heterophile test results during the first week of infection (up to 10 % during the second week; [136]). Similar to antibodies against VCA, heterophile antibodies may arise late in the course of IM [145, 146], and up to 75 % of children under the age of 12 years (particularly, under the age of 4 years) do not have detectable heterophile antibodies [181].

Laboratory investigations, rather than giving clarity, may add to diagnostic difficulty. In particular, false-positive heterophile antibody tests have been noted in health as well as in the context of other infections (notably HIV), connective tissue diseases and lymphoma [18], although, in general, primary viral infections other than EBV only rarely give reactive readings in the test [182]. False-positive VCA IgM+ve antibody readings have also been noted in the presence of rheumatoid factor [183] which is compounded further by the observation that rheumatoid factor (IgM or IgG) may be produced in the acute phase of IM [184]. Also, patients with EBV-induced IM may show reactivity in CMV IgM tests [185] which may be a result of cross-reactivity in EIA assays or a consequence of EBV being a polyclonal activator of B lymphocytes. In the immunocompromised setting, delayed, or atypical, serological profiles of primary infection, and virus reactivation, may occur [163, 186].

5 Pathogenesis and Immunity

Infection with EBV is a significant public health concern. Understanding of the host immune response, and strategies evolved by the virus to evade immune control, is important in devising vaccines, therapies and public health measures to reduce disease burden.

5.1 Persistent Infection

Stable levels of circulating IgG antibodies to VCA, MA and EBNA1 are detected in healthy virus carriers, and low levels of IgG antibodies to EA may also be present [155]. IgG antibodies against gp350/220 of the MA complex are retained and neutralising. Additionally, 21–30 % of virus carriers have IgA antibodies against gp350/220 in serum, and these antibodies are found in saliva of 12–19 % of virus carriers [187, 188].

Immune control of EBV infection is mediated primarily by CD8+ve HLA class 1-restricted EBV-specific CTLs against all the latent viral proteins (CTL precursor frequency ranges from 1:400 to 1:42,000 of the total T cell population) although the role of T cell responses to EBNA1 is still unclear ([189]; for an overview of immunodominant CTL epitopes and their HLA restriction, see [190]. In particular, CTL responses to EBNA3a, b and c antigens are immunodominant followed by LMP2 antigens [189, 191, 192], and cytolysis of the CD8+ve T cells is mediated by granule exocytosis mechanisms (perforin, granzyme). CD8+ve CTL specific for EBNA2, LP and LMP1 epitopes are less commonly detected. Analysis of phenotypic markers including IL7 receptor alpha and programmed death 1 (PD1) can aid delineate EBV epitope responses at different stages of infection [193, 194]. EBNA1 contains glycine-alaninine (gly-ala) repeats that interfere with proteosomal proteolysis necessary for HLA 1-restricted epitope presentation to CTLs [195, 196] and inhibit translation of EBNA1 [197]. Recent studies indicate that the protein may reduce its own translation by suboptimal codon usage within the gly-ala sequence [198] although transcriptional control may also be involved [199, 200]. Evidence suggests that EBNA1-specific CD8+ve CTLs can be generated in vitro [201–203]. Such EBNA1-specific CTLs could play a future role in adoptive immunotherapy against EBV-associated malignancies – all of which express EBNA1. Collectively, up to 5 % of circulating CD8+ve CTLs are committed to EBV immune control [204, 205].

In addition to immunosurveillance mediated by CD8+ve T cells, CD4+ve T cells also have a role to play, and EBNA1-reactive CD4+ve T cells have been detected in healthy seropositive individuals. In particular, such T cells have been shown to lyse EBNA1+ve cells [206, 207], and EBNA1 (and EBNA3c) is now considered highly immunogenic for CD4+ve T cells [208, 209]. In contrast to CD8+ve CTL, such CD4+ve T cells mediate their effector mechanisms primarily via interferon (IFN)-gamma secretion and Fas/Fas ligand (FasL) interactions rather than granule exocytosis [210]. The role of IFN-gamma in mediating CTL defences against EBV is further highlighted by studies of X-linked lymphoproliferative syndrome (XLP, or XLPS; see below), which results from a defect in the signalling adaptor SLAM-associated protein (SAP) gene that signals through signalling lymphocytic activation molecule (SLAM; CD150) and other Ig superfamily receptors including 2B4 (CD244). Using autologous BLCL as stimulators, EBV-specific T cell lines generated in vitro from XLP patients show markedly reduced IFN-gamma production and cytotoxic capacity compared to healthy controls [211].

During persistent infection, CTLs also control lytic infection and recognise specific IE (BZLF1, BRLF1) and EA (BMLF1, BMRF1, BALF2) antigens [212, 213].

Immunosuppression reduces EBV-specific CTL activity, and this can lead to EBV-driven proliferation of B cells that may, in the organ transplant setting, culminate in PTLD. Such lesions may be treated successfully by adoptive T cell immunotherapy [214, 215] which further underlines the role CTL surveillance plays in immune control of EBV.

5.2 Infectious Mononucleosis (IM)

IM is manifest by an absolute lymphocytosis including 'atypical' lymphocytes [131], and over 70 % of the lymphocytes have been shown to be antigen-driven mono- or oligoclonal HLA DR+ve, CD45RO+ve, CD8+ve, and CD38+ve CTLs when analysed using PCR amplification of, and monoclonal antibodies (mAb) to, the T cell receptor (TCR) Vβ-chain [216–219]; for serological responses, see Sect. 4. These cells express the CD45RO memory marker together with low expression of the anti-apoptotic gene *bcl*-2 that correlates with their apoptosis in vitro [220]. Evidence suggests that efficient resolution of IM symptoms is associated with a broad CTL response to a wide range of EBV-derived target latent and lytic epitopes [221]. To date, over 50 HLA class 1 and 2 epitopes have been characterised for EBV. Whilst EBV DNA VL in peripheral blood decreases rapidly during convalescence, salivary VL remains high (up to 6 months post-diagnosis), and IM patients remain highly infectious during this time [178, 222]. A role for superantigen (sAg)-driven expansion has not been demonstrated despite earlier reports [223, 224]. The transiently expanded T cell clones recognise primarily early (IE and EA) lytic (rather than latent) EBV antigens (e.g. BZLF1 and BRLF1) with up to 40 % of circulating CD8+ve CTLs being directed against a single virus epitope as evidenced by tetramer analysis, although the exact epitopes eliciting the CD8+ve CTL response varies with the HLA profile of the individual [213, 225, 226]. In contrast, only a minor component of the CTL response in IM is directed against the latent virus antigens. As the primary infection progresses, the vastly expanded CD8+ve T cells against lytic antigens reduce in number and may even become undetectable [204, 227–229].

Whilst CD4+ve T lymphocytes form a minor part of the observed lymphocytosis of IM, the cells display an activated phenotype and respond to lytic and latent (e.g. EBNA3a) viral epitopes [230–233]. In particular, CD4+ve T cell

responses have been described against the early lytic (BZLF1 and BMLF1) and latent EBNA1 and EBNA3a antigens in IM patients [231, 234]. However, such CD4+ve T cell-mediated responses decline rapidly during the disease and are at a low (or undetectable) level at 1 year after diagnosis of IM.

The massive CTL response observed in IM is thought to cause its characteristic symptoms and signs through excessive cytokine release such as raised Th1-type cytokine levels (e.g. IL2 and IFN-gamma [235, 236]). NK (CD56) cells form a component of the atypical lymphocytes observed in IM [219] and contribute to control of EBV [237, 238]. Further studies have demonstrated a correlation between the severity of IM symptoms and the level of activated T lymphocytes [233]. SLAM (CD150), SAP and 2B4 (CD244) were significantly upregulated on CD4+ve and CD8+ve T cells at time of IM diagnosis. At that time, NK cell levels were also significantly elevated suggesting a role for NK cells in immune control of primary EBV infection, and higher NK cell numbers at IM diagnosis were observed to correlate with significantly lower circulating EBV VL [239]. Also, human tonsillar NK cells can be induced to produce IFN-gamma in vitro that delays in vitro immortalisation of B cells [240] which further underlines possible role of NK cells in innate immune defences against EBV.

There is evidence to suggest deficiencies in CTL immune surveillance in patients suffering EBV-associated cancer [241, 242], but stronger links with EBV immune defences arise through work linking microsatellite markers close to the HLA-A locus to enhanced risk of EBV-associated HL [243], and these same markers have also been linked with increased risk of IM [244]. Similarly, markers linked with the HLA-A locus are strongly associated with risk of NPC [245, 246].

The role high-dose salivary and/or genital tract EBV exposure plays in IM is still unclear [247, 248]. Equally, it seems plausible that the release on a large scale of EBV-derived antigens from infected B cells under attack from CTL-mediated immunity may contribute to the signs and symptoms of IM [130].

5.3 Immune Evasion

Following acquisition, herpesviruses persist in the host for life and have evolved strategies to evade immune eradication, whilst sporadic reactivation from latency facilitates maintenance of the infected host cell pool and onward transmission. By providing all the necessary survival signals, EBV has evolved a strategy of persistence that entails mimicking antigen-mediated activation and maturation of its target B cell (see Sect. 3). To this end, it also shuts down expression of immunogenic viral proteins – apart from sporadic reactivation from latency that results in lytic infection with its ensuing replenishment of the virus-infected B cell pool and potential for onward transmission.

Similar to other herpesviruses, the EBV genome contains homologues of human genes which are thought to modulate the host's immune response. One such gene is BCRF1 whose product shows 84 % amino acid (and 71 % nucleotide) sequence homology to the human IL10 gene [249], the vIL10 homologue [250]. Like its human counterpart, vIL10 represses IL2 and IFN-gamma secretion (Th1 response) [249, 251] and promotes B cell growth and differentiation [252]; vIL10 is a lytic cycle protein that is non-essential for in vitro growth of latently infected B cells [253]. However, cells infected with deletion mutants were not able to inhibit IFN-gamma secretion by cocultured autologous mononuclear cells. IFN-gamma and NK cells provide non-specific immune defences against EBV infection [253–255], which vIL10 is postulated to inhibit. Furthermore, IL6 and IL10 are autocrine growth factors in vitro for BLCL [256, 257], and both growth factors are secreted by CD4+ve Th cells. IL10 has also been shown to be induced by LMP1 [258] produced by EBV+ve BL cell lines [259] and found at high levels in serum from humanised scid mice bearing PTLD-like tumours [260]. In such animals, a model of PTLD formation has been proposed that centres on CD4+ve T cell help for outgrowth of EBV-driven B cell lymphoproliferations followed by B cell-derived autocrine tumour growth involving B cell growth factors such as IL6 and IL10 [261–263]. Taken together, it is likely that EBV has a direct role in the induction and maintenance of autocrine growth factor production. Conversely, it has been suggested that IL10 gene promoter polymorphism correlates with susceptibility to primary EBV infection and that low IL10 production resulting from such mechanisms renders individuals more susceptible to primary EBV infection [264, 265].

EBV subverts the effects of class I and II IFNs by synthesising viral receptors which compete with the intended IFN receptor, generating interfering RNAs which inhibit IFN-directed protein synthesis and downregulating IFN-induced transcription [266–269]. The survival of EBV-infected cells is promoted by several anti-apoptotic mechanisms including the production of two homologues of the human gene *bcl*-2, BHRF1 and BALF1, and the upregulation of *bcl*-2 itself by the viral gene LMP1 [270–272]. The two genes appear to be required to prevent apoptosis at the outset of virus infection of B cells that will become latently infected but not necessarily during latency itself [273, 274]. Lytically infected cells secrete soluble gp42, a glycoprotein that binds HLA class 2 molecules, which may help EBV-infected cells to evade recognition by CD4+ve T cells [275]. Further studies have shown that the combined effect of the lytic viral proteins BNLF2A, BILF1 and BGLF5 is to lower the surface level of HLA class 1 molecules on infected cells. Whilst this may trigger NK cell recognition, the EBV micro-RNA BART2 reduces expression of the NK cell-activating ligand MICB that facilitates NK evasion [276]. Additionally, the IE protein BZLF1 has been shown to reduce expression of HLA class 2 molecules [277].

The immune evasive aspects of EBNA1 have been discussed already (see above). Clearly, the success of adoptive T cell immunotherapy for EBV-associated tumours arising following transplantation in the context of immunosuppression highlights the key role T cells have in mediating immune control of EBV.

6 Transmission

Studies of the epidemiology of IM have not shown any increased risk of IM amongst susceptible room-mates of cases [278, 279], whilst a retrospective study found a history of intimate oral contact with exchange of saliva in many IM patients [280, 281]. Transmission of EBV even in the context of a close personal relationship may be slow – a study of 45 EBV seronegative women, who were seen every 6 months in a British family planning clinic, reported a median time to seroconversion of 25 months (range 1–60 months) [282].

6.1 Oral Secretions

Saliva is thought to be the main route of EBV infection in children and adults. Cell-free virus, present in throat washings of seropositive individuals, may be detected by the immortalisation of cultured B lymphocytes obtained from an EBV seronegative donor. This technique, utilised in early studies, demonstrates the presence of infectious virus in the throat gargles of 14–25 % of healthy asymptomatic adults [283–285]. Longitudinal study of EBV-infected individuals showed that the excretion of cell-free virus in throat gargles was present on every occasion in 25 % of cases and intermittently detected in a further 66 %, with only 2/24 (8 %) individuals not having detectable EBV on any occasion [69]. In acute IM, 50 % of patients had cell-free virus in their throat gargles using the same technique [284]. The more sensitive technique of PCR has demonstrated EBV DNA in the 97–100 % of IM throat wash samples [178, 222] and in 48–62 % of samples from asymptomatic individuals [122, 285]. The salivary VL remains high for at least 6 months after diagnosis, and IM patients remain highly infectious during this time [178, 222]. Throat wash samples obtained from immunosuppressed patients show higher rates of B cell immortalisation of 24–100 % [283, 285].

6.2 Genital Secretions

Whilst saliva is thought to be the major route of EBV transmission, EBV has also been detected in genital secretions. Infectious cell-free virus was detected in cervical washings in 4/28 (14 %) of women [127], and additional studies have detected EBV DNA by PCR in 6–40 % of cervical samples [128, 286, 287]. Five to 48 % of male urethral specimens collected in sexually transmitted diseases clinics had EBV detected by PCR [126, 128]. EBV DNA has also been detected in 0.4–41 % semen specimens collected in infertility clinic [288, 289] and 3–3.5 % of sexually transmitted diseases clinic settings [128, 290]. In the sexually transmitted diseases clinic setting, males with concurrent HIV infection have higher rates of EBV detection in semen (41–56 %; [290, 291]).

Sporadic case reports record the temporal association of genital ulceration and IM, mostly in female patients, although not all had been sexually active [292, 293]. The VL in genital specimens appears lower than that in saliva, and sexual partners are more likely to share indistinguishable EBV strains in common than are individuals known to each other but not in a sexual relationship [128].

6.3 Breast Milk

Like CMV, EBV has been detected in breast milk. EBV DNA was present in 60 of 132 (46 %) of samples donated to a Canadian breast milk bank [294]. However, it is not clear whether breast milk can be a source of EBV infection in infants; the transplacental transmission of maternal antibodies to EBV in term newborn infants would appear to protect against early infection as evidenced by the abrupt onset of seroconversions after 8 months of age [295]. A seroepidemiological survey of bottle- and breast-fed Japanese children aged 12–23 months did not find any difference in age of EBV acquisition [296].

6.4 Intrauterine Infection

Primary EBV infection occurring during pregnancy is rare as most adult females are infected before pregnancy. A specific congenital syndrome relating to intrauterine EBV infection has not been described, although cases of congenital malformations associated temporally with primary infection in the mother during pregnancy have been reported [297, 298].

6.5 Tissue Transmission

EBV can be transmitted with grafted bone marrow or transplanted solid organs from seropositive donors to seronegative graft recipients [129, 299, 300]. In a study, two EBV seronegative heart/lung transplant recipients seroconverted shortly after transplantation and developed EBV-positive PTLD, and the lesions were shown by molecular analysis to harbour the donor EBV isolate. In contrast, EBV-positive PTLD from two seropositive heart/lung patients

were shown to contain the recipient original virus isolate. This indicates the significance of EBV transmission via the grafted organ as a risk factor for the development of PTLD in seronegative recipients [301].

EBV has also been shown to transmit with blood donations [302] prompting calls at the time for the blood from donors with a recent history of IM not to be given to EBV seronegative organ transplant recipients. However, the use of leukodepleted blood products has, to an extent, addressed the issue [303, 304].

7 Epidemiology

EBV achieves near universal infection in humans with over 90–95 % of the world population becoming seropositive [305–309]. The timing of primary infection shows marked geographical and socio-economic variation (see Fig. 38.2).

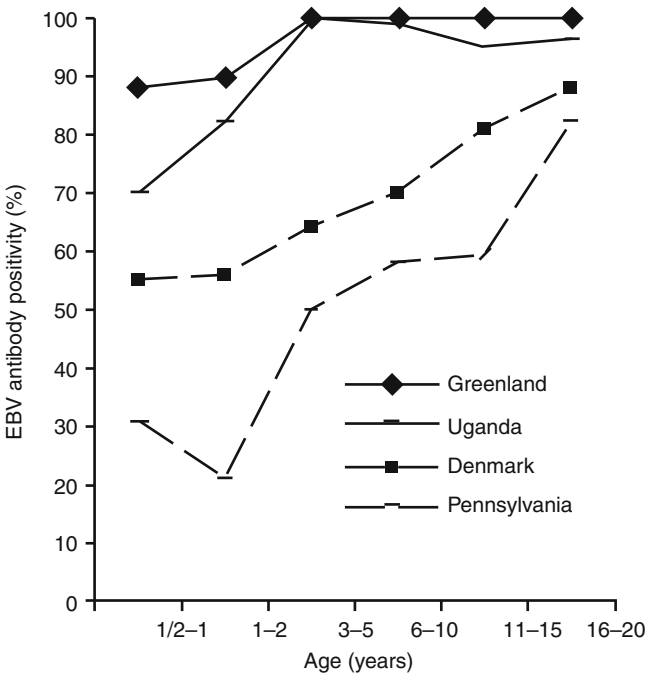

Fig. 38.2 Seroconversion by age in different countries (From Hjalgrim et al. [310])

7.1 Socio-economic and Geographical Factors

Seroepidemiological studies in Africa demonstrated very early EBV acquisition with 80–100 % of infants infected by their first birthday [311, 312]. Urban African children residing in more affluent homes showed slightly delayed EBV acquisition, in some cases until the third birthday [311]. Early serocoversion has also been demonstrated in other continents [313–315].

Studies in Europe and the USA have shown later acquisition of EBV, with only 39 % of children aged between 5 and 14 years having serological evidence of infection in a laboratory-based UK study [307] and 50 % acquisition by 2 years of age in a hospital-based study serving an area of low socio-economic status in Philadelphia [316]. Intermediate results have been obtained in Japan [309] and Brazil [317], with the Brazilian investigators noting later seroconversion in a neighbourhood of higher family income and maternal education.

A Danish study found an association between positive EBV serology and the occupation of the head of the household. Where the head of the household followed an 'unskilled' occupation or was unemployed, 54 % of children aged 0–6 years had antibodies as opposed to 34 % of children aged 0–6 years from a 'skilled' or 'professional' background [305]. Persistence of EBV seronegativity into teenage years has been associated with higher socio-economic status as assessed by the occupation of the head of the household [318], the income of the household [278] or residence in owner-occupied housing [318]. A study of over 1,000 children aged 6–7 years in primary schools in the UK, using a salivary antibody detection method, found significant associations between seropositivity and unemployment, or manual occupation, of the head of the household, sharing a bedroom or attending a school in an area with predominantly rented housing estates [319].

7.2 Serological Status by Age and Gender

IgG antibodies to EBV cross the placenta so almost all term newborn babies are seropositive. This wanes by 4 months of age with natural infection starting to occur around 6 months of age [295, 305, 320], and the rapidity of acquisition depends upon the affluence of the household and the community [311]. In affluent communities, where seroconversion is delayed, two peaks of acquisition may be seen; one in children under 5 years and a second in teenage years [306, 321]. A UK study, based on serological samples submitted for diagnostic purposes, showed 35 % of children aged 1–4 years and 54 % of 10–14-year-olds, and 72 % of 15–19-year-olds had evidence of past EBV infection [321]. In countries with late EBV infection, acquisition in adolescents aged 10–14 years occurs earlier in girls than boys [321] so that by age 19 significantly fewer males (64–73 %) than females (72–88 %) are seropositive [247, 306].

Studies from the UK and Japan suggest that age of primary EBV infection may be changing with virus acquisition now occurring later in childhood than previously [309, 321].

Table 38.3 Incidence of IM in general populations in the USA and UK

Author, year of publication	Location	Year	Criteria	Rate per 100,000
Henke et al., 1973 [327]	Rochester Minnesota	1950–1969	Reported to health department	181
			Strict based on laboratory and clinical features	99
Heath Jr et al., 1972 [325]	Atlanta, Georgia	1968	Collation of positive laboratory tests	45
Davidson, 1970 [326]	Grampian, UK	1969	Collation of positive laboratory tests	44
		1966–1968	Subgroup of two general practice populations above	100
Niederman and Evans, 1997 [328]	Connecticut	1983		71
		1985		61
White et al., 1998 [329]	England and Wales	1993–1995	Personal communication from Communicable Disease Surveillance Centre	69

7.3 Other Factors: Siblings and Day Care

The evidence for siblings and day care favouring EBV seroconversion is less consistent than age and socio-economic status. Some studies report no such association [278, 318], whilst others found an excess of seroconversions in those with siblings [306, 322]. A large study based in primary schools in the UK, using a salivary antibody detection method, also failed to find a significant association with numbers of children in the home [319]. Attendance of preschool children at nursery appears to promote seroconversion, although the studies to date are small and not all results achieved statistical significance [305, 308, 323].

7.4 Serological Status and Sexual Behaviour

In countries where EBV seroconversion is delayed into adolescence and young adulthood, several studies have noted an association between sexual activity and acquisition of EBV [88, 247, 324]; see also Sect. 6.

7.5 Epidemiology of IM

IM may result when primary EBV infection is delayed beyond infancy, predominantly occurring between the ages of 12 and 25 years [325].

The incidence of IM in a population may be estimated by the number of positive laboratory tests (heterophile antibody and/or EBV-specific IgM) or, where IM is notifiable, notifications to public health departments or by specific surveys. A limitation of population studies based on the finding of positive heterophile antibody tests is that they are likely to under-report IM, particularly in children, who are less likely to mount a heterophile antibody response before 4 years of age (see Sect. 4, [145, 146, 179, 181]). A UK study based on positive heterophile tests in 1970 found that the peak incidence of IM occurred between the ages of 15 and 19 years in both sexes, with incidence rising in females at a younger age than males [326]. A US study reported a similar incidence in the overall population of 45 cases per 100,000, a peak incidence in those aged 15–19 years, and noted that the peak incidence in females occurred 2 years prior to that observed in males ([325]; for an overview, see Table 38.3).

The incidence of IM in populations of young adults such as universities and military forces is much higher than in general populations as shown in Table 38.4. A recent report from the Israeli Defence Force gives an annual incidence of 880 per 100,000 between 2002 and 2009 [334]. A much earlier report from 19 US colleges and universities gave an overall incidence of 1,112 per 100,000 students in the 9-month academic year, with the rate from individual institutions ranging from 110 to 2,235 [335].

Akin to the seroepidemiological studies showing a relationship between affluence and delayed EBV acquisition, a study in London (UK), which compared the occupation of the head of the household of IM cases with that of the surrounding population, showed an excess of IM in those in higher socio-economic grouping [336].

Published information on hospitalisation rates for IM is scarce (see Table 38.5); however, in the UK, the incidence of hospital admissions for IM may be rising [337].

7.6 Epidemiology of IM in Student and Military Populations

IM is recognised as an important cause of ill-health in populations with large numbers of young people, including universities and the armed forces especially where a high proportion of new entrants are EBV seronegative. In the 1960s, IM was noted to be the third most common cause of days lost to hospitalisation in the US Air Force and fourth most common in the US Navy ([340]; for a summary of studies of IM in military recruits and students, see Table 38.4). Annual rates of IM in seronegative entrants range from zero to 13 %, but the proportion of EBV seroconversions that result in documented illness varies widely – from none to 74 % [4, 278, 279, 318, 331–333]. However, this may reflect the intensity of clinical follow-up.

Table 38.4 IM in military recruits and students

Author, Year of publication	Location	Sex	EBV seronegative at entry	Seroconversion rate per year	IM rate in seronegatives per year	Proportion of seroconversions symptomatic
Lehane, 1970 [330]	American Marine Recruits	Male	18 % (117/648)	7 % in training (calc) 2 % in Vietnam (calc)	Not stated Hospitalisations for IM in Vietnam 0.2 % per year	9 % (based on rate of hospitalisations for IM in Vietnam troops)

8 Host Response

8.1 Clinical Features of Acute Infection in Children and Adults

After an incubation period of between 4 and 7 weeks, the symptoms and signs of IM typified by fever, sore throat and lymphadenopathy may arise in up to 74 % of older children and adults [279, 281, 341–345]. In younger children, symptomatic seroconversion is much less frequently recognised, lymphadenopathy and pharyngitis is less prominent, and, when EBV seroconversion is detected, it may be associated with upper respiratory tract illness, otitis media, rash and/or pneumonia [316, 346].

In adults, IM may be subacute in presentation resulting in difficulty in pinpointing the exact date of onset [343]. Not all cases have pronounced sore throat or lymphadenopathy; in some, fever may predominate, whilst occasionally in others, the presentation may be with an unusual complication. Pharyngitis is evident in 85 %, and exudates may be seen in 22–58 % [342, 343, 346]; see Fig. 38.3. Lymphadenopathy, particularly affecting the posterior triangle of the neck, is present in most cases; axillary or groin nodes are detected in around half of cases [347]. Splenomegaly is clinically detectable in up to 17 %; an ultrasound study demonstrated splenic enlargement in all of 29 cases studied [348]. Hepatomegaly is clinically detectable in 10–37 % of cases, and in 50 % by ultrasound [341, 344, 348]. Other features include petechiae at the junction of the soft and hard palate and eyelid oedema [347]. Rashes, including macular erythema, petechiae and urticaria are reported in 3–16 % of cases; however, the concurrent administration of ampicillin results in a red rash in around 95 % [18, 341, 347, 349].

The acute features resolve over 3–4 weeks [350]. Thereafter, however, a fatigue state, lasting a median of 8 weeks, is common [329], and depression may follow occasionally [329, 351, 352]. Patients with IM also report prolonged hypersomnolence, impaired concentration and disruption of their usual work and recreational activities [161, 329, 353, 354].

A number of complications of IM are well recognised (see Table 38.6) – particularly hepatitis, jaundice, thrombocytopenia, haemolytic anaemia, splenic rupture and fatigue. Rarer complications include encephalitis, demyelination, arrhythmia, pancreatitis, gastrointestinal haemorrhage, interstitial nephritis and pulmonary infiltrates [342, 344]. When IM occurs beyond young adulthood, a more severe clinical presentation may be seen with protracted fever and severe hepatitis. Unusual complications may also be present, and

the patient is likely to be investigated or treated for other conditions including haematological malignancy or hepatobiliary disease, as IM may not be considered at the outset of disease [143, 355, 356].

Death as a result of IM is very rare and may be the result of an underlying immunological defect, particularly XLP (see below). Other underlying defects resulting in severe disease are recognised, including defective NK cell function [237], perforin gene mutations [357] and selective IFN-gamma deficiency [358]. Even in those without immune defects, fatal outcomes may sometimes occur as a result of airway obstruction, neurological complications, hepatic failure, splenic rupture, myocarditis, cardiac arrhythmia, secondary bacterial infection or haemorrhage [144, 342, 344, 356, 359–361].

8.2 Fatigue After IM

Fatigue is reported by 77–100 % in the acute stages of IM and lasts longer than fatigue associated with other upper respiratory tract infections [154, 161, 329, 345, 352]. Studies in adults give a median duration of self-reported fatigue after IM of 4–16 weeks (interquartile range) [329], with 12–13 % of patients still fatigued at 6 months [345, 362–364]. The reasons for the prolonged fatigue are not understood, but risk factors for fatigue at 6 months include female sex, older age, negative beliefs about illness duration and severity of acute illness [352, 362–365]. Altered gene expression has been noted in a small study although it is not clear whether this reflects aetiology or is a consequence of altered behavioural patterns [366]. Most patients with IM recall being advised to rest by their general practitioner [367], yet the available evidence suggests that this impedes recovery [353, 368, 369]. A small study based in primary care found that an intervention of an individual treatment session which delivered ‘a personalised strategy of graded time-targeted activity and advice about a balanced lifestyle’ resulted in a significantly less fatigue at 6 months than in controls [370]. More studies are required in this area; however, the approach is in line with current practice in the management of chronic fatigue [371–374].

8.3 Treatment of IM

Treatment of IM is supportive, and no specific therapy is routinely recommended at present. The antiviral acyclovir reduces virus production in the throat during treatment; however, it does not alter the clinical symptoms or course of the illness, and its use is not recommended [375]. More recently, based on a small pilot study, it has been suggested that valacyclovir should be investigated for the treatment of acute IM; however, larger studies are required before this approach can be recommended [376]. Corticosteroids are not recommended for routine use in uncomplicated IM, but may be useful to reduce the need for surgical intervention when the degree of swelling in Waldeyer’s ring is compromising or threatening to compromise the airway [377–380]. Corticosteroids have also been used in the treatment of autoimmune haemolytic anaemia and severe thrombocytopenia [136, 344, 379]. Oral phenoxymethylpenicillin or intravenous benzylpenicillin may be given if superadded streptococcal infection is present; however, caution is advised as the risk of rash may be increased [136, 349]. Concurrent ampicillin or amoxicillin is contraindicated as almost all (around 95 %) patients will develop a generalised erythematous macular rash [136, 380, 381]. IM may be complicated by spontaneous or traumatic splenic rupture, and therefore it is advised that vigorous athletic participation should be deferred for at least 1 month, or until the patient is well and has no splenomegaly [382–384].

Table 38.6 Complications of IM

Organ/system	Complication
Respiratory	Respiratory tract obstruction, interstitial pneumonitis (rare)
Skin	Rashes 3–16 %; following the administration of ampicillin 86–98 %
Liver	Clinical jaundice 5 %, fulminant hepatitis (rare)
Haematological	Thrombocytopenia, haemolytic anaemia, neutropenia
Psychiatric	Depression, anxiety
Immunological	Secondary infection, streptococcal sore throat, sepsis in association with neutropenia, mesenteric adenitis, depressed cell-mediated immunity
Spleen	Splenic rupture 0.1–0.5 % spontaneous or after mild trauma (usually in males), splenic infarction
Neurological[a]	Encephalitis, acute cerebellar syndrome, aseptic meningitis, Guillain-Barré syndrome, cranial nerve palsy especially VII, transverse myelitis, seizures, mononeuritis, optic neuritis, cerebral haemorrhage
Gastrointestinal	Haemorrhage secondary to mucosal erosion, pancreatitis
Genito-urinary	Haematuria, interstitial nephritis, glomerulonephritis (rare), genital ulceration
Cardiac	Myocarditis, pericarditis, arrhythmia, electrocardiogram changes

Adapted from Macsween and Crawford [18]
[a]Pharyngitis and lymphadenopathy may be absent

8.4 X-Linked Lymphoproliferative Syndrome (XLP or XLPS)

In the early 1970s, deaths were reported from acute IM and/or malignant lymphoma of 6 male kindred within the same (Duncan) family [385, 386]. Similar disease was also reported in a 16-year-old boy whose 3 male cousins had succumbed to a similar disease [387] as well as in another three related young males [388]. The syndrome is due to a defective gene on the X chromosome [389] which results in the inability to control primary EBV infection – XLP, or XLPS – and is characterised by the clinical triad of susceptibility to severe primary EBV infection (IM), dysgammaglobulinaemia and lymphoma.

The typical clinical presentation of XLP is of a young male who is well prior to primary EBV infection but rapidly succumbs to fulminant IM following acquisition of EBV [390, 391]. Death may result from hepatic necrosis secondary to massive CTL infiltration and cytokine release, aplastic anaemia or pancytopenia or, in some cases, superimposed bacterial and/or fungal infection. A more chronic disease may also ensue which often progresses to a fatal B cell lymphoma, and death may occur by 40 years of age [392]. XLP is characterised histologically by massive solid organ lymphoproliferations of EBNA+ve B lymphoblastoid/plasmacytoid cells of polyclonal origin admixed with T, NK and phagocytic cells [393–397]. Haemophagocytosis is a frequent histological finding [393, 396]. Other phenotypes – including dysgammaglobulinaemia, lymphoproliferative disorders or autoimmune phenomena (including vasculitis, colitis or aplastic anaemia) – may arise before, or after, EBV infection [398].

Most XLP cases are caused by a defective gene located on the long arm of the X chromosome. SH2D1A (Src homology 2 (SH2) domain-containing gene 1A) that encodes for SAP [399–401]. SAP, a 128 amino acid protein with an SH2 domain, is an adaptor molecule expressed in T and NK (but not normal B) cells which binds to the cytoplasmic end of several cell surface proteins including SLAM, 2B4, CD84, Ly9 and NK-T-B antigen [402, 403]. Thus, SAP receives signals from the cell surface and modulates intracellular signalling through its association with the SLAM receptor family, such as SLAM and 2B4 [404], resulting in regulation of aspects of NK and T lymphocyte function including cytokine production, proliferation, cytotoxicity and antibody formation. If SAP is defective or absent, it is postulated that the SLAM family of receptors are unable to signal normally [398]. To date, over 70 mutations of the SAP gene have been identified [405–407] and most result in reduced or absent protein [398]; currently, there does not appear to be a correlation between mutation, phenotype and disease severity although the complex signalling interactions between SAP and its receptors are not fully understood [398, 408]. Recently, however, SAP has been shown to have pro-apoptotic, and EBNA1 anti-apoptotic, function that may provide an insight into XLP as well as EBV-associated tumourigenesis [409, 410]. Association of XLP with other genes – in particular, the X-linked inhibitor of apoptosis protein (XIAP) gene – and its subdivision into XLP 1 and 2 remains to be clarified.

XLP is usually fatal unless treated with either bone marrow transplantation [411] or, more recently, a humanised murine mAb against the B cell surface marker CD20, rituximab [412].

8.5 Chronic Active EBV (CAEBV)

Chronic active EBV (CAEBV) infection is a rare condition, distinct from chronic fatigue, which is typified, in a previously healthy person, by severe, chronic or recurrent IM-like symptoms following a well-documented primary EBV infection. An abnormal EBV antibody profile is present with

greatly increased antibody titres against VCA and EA – often accompanied by persisting IgM and IgA to VCA – together with the failure to mount antibodies against EBNA during the convalescent phase. In addition, there is a marked increase of EBV VL in tissues and peripheral blood [413] and evidence of major organ involvement – for example, interstitial pneumonia, bone marrow hypoplasia, splenomegaly, extensive lymphadenopathy, hepatitis, meningoencephalitis and uveitis [414–416]. EBV DNA testing aids diagnosis and assessment of prognosis in CAEBV [171].

CAEBV has a high morbidity and mortality from severe fever, hepatic failure, lymphoma, sepsis, cardiac failure or haemophagocytic syndrome. Diagnostic criteria have been proposed that include clinical features and virological and haematological parameters and, pre-fixing the acronym with 'severe', exclude patients with minor symptoms [415].

The exact pathogenesis is unclear although a perforin defect has been described that is not a constant phenomenon [417]. Interestingly, clonal expansion of EBV-infected T or NK cells takes place in preference to infection of the usual B cell target [357, 414, 418]. Severe cases are more common in Japan, China and Korea than elsewhere suggesting a possible genetic predisposition to CAEBV.

CAEBV is difficult to treat; bone marrow transplantation, and/or adoptive immunotherapy, may be helpful [419–421].

8.6 Multiple Sclerosis (MS)

EBV is one of several agents proposed as having an aetiological role in the pathogenesis of multiple sclerosis (MS). A Danish population-based study examined the subsequent occurrence of MS amongst over 25,000 patients diagnosed with IM. This study involved more than 550,000 person-years of follow-up and found a more than 2-fold increase in the risk of MS after IM [422].

8.7 Oral Hairy Leukoplakia

The corrugated white lesions on the lateral borders of the tongue occur in states of significant immunosuppression, including advanced HIV infection [423, 424], organ transplantation or, occasionally, systemic glucocorticoid therapy for other conditions [425–427]. As it is a productive (lytic) EBV infection [428], it may be controlled with oral acyclovir therapy [429].

9 Prevention and Control

Whilst EBV infects most of the human population and coexists without causing disease in the majority, it is an oncogenic virus that is an established factor/cofactor in the aetiology of many human cancers and (more recently) has been associated with the development of MS. In addition, primary EBV infection is a life-threatening condition for those with genetic defects, such as XLP (see above), and for those with profound immunodeficiency following organ transplantation. Furthermore, IM remains an important cause of morbidity in older children and young adults, occasionally causing very severe disease – especially in older age groups. Importantly, economic development may result in a rising incidence of IM due to delays in the age of primary acquisition of the virus.

9.1 Immunisation

The traditional approach to immunisation, using whole killed or live-attenuated virus, has been avoided by researchers in view of the known oncogenic potential of EBV and the difficulties in producing large quantities of virus [430]. Two main types of recombinant vaccine have been considered for prophylactic use prior to the occurrence of any disease. These include the use of the subunit glycoprotein gp350, which is known to induce neutralising antibody, and a peptide (epitope) vaccine – so-called polytope when multiple peptides are used – designed to induce cytotoxic cellular immunity [431]. Due to HLA diversity, however, it is estimated that 25 $CD8^+$ T cell epitopes would be needed to provide coverage for over 90 % of the population in Western countries [432].

The use of gp350 as a subunit vaccine has long been considered and was previously studied in the cotton-top tamarin (*Saguinus oedipus*) primate model. Following intraperitoneal and intramuscular injection of EBV, these small Colombian (New World) non-human primates develop large oligoclonal lymphomas, which could be prevented by prior injections with gp350 presented in artificial liposomes. However, only the animals with very high levels of virus neutralising activity in their serum were protected [433].

After a delay of over 25 years, phase 1 and phase 2 studies were undertaken in Belgium with a gp350 subunit vaccine, using glycoprotein expressed in Chinese hamster ovary cells [434, 435]. Fortunately, there is little sequence variation in this gene between the two EBV types [436]. After 3 vaccine doses, all subjects had produced anti-gp350 antibodies; however, one serious adverse event (reactive arthritis) occurred when gp350 with the adjuvant AS04 (a lipid and aluminium hydroxide adjuvant)* was given to an already EBV seropositive recipient, and there was also a tendency towards a higher frequency of local symptoms postvaccination in those who were already EBV positive. The subsequent part of the study and phase 2 placebo-controlled study were undertaken in EBV seronegative subjects [435, 437]. In the randomised double-blind placebo-controlled trial, 181 seronegative young adults in Belgium received either three

doses of gp350 with AS04 or three doses of a placebo-containing aluminium hydroxide alone. Asymptomatic primary infection was not reduced by vaccination with gp350; however, the number of cases of IM was reduced in the gp350 group (2 cases *versus* 8 in the placebo group, which was significant by intention to treat analysis; [437]). Unfortunately, this trial did not investigate VL or CTL responses in either group.

To date, trials to prevent IM using a polyepitope vaccine have not been conducted. A very small phase 1 study using a single EBV peptide epitope from EBNA3a mixed with tetanus toxoid and formulated in a water in oil squalene adjuvant 'Montanide ISA 720' has been conducted in ten HLA B*0801-positive subjects and 4 controls. Half of the epitope recipients, and 2/4 (50 %) of the placebo recipient, seroconverted to EBV. One case of IM occurred in each group. Although the study was too small to estimate vaccine efficacy, the authors concluded that the vaccine was safe, produced epitope specific T cell responses in 8/9 (89 %) recipients and was generally well tolerated [432, 438]. The decision to incorporate tetanus toxoid to provide CD4+ve T cell help was questionable as this probably led to increased local adverse reactions to the vaccine and excluded 45 % of potential volunteers due to pre-existing high levels of tetanus toxoid antibodies. The authors suggested that gp350 could be incorporated with the peptide vaccine as an alternative source of CD4+ve T cell help, although to date no trials combining the vaccine approaches have been published.

More recently, an EBV virus-like particle has been produced, and its use as a vaccine been proposed; however, this work is at an early stage, and further modification to remove additional EBV proteins and possibly RNA may be desirable before any in vivo work is undertaken [439].

Taken together, gp350 seems the most promising candidate for further trials at the present time, although epitope-based approaches may find a role as adjuvant therapies in EBV-associated malignancies [440].

*AS04 (adjuvant system 04) = 3-O-desacyl-4′-monophosphoryl lipid A (derived from Salmonella lipopolysaccharide) with aluminium salt [441]

9.2 Prevention of Disability After IM

Fatigue after IM – see above.

9.3 Other Methods of Control

EBV is occasionally transmitted by blood transfusion and organ transplantation – see Sect. 6.5.

10 Unresolved Problems

Although 50 years have elapsed since the discovery of EBV, many aspects of epidemiology, biology, pathogenesis, treatment and prevention remain incompletely understood or researched.

Many of the epidemiology studies were undertaken in the 1960s and 1970s, and there have been few recent studies to explore the effects of industrialisation and development in poorer parts of the world and the effects of changing behaviours (e.g. increased child care outwith the home), changing sexual behaviours and reduced household and family size. The events during the window period between virus entry and symptoms are largely unknown, as are the reasons leading to symptomatic rather than asymptomatic seroconversion. The proportion of infections that are symptomatic in children is not well studied, and the explanation for mainly asymptomatic acquisition in young children is not resolved. Whilst the main route of transmission is thought to be via saliva, the contribution from genital transmission in adolescents and adults is not clear.

There is no recommended specific treatment for IM despite the severity of the illness and its occurrence at often time critical periods of education, examinations, and early working life. This may become an increasing (and costly) problem as EBV epidemiology changes and primary infection is delayed into adolescence and young adulthood. IM is often followed by prolonged fatigue, hypersomnolence and disruption to usual work and other patterns of activity, and further studies to reduce or prevent this disability are required [161, 353, 370].

Work to produce an EBV vaccine has been limited, with to date only a single phase 2 study to prevent IM with the leading candidate gp350. The effect of vaccination with gp350 on VL and lymphocyte responses in natural EBV infection is so far unassessed, and any negative outcomes of immunisation such as increased severe IM are unquantified, or the effects of potentially altering the CTL repertoire are unknown [430]. It is not known whether EBV-related conditions such as BL, HL and MS might be prevented by immunisation.

Kaposi's Sarcoma-Associated Herpesvirus: Epidemiology, Biological Characteristics and Pathogenesis

39

Ronit Sarid and Maria Luisa Calabrò

1 Introduction

Kaposi's sarcoma-associated herpesvirus (KSHV), formally designated the human herpesvirus 8 (HHV-8), was first identified in a Kaposi's sarcoma lesion from a patient with AIDS [78]. KSHV is now recognized as the causative agent of all clinical and epidemiological types of Kaposi's sarcoma (KS) [286]. Based on adequate evidence supporting its etiologic association with KS, KSHV has been recognized by the International Agency for Research on Cancer (IARC) as one of seven known human tumor viruses (group 1) [44, 356]. KSHV is also causally associated with primary effusion lymphoma (PEL) [73] and a subset of multicentric Castleman's disease (MCD) [377]. In addition, it is related to large B-cell lymphoma arising in KSHV-positive MCD and to a germinotropic lymphoproliferative disorder. KSHV inflammatory cytokine syndrome (KICS) has been recently described as an additional condition related to KSHV [398].

The tumorigenic potential of KSHV is illustrated by its ability to alter the growth properties of cells in culture and to induce KS-cell-like morphology upon infection of endothelial cells. Viral-encoded genes are expressed in all KSHV-related disorders. At the molecular level, several KSHV gene products can induce cell proliferation, inhibit cell death, and may also generate genomic instability.

2 Historical Background

In 1872 the Hungarian dermatologist Moritz Kaposi described five elderly male patients who presented an "idiopathic multiple pigmented sarcoma of the skin," which was characterized by multifocal nodules, localized mostly on the lower limbs but also on the mucous linings of certain organs and on the liver [45]. This disorder, later termed Kaposi's sarcoma (KS), is now classified into four epidemiological variants on the basis of clinical characteristics (localization and clinical course) and particular risk factors (age, gender, extent of immune suppression, and ethnogeographical origin) (Table 39.1).

The classic KS has a mostly benign course and is slowly progressing and not life threatening; it affects apparently immunocompetent elderly individuals, mostly men of Mediterranean or Eastern European origin [203]. The endemic or African KS, first described in the 1950s, is prevalent in parts of Central and Eastern Africa and affects adults, but also can develop in children, frequently as a disseminated lymphadenopathy with no cutaneous involvement [214]. The iatrogenic, or posttransplant KS, develops in immunosuppressed patients, mostly after organ transplantation [369]. Finally, the epidemic or AIDS-associated KS was initially described in 1981 in young men who have sex with men (MSM) infected by the human immunodeficiency virus type 1 (HIV-1) and subsequently became an AIDS-defining pathology and one of the most commonly observed malignancies in AIDS patients [200]. This variant is highly aggressive and is characterized by multiple, disseminated lesions with gastrointestinal and lymph node involvement. In Western countries, AIDS-KS develops mostly among HIV-infected MSM, whereas in Africa it has a similar incidence rate among males and females. In certain sub-Saharan African countries, KS is one of the most common cancers and is associated with significant morbidity and mortality [314, 406]. All four epidemiological forms of KS share similar histologic characteristics, though AIDS-KS tends to be highly aggressive whereas classic KS is relatively indolent.

Table 39.1 Kaposi's sarcoma variants

Variant	First evidence	Population at risk	Age range	Gender ratio (M:F)	Cutaneous	Lymph nodes	Visceral	Clinical course	Reference
Classic KS	1872	Mediterranean area and Middle East origin	>50	3:1	Symmetrical, mainly localized lesions in lower limbs	Rare	Rare	Frequently slowly progressing and not life-threatening	[143, 203]
		Indigenous (Quechuas) and mestizo populations from Colombia and Peru	22–81 (Colombia)	8:1 (Colombia) 3:1 (Peru)	Confluent non-symmetrical nodules or ulcerated lesions in upper and lower limbs, associated with edema in 20–50 % of patients	20 % of patients	Rare	Locally aggressive	[284]
Endemic/African KS	1950s	African adults	25–40	10:1 (before the AIDS epidemic) 2:1	Localized or disseminated lesions in lower limbs	Rare	Rare	Indolent to locally aggressive; frequently observed prior to the AIDS epidemic	[5, 263]
		African adults	20–35	2:1	Disseminated lesions	Frequent	Frequent	Aggressive, more frequent after the AIDS epidemic, likely reflecting HIV infection	[263, 434]
		Prepubescent African children	11–13	5:1 (Tanzania)	Disseminated lesions	Rare	Rare	Locally aggressive, more frequent after the AIDS epidemic, likely reflecting HIV infection	[5, 6, 433]
		Young African children (around 3-year-old children)	<15	3:1	Rare	Diffused lymphadenopathy	Frequent	Rapidly fatal course in both HIV-infected and uninfected children	[215, 309, 433]
Iatrogenic KS	1969	Patients under immunosuppressive treatments or with autoimmune disorders	All	3:1	Frequent	Frequent	Frequent	Variable, ranging from chronic to rapidly progressing; may regress after modification of the immunosuppressive treatment	[132, 369]
Epidemic/AIDS-associated KS	1981	HIV-1-infected individuals, mainly MSM in developed countries	All	20:1	Disseminated lesions	Frequent	Frequent	Rapidly progressing before the introduction of HIV therapy; may regress after antiretroviral therapy	[29]

Epidemiological studies conducted on subjects affected by epidemic KS suggested an infectious etiology for this disorder. Indeed, KS incidence was higher among subjects infected via sexual contact as compared with other transmission groups, such as hemophilia patients and injection drug users (IDUs) [30]. A number of pathogens were initially proposed as potential KS agents, including human papillomavirus 16, hepatitis B virus, Cytomegalovirus (CMV), human herpesvirus type 6, *Mycoplasma penetrans*, and several others, yet a causative role could not be confirmed for any of these candidates. Herpesvirus-like particles had already been observed in KS neoplastic cells in 1972 [160], but those virions were subsequently ascribed to CMV infection [161]. Herpesvirus-like particles were also detected in KS biopsies by other researchers [407].

In 1994 Chang and colleagues identified DNA sequences of a previously unrecognized herpesvirus in a lesion from a patient affected by AIDS-KS [78]. These sequences were identified by using Representational Difference Analysis (RDA), a powerful technique available at the time to detect unique sequences through a comparison between DNA from pathological tissue and DNA of normal tissue from the same patient [246]. Sequence analysis revealed close homology of the newly discovered DNA sequences with two herpesviruses, Epstein-Barr virus (EBV) and herpesvirus saimiri (HVS), which belong to the *Gammaherpesvirinae* subfamily. These sequences were subsequently found in KS lesions from patients affected by all variants of KS, supporting the involvement of this putative novel herpesvirus in KS. These herpesvirus-like sequences were subsequently detected in tumor cells from patients with a rare form of non-Hodgkin's lymphoma. This lymphoma presents primarily as lymphomatous effusion in serous body cavities, and it was thus named body cavity-based lymphoma, BCBL, or primary effusion lymphoma, PEL [73]. In light of a recognized clinical association of KS with multicentric Castleman's disease (MCD), a rare polyclonal lymphoid disorder characterized by lymphoid hyperplasia, the presence of KSHV sequences in MCD samples was also investigated, providing evidence for a possible link with a subset of MCD cases [377].

Cell lines established from effusion of PEL patients were found to stably maintain the virus, thus permitting the cloning and sequencing of its entire genome [351] and visualization of the viral particles by electron microscopy [340]. Nucleotide sequence analyses of the entire genome confirmed its initial classification as a gammaherpesvirus belonging to the genus of rhadinoviruses or gamma-2-herpesviruses.

Initial serological studies performed using PEL-derived cell lines as source of viral antigens confirmed the presence of antibodies against viral antigens in all patients affected by KS, while infection was shown to precede KS onset [152, 153, 218, 370]. Several subsequent serosurveys showed that KSHV seroprevalence globally mirrors the distribution of classic and endemic KS in the general population and is high in HIV-1 transmission groups in which epidemic KS is frequent. Taken together, these initial findings strongly supported the notion that KSHV is etiologically linked to the development of KS.

3 Methods of Epidemiological Analysis

Soon after the discovery of KSHV, most studies aiming to understand the epidemiology of KSHV infection were based on the detection of viral DNA in biopsy specimens and in peripheral blood mononuclear cells (PBMCs) through polymerase chain reaction (PCR) and by nested PCR. The initial search for KSHV sequences identified their presence in all epidemiological variants of KS, although the detection rates did not reach 100 %. Rates of PCR positivity were largely dependent on the sample type. DNA could be detected easily in fresh biopsies by standard PCR, but not all archival paraffin-embedded samples were found to be positive, largely because of the fixation conditions. In PBMCs, KSHV DNA was detected mainly by nested PCR in only 5–20 % of infected subjects, and the proportion was higher in KS patients [36, 413]. A highly sensitive and specific assay for detection of KSHV infection was based on nested PCR using two nonoverlapping primer sets for the open reading frame *(orf)25* and *orf26* genomic regions [41, 56]. Initial PCR analyses detected KSHV infection more frequently in PBMCs from HIV-infected patients prior to KS onset as compared with control HIV-1-infected subjects who did not develop KS [289]. This technique remains, however, highly prone to cross-contamination as well as contamination from previous amplification products and requires all procedures to avoid false-positive results. Since viral load in the systemic compartment of infected individuals, with or without KSHV-related pathologies, may be low or undetectable even by sensitive PCR techniques, the prevalence of infection cannot be reliably determined by qualitative or quantitative PCR.

The development of serological assays to detect antibodies to KSHV enabled more extensive studies and estimation of KSHV prevalence in the general population. KSHV-specific antibodies were detected initially by using PEL-derived cell lines as source of viral antigens. One of the most useful tests relies on an indirect immunofluorescence assay (IFA), performed on latently infected PEL-derived cell lines. Using these cells, sera from KSHV-infected subjects react with a viral nuclear antigen resulting in a characteristic speckled pattern of staining for the viral latency-associated nuclear antigen 1 (LANA-1), encoded by *orf73* (Latent IFA) [152, 153, 218]. PEL cell lines can also be chemically induced to increase the fraction of lytically infected cells and thus serve to measure antibodies against lytic viral antigens. In this case, sera from KSHV-infected individuals react with

several viral antigens and produce both cytoplasmic and nuclear fluorescence (Lytic IFA) [240]. In addition, various enzyme-linked immunosorbent assay (ELISA)-based diagnostic tools have been developed, using recombinant viral proteins, peptides, or whole virus lysates. The major antigenic proteins are LANA-1 and structural proteins of the viral capsid (encoded by *orf65*) and envelope (encoded by *orfK8.1*) [370, 379].

Combined serological analyses, using in-house or commercially available serological assays, have been proposed to estimate the seroprevalence of KSHV in different populations [233]. Serological tests may be performed by detecting antibodies to latent (employing latent IFA or ELISA) and lytic antigens (employing lytic IFA or ELISA using *orf65*- or *orf K8.1*-derived recombinant proteins) [333, 370]. These analyses should be followed by confirmatory immunoblots with a panel of latent and lytic antigens [370, 430]. The overall seroprevalence can be estimated as reactivity to at least one of the two analyzed antigens [55, 370]. These and other combinations of serological techniques were proved to be suitable for epidemiological studies, although the interpretation of some published prevalence data remains challenging. In fact, these techniques show only moderate concordance between each other and among different laboratories [319, 334, 379].

A standardized and universally accepted algorithm for KSHV diagnostics is not presently available. KSHV diagnostics should combine serological and molecular techniques to ideally delineate a broad virological profile. As asymptomatic KSHV-infected subjects may have antibodies to only latent or lytic antigens, and with very low titers, serological tests should include detection of antibodies to at least one latent and one lytic antigens. Antibody titration may also provide additional information. Higher antibody titers were associated with increased risk and faster progression to KS in HIV-1/KSHV-coinfected subjects [343]. Anti-lytic antibody titers may also reflect tumor burden and evolution in AIDS-KS patients [58, 70]. Lower CD4+ and CD8+ T-lymphocyte counts were found to influence antibody response to KSHV latent antigens in AIDS-KS patients [105, 175].

Concerning viral load assessment, initial studies indicated that detectable cell-associated KSHV viremia was correlated to a tenfold increased risk of KS in HIV/KSHV-coinfected individuals [129]. In untreated AIDS-KS patients, systemic KSHV load generally directly correlates with HIV-1 RNA levels in plasma. Introduction of highly active antiretroviral therapy (HAART) was shown to decrease systemic HIV and KSHV loads in patients, resulting in complete remission and durable responses. However, increasing KSHV loads in KS patients with partial or complete response to therapy, undetectable KSHV load before and after HAART, or lack of detection of KSHV DNA in the peripheral blood during KS progression were also reported [59, 71, 392, 419]. Therefore, viral load may be quantified in blood compartments (plasma and PBMCs) to determine the systemic levels of cell-free and cell-associated virus, but particular caution must be paid to data interpretation in HIV-1-infected subjects under HAART and in HIV-negative KS patients [184, 392]. In addition to peripheral blood, KSHV load analysis can be also carried out using saliva. Oral samples represent a site at which KSHV can be detected more frequently and at higher loads than in blood samples [270, 318], although detection may be intermittent [232], and factors controlling oral KSHV shedding must still be fully elucidated. Nevertheless, measurement of KSHV in saliva represents an estimate of the transmission potential of the subject. Viral load analysis should be thus performed in parallel with the search for anti-KSHV antibodies, although first-generation serological tests may not be fully adequate for diagnosis. Introduction of novel antigenic viral proteins, such as KSHV complement control protein (KCP) and vCYC [50, 307] in serological assays may be useful to better monitor the humoral responses of KSHV-infected subjects. In addition, innovative multiplexing techniques that combine the simultaneous detection of antibodies toward different latent and lytic viral proteins may, in the future, bypass the drawbacks of separate determinations by increasing sensitivity and by standardizing data interpretation.

4 Biological Characteristics

4.1 The Virus

KSHV is a lymphotropic gamma-2 herpesvirus (rhadinovirus) and is the only member of this group that infects humans. KSHV shares close homology with several primate and non-primate mammalian viruses, having the closest homology with retroperitoneal fibromatosis herpesviruses (RFHV) and rhesus rhadinovirus (RRV) [110, 347, 363]. Among human herpesviruses, KSHV is most closely related to the Epstein-Barr virus (EBV), a ubiquitous lymphotropic virus which is associated causally with several human cancers, including nasopharyngeal carcinoma and certain types of lymphomas.

The overall size of the KSHV virion is 120–150 nm. Four structural proteins encoded by the *orf25*, *orf26*, *orf62*, and *orf65* encompass the icosahedral capsid shell of KSHV which has a diameter of ~130 nm. Three of these proteins share significant homology with capsid proteins in alpha and beta-herpesvirus subfamilies, whereas ORF65 differs from its structural counterparts in the other subfamilies [397]. Cryo-electron microscopy (Cryo-EM) and Cryo-EM tomography studies suggest that KSHV capsomers are hexamers and pentamers of the major capsid protein encoded by *orf25*, with the small capsid protein, encoded by *orf65*, binding around the tips of both hexons and pentons [108]. An amorphous, but highly organized, proteinaceous tegument, wrapped with a lipid bilayer envelope containing surface viral glycoproteins, surrounds the capsid. Several cellular

and viral proteins, including ORF6, ORF7, ORF11, ORF21, ORF33, ORF45, ORF50, ORF52, ORF63, ORF64, ORF75, and heat shock protein 70 and 90, are incorporated within the KSHV tegument [27, 432]. These proteins appear to facilitate virion trafficking to the nucleus, decrease innate antiviral immune responses, inhibit cell death, promote the establishment of latency, and support viral egress during the late phases of productive infection [362].

The KSHV genome is a double-stranded linear DNA having a similar organization to that of other rhadinoviruses. The genome contains a central 140.5-kbp long unique region (LUR) encoding 87 open reading frames (ORFs) [351]. ORFs are generally consecutively designated according to their relative location on the genome from left to right and were annotated according to the corresponding herpesvirus saimiri (HVS) genes with which KSHV shares a relatively high homology. The LUR contains clusters of genes that are conserved among all herpesviridae members, including genes encoding structural and replication proteins. Genes that are either limited to rhadinoviruses or are unique to KSHV lie between the conserved herpesvirus gene blocks. These genes are separately numbered and have a K prefix, while unique genes identified following the primary designation have decimal K numbers. KSHV is notable for molecular piracy and contains several genes with similarity to cellular genes, which were probably pirated from the host during evolution. These genes encode proteins that function as immune modulators, signal transducers, as well as transcriptional, cell cycle and cell fate controllers [206]. Generally, unlike their cellular homologs, the viral counterparts escape cellular regulatory pathways and hence have altered activity. Furthermore, the expression of these genes is regulated via viral promoters that do not necessarily operate in accordance with the cellular promoters of the homologous genes. The LUR also encodes genes for untranslated RNAs. These include the PAN/nut-1 transcript, a nuclear polyadenylated yet mostly untranslated mRNA, several microRNAs and long antisense transcripts [76]. Of note, a systematic genome-wide survey of viral transcriptional and translational activity by using mRNA-sequencing and ribosome profiling uncovered strategies to expand the virus coding repertoire including extensive alternative splicing, mRNA editing, and the use of alternative translation initiation codons as well as numerous upstream and small ORFs [13]. The LUR is flanked by a variable number of GC-rich (85.5 %) direct terminal repeat (TR) units of 801-bp length. Each TR unit contains the latent origin of replication and two binding sites for the KSHV latency-associated nuclear antigen 1 (LANA-1) [199]. The overall length of the KSHV genome is approximately 165-kbp, though this size is not fixed, predominantly due to length variations of the TR region.

KSHV has several distinct subtypes which are thought to have diverged at least 100,000 years ago and track human migration through Africa [191]. Based on variation in the leftmost *orfK1* (VIP) gene, the first subtypes to be identified were A, B, C, and D, followed by subtype E. Additional variations were identified at the right end of the genome, in *orf K15* (TMP). *K15* genes fall into two alternative allelic subtypes, referred to as prototype (P) and minor (M), which have diverged by 70 % at the amino acid level. Variability in *orfK15* exists primarily among subgroups A and C of *orfK1*. In addition, small variations have been identified in 10 internal genomic loci. It is believed that the principal *K1* subtypes arose during the migration of modern humans out of East Africa first into sub-Saharan Africa (variant B), then into south Asia, Australia, and the Pacific islands (variants D), and then through the Middle East into Europe and north Asia (variants A and C), with very little subsequent mixing. A later expansion introduced the virus to the Americas (variant E) and Northern Europe [437]. Accordingly, subtypes A and C predominate in Europe, the USA, China, Southern Siberia, and Australia, whereas subtype B predominates in Africa. Subtype D is rare and has been found in individuals of Polynesian and Australian aboriginal descent and in Japan and Oceania. Subtype E has been reported to be hyperendemic among Amerindian populations of the Brazilian and Ecuadorian Amazon regions. Several novel subtypes including subtype F, which was identified in an Ugandan Bantu tribe; subtype Z, which is present in Zambia; and subtype N which has been identified in South Africa have been recently described. Viral genome analysis can be applied to track the origin and modes of virus infection and has been used to establish inter- and intrafamilial transmission of KSHV and genotypic differences in virus isolated from different body compartments of a single patient. Yet, it is unclear whether certain genotypes are associated with increased rates of disease progression or different virulence [254, 265].

4.2 Life Cycle of KSHV

Humans are the only known natural hosts for KSHV. In vivo, KSHV has a relatively broad cell tropism as suggested by the detection of its DNA and transcripts in various cell types, including CD19+ peripheral blood B cells, circulating endothelial cells, KS spindle cells, CD45+/CD68+ monocytes, keratinocytes, and oropharynx and prostatic glandular epithelial cells [74].

Multiple envelope proteins participate in the binding and entry of KSHV into cells. Like many other viruses, the cell surface glycosaminoglycan, heparan sulfate, serves as an attachment mediator for KSHV and functions to promote the binding and concentration of virions. Interaction between the KSHV envelope glycoproteins gB, gpK8.1A, ORF4, gH, and gH-gL and heparan sulfate has been reported [3]. The major KSHV envelope protein is gB, encoded by *orf8*, which mediates viral binding and entry through a specific interaction with the integrins α3β1, αVβ3, and αVβ5. Interaction between the dimeric glycoprotein H (gH) and glycoprotein L (gL)

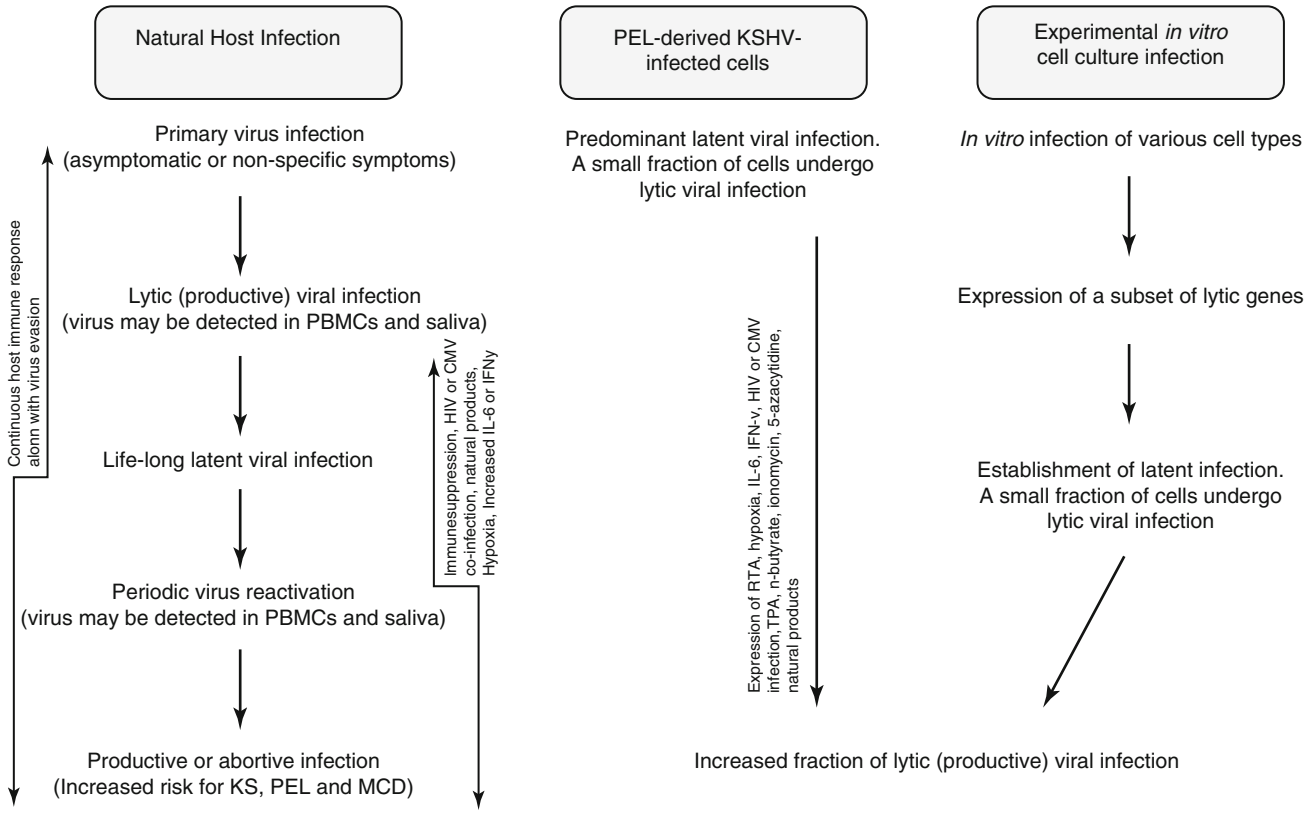

Fig. 39.1 Natural and in vitro KSHV infection. Primary host infection with KSHV involves a productive virus replication cycle, which precedes lifelong latent infection. Only a few viral proteins are expressed during KSHV latency, whereas extensive KSHV genome expression and viral DNA replication characterize the lytic phase of virus infection. Certain conditions, combined with reduced immune control, may lead to periodic virus reactivation, increasing the risk for disease onset. In PEL-derived cells and experimental cell culture infections, most cells undergo aberrant infection characterized by restricted expression of viral lytic proteins and virus latency in the majority of the infected cells. Spontaneous lytic virus reactivation in a small fraction of the cells may continuously take place while increased, but limited, virus reactivation is obtained following exposure to a variety of stimuli and treatment with chemical reagents

complex with the cellular ephrin receptor tyrosine kinase A2 (EphA2) also mediates entry and fusion of KSHV virions into different cell types including epithelial and endothelial [185]. The C-type lectin DC-SIGN/CD209 is another KSHV entry receptor used during infection of dendritic cells, macrophages, and activated B cells, yet its KSHV interacting glycoprotein(s) has not been defined [337]. Finally, the glutamate/cysteine exchange transporter protein xCT has been identified as a candidate entry receptor for KSHV [213]; however, the lack of evidence demonstrating a direct interaction between this protein and viral envelope glycoproteins suggests its involvement during other virus entry events. The interactions of KSHV glycoproteins with the cellular receptors initiate intracellular cascades that promote virus internalization by endocytosis or macropinocytosis, trafficking of viral capsids toward the nucleus, and later steps of infection.

Like all other members of the herpesvirus family, primary infection with KSHV results in the establishment of a lifelong infection. During lifetime infection, KSHV displays both latent and lytic (productive) phases, distinguished by their viral gene expression patterns (Fig. 39.1) [340, 357, 387, 428].

The latent phase is characterized by persistence of the viral genome as a highly ordered circular DNA (minichromosome/episome) which replicates synchronously with the host cell, expression of a limited subset of viral genes that ensure the maintenance of the viral genome while avoiding host recognition and promoting cell survival and proliferation, and lack of viral particle production. KSHV can establish latency in several cell types including CD19-positive B-lymphocytes, keratinocytes, and epithelial and endothelial cells. The host cell conditions and viral gene products required for avoiding lytic infection and initiating latency are currently unknown. Nevertheless, a limited number of viral lytic genes are transiently expressed prior to the establishment of latency and early after infection of endothelial and fibroblastic cell cultures, suggesting their ability to modify the intracellular environment to enable viral coexistence with the host cell during the initial time of infection and/or during the establishment of latency [223].

Extensive viral DNA replication and a well-controlled expression of a large array of viral genes characterize the lytic viral cycle, which may culminate in the assembly of

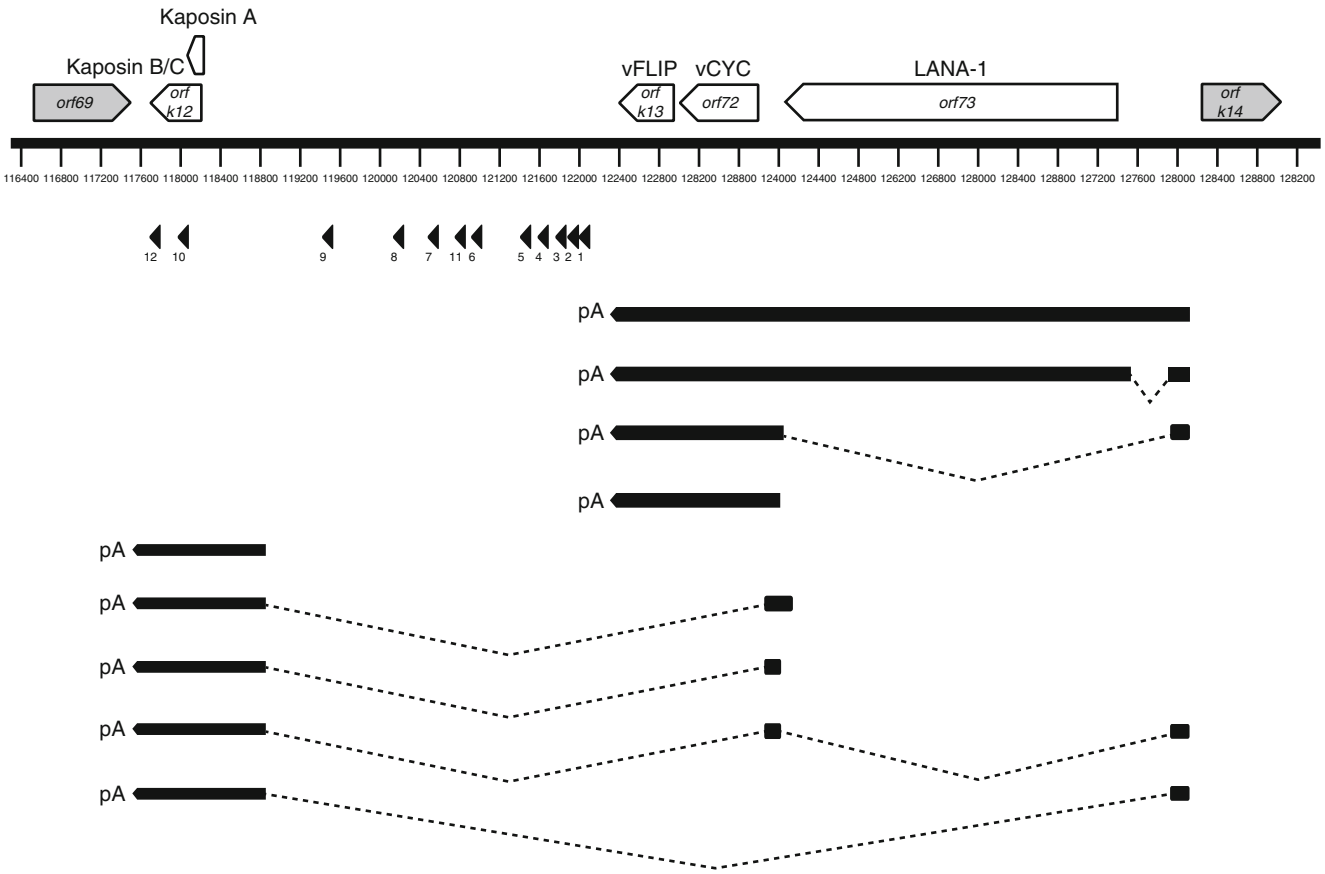

Fig. 39.2 Depiction of the major latent locus of the KSHV genome. The locus encodes four proteins, indicated by *open arrows*, as well as 12 pre-microRNAs (*black triangles*), and is flanked by lytic genes (*gray arrows*). Nucleotide positions are according to GenBank accession number AF148805.2. Latent transcripts are indicated by *black bars*, while introns are represented as *dashed lines* [53]

infectious mature virions that egress out of the cell while causing host cell death. A lytic cycle probably takes place during primary host infection, and it is crucial for virus dissemination within the host and between hosts. It is also likely to play an important role in preserving lifelong host infection and in the tumorigenesis induced by KSHV. Generally, the immediate-early lytic genes encode viral proteins that establish a permissive cellular environment and promote immune evasion; early genes encode proteins required for viral DNA replication and viral gene expression, whereas late genes include those encoding structural proteins necessary for assembly and maturation of the viral particles. Of note, certain viral genes can be expressed in a manner that does not follow the latent and lytic paradigm of the viral life cycle; hence, the expression of particular lytic viral genes can be inconsistent with their prescribed definition [77, 84, 300].

Latency is reversible, and certain conditions may periodically reactivate hidden latent virus to enter the lytic phase. Generally, reactivation occurs when the *orf50* viral gene promoter is activated, resulting in the expression of the replication and transcription activator (RTA) which acts as the principal switch for the viral lytic program [179]. Yet, an alternative apoptosis-initiated replication program, which produces virus with decreased infectivity and does not require RTA, may occur and have clinical significance [330]. Only some of the physiological factors involved in this switch are known, and the relationship between these factors is even less well understood.

4.3 Latent KSHV Genes

The major KSHV latent genes are clustered within a single genomic locus, located between *orfK12* and *orf73*, and are transcribed as polycistronic, differentially spliced, and alternatively polyadenylated mRNAs that are regulated through common promoters upstream to *orf73* and *orf72* [53, 114, 359]. These transcripts contain *orf73*, *orf72*, *orf71/K13*, and *Kaposin* and also serve as precursors for viral miRNAs. *orf K10.5*, encoding the viral interferon regulatory factor 3 (vIRF3), is exclusively transcribed in latently infected lymphoid cells to produce the latency-associated nuclear antigen 2 (LANA-2) [249, 346] (Fig. 39.2).

Below, we review some of the genes specifically expressed in the latent phase.

4.3.1 LANA-1

The major antigen expressed in all KSHV-infected cells is the latency-associated nuclear antigen 1 (LANA-1), encoded by *orf73* [336]. Upon infection, the expression of LANA-1 is promoted by the lytic immediate-early viral gene product, RTA, while LANA-1 subsequently represses the transcription of RTA and antagonizes its activity to promote the establishment and maintenance of latency [23, 229, 230, 400]. Thus, the tight control of LANA-1 and RTA expression and their mutual regulation appear to determine the fate of viral infection. LANA-1 is a multifunctional protein, which shares functional homology with EBNA1 encoded by EBV, and is required for the replication of the episomal viral DNA during cell division. It directly binds the latent origin of replication in the TR subunits and recruits multiple cellular proteins that act as components of the chromosomal replication machinery that also help in the efficient segregation of the viral episomes to daughter cells [22, 96, 199, 264, 313, 380]. In line, recombinant KSHV lacking LANA-1 fails to establish persistence and latency [421], while knockdown of LANA-1 reduces the copy number of viral episomes [164]. Similar to other oncoproteins encoded by DNA tumor viruses, LANA-1 interacts with various cellular and viral proteins and is capable of deregulating various cellular functions. LANA-1 binds and inactivates the retinoblastoma protein (pRB) [335], sequesters glycogen synthase kinase 3β (GSK-3β) in the nucleus and thereby stabilizes β-catenin [147], and inhibits transforming growth factor-β (TGFβ) signaling [111]. LANA-1 interferes with TP53-dependent transcriptional activation [145, 368] and forms a trimeric complex with TP53 and its E3 ubiquitin ligase HDM2 to promote cell survival [86, 355]. LANA-1 might impact angiogenesis, by targeting von Hippel Lindau (VHL) for degradation and by stabilizing hypoxia-inducible factor 1α [54]. LANA-1 alone does not transform cells in culture, but enhances cell activation events through the RAS/MAPK pathway and causes cells to become resistant to p16INK4-mediated cell cycle arrest [7, 335]. Furthermore, through interaction with the transcription factor Sp1, LANA-1 upregulates the transcription of telomerase reverse transcriptase (hTERT) and thus can extend the lifespan of cells [411]. When expressed in transgenic mice, LANA-1 causes increased B-cell hyperplasia and germinal center formation, as well as a B-cell lymphoma resembling MCD and plasmablastic lymphoma [133].

4.3.2 vCYC

vCYC is encoded by *orf72*, is expressed from a spliced latent transcript, and shares 54 % sequence similarity with cyclin D2 [53, 114, 359]. Like its cellular homolog, vCYC associates with specific cyclin-dependent kinases (CDKs), in particular CDK6, and phosphorylates pRB family members to overcome cell cycle arrest. Yet, the vCYC/CDK complex has more promiscuous substrate specificity, which is manifested by the phosphorylation of a broader range of cellular targets including histone H1, CDC6, Cdc25A, $p27^{KIP}$, $p21^{CIP}$, Bcl-2, human caldesmon (hCALD1), and nucleophosmin [79, 97, 163, 243, 306]. Unlike its cellular counterparts, vCYC/CDK imitates constitutively activated kinase complexes and is resistant to inhibition by the CDK inhibitors p16INK4, $p21^{CIP1}$, and $p27^{KIP1}$; likewise, it does not require CDK-activating kinase (CAK) for activation [212, 388]. In vitro expression of vCYC initiates S-phase but also results in cytokinesis defects and generation of polyploid cells that survive as an aneuploid population only in the absence of TP53 [401]. This phenomenon is probably related to the ability of vCYC to interact with nucleophosmin, which leads to the decreased formation of TP53-MDM2 complexes, and promotes TP53 accumulation [226]. In line with these findings, inactivation of the TP53 pathway has been shown to be strictly required for lymphomagenesis in transgenic mice expressing vCYC constitutively in the lymphoid compartment [402].

4.3.3 vFLIP

orf71/K13 is translated from an internal ribosome entry site located within the vCYC coding region and encodes vFLIP [174, 248], a homolog of the cellular FLICE (caspase 8)-inhibitory protein (FLIP) [394]. It blocks apoptotic pathways and protects cells from CD95/FAS-mediated apoptosis by inhibiting activation of caspase 3, caspase 8, and caspase 9 [116]. vFLIP also suppresses autophagy by preventing ATG3 from binding and processing LC3 [236]. Through interaction with TRAF2 and the inhibitor of κB kinase-γ (IKKγ), vFLIP constitutively activates nuclear factor-κB (NF-κB) signaling [137]. This in turn induces the expression of an array of cellular cytokines, chemokines, and antiapoptotic proteins implicated in the pathogenesis of KSHV. NF-κB prevents lytic reactivation, and hence, vFLIP may play a role in maintaining latency [102]. Furthermore, NF-κB activation by vFLIP appears to be responsible for the formation of spindle cells upon infection of endothelial cells [171]. vFLIP has been recently found to upregulate the host hsa-miR-146a which results in downregulation of CXCR4. Thus, it was suggested that vFLIP may promote premature release of KSHV-infected endothelial progenitors into the circulation [331]. vFLIP transgenic mice demonstrate an increased incidence of lymphoma, which develops after a long period of latency, while a reduced latent period is evident in mice co-expressing vFLIP and Myc [2]. Knockdown of vFLIP or inhibition of the NF-κB signaling in PEL cells induces apoptosis, further supporting the importance of this protein for lymphomagenesis [176].

4.3.4 Kaposin

Kaposin transcripts are abundantly expressed throughout all stages of KSHV infection. Increased levels of the Kaposin transcripts are evident during lytic virus reactivation as a result of the activation of its strong promoter [81]. A complex translational program involving initiation at non-AUG codons generates three protein isoforms of Kaposin – A, B, and C [352]. miRNA-K10, one of several microRNAs produced by KSHV, is derived from the middle of Kaposin A. Kaposin A has transforming potential in rodent fibroblasts and in athymic nude mice; however, this activity could be due to either its protein product, miRNA-K10, or both [294, 395]. Kaposin B activates the p38/MK2 signaling and blocks the degradation of particular short-lived transcripts that contain AU-rich elements (AREs) in their 3′-untranslated region [274]. As several cytokine mRNAs contain AREs, Kaposin B expression enhances production of proinflammatory cytokines creating a cellular environment more compatible with transformation. Stabilization of the mRNA encoding PROX1, a master regulator of lymphocytic endothelial cell (LEC) differentiation, is also modulated by Kaposin B [423]. Of note, editing of the Kaposin transcripts by the host RNA adenosine deaminase 1 controls certain functions of its products [150].

4.3.5 miRNAs

KSHV encodes 12 pre-miRNAs that produce 25 mature miRNAs through the cellular pathway of miRNA biogenesis [244, 324]. These miRNA precursors are clustered within the latency-associated locus in a uniform transcriptional orientation. Thus, all viral pre-miRNAs, produced through the usage of alternative polyadenylation signals, share common promoters with the above latent transcripts and hence are transcribed during latency [53]. These transcripts are also detected during lytic infection, and the expression levels of those controlled by the Kaposin promoter increase upon induction of lytic virus replication. RNA editing of pre-miR-K12-10 further increases the range of mRNA targets of this pre-miRNA. One of these miRNAs, miRNA-K12-11, is an ortholog of the human hsa-miRNA-155 which has the same seed sequence and is involved in immunity, hematopoiesis, and oncogenesis [167, 373]. Since miRNA-155 is known to function during late stages of B-cell differentiation, miRNA-K12-11 could contribute to the plasmablastic phenotype of PEL cells or may protect these cells from death. KSHV miRNAs are thought to be involved in various functions including control of lytic reactivation and viral latency maintenance, immune regulation, cell differentiation, and survival. The exact function of each of the viral miRNAs is just beginning to be revealed. Confirmed cellular targets include the NF-κB inhibitor, IκBα [238]; the stress-induced natural killer (NK) cell ligand, MICB [297]; the antiangiogenic molecule, Thrombospondin 1 [353]; and the cellular transcription factor, MAF, which promotes reprogramming of endothelial cells [188]. Furthermore, circulating viral miRNAs and intercellular transport of miRNAs via exocytosis has been demonstrated, suggesting possible modulation of the microenvironment through the transport of KSHV-encoded miRNAs to uninfected cells [88, 275].

4.3.6 LANA-2

LANA-2, also termed vIRF-3, is a viral homolog of interferon regulatory factors and is a latent protein that is constitutively expressed in PEL cells and KSHV-infected MCD cells, but not in KS lesions [249, 316, 346]. Experiments involving ectopic expression of LANA-2 revealed complex regulation of the interferon response by LANA-2. It activates the interferon promoter through its interaction with the cellular IRF-3 and IRF-7 proteins, but on the other hand may suppress interferon-mediated induction [249, 250]. Yet, LANA-2 inactivates TP53 and reduces the activation of the interferon-stimulated gene product, protein kinase R (PKR); thus, LANA-2 may function to evade the cellular antiviral response [131, 346]. Expression of LANA-2 appears to be required for the survival of PEL cells, as knockdown of LANA-2 in these cells results in reduced cell proliferation and increased caspase 3/7 activity [417].

4.4 KSHV Cultivation

One of the barriers to the study of KSHV has been the lack of an in vitro system that supports lytic virus replication and produces high viral titers. Cultures from KS lesions lose KSHV DNA and can only be maintained for a limited number of passages [28, 100, 299]. Therefore, they are of almost no use in the study of KSHV [385]. Several cell lines, retaining stable multiple copies of viral genome per cell, have been established from patients with PEL. Under standard growth conditions, PEL cells are predominantly latently infected by KSHV, while only a small, but steady, fraction expresses lytic viral proteins and produces new viral particles. An increased, but limited, lytic virus replication can be induced in these cells by various stimuli, including Rta overexpression [26, 300, 412], coinfection with another virus [399, 405], hypoxic conditions [101], interleukin 6 (IL-6) [80, 84, 375], gamma interferon [40, 80, 277], and chemical agents, such as 12-O-tetradecanoyl-phorbol-13-acetate (TPA) [288, 340], n-butyrate [280], ionomycin [436], 5-azacytidine [85], H_2O_2 [422], certain plant extracts [416], and cytotoxic chemotherapeutic agents [330]. The mechanisms and signal-transduction pathways that are activated by these manipulations are not fully understood; nevertheless, it appears that most involve the activation of the lytic replication and

transcription activator (RTA) which serves as an important trigger of the lytic phase [179]. By using PEL cells, KSHV genes have been classified as latent or lytic, and mechanisms that control the switch to lytic replication were initially revealed. These cells, however, do not support serial transfer of infection and therefore could not help elucidate mechanisms involving primary infection and establishment of latency. In addition, since PEL cells are of lymphoid origin, they cannot be used to study the consequence of viral infection on endothelial cells representing the predominant cells comprising KS lesions.

An in vitro model that allows transmission of KSHV in cell culture is valuable, since it would permit investigation of the early events of infection and the use of mutant recombinant viruses in which individual KSHV genes have been disrupted. Furthermore, such a system would allow the application of recombinant viruses containing marker genes, such as the green fluorescent protein (GFP), which can be used to track the infectious process. In vitro, KSHV has been shown to infect various human cells including primary endothelial cells of various differentiation states and lineages (vascular, lymphatic, endothelial, precursor cells), epithelial cells, fibroblasts, keratinocytes, monocytes, dendritic cells, and B cells. KSHV also infects monkey and baby hamster kidney cells, and mouse fibroblast cells [26], yet almost no virions can be generated in mouse cells [18]. These infections are nonproductive and in most cases, in a manner similar to PEL cells, result in the establishment of a latent infection that can be partially shifted into a lytic one. Infected endothelial cells develop an elongated spindle shape resembling that of KS spindle cells and acquire features of a transformed phenotype [89]. Infection of primary endothelial cells with KSHV induces the formation of spindle cells that express markers of the lymphatic endothelium. Interestingly, transcriptome analysis revealed that infection shifts the gene expression profile of vascular endothelial cells toward lymphatic endothelial cells (LEC) [63, 197, 410], suggesting that infection of blood or circulating endothelial cells by KSHV could drive them to differentiate into lymphatic endothelium. Yet, KSHV-infected primary endothelial cells cannot be maintained in long-term culture [89, 227]. By using LEC spheroids, it was shown that the viral proteins vFLIP and vGPCR cooperate in the activation of Notch pathway, leading to KSHV transcriptional reprogramming of LEC to mesenchymal cells via an endothelial-to-mesenchymal (EndMT) transition. Therefore, KSHV infection of LEC induces EndMT, leading to an increased invasiveness and survival of infected endothelial cells [83, 155]. Unlike infection with EBV, infection of primary B cells by KSHV does not produce immortalized cells in culture.

Several recombinant KSHV genomes have been generated and serve as important tools to investigate various aspects of this virus. rKSHV.219 has been isolated from the JSC-1 PEL cell line and expresses red fluorescent protein (RFP) from the strong KSHV early lytic promoter PAN, green fluorescent protein (GFP) from the EF-1α promoter, and a puromycin selection marker from the RSV promoter [403]. This recombinant virus allows detection of infected cells and discrimination between lytic and latently infected cells that can be accurately quantified by fluorescence microscopy or FACS analysis. The bacterial artificial chromosome (BAC) system serves as an alternative powerful tool for obtaining viral mutants that can be applied for examining the function of viral genes in the context of the full-length genome. BAC sequences, containing antibiotic resistance markers as well as a GFP marker, have been inserted into the entire KSHV genome without disruption of any known gene and thus allow the application of this powerful system for the study of KSHV [49, 429].

4.5 Animal Models

Host-virus interactions and virus pathogenesis are preferably investigated by using animal models that follow natural infection, including virus spread within the host, establishment of long-term infection, development of an immune response, and onset of disease. Given the close phylogenetic relationship between KSHV and RRV, experimental infections with RRV can serve as useful surrogate model for KSHV infection [115]. Indeed, coinfection of macaques with simian immunodeficiency virus and RRV produces in certain animals hypergammaglobulinemia, extranodal B-cell lymphoma, and proliferative mesenchymal disease, referred to as retroperitoneal or subcutaneous fibromatosis [311, 420]. Attempts to transmit KSHV into rhesus macaques failed to induce seroconversion or pathological alterations, suggesting that this primate host is unlikely to provide a useful model [341]. Persistent infection of KSHV has been established following experimental inoculation of common marmosets, a New World primate. Sustained serological responses, latent infection of PBMCs, and infrequent development of lesions with histopathological features similar to KS characterized this infection, which has been suggested to serve as an important animal model of KSHV infection [82].

Several tumor graft models of PEL and KS have been established. For example, injection of PEL cells to SCID/NOD mice leads to the development of ascites, diffuse infiltration of organs, and subcutaneous tumor formation that varies according to the injection route and PEL cells used [42, 326]. Injection of KSHV into normal human skin engrafted on SCID mice induces KS-like lesion formation containing spindle-shaped cells latently infected with KSHV coupled with substantial induction of angiogenesis [140]. Similarly, KSHV-infected normal mouse bone marrow endothelial cells form angiogenic KS-like tumors that express KS

signature genes in nude mice, with no evidence of productive KSHV replication. The lesions produced in this murine model require the presence of the viral genome [295]. Nevertheless, results obtained with graft models have limited application to the human disease, and spreading of KSHV infection to murine tissues has not been observed [42, 326]. However, intravenous injection of NOD/SCID mice with purified KSHV results in latent and lytic viral gene expression in murine spleens and long-term infection of specific leukocyte populations [317]. Taken together, current experimental systems employing murine models enable the study of immune responses and evaluation of potential therapies. Yet, most models do not take into account the dynamics of host-virus interactions that occur during natural infection and disease onset.

4.6 Transforming Capacity

The potential transforming capacity of KSHV has been shown in several systems. KSHV infection of endothelial cells leads to reduced growth factor dependence and to morphological alterations, higher survival, loss of contact inhibition, and growth factor and anchorage independence [89, 139, 290, 408]. Furthermore, transfection of a KSHV genome into murine endothelial progenitor cells generates KS-like lesions when transplanted into mice [295]. KSHV is required for continued survival of PEL cells in culture, and knockdown of several viral gene products, in particular that of vFLIP, LANA-1, and LANA-2, induces apoptotic death [164, 177, 417], supporting the requirement of the expression of viral genes for the survival of these cells.

Individual KSHV proteins exhibit transforming capacity in experimental systems and in transgenic mice. These include ORFK1/VIP, ORF74/vGPCR, ORFK9/vIRF-1, ORFK12/Kaposin A, and ORF73/LANA-1, which have been reported to have transforming capacity in classical transformation assays. Others, including ORF72/vCYC, ORF73/LANA-1, and KbZIP, have been shown to alter cell cycle control, while ORF71/vFLIP, ORFK2/vIL-6, ORF K7/IAP, and ORFK10.5/vIRF-3 were shown to increase cell survival. Other proteins that could promote cell transformation include the cellular homologs vBcl-2, vIRFs, and vCCLs. The expression of individual viral genes in transgenic animals provides information about the function of the viral proteins. However, these experiments involve expression of the gene out of the natural framework of the global viral effects; hence, these data must be carefully interpreted.

Based on the notion that productive virus infection culminates in cell death, most efforts to identify KSHV genes responsible for its tumorigenic potential focused primarily on the few viral genes that are expressed during latent infection. However, the KSHV latency program is not sufficient to initiate tumorigenesis, and many viral proteins that are expressed during the lytic phase harbor an oncogenic potential. Findings suggesting that oncogenesis is not directly linked to latency introduced the new concept in virus oncology of "paracrine tumorigenesis," in which viral latent and lytic proteins act in concert to promote the onset and the progression of the tumor. In fact, most KSHV-infected cells present in KS lesions and PEL tumors are latently infected, yet some of the cells express genes associated with lytic infection. These cells may release viruses to sustain infection but may also produce paracrine signaling molecules that modulate inflammatory and angiogenic processes within lesions allowing aberrant cell division and immune evasion.

Among the lytic genes, multiple lines of evidence were provided suggesting a role of the viral G protein-coupled receptor (vGPCR) in KSHV-induced transformation. Expression of vGPCR generates constitutive signaling and enhances proliferation [15, 20]. vGPCR can activate various key intracellular molecules, including mitogen-activated protein kinase, p38, c-Jun, and Akt, which in turn may control the expression and activity of numerous growth-promoting proteins. Because vGPCR induces the secretion of angiogenic growth factors, it was suggested to play a role both in direct autocrine and indirect paracrine maintenance of the transformed state. In line with the paracrine model, vGPCR generates KS-like lesions in transgenic mice, even when only expressed in a proportion of cells [196, 285]. Furthermore, xenografts of KSHV-transfected murine endothelial cell lines were found to require the signaling activities of vGPCR for tumorigenicity [169, 295].

The viral IL-6 homolog (vIL-6) is another cytokine that could act through a paracrine/autocrine mechanism. vIL-6 is expressed in vivo in a subpopulation of PEL cells and in a large number of KSHV-infected B cells in MCD lymphoid follicles [287, 316]. It induces proliferation, angiogenesis, and hematopoiesis and serves as an autocrine factor in PEL cell lines [12, 195]. Blocking the interaction of vIL-6 with the IL-6 receptor complex inhibits proliferation of PEL cells [222]. It also induces vascular endothelial growth factor (VEGF), which has been implicated in the pathogenesis of PEL and KS [11].

5 Descriptive Epidemiology

Before the AIDS epidemic, KS was viewed as a tumor affecting elderly individuals, predominantly men, of Mediterranean or Eastern European origin. This was based on crude rates from Israel [231] and population-based incidence data from the USA [202, 349]. A pronounced gradient of classic KS incidence from northern to southern Europe was reported [143, 172]. Similar variations were observed in Scandinavian

countries, with the lowest incidence rates in Denmark and the highest in Sweden; Italy exhibits similar gradients, with an increasing incidence from north to south and higher rates in towns along the Po Valley [157, 192]. In sub-Saharan Africa, incidence rates of endemic KS showed great variability between different areas and different native populations prior to the AIDS epidemic [305]. Immune suppression is associated with higher rates of disease, as 500- to 1,000-fold higher incidence rates of KS have been recorded in immunosuppressed renal transplant patients versus those seen in control populations [189, 258]. With the advent of the AIDS epidemic, KS begun to appear in young MSM; it was found to be 20,000 times more common in HIV-1-infected individuals than in the general population and 300 times more frequent than in other immunosuppressed groups, such as renal transplant recipients [30]. KS incidence was found to be higher among HIV-1-infected young homosexual or bisexual men than among other HIV-1 transmission groups, suggesting an infectious etiology of the tumor, and that the putative infectious agent was transmitted through sexual contact [30]. In several African countries, KS incidence in children and adults, mainly women, increased concomitantly with HIV-1 spread, and KS was found to represent up to 40 % of all adult malignancies and 10 % of all childhood cancers in certain regions of sub-Saharan Africa [406]. In this region, 22,000 KS cases in males and 12,000 cases in females were diagnosed in 2008, and the corresponding estimated age-standardized incidence rates were 8.1 and 3.6 per 100,000, respectively. The majority of these cases were observed in countries of Eastern Africa, including Ethiopia, Rwanda, Uganda, Zambia, and Zimbabwe [207]. The main epidemiological and clinical features of the four KS variants (classic, endemic, iatrogenic, and epidemic) are summarized in Table 39.1, while Fig. 39.3 illustrates worldwide incidence rates of KS and seroprevalence rates of KSHV.

5.1 Classic Kaposi's Sarcoma

Classic KS is a rare disease diagnosed primarily in elderly men (>50 years, with a 3:1 male:female gender ratio) of Mediterranean/Southern European, with relatively high incidence rates in Italy, Greece, Turkey, and Israel [143, 203]. Incidence rates are 10 times higher in these countries than in other European countries and in the USA [33, 172]. The disease is typically characterized by single or multiple pigmented skin lesions that primarily appear in the lower limbs and may spread to the arms, face, and torso over a period of years or decades. This disorder is mostly indolent, not life threatening, and only very rarely involves visceral mucosa. In Mediterranean countries KSHV seroprevalence increases with age, but KS remains a rare disease. For instance, in Italy only 0.03 and 0.01–0.02 % of KSHV-infected men and women above age 50, respectively, develop KS annually, indicating that cofactors influence the natural history of infection and contribute to tumor onset. Data on incidence rates over age 50 prior to the AIDS epidemic indicated that KS was more common in Italy (1.05/100,000 men, 0.27/100,000 women), especially in Southern Italy (Sicily and Sardinia) (3/100,000 men, 0.54/100,00 women), than in England and Wales (0.14/100,000 men and women), the USA (0.34/100,000 men, 0.08/100,000 for women), and Sweden (0.4/100,000 men, 0.31/100,000 women) [157, 172, 349]. The incidence rates of classic KS in two southern regions of Italy and in Israel are the highest registered in developed countries (2.07/100,000 men, 0.75/100,000 women) [181]. A higher risk of classic KS was reported for Israeli Jewish residents born in Iraq and North African and Eastern European countries as compared with Jewish immigrants from Western European countries and the USA and compared with the Israeli born population [181, 201]. Indeed, the Maghreb region of Northwest Africa, including

Fig. 39.3 Global incidence of Kaposi's sarcoma (KS) and seroprevalence of KSHV infection. (**a**) Age-standardized incidence rates (ASR) of KS (in males per 100,000) are reported. Incidences in Africa were taken from the Globocan database 2008 and [207]. The majority of KS cases diagnosed in 2008 occurred in the countries of Eastern Africa (including Uganda, Zambia, and Zimbabwe) with a corresponding ASR of 14.9. The countries of Southern Africa (including Botswana, Namibia, and South Africa) had the highest rates (11.5 in males per 100,000) after Eastern Africa. In sub-Saharan Africa, ASR was 8.1, followed by Middle Africa (4.1) and Western Africa (1.9). ASR were obtained also from the International Agency for Research on Cancer (Cancer Incidence in Five Continents). In the USA, the highest incidences were measured among Hispanics (6.6–13), non-Hispanic Caucasians (8.4–16.7), and African-Americans (8–14.5) in Los Angeles and San Francisco Bay areas (1993–1997). Slightly lower rates were observed in Georgia, New Orleans, New York, and Washington, whereas incidence rates were generally low in other US areas, mainly mirroring classic KS incidence in the general population. Classic KS was found to be frequent also in Israel (2.8), in Southern Italy (3), in the Xinjiang region of China, in Colombia, in the coastal region of Peru (>20), and in New South Wales in Australia (2.5). Low rates were reported all over Canada, except for British Columbia (2) and Quebec (2.1) (years 1993–1997). (**b**) Seroprevalence rates of KSHV infection among the general population, mainly blood donors, are reported as the percentage of seropositive subjects. KSHV infection is highly prevalent among Amerindians living in the Amazon regions, in countries of the Eastern Africa, in Peru, and among some Melanesian populations. KSHV seroprevalence is intermediate in the Mediterranean area, in some Middle Eastern countries, in other parts of South America, and in some ethnic groups and regions of China, with the highest rates reported in the Xinjiang region. KSHV is less prevalent in Northern Europe, North America, and most of Asia

Morocco, Tunisia, and Algeria, is a geographical area where KS is frequent [291].

Classic KS is a prevalent pathology also in South America, and three large studies were done in Argentina, Colombia, and Peru. Reports from Colombia and Peru observed KS cases mainly in indigenous populations (Quechuas) and in mestizos, while cases from Argentina presented more frequently in European descendents. An overall incidence of 2.54/10,000 attended patients (1946–2004) was reported in a study conducted in Peru, and some clustering was observed in the coastal region [283, 284]. An interesting clinical feature observed among certain classic KS cases from Colombia and Peru is an unusual presentation with confluent exophytic, nonsymmetrical nodules or eroded or ulcerated lesions. Low socioeconomic status and delayed consultation very likely represent the main cause of the numerous and extensive lesions in these patients. A few cases of classic KS were also reported in the Inuit population of Northern Quebec [21, 348], suggesting that KSHV may circulate in this population.

5.2 Endemic Kaposi's Sarcoma

Endemic or African KS is highly prevalent in sub-Saharan Africa. This form affects mainly young adults (median age 35 years, 2:1 male to female gender ratio) and children (median age 3 years), in contrast to the other three epidemiological forms [406]. Endemic KS has complex features and wide heterogeneity in terms of clinical presentation and affected population. At least four sub-variants have been described; one has a relatively indolent clinical course, with localized lesions similar to that of classic KS, but presenting at a younger age. The other three forms are more aggressive and quite similar to epidemic KS in their clinical progression; one has a prevalent disseminated cutaneous localization and may also affect prepubescent children, the other is characterized by extended mucocutaneous and visceral involvement, while the last one presents mainly in children with a median age of 3 years and shows a rapid diffusion to lymph nodes and internal organs, frequently without cutaneous involvement. The onset of AIDS led to an increase in prevalence rates of KS in both adults and pediatric populations in African countries where KS was endemic and complicated the study of the epidemiological and clinical features of endemic KS. However, the wide variety of clinical presentations in African KS was also present prior to the spread of HIV-1 [263]. Localized nodular KS was the most common presentation before the AIDS epidemic, in addition to a locally invasive form, which had a worse prognosis. KS with a disseminated mucocutaneous involvement, frequently associated with lymphadenopathy, and/or visceral diffusion was rare before AIDS, though it is very common at present. Visceral KS is highly aggressive and consistently fatal whether it occurs in association with HIV-1 infection or not. The lymphadenopathic type was the most common presentation in children, but rare in adults. Starting from the AIDS epidemic, this presentation became common in young adults, mainly women, but continues to have a rapidly fatal course in children whether associated with HIV infection or not.

During the AIDS epidemic, many of the epidemiological features of African KS changed. KS presented in adulthood at a younger age (30–39 years of age in men, 20–29 years of age in women), and the rising incidence of KS in women led to a decline of the gender ratio from 10:1 in the 1970s to 2:1 in the mid-1990s. Women from South Africa experienced an increase in KS incidence, changing the gender ratio from 7:1 in 1998 to 2:1 in 1996 [372, 433]. In Uganda, prior to the spread of HIV-1 (1954–1970), KS represented 6.5 % of all male cancers and no KS cases in women were registered. After the beginning of the AIDS epidemic (period analyzed: 1989–1991), the prevalence of KS among all cancer patients was 48.6 % in men and 17.9 % in women, and the incidence increased from 2.6 to 30.1/100,000 in men and from 0 to 11/100,000 in women [406]. In parallel with HIV-1 spread, the incidence of pediatric KS rose up to 40 % in Uganda, and an increase in oral and facial-cutaneous KS was reported among prepubescent children in central African countries. In Zambia, analysis of the clinical course of KS before puberty (age 3–15 years) revealed a more frequent primary lymphadenopathy in younger children [215]. In African countries where AIDS did not dramatically increase KS incidence, clinical features of this tumor were nevertheless profoundly changed. In pediatric populations of Tanzania, KS incidence rates and gender ratio (about 5:1) did not vary, but the disease acquired a more aggressive clinical course and a change in the anatomical distribution of KS lesions, reflecting an association with HIV-1 infection [6].

5.3 Iatrogenic Kaposi's Sarcoma

Iatrogenic or posttransplant KS occurs in patients undergoing immunosuppressive therapy mainly after organ transplantation but also in association with other pathological conditions and autoimmune disorders. This variant presents two peculiar features. First, the course of these KS lesions can be modulated, as documented by KS regression after withdrawal, reduction, or replacement of immunosuppressive agents [322], thus highlighting the significance of immunosuppression as a risk factor for KS development. Second, the presentation and clinical course is variable. Patients may show localized or disseminated skin lesions, and visceral involvement may be frequent in the more

aggressive cases, with a clinical course ranging from a chronic to a rapidly progressing disease.

Incidence of this form follows the ethnogeographical differences characteristic of KSHV seroprevalence and also depends on the type of organ received. Posttransplant KS affects 0.4 % of posttransplant recipients in the USA and Europe, but about 4–5 % of patients in Saudi Arabia, where KS represents 87.5 % of all posttransplant neoplasia [134, 321, 332]. This form is more frequent in renal recipients compared to other solid-organ or bone marrow recipients. Among kidney transplant recipients, reported KS incidences are 0.2–0.6 % in Spain, Germany, the USA, and Canada; 0.4–3.3 % in France, Italy, Israel, and Turkey; and 4–5.3 % in South Africa and Saudi Arabia [258]. An Italian study measured a seroconversion rate that was higher among liver recipients (21.4 %) compared to renal recipients (8.6 %), but the renal recipients showed a higher risk of developing KS [9]. The degree of immunosuppression represents a critical factor for KS occurrence in posttransplant patients. In fact, regimens including cyclosporine A were found to increase the risk of KS [320]. Regression of posttransplant KS was achieved by substituting the immunosuppressive regimen including mycophenolate mofetil and cyclosporin A with sirolimus [98]. Sirolimus was also shown to promote the development of KSHV-specific T-cell immunity and the recovery of a functional T-cell repertoire, able to contribute to the regression of posttransplant KS [25].

In countries with intermediate and high seroprevalence, the majority of posttransplant KS cases develop in transplant patients with a preexisting KSHV infection, indicating that KS occurrence is mainly linked to KSHV reactivation due to the immunosuppressive regimen. A French study showed that 8 % of renal transplant recipients were seropositive before transplantation, and 28 % of them developed KS within 3 years after surgery, whereas none of the patients seronegative before transplantation developed KS [141]. In areas with lower seroprevalence, posttransplant KS is primarily due to primary infection through the donated organ [339].

5.4 Epidemic Kaposi's Sarcoma

Epidemic or AIDS-associated KS develops in HIV-1-infected individuals. According to the Centers for Disease Control and Prevention (CDC) guidelines, KS is considered an AIDS-defining disorder. Although KS develops in all groups at risk for HIV-1 infection, it is more common among men who have sex with men (MSM) and bisexual men than among transfusion recipients, women and children, hemophiliacs, and heterosexual IDUs [30]. Similar to classic KS, KSHV seroprevalence reflects AIDS-KS incidence in the different groups at risk for HIV-1 infection [365, 413]. The clinical course of AIDS-KS is characterized by a wide spectrum of disease manifestations ranging from the incidental finding of asymptomatic skin nodules to explosive growth of ulcerative plaques associated with edema and visceral involvement, resulting in significant morbidity and mortality [242].

While the frequency of AIDS cases presenting with KS was 40 % in the early 1980s in MSM, this figure decreased subsequently to 13–25 %, due to the introduction of initial antiretroviral therapies (ART) and safer sexual practices that reduced new HIV-1 infections [30, 260]. KSHV seroprevalence was 24.6 % in MSM in San Francisco in 1978, while HIV-1 infection was present in only about 2 %, indicating that KSHV infection was present in the homosexual population prior to the AIDS epidemic [312]. After the introduction of HAART, the incidence and severity of KS declined consistently [148, 235], mainly in association with improved immune function directly related to this therapy. A large study including HIV-1-infected subjects from North America, Europe, and Australia showed a decrease in incidence rates of KS from 15.2 in 1992 to 1996, to 4.9 in 1997 through 1999 [60]. KS incidence rates in San Francisco over a period of 25 years were 0.5/100,000/year in 1973, prior to the AIDS epidemic, increased to 31–33.3/100,000/year from 1987 to 1991, and then declined to 2.8/100,000 in 1998, in the post-HAART era [124].

Several studies have shown a direct correlation between the course of HIV-1 infection and the onset and progression of KS. Untreated patients presenting with progressive AIDS-KS typically exhibit low CD4+ T-lymphocyte counts (below 150–200 cells/ul) and high HIV-1 loads (above 10,000 RNA copies/ml). In the majority of patients, time to KS regression after the initiation of HAART depends upon tumor burden at baseline. Complete or partial response may occur within 6–24 months and is frequently accompanied by a significant increase in CD4+ T-lymphocyte count and suppression of HIV-1 viremia, two markers of good clinical efficacy of HAART, as well as a decline in systemic KSHV load. HAART-induced reconstitution of immune function may drive KS regression [70, 235, 383]. During 52 weeks of HAART, some AIDS-KS patients showed a significant decrease in HIV-1 and KSHV loads, which was associated with significant increases in CD4+ T-lymphocyte counts, and restored anti-KSHV cytotoxic activity [418]. Moreover, HAART-driven immune restoration was also associated with improved NK-cell-mediated immunity directed against KSHV-latently infected cells [371]. It was proposed that HAART-induced KS remission may be also mediated by direct antiangiogenic and antitumor effects on KS neoplastic cells exerted by some protease inhibitors (PI). Systemic treatment with PI, mainly saquinavir and indinavir, was shown to control the development and to induce regression of angioproliferative KS-like lesions in murine models [396].

KS regression and HIV suppression may also be achieved using non-PI-based HAART regimens [261]. Moreover, persistent or de novo KS was also reported in clusters of AIDS patients with high CD4+ T-lymphocyte counts and low or undetectable HIV-1 viremia [224, 266], indicating that some patients may experience effective HIV-1 suppression and restoration of immune function not accompanied by KS remission. Other factors possibly associated with the lack of partial or complete response of KS, such as age, duration of HIV-1 infection, tumor burden, and KSHV pattern of expression, need to be analyzed in-depth.

In a subset of HIV-1-infected subjects, KS may initially worsen following the initiation of HAART, as a result of an inappropriate immune reconstitution and a pathological inflammatory response to either previously treated or subclinical infections. This process is known as immune reconstitution inflammatory syndrome (IRIS). The risk of IRIS was found to be mainly associated with low CD4+ T-lymphocytes at baseline [293], although other factors, such as detectable plasma KSHV DNA, were proposed to predict IRIS-associated KS [241].

5.5 Epidemiology of KSHV Infection

Unlike most other human herpesviruses, the infection with KSHV is not ubiquitous. Prevalence of KSHV infection in the general population mainly reflects the local incidence of classic or endemic KS and depends on the geographical area and analyzed population. Factors that influence the epidemiology of KSHV infection in a given population mirror the predominant modalities of KSHV transmission and the prevalence of risk factors for KS [358]. Older age, Mediterranean or Eastern European origin, HIV-1 infection, homosexual, and high-risk sexual behaviors are predictors of higher seroprevalence. A higher risk for KSHV infection is associated with having a seropositive mother or siblings in endemic countries [183, 327]. Seroprevalence is almost equally distributed between men and women, and a gradual increase with increasing age in both endemic and non-endemic populations has been frequently observed [55, 240]. However, the age-related increase in seroprevalence begins during childhood in endemic countries, and after puberty in countries with lower seroprevalence [240, 267], indicating a difference in the prevalent modality of transmission among these populations.

Globally, KSHV infection is highly prevalent in sub-Saharan Africa and among some Amerindian and Melanesian populations and diffuse in the Mediterranean area, in some Middle Eastern countries, and in parts of South America. KSHV is less prevalent in Northern Europe, North America, and most of Asia. Variation of KSHV seropositivity across small-area regions within countries also exists, and the KSHV-KS geographical correlation does not apply everywhere. In fact, high KSHV seroprevalence matched with relatively low KS incidence has been reported in Gambia [14], in some Amerindian populations [34], and among Ethiopian immigrants to Israel [170]. This incongruence may reflect biases, but it could also indicate the presence of yet unidentified cofactors that protect these populations from KS development.

Seroprevalence rates in the general population, mainly based on blood donor surveys, but also on other specific categories, are reported below and illustrated in Fig. 39.3. It has to be kept in mind that data are taken from serosurveys that may use different serological assays and criteria to estimate the overall seroprevalence in the analyzed populations.

The highest KSHV seroprevalence rates worldwide have been reported in Native American populations (up to 93 % in adults) in South America, mainly among Amerindians living in the Amazon regions from Brazil and Ecuador (77 %) and in the transitional area between the Amazon forest and the savannah of central Brazil (50–83 %). KS incidence in these populations appears to be low, although difficulties in diagnosis and records of diseases in subjects of remote villages may underestimate the actual prevalence of KSHV-related malignancies [34, 105, 216, 284, 302]. Amerindians from Bolivia, Paraguay, and French Guiana showed an intermediate seroprevalence (18–45 %), and those from Southern Brazil the lowest rates (0–14 %). Amerindian and non-Amerindian populations living in the same geographical area showed diverse KSHV seroprevalences, suggesting differences in the prevalent transmission routes between the two populations. In the Amazon region, KSHV seroprevalence was 65 % in children and increased to 93 % in adults (≥35 years) among Mapuera Amerindians, whereas it was 10 % in children and 50 % in adults among Mapuera non-Amerindians [302].

KSHV antibodies were found in lower proportions of the general population, mainly blood donors, from Chile (3 %), Jamaica (3.6 %), Argentina (4–8 %), Southeast Brazil (3–7 %), Costa Rica (10 %), Honduras (11.3 %), French Guiana (11.8 %), Colombia (13 %), and Cuba (17 %) [67, 104, 135, 136, 284, 323, 376]. In contrast, a seroprevalence of 56 % was found in Peruvian blood donors [283]. A large multicenter survey of Brazilian blood donors from three state capitals, representing a population composed of descendents of three ethnic groups (Caucasian, African, and Indigenous populations), reported an overall seroprevalence of 25 % [301].

KSHV seroprevalence is much lower in North America. Large studies in the USA showed a seroprevalence of 0.5–7 % among the general population [130, 153, 219, 319]. The prevalence in Canada has been documented by studies on transplant recipients, showing 0–2 % seropositivity before transplantation [364]. Cases of classic KS reported in Inuit

people living in northern Quebec may indicate that KSHV is more diffuse in this population [348], although seroprevalence data are not yet available.

In Africa, KSHV prevalence is generally high, but is unevenly distributed. Overall, adults living in sub-Saharan countries show infection rates that reflect the cumulative incidence of endemic KS [93, 106]. Uniform criteria to estimate seroprevalence were adopted in a reanalysis of five seroepidemiological studies conducted in sub-Saharan Africa. Among adults (>20 years of age), seropositivity was 23.5 % in Nigeria, 40.2 % in Kampala and Uganda, 45.4 % in Tanzania, and reached 70.6 % in the rural West Nile, in Uganda. Among children, seroprevalence rates ranged from 18.1 % in Kampala to 33.8 % in Tanzania and increased steeply with age in all populations [325]. Consistently, other studies showed that about 55 % of the general population in Uganda had KSHV antibodies [38, 367], and higher rates were reported in rural territories [38, 52, 118]. Seroprevalence estimates in Tanzania ranged from 30 to 89 %, depending on the studied population and the geographical area, with a mean prevalence of about 50 % in blood donors [118, 269, 278]. KSHV seroprevalence was reported to be 43 % in Kenya [19], 54–67 % in Malawi [109], 58 % in Zambia [308], and 82 % in the Democratic Republic of Congo [128].

In West Africa, KSHV seropositivity was found to be 60 % in the adult population of Cameroon [328, 344] and 32.3 % in Ghana [304]. Early epidemiological surveys found a higher seroprevalence (75 %) in Gambia [14], not matched by the low KS incidence in this African region, whereas a seroprevalence of 14.3 % was reported among pregnant women in Senegal [156]. In Northern Africa, seroprevalence estimates are available for Tunisia (14 % in blood donors) [187] and Egypt (24–42 %) [272, 366]. In North-Eastern Africa, seroprevalence in Eritrea was found to be 5–8 % among women and 26 % among members of the Rashaida tribe [125]. A seroprevalence of 37 % was reported among HIV-1-uninfected pregnant women in Ethiopia [239], a rate similar to that found among Ethiopian Jewish immigrant to Israel [170].

In Southern Africa, a seroprevalence of 21.4 % was found in Mozambique among individuals attending public health centers [68], and a similar rate (20.3 %) was reported in Zimbabwe [118]. Seroprevalence rates ranging from 17.6 to 30 % were measured in South Africa [118, 253], whereas higher estimates (87 % in Sans, an indigenous group, and 76 % in Bantus) were found in Botswana [128].

A marked variation of KSHV seroprevalence/KS incidence is also present in Europe. In general, KSHV infection is diffuse in Mediterranean countries, such as Italy, and lower in Northern Europe. Italy showed an increasing gradient of KSHV prevalence from north (7–13 %) to south (22–35 %), as well as some hot spots in the Po Valley (16–27 %), mirroring classic KS incidence at the microgeographical level [55, 69, 354, 390, 414]. KSHV seroprevalence similar to that reported among blood donors from Central/Southern Italy was found in subjects from Albania (20–29 %) and from the Kosovo region of former Yugoslavia (18 %) [87, 168].

Lower KSHV seroprevalence rates were reported in the UK (5 %) [370], France (1–4 %) [121, 256], Germany (3 %) [292], Switzerland (5 %) [338], and in a cohort of IDUs in the Netherlands (1–3 %) [342]. Slightly higher rates were measured in Spain (4–8 %) [104, 149] and Greece (6–14 %) [370, 425].

The prevalence of KSHV in Nordic countries showed pronounced variation among and within countries, again reflecting classic KS incidence [192], as KSHV seroprevalence was found to be 16 % in Northern Sweden [393], but only about 4 % in young adults attending an STD clinic before the AIDS epidemic in Denmark [193].

A low seroprevalence was found in the general population of Russia (0–5 %) [180], Czech Republic (0.3–2.4 %) [386], and Hungary (2 %) [209], whereas higher rates (25 %) were reported in an adult population of Southern Siberia [65].

Prevalence in Asia varies from low to moderately high. A systemic review and meta-analysis based on the available literature showed that KSHV seroprevalence in China is 11.3 % in the general population, but it varies in different regions, being higher (18–23 %) in Xinjiang, an area in which incidence rates of classic KS are high [113, 427]. KSHV seroprevalence (0.2–1.4 %) and KS incidence were found to be low among the general population in Japan [146]. Of note, a higher KSHV prevalence has been reported in patients with adult T-cell leukemia/lymphoma, suggesting an increased risk of KS in these patients [282]. A large study reported a prevalence of 5 % for the Republic of Korea, 8–10 % for Thailand, and 11–16 % for Vietnam [104]. In India, a prevalence of 4 % has been reported among healthy individuals [1].

In Middle Eastern countries, similar seroprevalence rates were reported in Saudi Arabia (2 % in healthy controls, 18 % in renal transplant recipients) [4] and in Iran (2 % in blood donors, 17 % in hemodialysis patients, 25 % in renal transplant patients) [205]. In Israel, KSHV seroprevalence among the different Jewish groups was found to correlate with the incidence of KS. KSHV seroprevalence rates ranged from 3 to 10 % among Israeli Jewish populations, and higher figures were reported among Ethiopian immigrants (26–39 %) [99, 170, 183, 204].

Some indigenous Melanesian adult populations were shown to harbor KSHV infection. Seropositivity rates ranged from 21 % in Port Moresby to 30 % in rural Bensbach in Papua New Guinea [345], and native Melanesians from New Caledonia, located in the southwest Pacific, and Vanikoro island, belonging to the Solomon Archipelago, showed an overall seroprevalence of about 24 % [66]. A seroprevalence of 11.2 % was reported among HIV-negative homosexuals from Sidney, Australia [173].

6 Mechanisms and Routes of Transmission

Modalities of circulation of KSHV infection in the general population depend on the geographical area and on the relative seroprevalence in the analyzed group. KSHV is transmitted mainly via nonsexual routes during childhood in areas with intermediate and high seroprevalence and primarily via sexual contact during adulthood in countries with low seroprevalence. Saliva is an important reservoir of infectious virus [404]. This biological fluid has a highly infectious potential, as viral particles isolated from saliva can establish productive infection in B cells regardless of KSHV load [154]. Therefore, saliva represents the foremost vehicle of KSHV in the context of both sexual and nonsexual routes. Oral transmission of KSHV may also involve the IgMλ subset of tonsillar B-lymphocytes, which, once latently infected, would increase their proliferation rate and differentiate toward a plasmablast phenotype highly reminiscent of MCD [190].

6.1 Horizontal Transmission

In areas with intermediate and high seroprevalence, horizontal, primarily intrafamilial transmission is the main modality of KSHV spread. Infection is acquired early in childhood, from members in and outside households, and infection rates increase with age [51, 55, 159, 183, 267, 269, 327]. A high KSHV load in maternal saliva was associated with transmission to the child [107, 269, 391]. Other risk factors for infection before puberty include HIV infection [253, 281] and environmental factors [271]. It has been also postulated that horizontal transmission may take place through exposure to food premasticated by the mother [269, 327], although a more recent population-based study in a rural community in Uganda failed to prove this hypothesis [52]. The habitual use of maternal saliva as first-aid medication of insect bites has also been suggested to play a role in promoting mother-to-child transmission of KSHV in endemic countries [91].

6.2 Vertical Transmission

Vertical mother-to-child transmission, not involving saliva exchanges, may also occur in areas with intermediate and high KSHV seroprevalence. Initial studies on vertical transmission showed that KSHV seroreactivity in newborns is mainly due to transplacental passage of maternal antibodies [57, 159]. However, rare cases of in utero or intrapartum KSHV transmission were documented in newborns by the detection of KSHV DNA in a newborn's blood at birth [46, 245, 255, 273] and by the detection in an infant of primary infection with the mother's *orfK1* subtype [245]. African women also showed higher KSHV detection rates in cervicovaginal secretions compared to women from non-endemic or subendemic areas [56, 228, 415], indicating that KSHV load in the female genital tract might influence vertical transmission. Like other herpesviruses, KSHV may be reactivated during pregnancy, as demonstrated in HIV-1-infected women [245]. KSHV can also infect trophoblasts and placental endothelial cells in vitro and in vivo, providing evidence that transplacental transmission may, though rarely, occur in endemic countries [112].

6.3 Transmission Through Sexual Contact

In areas where KS is sporadic, KSHV infection is acquired in adulthood and is mainly associated with sexual activity [39, 260]. KSHV infection is common among MSM, and KSHV seroprevalence is higher in those infected by HIV-1. Epidemiological surveys indicated that the risk of KSHV acquisition in MSM is associated with the number of lifetime sexual partners, a history of other sexually transmitted diseases, HIV-1 infection, and specific sex practices [39, 165, 173, 218, 260, 374]. Prevalence of KSHV infection and incidence of AIDS-KS are higher among HIV-1-positive MSM or bisexual men compared with other HIV-1 transmission groups, and this finding suggests that KSHV could be a sexually transmitted agent. Several studies validated the association of KSHV seropositivity with the number of sexual partners, thus confirming the relevance of sexual transmission among HIV-infected MSM [259, 262].

In endemic countries, KSHV seroprevalence increases with age among adults as well, suggesting that transmission is ongoing in adulthood, very likely including both sexual and nonsexual routes [19, 51, 234, 367].

KSHV loads in cervicovaginal, seminal, and prostatic secretions are much lower than in saliva [56, 103, 318, 415], and the infectious potential of these biological fluids has not been fully elucidated, to date. It is conceivable that saliva also plays a predominant role in KSHV dissemination in the setting of sexual transmission [259, 262].

6.4 Parenteral Transmission

Parenteral transmission of KSHV appears to be highly inefficient [75, 127, 162, 310]. Some reports indicated prolonged use of injecting drugs, with extensive needle sharing, as a risk factor for KSHV infection [17, 61, 138, 166].

Infection through the administration of blood or blood products is also infrequent. Several variables, including lack of viremia in healthy donors and pretreatment and storage of blood, may limit KSHV spread through this route [126]. Nevertheless, some studies indicated increased risk and

KSHV transmission by blood transfusions in endemic countries [117, 194, 268].

6.5 Transmission Through Organ Donation

Posttransplant KS has been reported in solid-organ transplant patients, mainly recipients of kidney grafts. In endemic countries, posttransplant KS is primarily due to reactivation of a preexisting KSHV infection in the recipient. However, reported cases of KSHV seroconversion in pediatric and adult recipients after organ transplantation indicate that KSHV transmission through organ donation may also occur [92, 251, 252, 315, 360]. Furthermore, it was shown that KSHV-infected neoplastic cells in the posttransplant KS lesions from some renal transplant recipients may harbor either genetic or antigenic markers of their matched donors, suggesting that KS progenitor cells may be transmitted through solid grafts [24]. It has suggested that transfusions during surgery could also play a role in reported cases of primary infections after organ transplantation in countries with intermediate and high KSHV seroprevalence.

7 Pathogenesis

7.1 Primary Infection with KSHV

The characteristics of primary or acute infection with KSHV have been incompletely defined, though like all other infections with herpesviruses, it results in a long-term lifelong latent infection. A febrile illness that was sometimes associated with maculopapular skin rash and active KSHV viremia has been associated with KSHV primary infection in immunocompetent children [8, 215, 361]. Primary KSHV infection in immunocompetent adults is associated with mild diarrhea, fatigue, localized rash, and lymphadenopathy [409]. Fever and cutaneous rash, coinciding with KSHV viremia, have been reported as part of primary infection in immunosuppressed patients after transplantation [252], while a severe, sometimes fatal, outcome (e.g., bone marrow or multiorgan failure) of primary infection was described in rare cases in immunocompromised patients [257, 360].

Generally, the development of KSHV-related disorders in KSHV-infected individuals occurs after long-term infection and is fairly rare, suggesting the involvement of cofactors. Along with the major clinical entities (KS, PEL, and MCD) that are etiologically associated with KSHV, additional, less common, clinical manifestations related to KSHV infection are also described below. The involvement of KSHV with other disease conditions has been widely investigated, and its association with a broad spectrum of diseases has been ruled out [90]. Of note, several cases exhibiting the concomitant occurrence of two or three of the KSHV-related syndromes have been reported in the literature, thus supporting their common causative agent.

7.2 Kaposi's Sarcoma

The most frequent KSHV-associated malignancy is Kaposi's sarcoma (KS). KS is an unusual multifocal angioproliferative disease presenting various-sized lesions composed of multiple cell types. KS lesions contain spindle-shaped endothelial cells and abnormal and leaky vessels with extravasation of red blood cells and hemosiderin deposits. Inflammatory lymphocytic infiltrates including monocytes, T cells, B cells, histiocytes, and plasma cells are also present in these lesions, in particular during early development. KS may develop in various organs but lesions are mostly seen on the skin. Cutaneous presentation usually has a benign course, whereas visceral dissemination, involving the lungs, liver, lymph nodes, and the gastrointestinal tract, can be aggressive. Clinically, lesions have been classified as patch, plaque, nodule, or tumor stages; though a given patient may simultaneously present different types of lesions, while certain lesions never progress and others initially present at an advanced stage. Of note, although KS was originally defined as a malignant tumor, this classification is still a matter of debate, and the current model suggests that KS represents a consequence of a multistep proliferative, inflammatory, and angiogenic process involving both viral and cellular factors, which could give rise to a clonal metastatic neoplasm under certain conditions [151, 279]. This view is supported by studies showing that KS lesions display several patterns of clonality (mono-, oligo-, and polyclonal), suggesting that KS begins as a polyclonal hyperplasia with potential for subsequent evolution to a monoclonal tumor.

KS lesions harbor KSHV mostly as a latent genome, while a small fraction of the cells undergo lytic infection, as demonstrated by the expression of early and late transcripts and proteins [381]. Cells undergoing lytic infection produce viral and cellular cytokines and chemokines that probably support the growth of latently infected cells allowing sustained growth of the lesions.

The predominant cell type in advanced lesions is the elongated-shaped spindle cells that proliferate and promote disease progression. The cellular origin of these cells remains a subject of debate. Most spindle cells express markers of lymphatic endothelial cells (LECs), including CD31, CD34, PROX1, lymphatic vessel endothelial hyaluronan receptor 1 (LYVE1), vascular endothelial growth factor receptor 3 (VEGFR3), and podoplanin [122, 210]. Yet, some spindle cells also express markers of dendritic cells, macrophages, or smooth muscle cells [350]. Interestingly, in vitro infection of blood vessel endothelial cells (BECs) induces LEC markers,

whereas infection of LEC induces transcriptional reprogramming toward BEC-like characteristics [197, 410]. The finding of endothelial cell reprogramming by KSHV provides insights into the pathology of KS, and suggests that KSHV infects circulating endothelial precursor cells, and reprograms their transcriptional profile toward a unique lymphatic lineage [279].

KSHV is a prerequisite etiologic agent for all variants of KS. This notion is based on consistent and reproducible evidence obtained by several research groups worldwide. Specifically: (1) almost all KS lesions test positive for KSHV DNA, yet KSHV is absent from the adjacent tissue. (2) Infection with KSHV precedes the onset of KS. Detection of antibodies directed against KSHV antigens in the blood of untreated HIV-infected subjects is strongly predictive of their future development of KS. Furthermore, elevated antibody titer, both for lytic and latent viral antigens, is associated with increasing risk of KS. (3) Elevated levels of viral DNA in PBMCs are detected among KS patients and in individuals subsequently progressing to KS, compared with healthy subjects. (4) A general correlation is well established between KSHV prevalence and population risk for developing KS. (5) KSHV is present in critical cellular components of KS, namely, the spindle cells. (6) KSHV encodes several potentially oncogenic proteins, and it is closely related to other mammalian tumorigenic viruses.

Infection with KSHV is not sufficient to cause KS. Most carriers of KSHV never develop KS, suggesting that other host-related factors along with lifestyle and environmental cofactors are likely to affect the risk of KS development. The most important cofactor predisposing KSHV-infected individuals to KS is immunosuppression, which could be iatrogenic but is most commonly due to HIV infection. The introduction of effective antiretroviral therapy led to a sharp decrease in KS incidence among HIV carriers, yet the risk of KS remains relatively high in HIV-infected individuals [144]. This illustrates the significance of the immune system in the development of KS but also reflects specific interactions between HIV and KSHV proteins that yield a synergistic effect which stimulates KSHV replication. Age is an established cofactor for the development of KS. Except in areas endemic for KSHV, KS in immunocompetent individuals usually develops after 50 years of age. Whether the early age of KSHV acquisition in Africa is a contributing factor to KS development in children in this area is unknown. In addition, the reasons for the tendency of KS to selectively affect men are unknown. Additional possible cofactors for the endemic disease include malaria, schistosome and other parasitic infections, and contact or ingestion of specific plants that might increase lytic reactivation of KSHV [416]. Genetic determinants, possibly those that reflect ethnicity, such as the human leukocyte antigen (HLA) tissue type may be influential. Selected alleles of the interleukin-6 promoter and of the low-affinity Fcγ receptors IIIA for IgG are associated with an increased lifetime risk of the development of KS in men infected with HIV. Among KSHV-seropositive Italians, the risk of classic KS is associated with diplotypes of IL-8RB and the promoter region of IL-13 [47]. Underlying immune activation, reflected by elevated levels of neopterin or β-2 microglobulin, was also found to be associated with the disease.

Environmental factors probably play an important role, and certain were evaluated. For example, KS is associated with exposure to volcanic soil, and this disease seems to be more common in highland areas located at altitudes >2,000 ft, although high incidence rates have been found at a broad range of altitudes and temperatures. Chronic exposure of the skin to aluminosilicate or ferrous particulates, leading to lymphatic obstruction and local inflammation, has been also suggested to increase the risk of KS emergence [435].

Lifestyle factors have been demonstrated to influence KS. Cigarette smoking is inversely associated with classic KS risk, and HIV-infected MSM in the USA who also smoke were found to have a reduced risk of AIDS-associated KS. However, in other studies, tobacco use was not associated with reduced risk of classic, AIDS-associated, or endemic KS. Crack cocaine also has been inversely associated with KS. Infrequent bathing was demonstrated to be associated with an increased risk of classic KS. A history of several diseases, including asthma and allergies, was associated with an elevated risk of KS. At present, it seems that the virulence of specific strains of KSHV is not likely to play an important role in its ability to induce KS. However, the effect of viral factors remains to be further explored.

Familial clustering of KSHV infection has been reported [10, 99]. However, only few cases of familial clustering of KS have been documented [182, 211]. The rarity of familial clustering of KS may be because individuals infected with KSHV have a low lifelong risk of developing the disease; yet, familial cases suggest that virological, environmental, and genetically determined susceptibility factors, independently or in combination, may determine the development and pathogenesis of KS.

7.3 Primary Effusion Lymphoma

The etiologic association between lymphoma and KSHV is mainly based on cases of primary effusion lymphoma (PEL) that were primarily observed in HIV-infected patients, and on a small number of cases that have been described in post-transplant immunosuppressed patients, and in elderly individuals who are apparently immune competent except for functional immune senescence [62, 73, 298]. PEL is a rapidly fatal distinct type of non-Hodgkin B-cell lymphoma (also referred to as body cavity-based lymphoma). In elderly subjects, PEL may have a less aggressive clinical course and less

frequent EBV coinfection. It typically presents as lymphomatous effusion in the pleural, peritoneal, or pericardial body cavities without an associated tumor mass. Rarely, lymphomatous cells, presenting similar molecular and immunophenotypic characteristics, occur as solid tumors with or without evidence of effusions and are considered as an extracavitary/solid variant of PEL [426]. This presentation sometimes precedes or follows a typical case of PEL and may involve the skin, gastrointestinal tract, lung, central nervous system, and lymph nodes. Recurrent and aggressive polyclonal effusions containing KSHV-infected atypical lymphomononuclear cells may also develop in body cavities of patients with concomitant KSHV-associated disorders (KS and/or MCD), not exclusively in association with HIV infection [16, 43].

The tumor cells in PEL present diverse morphologic features ranging from large immunoblasts or plasmablasts to anaplastic morphology. Binucleated or multinucleated cells resembling Reed-Sternberg cells are found as well. Indicative of their B-cell origin, PEL cells display clonal immunoglobulin (Ig) gene rearrangements, yet they lack pan-B-cell markers including CD19, CD20, CD79a, and surface and cytoplasmic Igs. Expression of plasma cell markers, such as CD30 and CD138/syndecan, and hypermutation of Ig genes as well as frequent somatic hypermutation of the noncoding region of the *BCL6* gene suggest that PEL cells originate from postgerminal center B cells. Unlike several other lymphoid disorders, PEL cells lack c-*myc* rearrangement and do not exhibit dysregulated c-Myc expression [208, 221].

PEL cells harbor dozens of copies of episomal KSHV genome per cell and are generally latently infected. Accordingly, these cells express LANA-1, vCYC, vFLIP, and LANA-2 proteins as well as Kaposin and microRNAs, while viral interleukin 6 (vIL-6) is expressed by a variable proportion of the tumor cells. The involvement of KSHV gene products in the pathogenesis of PEL is supported by the requirement for latent KSHV gene expression for the survival of PEL cells [164, 176]. Given the strong association between PEL and KSHV infection, immunohistochemical analyses, in particular using antibodies to the major KSHV antigen, LANA-1, serve as a helpful diagnostic procedure. This approach allows the distinction between PEL and secondary lymphomatous effusion and also serves to diagnose extracavity PELs that otherwise could be incorrectly classified.

PELs are frequently coinfected with EBV; however, there is no difference in the clinical presentation, tumorigenicity in mice, and response to treatment between EBV-positive and EBV-negative PELs. In PELs, EBV presents a restricted latency I gene expression pattern, involving the expression of EBNA1 protein, and the small noncoding RNAs EBERs and microRNAs [198, 389]. The rarity of PEL suggests that KSHV infection represents only one of the several events involving the cascade that leads to the development of PEL. EBV infection has been included among cofactors associated with the establishment of PEL, yet its limited viral gene expression suggests that the major driving force of PEL is KSHV infection.

7.4 Multicentric Castleman's Disease (MCD) and KSHV Inflammatory Cytokine Syndrome (KICS)

Multicentric Castleman's disease (MCD) is a rare polyclonal lymphoproliferative disorder which manifests as a generalized lymphadenopathy with systemic inflammatory symptoms of fever, cachexia, weight loss, hypoalbuminemia, cytopenia, and hyponatremia [72]. Like PEL, MCD occurs at increased frequency in AIDS patients and in this setting is almost always associated with KSHV infection. MCD also may occur in HIV-negative individuals, yet only 40–50 % of these cases are KSHV positive.

In MCD, the cells harboring KSHV occur predominantly in the mantle zone of B-cell follicles. These cells are monotypic plasmablasts that almost invariably express high levels of cytoplasmic IgM with an exclusive λ light chain restriction. Microscopic foci of clonal plasmablastic lymphoma may eventually occur within MCD-affected tissue [119].

KSHV-infected MCD is associated with an abundant viral lytic infection, suggesting the involvement of viral lytic proteins in the pathogenesis of this disease. A major role in the pathogenesis of MCD has been attributed to the lytic gene product vIL-6 that is expressed in scattered plasmablasts surrounding the lymphoid follicles and acts as a stimulator of B-cell proliferation and VEGF secretion. This notion is based on the association between high levels of IL-6 and worse prognosis of MCD. Treatment of three MCD patients with ganciclovir, an inhibitor of herpesvirus lytic replication, has been reported to ameliorate MCD [64], while treatment with cidofovir, an inhibitor of herpesvirus DNA polymerase, was not effective [31, 94].

An IL-6-related systemic inflammatory syndrome has been recently reported in patients with HIV and KS, but without a pathologic diagnosis of MCD. This clinical condition, termed KSHV inflammatory cytokine syndrome (KICS), resembles KSHV-MCD but lacks prominent lymphadenopathy and pathological nodal changes [329, 398]. Like MCD patients, elevated loads of KSHV and high vIL-6 and IL-10 levels characterize KICS patients.

7.5 Other KSHV-Associated Lymphomas

KSHV is associated with large B-cell lymphoma arising mostly in HIV-positive patients with KSHV-associated MCD [62]. The lymphoma cells present features of MCD plasmablasts, including IgMλ expression and absence of EBV

infection. Unlike PEL, large B-cell lymphomas arising in KSHV-infected MCD lack somatic hypermutation of Ig genes; hence, they are thought to originate from pre-plasma cells that circumvented the germinal center [123].

Germinotropic lymphoproliferative disorder, predominantly involving germinal centers of lymph nodes and characterized by plasmablasts that are EBV and KSHV coinfected and a favorable response to chemotherapy or radiotherapy, has also been associated with KSHV [120].

8 Immunity

Acquired and genetic deficiencies in cellular immunity are strongly associated with increased risk of KSHV-associated disorders. Decrease in the number of CD4 cells is associated with AIDS-KS [35] and classic KS [48]. Furthermore, lower KSHV-specific CD4 cell counts are detected among HIV-infected KS patients as compared with HIV- and KSHV-coinfected individuals without KS [178]. Similarly, increases in both absolute CD4 count and KSHV-specific T-cell responses are coupled with response to therapy, hence illustrating an interaction between the clinical state and cellular immunity [25, 37].

Defects in the humoral activity may also play a role in the pathogenesis of KSHV. Reduction of B-lymphocyte counts correlates with the development and progression of KS [382, 384]. Lower levels of KSHV neutralizing antibodies have been recorded in the serum of patients with clinical KS, as compared with KSHV-infected individuals with no evidence of KS [220].

At the same time, KSHV is an active regulator of the host immune response, encoding multiple proteins that inhibit innate and adaptive host immunity [95, 237]. Two modulators of immune recognition, MIR1 and MIR2, are encoded by KSHV *orfK3* and *orfK5*, respectively, and strongly impair MHC-I presentation. Four homologs of cellular IRF, encoded in a single cluster, which probably originated through gene duplication, regulate the antiviral interferon response. Two other proteins that are not members of the IRF family, ORF45 and RTA, abrogate induction of interferon response by IRF-7 [424, 431]. Furthermore, vIL-6 impairs the formation of STAT1-STAT2-IRF-9 complexes that ordinarily promote expression of interferon-stimulated genes. Three viral homologs of CC chemokines, vCCL-1/MIP-I, vCCL-2/vMIP-II, and vCCL-3/vMIP-III, encoded by *orfK6*, *orfK4*, and *orfK4.1*, respectively, function as negative regulators of inflammatory and immune responses. A homolog of the cellular CD200/OX2, encoded by *orfK14*, suppresses TNF-α production by macrophages and represses inflammation. Another viral gene which has a cellular counterpart is the KSHV complement control protein (KCP), encoded by *orf4*, and functions to limit and disrupt the progression of the complement activation cascade. In addition, KSHV encodes a microRNA which represses the expression of the stress-induced NK cell ligand, MICB, allowing recognition escape and consequent elimination by natural killer (NK) cells [297]. However, most of these genes are expressed during lytic infection and thus probably enable virus evasion from the host response and promote greater virus production.

9 Control and Prevention

Prevention of primary KSHV infection could reduce the incidence of KSHV-related disorders. Yet, no successful attempts to control virus transmission have been described. The reason for this is because most infections are asymptomatic, while salivary exchange, which probably represents the predominant route of virus transmission, cannot be feasibly controlled. Nevertheless, improvement of hygiene could reduce the spread of the virus. Cost-effectiveness of a KSHV vaccine has not been thoroughly evaluated and is hard to predict, but at present, vaccine development appears to be unwarranted.

KSHV transmission via organ donation is of great clinical concern, since transplant recipients undergo immune suppression. Threefold higher risk of KS has been reported among KSHV-seropositive recipients of solid organs as compared with seronegative recipients, with no significant differences in the clinical outcome in both groups [142]. This suggests that screening of potential transplant recipients and donors may be required for clinical monitoring, yet the presence of antibodies in either recipient or donor should not exclude transplantation. Preemptive antiviral therapy could offer an approach for the prevention of KS among transplanted patients who are KSHV positive or receiving an organ from a donor infected with the virus. Hence, routine screening for KSHV should be considered prior to transplantation, at least in countries with intermediate and high KSHV seroprevalence.

Lytic KSHV infection can be inhibited in vitro by antiherpesvirus drugs, including ganciclovir, foscarnet, and cidofovir, but not acyclovir [217, 276]. The ability of these drugs to reduce the risk of KS in AIDS patients and to induce regression of KS has been evaluated by several investigators, providing inconsistent results. A recent study reported no detectable effect of oral valganciclovir therapy on tumor growth, KSHV antigen positivity, or gene expression [225], and together with negative findings reported for cidofovir [247] provide little support for the use of these drugs alone for KS treatment. HAART decreases circulating HIV and hence reduces the incidence of KS and can induce regression of AIDS-KS, yet KS remains a clinical issue, and only 50 % of cases completely resolve [303]. Adoptive immunotherapy, involving infusion of specific cytotoxic T cells, is already in

use for the treatment of patients with EBV-infected lymphomas and is expected to be effective toward KSHV-associated diseases as well. Finally, the accumulated knowledge about the biology of KS and KSHV is expected to be translated into new therapeutic approaches targeting KSHV infection and paracrine mechanisms.

The prognosis of PEL patients is poor even with standard chemotherapy regimens. Several nonchemotherapy approaches have been tested including HAART alone or antiviral treatments with promising results [32, 186, 378], while therapies that target specific viral oncogenes may provide benefits in the future [32]. A monoclonal antibody targeting CD20, rituximab, has been evaluated in the treatment of KSHV-positive MCD, yet was associated with slight exacerbation of KS in some patients [158].

10 Unresolved Problems

Research on KSHV during the recent years has led to better understanding of its pathogenesis and its related disorders. The functions of several proteins and microRNAs encoded by KSHV have been studied extensively, yet various aspects are still poorly understood. Much of what we know so far has yet to be translated into clinical practice. Furthermore, understanding the involvement and regulation of host genes, including microRNAs, during infection may shed light on cellular pathways that could be targeted and thus could offer new treatment approaches.

The site of KSHV latency has not been resolved yet. Some of the signaling cascades that induce virus reactivation have been identified, but we cannot yet combine them into a model with pathophysiological relevance. Furthermore, the events and conditions that determine long-term asymptomatic infection, cell proliferation, angiogenesis, and transformation among infected individuals have not resolved yet. Since the fate of infection is determined by several signaling networks, involving multiple viral and cellular gene products, this issue is complex. Furthermore, the interactions of KSHV with other microbial agents, such as malaria, that could affect its replicative phase remain to be elucidated. Specific immunological factors and events controlling disease onset are not fully understood. Newly identified animal models as well as in vitro systems to study the biology of KSHV employing recombinant viruses are expected to largely increase our understanding on molecular mechanisms involved in KSHV pathogenesis.

A standardized algorithm for KSHV diagnostics in subjects at risk for KSHV-driven malignancies, such as post-transplant patients and HIV-1-infected individuals, is not yet available, and uniform criteria to estimate seroprevalence in a given population have not yet been defined. Research and diagnostic laboratories should work in concert to develop and test new serological assays and search for a consensus on the diagnostic flowchart related to detection and follow-up of KSHV infection. Moreover, there is the need to provide laboratories in developing countries with simple and reliable tests for KSHV detection, which would help pathologists to confirm KS diagnosis in suspected and/or borderline tumor conditions in adults and in children. Newly defined parameters, such as circulating exosome-associated viral or cellular miRNAs, may in the future provide more reliable predictive and prognostic markers and guide physicians to plan and tailor therapeutic strategies.

Human Herpesviruses: Malignant Lymphoma

40

Jennifer A. Kanakry and Richard F. Ambinder

1 Introduction

The human gammaherpesviruses, Epstein-Barr virus (EBV, or HHV4) and Kaposi sarcoma-associated herpesvirus (KSHV, or HHV8), are associated with lymphoma. EBV was first discovered in the 1960s in association with Burkitt lymphomas arising in sub-Saharan Africa, while the discovery of KSHV in 1994 was associated with Kaposi sarcoma tumors and driven by the AIDS epidemic. While EBV infection is ubiquitous, KSHV is restricted to certain populations. EBV-associated lymphoproliferative diseases are likewise more common than KSHV-associated lymphoproliferative disease. These two herpesviruses nonetheless share many characteristics. Particularly relevant to lymphoma and lymphoproliferative disease is the ability of these two viruses to infect and establish a reservoir of infection in lymphocytes. Whereas some herpesviruses establish latency in nondividing terminally differentiated cells such as neurons, the gammaherpesviruses establish latency in lymphocytes. The gammaherpesviruses have evolved mechanisms for persisting as extrachromosomal genomes in dividing cells. These cells may be driven to proliferate or be protected from cell death pathways by viral gene expression. The result may be a self-limited lymphoproliferation that establishes or maintains a reservoir of latently infected cells or, under certain circumstances, a malignant lymphoproliferation.

Although the focus of the chapter is EBV- and KSHV-associated lymphomas, the development of lymphoma is a rare outcome of viral infection. Some lymphoma entities are nearly universally virus associated, such as African Burkitt lymphoma (BL), nasal-type extranodal NK-/T-cell lymphoma, AIDS-associated primary central nervous system lymphoma, and AIDS primary effusion lymphoma (PEL); others such as diffuse large B-cell lymphoma (DLBCL) and Hodgkin lymphoma (HL) are variably associated with the virus. Consistent association with the virus does not indicate that herpesvirus infection is sufficient to cause these lymphomas. As the names of some of these lymphomas hint, geographic, anatomic, or immune factors contribute to the pathogenesis of these diseases. In this chapter, we review aspects of the biology of the viruses and aspects of the relevant lymphoma entities and discuss approaches to diagnosis, treatment, and prevention that are virus specific.

2 Aspects of Viral Biology and Viral Gene Expression

EBV is a ubiquitous gammaherpesvirus that infects over 90 % of the world's population by adulthood [1, 2]. By contrast, KSHV infection is unusual in most parts of the world. KSHV seroprevalence is greatest in regions of Africa, Mediterranean populations, and among men who have sex with men in North America and Europe [3, 4]. Both viruses are primarily transmitted through saliva, and both infect B lymphocytes and establish a lifelong reservoir. In healthy adults, the EBV reservoir is in resting memory B cells. The KSHV B-cell reservoir is less completely characterized, and there may be reservoirs in other tissues.

EBV and KSHV genomes are present in cells as closed circular plasmids in the nucleus. Viral DNA may be replicated either as part of the process that leads to the production of virions or in tandem with cellular DNA in cycling cells. For virion production, linear double-stranded viral DNA is synthesized in a process that relies on viral DNA polymerase and a variety of other viral enzymes. This process is referred to as lytic replication, and the viral gene expression that

Fig. 40.1 Latent EBV gene expression patterns and the lymphomas associated with each are shown. Pro-survival and antiapoptotic pathways are targeted by EBV latent membrane protein-1 (*LMP-1*) and LMP-2A. Viral antigen presentation by major histocompatibility complex (*MHC*) class I receptors varies by latency pattern. In all cases, the EBV genome is present as a nuclear plasmid and replicates in tandem with cell division using cellular machinery

makes it possible is the lytic program. Most of the open reading frames encoded by the virus are expressed in the lytic program. For viral plasmid replication, which occurs during latency in tandem with cellular DNA replication during normal cell division, only a single viral protein is required. For EBV, this is the EB nuclear antigen 1 (EBNA-1). It serves to activate an origin of replication in the viral genome, allowing cellular enzymes to replicate the viral DNA plasmids. The KSHV latency nuclear antigen (LANA-1) serves a similar function for plasmid replication.

Several different EBV gene expression programs may accompany latency replication. These expression programs have been most completely defined in tumors. A schematic of these latency viral gene expression programs and associated lymphoma types is shown in Fig. 40.1 [5]. Expression of viral proteins may be limited to EBNA-1 (latency 1) or may include other latency proteins. Expression of the full spectrum of latency proteins drives host cell proliferation and has been referred to as the growth program or latency 3.

EBV infection of resting B cells in vitro leads to proliferation and ultimately to immortalized cell lines, referred to as lymphoblastoid cell lines (LCL). LCL grow as EBV-driven human B-cell tumors in immunodeficient mice [6]. Viral DNA replication is almost exclusively in a latency program, and viral gene expression is that of the growth program (latency 3). Among the viral proteins expressed in the growth program are viral proteins that activate and modulate key cellular pathways including the notch and nuclear factor kappa B (NF-κB), drive cell proliferation, and confer resistance to apoptosis [7–9]. Some of these proteins mimic normal B-cell signaling and activation, perhaps allowing B lymphocytes that harbor EBV plasmids but fail to express functional, high-affinity immunoglobulins to escape regulatory checkpoints and survive [2, 10, 11]. KSHV infection of B cells does not lead to immortalization, and establishment of the B-cell reservoir that harbors latent KSHV genomes is less well understood.

Following primary EBV infection, there is a brisk cytotoxic T-lymphocyte (CTL) response to viral antigens, particularly lytic and growth program antigens. This cellular immune response limits the production of virions and virus-driven B-cell proliferation. The EBV plasmids in memory B

lymphocytes, which are long-lived cells that divide at low frequency, do not express the viral antigens targeted by this cellular immune response and thus elude immune surveillance. The periodic activation of viral lytic gene expression necessary for virion production likely accounts for intermittent viral shedding that occurs throughout the lifetime of the host. Inadequate or waning cellular immunity to viral antigens associated with the growth program may allow virus-driven lymphoproliferation.

Both EBV and KSHV encode mimics of host cytokines and chemokine receptors. EBV encodes a viral homologue of IL-10 homologue, among others [12–14]. IL-10-mediated inhibition of interferon-gamma production may impact on the function of NK cells and cytotoxic T cells, lessening their reactivity against virus-infected B lymphocytes [15]. Viral IL-10 may also limit the presentation of viral antigens by MHC I molecules, again impairing the responsiveness of CTLs to EBV infection. LCL do not require IL-10 to maintain latent infection, but IL-10 appears to be important for the initial steps in immortalization of these cell lines [16]. KSHV encodes a viral homologue of IL-6 as well as a G-protein receptor homologue. These cytokines function during lytic replication, perhaps to dampen immune responses and allow latent infection to be established. There is also evidence that Toll-like receptor (TLR) stimulation is important for EBV-infected B-lymphocyte proliferation. It has been postulated that pathogens bearing TLR ligands, such as malaria, may serve this function and potentially perpetuate latent EBV infection. Other coinfections may also contribute to the increased risk for EBV-associated lymphomas seen in immunosuppressed patients by acting in similar ways.

Both viruses also encode viral homologues of the anti-apoptotic protein bcl-2 [17, 18]. The EBV proteins BHRF1 and BALF1 act as homologues of Bcl-2 (B-cell lymphoma 2), blocking apoptotic signals and allowing dysregulated or mutated lymphocytes to persist. The function of EBERs is only beginning to be elucidated, but there is evidence that they may upregulate Bcl-2 expression; facilitate the maintenance of malignant molecular events, such as the c-myc translocation in BL; and prevent interferon-α-mediated apoptosis [19]. In some cases, viral gene expression may hinder p53 tumor suppressor protein activity [20]. In particular, EBV BALF1 can block the FAS-mediated cell death pathway [18].

3 Overview of EBV- and KSHV-Associated Lymphoma

EBV is associated with B-, T-, and NK-cell lineage lymphoma or lymphoproliferative disease. KSHV is only known to be associated with B-cell lineage lymphoma or lymphoproliferative disease. Some B-lineage tumors are nearly always EBV positive, including African BL, DLBCL associated with chronic inflammation, AIDS-associated primary DLBCL of the central nervous system, and post-transplantation lymphoproliferative disorder (PTLD). Other B-cell lymphomas are associated with the EBV, but not universally so. These include sporadic and HIV-associated BL, classical HL – particularly mixed cellularity and lymphocyte-depleted subtypes – and systemic HIV-/AIDS-related lymphomas. EBV-associated hematologic diseases of T-cell or NK-cell lineages include extranodal NK-/T-cell lymphoma (ENKTL), aggressive NK-cell leukemia, peripheral T-cell lymphoma not otherwise specified, angioimmunoblastic T-cell lymphoma (AITL), and EBV-positive T-cell lymphoproliferative disorders of childhood [21–24]. While the nasal type of ENKTL is always EBV(+), the same lymphoma presenting at other anatomic sites is often but not always EBV(+). AITL is a T-cell lymphoma in which the tumor cells are EBV negative but are amid a background of EBV-positive B lymphocytes. Lymphomatoid granulomatosis, a lymphoproliferative disorder, is also consistently associated with EBV [25].

KSHV is associated with B-lineage lymphomas and lymphoproliferative disorders. Primary effusion lymphoma (PEL) is always associated with KSHV and is often associated with EBV. Germinotropic lymphoproliferative disorder is always associated with both KSHV and EBV coinfection of tumor cells. Multicentric Castleman disease (MCD) is a lymphoproliferative disorder often associated with KSHV, particularly in HIV-infected individuals, but is EBV negative. Table 40.1 lists various types of lymphoma and comments on consistency of the viral association and other cofactors.

Although the list of EBV- and KSHV-associated lymphomas includes many varieties of lymphoma, it is important to recognize that there are many histologic subtypes that seem never to be associated with either virus. Thus, among common B-cell lymphomas, follicular lymphomas are not EBV or KSHV associated; and among common T-cell lymphomas, lymphoblastic lymphoma is never EBV associated. The determinants of the association remain poorly understood, but the cell of origin; the histologic subtype; and host factors including age, gender, HIV status, comorbid conditions such as chronic inflammation, ethnicity, HLA, and other genetic polymorphisms all seem to be important.

4 EBV Lymphoma and Lymphoproliferative Diseases

4.1 Burkitt Lymphoma (BL)

Denis Burkitt called attention to what is now known as endemic Burkitt lymphoma (BL) and highlighted its

Table 40.1 EBV- and KSHV-associated diseases

Disease	EBV association	Associated factors
Burkitt lymphoma		
Endemic	~100 %	*Plasmodium falciparum*, male predominance
Sporadic	15–30 %	
Immunodeficiency associated	25–40 %	HIV
Hodgkin lymphoma		
Classical	30–40 %	Hispanic ethnicity, heightened risk for ~10 years following primary EBV infection, male predominance
HIV associated	90 %	CD4 counts typically >200 cells/μL – HAART therapy does not decrease risk
Nodular, lymphocyte-predominant subtype	~0 %	
PTLD		
B-cell origin	90 %	Use of immunosuppressive agents or transplant techniques that selectively deplete T cells
T-cell origin	20–30 %	
NK-cell origin	70–90 %	
DLBCL		
AIDS-associated primary CNS lymphoma	100 %	Advanced HIV/AIDS with very low CD4 count (<50 cells/μL)
Plasmablastic lymphoma	70–80 %	HIV, advanced age, congenital immunodeficiencies, male predominance
HIV associated	40 %	
DLBCL associated with chronic inflammation	>80 %	Long-standing foreign material or seromas, Asian ethnicity, male predominance
EBV(+) DLBCL of the elderly	100 %	possible immunosenescence with aging
Without immunodeficiency	<5 %	
Lymphomatoid granulomatosis	100 %	Immunodeficiency
Extranodal NK-/T-cell lymphoma	100 %	Asian ethnicity, CAEBV with associated hemophagocytosis
Aggressive NK-cell leukemia	>95 %	Mosquito bite allergy, Far East Asian ethnicity
Angioimmunoblastic T-cell lymphoma	90 %	EBV present in B cells of the tumor microenvironment, but not within malignant T cells

Disease	KSHV association	Associated factors
Primary effusion lymphoma	100 %	EBV – 80 %, advanced HIV/AIDS, transplant patients Mediterranean individuals, male predominance
KSHV-positive multicentric Castleman disease	100 %	EBV – 0 %, HIV/AIDS, older age, no previous HAART exposure, CD4 nadir >200 cells/μL, male predominance
Germinotropic lymphoproliferative disorder	100 %	EBV – 100 %

Abbreviations: *HIV* human immunodeficiency virus, *HAART* highly active antiretroviral therapy, *PTLD* posttransplantation lymphoproliferative disorder, *NK cell* natural killer cell, *DLBCL* diffuse large B-cell lymphoma, *AIDS* acquired immunodeficiency syndrome, *CNS* central nervous system, *CAEBV* chronic active EBV

occurrence in equatorial Africa in 1958 [26, 27]. The epidemiology hinted at an infectious etiology. Epstein and Barr succeeded in culturing tumor cell lines in which herpesviruses were observed by electron microscopy [28]. Serologic studies in African children solidified the viral association [29, 30]. Demonstration that the virus could immortalize B lymphocytes in vitro lent biological plausibility to the association as did evidence of experimental induction of EBV lymphoma in nonhuman primates [31, 32]. Thus, EBV was the first virus associated with a human cancer.

Endemic BL or African BL has several distinctive features: it arises in young children in areas where malaria is holoendemic, including equatorial Africa (Fig. 40.2, adapted from Burkitt and Wright [33]) and Papua New Guinea. It characteristically presents as a rapidly enlarging jaw or abdominal mass, and it is nearly 100 % associated with EBV. It is 3–5 times more common in boys than girls [34].

BL is also recognized outside these regions. The age distribution and the clinical presentation of sporadic BL are distinct. BL outside endemic regions is relatively rare, accounting for only about 1 % of adult-onset lymphomas and 30 % of lymphoma in children in the Western world [34, 35]. Whereas endemic BL occurs with an incidence of 50 per million, the incidence of BL in non-endemic areas is only 2 per million [34, 35]. It only very rarely presents as a jaw

Fig. 40.2 The distribution of endemic Burkitt lymphoma, depicted as *circles*, is contained within the malaria belt of Africa (outlined and shaded in *gray*)

mass. The EBV association is variable but is higher in other equatorial areas, such as parts of Brazil, Columbia, and Malaysia [36]. In the United States, it has been estimated that 20 % of sporadic BL cases are EBV positive. BL also occurs with increased frequency in HIV-infected patients (see below).

Histologically, BL appears as a relatively homogeneous proliferation of medium-sized lymphocytes with scant, intensely basophilic cytoplasm filled with lipid vacuoles. The mitotic index is high and apoptotic cells, often engulfed by macrophages, give the classic "starry sky" appearance. BL tumor cells express CD10 and Bcl-6, both germinal center markers, as well as CD20, CD19, and CD79a [37]. Essential for diagnosis is a Ki67 of greater than 99 % and demonstration of a c-myc translocation [37, 38]. The chromosomal translocation occurs between the c-myc gene on chromosome 8 and one of the B-lymphocyte immunoglobulin genes (on chromosomes 2, 14, or 22). The characteristic chromosomal abnormalities are common to both endemic and non-endemic BL (although differences in the precise chromosomal breakpoints have been noted between the endemic and sporadic variants of BL) [39, 40].

Whether EBV-associated BL occurs in the setting of malaria endemic areas, HIV infection, or sporadically, the pattern of viral gene expression appears to be the same. EBNA-1 is the only viral protein expressed. Regulatory RNAs are also expressed. Investigation of the EBV-positive BL cell lines such as the Akata cell line and an isogenic derivative cell line which lacks EBV genomes demonstrates that loss of the viral genome corresponds to slower proliferation, increased sensitivity to apoptotic stimuli, and loss of tumorigenicity in immunocompromised mice. The precise roles that EBNA-1 and viral RNAs play in determining these characteristics have yet to be determined.

The geographic distribution of endemic BL is that of holoendemic malaria. The prevalence of active malarial parasitemia in young children in these regions is approximately 60 % and the risk of transmission is yearlong [41]. Primary EBV infection usually occurs before 1 year of age [42]. Holoendemic malaria may alter the risk of primary EBV infection in very young children [43]. Malaria may alter the character of the EBV-infected B-cell population and predispose to the chromosomal translocations that are associated with BL. The details of the interplay between viral infection, malaria, and associated immune dysfunction or other environmental factors remain a subject of speculation. However, attention has been called to the observation that the *Plasmodium falciparum* erythrocyte membrane protein-1 (PfEMP1) on the surface of malaria-infected erythrocytes activates memory B lymphocytes and induces lytic EBV replication [44, 45]. This might provide an explanation for the observation that EBV DNA is detected at higher levels in blood from children in areas with holoendemic malaria in comparison with blood from children in other areas [42, 46]. Malaria infection may also blunt the interferon-γ-mediated EBV-specific cytotoxic T-cell responses, activate Toll-like receptors (TLR), and increase the frequency of immunoglobulin double-strand breaks and translocations, with potential mechanisms of pathogenesis depicted schematically in Fig. 40.3 [41, 47–50]. EBV gene expression may permit genetically Unstable B lymphocytes to escape apoptotic signals [51, 52].

4.2 Hodgkin Lymphoma (HL)

EBV can be detected in tumor cells of HL in a variable fraction of cases [53–55]. When present in tumor cells, the virus is usually present at all sites involved by tumor, both at presentation and at relapse [56]. Approximately 9,000 new cases of HL are diagnosed annually in the United States, representing around 12 % of all lymphoma [57]. Approximately one third of HL tumors in the United States and Europe are EBV associated, making HL the most common EBV-associated lymphoma in the Western world [58, 59]. In Latin America and Africa, HL are more frequently EBV positive [60–62].

Factors associated with EBV positivity include mixed cellularity subtype, history of symptomatic infectious mononucleosis, male gender, Hispanic ethnicity, low

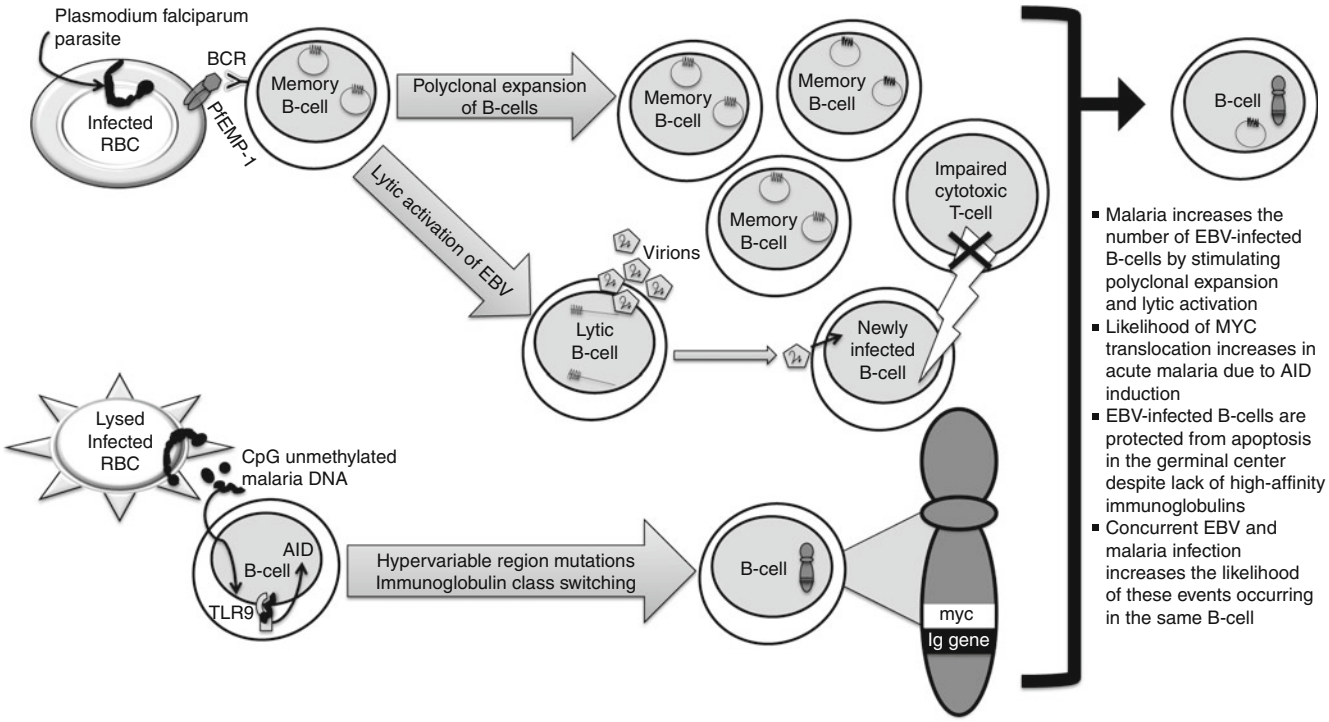

Fig. 40.3 Potential mechanisms by which *Plasmodium falciparum* (malaria) infection interacts with EBV to promote the development of endemic Burkitt lymphoma. The cysteine-rich interdomain region 1α of the *Plasmodium falciparum* erythrocyte membrane protein 1 (*PfEMP1*) interacts with B cells via the B-cell receptor (*BCR*). Infected red blood cells (*RBC*s) release CpG-unmethylated malaria DNA, which may stimulate Toll-like receptor 9 (*TLR9*) and induce activation-induced cytidine deaminase (*AID*) gene expression, thereby increasing the likelihood of a MYC translocation during immunoglobulin class switching and hypervariable region mutation. Impaired function of EBV-specific cytotoxic T cells may also play a role in endemic Burkitt lymphoma pathogenesis

socioeconomic status, and very young or very old age [58, 60, 63, 64]. Other at-risk populations for EBV-positive HL include HIV-positive patients and recipients of solid organ or hematopoietic stem cell transplants, with EBV positivity seen in 90 % of the HL tumors in these immunosuppressed populations [65–67]. The risk of developing EBV-positive HL after symptomatic primary EBV infection is approximately threefold over baseline, peaking at 2 years postinfection and remaining elevated for about 10 years after infection [64]. There is also evidence that the serologic response to viral infection differs in patients who develop EBV-associated HL [68].

In industrialized countries, HL follows a bimodal age distribution, occurring more commonly in young adults and the elderly. In economically developing countries, there is a higher incidence of HL in young children. Variation in the incidence of HL with regard to age seems to depend also on factors such as social class, hygiene, and housing density. Children who grow up in economically developed countries with fewer infectious exposures and low housing density may have a higher risk of HL in young adulthood [69]. In the United States, day care attendance is associated with lower risk of HL, although not specific to EBV-positive HL. One hypothesis to explain these results is that immune stimulation following infectious exposures is protective [70].

The EBV gene expression pattern in HL is latency 2, including latent membrane protein 1 (LMP-1), LMP-2A, and EBNA-1 expression and lacking EBNA-2 expression [71]. LMP-1 and LMP-2A may allow B cells lacking functional immunoglobulin genes rearrangements to circumvent apoptotic signals. The cellular gene expression profile in HL may reflect the effects of EBV gene expression in tumors. HL tumors expressing the tyrosine kinase Lyn cytoplasmic protein, a Src family protein tyrosine kinase, are more commonly EBV positive [72]. LMP-2A, a viral gene whose expression interferes with normal B-cell receptor signaling, appears to exert its effects by signaling through the Lyn protein [10]. In contrast to BL, there are no tumor-derived cell lines that retain EBV genomes and show this pattern of gene expression.

HL tumor cells (Reed-Sternberg cells) are infrequent amid a mix of infiltrating macrophages, lymphocytes, and eosinophils. A skew toward Th1 activity in the microenvironment of EBV-positive tumors has been described, although the significance of this remains undefined [73].

EBV-positive HL tumors have also been found to have increased expression of the chemokine CCL20, which increases the migration of regulatory T cells in HL tumors [74]. Several reports have described increased numbers of CD68(+) or CD163(+) tumor-infiltrating macrophages (TAMs) in EBV-associated HL, but not EBV-negative HL the same histologic subtypes [75–80].

4.3 Posttransplantation Lymphoproliferative Disorder (PTLD)

PTLD was first recognized when EBV-associated lymphomas were noticed with increased frequency in the posttransplant period. Over the years, PTLD lacking EBV has also been recognized. PTLD occurs weeks to decades after solid organ transplantation (SOT) or hematopoietic stem cell transplantation (HSCT) [81–83]. In the first year after transplant, most cases of PTLD are EBV positive, while cases occurring many years after transplantation are rarely EBV positive [84–89]. Advances in immunosuppressive regimens and approaches have lowered the incidence of EBV-PTLD, especially those that typically arise within the first year of transplantation. The percentage of transplant recipients varies from less than 1 % in some series to greater than 25 % in others. The organ transplanted, the EBV serostatus of the recipient, the age of the recipient, the immunosuppressive regimen, the occurrence of organ rejection or graft-versus-host disease, and the treatment for these complications are all important determinants. Immunosuppression to prevent or treat graft rejection, and in HSCT recipients to prevent or treat graft-versus-host disease (GVHD) leads to an inadequate cellular immune response to the proliferation of EBV-infected lymphocytes [90–92]. EBV-PTLDs most commonly exhibit a type 3 latency pattern. Such tumors never arise in an immunologically intact host.

Clinically, PTLDs are a heterogeneous group of lymphoproliferative disorders. They are often extranodal and are often associated with systemic symptoms. In SOT recipients, they very often involve the transplanted organ. Pathologically, most are of B-cell lineage but T-cell PTLD is also well recognized in this setting. PTLD has been classified into four major categories by the World Health Organization: early lesions, polymorphic PTLD, monomorphic PTLD (subclassified by cell lineage and then by lymphoma), and classical HL-type PTLD [93]. Early lesions are always EBV positive and tend to occur in the weeks to months following transplantation [91]. Polymorphic lesions contain a mixture of lymphocytes, immunoblasts, and plasma cells. Unlike early lesions, the lymph node architecture is not preserved, and cellular atypia, high proliferation, and necrosis will often be present. The involved B lymphocytes are EBV positive and have both clonal immunoglobulin rearrangements and clonal EBV genomes [89]. Monomorphic PTLDs are lymphomas that are morphologically similar to aggressive non-Hodgkin lymphomas (NHLs). However, these lesions are classified as PTLDs based on a history of transplantation, even if remote [89]. Monomorphic lesions are less often EBV positive and typically harbor more cellular mutations and cytogenetic abnormalities than polymorphic or early lesions [84, 85]. NK-cell and T-cell PTLDs can arise, typically years after transplantation [94, 95]. Most NK-cell PTLDs are EBV positive [95, 96]. Classical HL-type PTLD tumors are nearly always EBV positive, despite their tendency to arise years after transplantation [89]. Primary CNS PTLD is rare (less than 1 % of PTLD cases), yet they are much more common than primary CNS lymphoma in the general population, and in contrast to the general population, over 90 % are EBV positive [97, 98].

In SOT, PTLD typically arise in the lymphocytes of the recipient, and thus the EBV status of the donor is important, with higher incidence of EBV-PTLD seen in EBV-seronegative transplant recipients receiving organs from EBV-seropositive donors [99–101]. Not unexpectedly, EBV-PTLD is more common in the pediatric SOT population as compared to the adult SOT population, as this patient group has often not yet been exposed to primary EBV infection.

In contrast to SOT, the lymphocytes that evolve into EBV-PTLD in HSCT patients are typically donor derived [99]. The most vulnerable period for HSCT patients to develop an EBV-PTLD is in the first several months following transplantation, before reconstitution of an EBV-specific CTL+ response, with the majority of cases arising within the first year post-HSCT. In HSCT, risk factors for EBV-PTLD revolve mainly around aspects of the conditioning regimen, graft manipulation, and the pharmacologic approach to GVHD prophylaxis. With regard to conditioning, the use of antithymocyte globulin (ATG) is associated with high risk of EBV-PTLD [102–105]. Grafts can be unmanipulated, both T and B cell depleted, or selectively T cell depleted, with selectively T-cell-depleted grafts being associated with a 15-fold higher incidence of EBV-PTLD [91, 102]. The pharmacologic approach to GVHD prophylaxis or its treatment also modulates EBV-PTLD risk, again with the highest risk being associated with agents that selectively deplete T lymphocytes [106]. A shorter duration of post-HSCT immunosuppression decreases the risk of EBV-PTLD. As an example, high dose, posttransplantation cyclophosphamide as GVHD prophylaxis seems to be associated with very low rates of PTLD in HSCT patients [107]. Chronic GVHD is associated with increased risk of EBV-PTLD [108–110].

Particular immunosuppressive regimens have been implicated in PTLD. However, because agents are mainly used in combination, the risks associated with particular drugs are often difficult to discern [101, 111, 112], and EBV-PTLD incidence may reflect the impact of a regimen than a particular drug. Historically, the incidence of PTLD has

risen as novel immunosuppressive drugs emerged and then fallen again with improved drug level monitoring and tighter therapeutic windows [113, 114]. Monoclonal antibodies that selectively deplete T cells, such as muromonab-CD3 (OKT3) and ATG, have been associated with heightened risk of EBV-PTLD, while those that deplete both B and T cells, such as alemtuzumab, may be associated with a lesser risk [115–118].

4.4 EBV-Associated Lymphoma in HIV Patients

Patients with HIV are 60- to 200-fold more likely to develop lymphoma than the general population [119]. A number of different B-cell lymphomas are increased in HIV patients. The first recognized were primary central nervous system lymphoma, BL, and DLBCL. These lymphoma types were thus recognized as "AIDS-defining" illnesses before HIV was recognized. More recently, HL has been recognized to be increased in HIV patients.

Primary central nervous system lymphoma is rare in the general population and generally not EBV associated. However, in AIDS patients in the era before highly active antiretroviral therapy (HAART), the incidence was increased 5,000-fold. In the mid-1990s, almost half of all primary central nervous system lymphoma in the United States were AIDS associated [120]. These tumors almost exclusively occurred in patients with very low CD4 counts and are virtually all EBV associated. With HAART therapy, their incidence substantially decreased. DLBCL (including immunoblastic lymphoma) is also increased in patients with HIV, but only approximately 98-fold. Less than half of these are EBV associated. The incidence of DLBCL dropped with HAART, but not nearly as dramatically as that of primary central nervous system lymphoma. The incidence of BL in the United States and Western Europe is also increased with HIV infection. In the United States, the estimate is a 57-fold increase. Approximately 30–50 % of AIDS-associated BL cases are EBV positive [34, 121]. Patients often have CD4 counts above 200 cells/μL at BL diagnosis [122]. In contrast to primary central nervous system lymphoma and DLBCL, the incidence of BL seems not to have changed with HAART. Little is known as to the specific impact of HAART on the proportion of EBV-associated DLBCL or BL among patients with AIDS.

AIDS primary central nervous system lymphoma seems to reflect profound end-stage cellular immune dysfunction. These lymphomas often express the full spectrum of EBV genes (latency 3 in Fig. 40.1), and as end-stage immune dysfunction is prevented by HAART therapy, the incidence has waned. At the other extreme are the BL, which when EBV associated express only EBNA-1 (latency 1). EBNA-1 is not as readily targeted by cytotoxic T cells as are some of the other EBV latency genes, and the incidence of these tumors may relate to other aspects of chronic HIV infection such as polyclonal B-lymphocyte activation and not simply loss of cellular immunity. The limits of our understanding of the interplay of viruses and parasites in the pathogenesis of BL are underscored by the report that in regions of Africa where malaria is endemic and vertical transmission of HIV to infants is common, there does not appear to be a heightened risk for endemic BL among those who are HIV positive [123].

Plasmablastic lymphoma (PBL) is a subtype of DLBCL that is typically EBV positive, tends to arise in the oral cavity and jaw, and is most commonly described in young men with HIV/AIDS, although they can arise in other settings of immunosuppression or immunosenescence [124]. As the name would suggest, the morphologic appearance is of blastoid plasma cells, CD20 staining is typically negative, the proliferative index is high, and plasma cell markers are expressed [124]. Translocations between the myc gene and immunoglobulin genes are a common finding [125, 126]. Similarities between PBL and plasmablastic transformation of multiple myeloma have been noted, with suggestion that these two diseases may be closely related [127]. Monoclonal immunoglobulins can be detected in the serum of patients with PBL and lytic bone lesions, classically seen in multiple myeloma, have also been reported [127].

There are also lymphomas that occur in HIV patients that harbor both EBV and KSHV genomes. These are discussed separately below.

4.5 DLBCL Associated with Chronic Inflammation

EBV-associated lymphomas have been recognized to arise in the setting of chronic inflammation [93]. The association between chronic inflammation and NHL was first reported in 1987 in Japanese patients with long-standing pyothoraces. These pyothoraces developed as a result of iatrogenic induction of pneumothoraces for the treatment for pulmonary tuberculosis before antituberculosis drugs were available [128]. These patients developed NHL decades after their tuberculosis treatment, most commonly of DLBCL histology, always involving the pleural cavity, and often with extensive necrosis and immunoblastic morphology [129]. The association with EBV was later noted upon examination of additional cases, with over 70 % of cases reported to harbor EBV [130–132]. Since the first description, EBV-positive lymphomas have been described to arise in other areas of foreign-body-associated chronic inflammation, including prosthetic cardiac valves, pacemaker pockets, surgical mesh implants, and joint prostheses [133–137]. Additional cases have also been described in areas of chronic fluid collections or infection, arising in renal, tes-

ticular, and adrenal gland pseudocysts, in inflamed synovial joints of patients with rheumatoid arthritis, in bones harboring chronic osteomyelitis, in empyemas, and in skin in areas of venous stasis ulcers, again developing after decades of inflammation and nearly all EBV positive [138–141]. These lymphomas typically have a latency 3 pattern of EBV gene expression [142].

4.6 EBV-Positive DLBCL of the Elderly

First described in older, apparently immunocompetent Japanese patients and referred to as age-related EBV-positive B-cell lymphoproliferative disorder [143], this entity has been given the provisional category "EBV-positive DLBCL of the elderly" by the World Health Organization in 2008 and has been reported in Western countries as well [93]. The incidence appears to be higher in Asian and Latin American countries, compared to European countries and the United States [144]. Typically, these lymphomas arise in older individuals (>50 years, median age 75 years) without known immune dysfunction and tend to be of non-germinal center, activated B-cell phenotype (CD10 and BCL6 negative, MUM1 positive) [145–148]. The association between these lymphomas and advanced age has led researchers to postulate that they arise in the setting of immune senescence and decreased control of latent EBV infection. Supporting this is the observation of less restricted, latency 2 or 3 patterns of viral gene expression in these lymphomas [143, 149]. Polymorphic, monomorphic, and lesions resembling classical HL have been described [125, 150]. These lymphomas are typically aggressive, and outcomes for these patients appear to be worse than for EBV-negative DLBCL, with older age (>70 years) an additional independent predictor of inferior outcomes among these patients with EBV-positive tumors [143, 146]. NF-κB activation has been described in these lymphomas [146].

4.7 Methotrexate-Associated Lymphoproliferative Disease

There may be increased risk for patients with autoimmune diseases that are treated with methotrexate to develop lymphoproliferative diseases, 40 % of which are EBV positive [151–153]. While it is difficult to distinguish the increased risk for lymphoma that is associated with autoimmune diseases from the potential increased risk for lymphoma associated with the immunosuppressive treatment [154], reports of spontaneous regression of these lymphomas upon cessation of methotrexate suggest that the latter has a possible role in lymphomagenesis [152]. Furthermore, spontaneous regression with methotrexate withdrawal was mainly observed in patients with EBV-positive lymphomas, suggesting that drug-induced decreases in immune control of EBV may have driven the lymphoproliferation [152]. The presence of immunoblasts and plasmablasts is often described [151, 153]. Patients treated with methotrexate have also been reported to subsequently develop LYG.

4.8 Congenital Immunodeficiency

Many congenital immunodeficiencies are linked with an increased risk of lymphoma. These include severe combined immunodeficiency, Wiskott-Aldrich syndrome, ataxia-telangiectasia, X-linked lymphoproliferative syndrome, and common variable immunodeficiency [155]. In some of these syndromes, such as severe combined immunodeficiency and X-linked lymphoproliferative syndrome, virtually all of the lymphoproliferative disease is EBV associated. In other syndromes such as ataxia-telangiectasia, approximately half of cases are EBV associated. Patients with X-linked lymphoproliferative disease (XLP, or Duncan's disease) have a rare, X-linked primary immunodeficiency in which patients are highly susceptible to severe EBV infection. It is the encounter with EBV that often leads to the diagnosis of XLP. Primary EBV infection is typically fulminant in XLP patients, and fatality rates are high due to either complications of lytic infection or the development of EBV-associated lymphomas. XLP patients have a mutation in the gene *SH2D1A*, which codes for a signaling lymphocyte activation molecule (SLAM)-associated protein (SAP). SAP is normally expressed on all T and NK cells. The deficiency of SAP in XLP leads to the inability of NK cells and T cells to recognize and eradicate EBV-infected B lymphocytes.

4.9 Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LYG) is a rare EBV-associated lymphoproliferative disorder of B-cell origin that may involve the lungs, skin, central nervous system, and kidneys [156–158]. LYG is graded based on the number of EBV-positive cells in the biopsy specimen, and prognosis is inferior for higher-grade disease. Low-grade lesions often undergo spontaneous remission, but LYG can evolve into high-grade, aggressive EBV-associated DLBCL [158]. Patients typically have no known preexisting immunodeficiency but often have a history of autoimmune disease, recurrent viral infection, or low CD4 or CD8 cell counts [158]. Patients with Wiskott-Aldrich syndrome and common variable immunodeficiency or those receiving intensive chemotherapy for leukemia have been reported to develop LYG, again pointing to immune dysfunction as a predisposing factor [159]. Interestingly, LYG seems to be a very rare entity in HIV patients.

4.10 Extranodal NK-/T-cell Lymphoma and Aggressive NK-Cell Leukemia

Extranodal NK-/T-cell lymphoma is a very aggressive lymphoma that is more common in Asian countries and in Native American populations in parts of Central and South America, accounting for up to 10 % of all NHLs in some regions of the world [160–162]. Epidemiology studies in the United States have identified higher rates in Hispanics and Asian Pacific Islanders [163]. EBV is universally present in these lymphomas. Patients present with destructive lesions involving the nasal cavity, and historically, this disease entity was called "lethal midline granuloma." The prognosis is typically poor, especially for advanced stage disease.

Other high-risk groups for EBV-associated T-cell lymphoproliferative disorders and lymphomas include patients with a history of chronic active EBV (CAEBV) infection [164]. In Asians, particularly in the Far East, an association between CAEBV infection, mosquito bite hypersensitivity, and subsequent risk for NK-cell leukemia/lymphoma is noted, and Tokura-Ishihara disease is defined by this triad [165–169]. Patients with NK-cell leukemia often present with hepatosplenomegaly and cutaneous lesions. The presence of EBV in NK-cell leukemia distinguishes it from a more indolent disease, NK lymphoproliferative disease. Hemophagocytic syndrome is a common complication of disseminated disease or can precede the development of an EBV-associated T-cell malignancy in patients with CAEBV or congenital immunodeficiencies.

4.11 Angioimmunoblastic T-Cell Lymphoma (AITL)

Angioimmunoblastic T-cell lymphoma (AITL) is a mature T-cell lymphoma where patients classically have associated immune dysfunction (autoimmune cytopenias, hypergammaglobulinemia, and/or opportunistic infections). AITL tumors will often have polyclonal, or more rarely monoclonal, proliferations of EBV-positive B cells amid the malignant T cells. HHV6-positive B cells have also been reported to be present in AITL tumors, and coinfection with both herpesviruses can occur [170]. A reported phenomenon has been the development of a subsequent EBV-positive B-cell lymphoma after treatment for AITL [171]. One series noted that AITL patients with high EBV viral loads were more likely to have monoclonal, rather than polyclonal, B cells in their tumors; these patients were also more likely to subsequently develop an EBV-positive B-cell lymphoma [170].

4.12 KSHV and KSHV/EBV Lymphoma and Lymphoproliferative Disease

4.12.1 Primary Effusion Lymphoma (PEL)

Primary effusion lymphoma (PEL) is a very rare KSHV-associated body cavity-based lymphoma that occurs in the context of severe immunodeficiency, such as patients with AIDS and very low CD4 counts or rarely in solid organ transplant recipients [172]. PEL tumors are characterized by lymphomatous effusions involving the pleural, pericardial, or peritoneal spaces [172]. Lymphadenopathy is not present in the majority of cases, although spread to extracavitary sites does occur [173]. These tumors are always KSHV positive and 80 % are also EBV positive [172]. EBV gene expression is very restricted (type 1 latency), while KSHV gene expression includes latency and sometimes lytic viral genes. Although these tumors are quite rare, tumor-derived cell lines are readily established in vitro. These tumor cell lines have been extensively studied. It is not uncommon for patients with PEL to have other KSHV-associated diseases concurrently, such as Kaposi sarcoma or multicentric Castleman disease (MCD). Thus, lymphadenopathy or masses on staging evaluations should be thoroughly investigated. The lymphoma itself typically has a very aggressive course, and the prognosis for patients with PEL is extremely poor with median survival on the order of months [174]. Due to the rarity of the disease, treatment options are by no means standardized and rely on best available practices and expert opinion.

KSHV-positive solid lymphomas that are morphologically very similar to PEL have also been reported, again rare and predominantly in the setting of advanced HIV [173]. There is a tendency for these lesions to involve the gastrointestinal tract or skin, notably the same tissues of the body that tend to be involved in Kaposi sarcoma [173].

Cytologically, PEL tumor cells are large, monoclonal immunoblasts with prominent nucleoli. The tumor cells are of B-cell origin, exhibiting clonal immunoglobulin gene rearrangements, although they lack B-cell markers. On flow cytometry, CD45 positivity is typical, and CD30 or CD38 positivity is sometimes present. The association with KSHV can be confirmed by staining for a KSHV latent nuclear antigen, LANA-1.

KSHV is well recognized to produce viral IL-6, as well as potentially increase human IL-6 production, both contributing to the systemic inflammation seen in several KSHV-associated diseases [12, 15]. Viral IL-6 has been shown to activate various signaling cascades, including the STAT1, STAT3, and MAP kinase pathways, function as a pro-growth signal, and stimulate the production of acute phase proteins that reduce recognition of virally infected cells by the immune system [15].

4.12.2 Multicentric Castleman Disease (MCD) and KSHV/EBV Dual Positive Diseases

The plasma cell variant of MCD is usually associated with KSHV, and in HIV patients, it is virtually always KSHV associated [121]. MCD is a non-clonal lymphoproliferative disorder, although it characteristically has monotypic expression of the IgM heavy chain and the lambda light chain. In contrast to PEL, it is associated with lytic KSHV gene expression. Among the viral genes expressed is the viral IL-6 homologue, and this likely accounts for some of the constitutional symptoms such as fever and night sweats that are often associated with MCD. In some instances, it can progress to KSHV-positive lymphoma.

There are also reports of dually infected lymphomas. Germinotropic lymphoproliferative disorder, an indolent lymphoproliferative disease that harbors EBV and KSHV coinfection within involved cells, has been reported in a handful of immunocompetent, HIV-negative patients [175]. The disease has been reported to be localized, with good responses to a variety of therapies. An EBV-positive, KSHV-positive lymphoproliferative disorder similar in some ways to germinotropic lymphoproliferative disorder, but occurring in an HIV patient with a very aggressive clinical course, has also been reported [176, 177].

The presence of KSHV in tumor tissue is confirmed by immunohistochemistry for latency-associated nuclear antigen (LANA-1). MCD is often associated with high levels of lytic viral replication, and KSHV viral loads in the peripheral blood may be quite elevated.

5 Tools for Epidemiology: EBV or KSHV and Clinical Specimens

Tumor Specimens. Recognized EBV or KSHV lymphoma associations reflect the presence of viral genomes in tumor cells. A variety of techniques have been used to demonstrate the association. Extremely sensitive methods for detection of viral DNA in tumor tissues may be difficult to interpret because lymphocytes that harbor virus but are not malignant may be detected in tumor tissue. Histologic approaches that demonstrate the presence of viral DNA, RNA, or protein in tumor cells have become standard. Among the most useful tools for establishing EBV association has been the detection of EBER RNA by in situ hybridization. These noncoding short viral RNAs are expressed at high abundance and are readily detected in most EBV-associated tumors. Immunohistochemistry for viral antigens such as LMP-1 is also routinely performed to assess the EBV status of a tumor. This technique is particularly sensitive in HL but less so in other EBV-associated lymphomas where LMP-1 may not be expressed [178]. For detection of KSHV, the most standard assay has been immunohistochemistry for LANA-1. LANA-1 is expressed in all KSHV-associated malignancies.

Serology. Antibody responses to viral antigens have been a key tool in defining some of the virus-disease associations [43, 179]. Antibodies against viral antigens show clear evidence of past infection and, when appropriate serum collections are available, allow the timing of infection to be established. However, most individuals with EBV- and KSHV-associated lymphomas show antibody response patterns that do not readily distinguish them from healthy individuals also harboring the virus. Thus EBV serology at present does not allow individuals with EBV-associated HL to be distinguished from individuals with HL without EBV, although there are statistical associations with particular patterns of response. Thus among patients with HL with EBV in the tumor, the ratio of antibody titer against EBNA1 to antibody titer against EBNA2 is lower than among other patients with HL or among healthy controls [68]. New approaches to serology involving arrays of antigens may emerge as useful tools for investigation [180].

EBV and KSHV DNA. Viral DNA detected in the peripheral blood by real-time quantitative polymerase chain reaction (qPCR) techniques, both in lymphocytes (PBMCs – peripheral blood mononuclear cells) and in cell-free fractions (serum or plasma). However, detection of EBV DNA in the peripheral blood is not specific for any particular EBV-associated disease entity. As EBV infection is ubiquitous with lifelong infection in the majority of adults, even healthy adults with no EBV-related lymphoproliferative disorder will have EBV DNA detected by qPCR in a small percentage of circulating B lymphocytes. In cell-free fractions such as serum or plasma, EBV DNA may be tumor derived or virion derived. While healthy EBV-seropositive adults will rarely have EBV DNA detected in cell-free fractions, immunocompromised patients, such as patients with HIV, posttransplantation immunosuppression, or congenital immunodeficiencies, can often have elevated EBV DNA detected in the blood, with or without an associated EBV-positive malignancy [181]. EBV DNA quantification by qPCR is used clinically in some malignancies, such as EBV-positive undifferentiated nasopharyngeal carcinoma (NPC). Cell-free EBV DNA quantification has been shown to perform well as a clinical tool for staging NPC patients, assessing response to therapy, and prognostication [182–184]. EBV DNA monitoring is often used in the posttransplant setting to identify patients at high risk for developing EBV-PTLD. Recently, there has been growing evidence that plasma EBV DNA viral load may have prognostic and predictive significance in other EBV-associated lymphomas, such as ENKTL and HL [185–190].

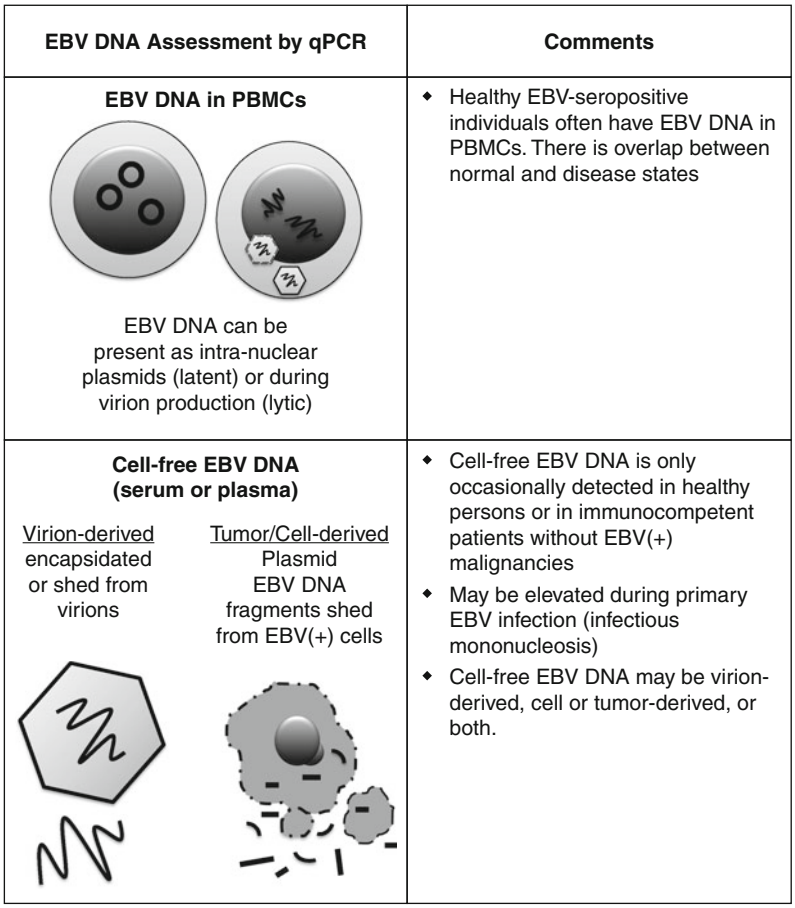

Fig. 40.4 Quantification of EBV DNA copy number by real-time polymerase chain reaction (*qPCR*). EBV DNA can be detected in peripheral blood mononuclear cells (*PBMCs*), as well as in cell-free specimens (serum or plasma). Viral DNA can be virion-derived or tumor/cell-derived

KSHV DNA can also be detected in PBMC or in cell-free fractions of blood. As with EBV, viral DNA may be detected in individuals without KSHV-associated tumors [191]. There have been few studies in patients with KSHV-associated lymphoma or lymphoproliferative disease, although very high viral DNA copy numbers have been reported in HIV patients with MCD and KSHV viral loads appear to be predictive of relapse [192]. Figure 40.4 outlines the sources of EBV detected in the blood by real-time polymerase chain reaction.

6 Vaccines for EBV-Positive Lymphomas

A vaccine that prevented primary infection might well reduce the incidence of EBV-associated disease including lymphoma [189]. A subunit vaccine targeting the viral glycoprotein gp350 has been evaluated in small clinical trials [194]. The vaccine did not prevent primary infection but did reduce the incidence of symptomatic infectious mononucleosis. Whether vaccination would have any impact on the incidence of EBV lymphoma is not clear. However, insofar as EBV-associated HL is more common in patients with history of symptomatic primary EBV infection, the argument has been made that reducing the incidence of infectious mononucleosis might reduce the incidence of EBV-associated HL [193]. An alternative approach to prevention has involved trials of polypeptides encoding epitopes from especially immunodominant latency viral antigens such as the EBNA-3 family of proteins [195]. Finally, there may also be a role for "therapeutic vaccines" for patients with EBV-associated tumors. Such an approach is being actively explored in another EBV-associated malignancy, nasopharyngeal carcinoma [196]. Underlying immune dysfunction in some target patient populations may hinder the efficacy of such vaccines [197].

7 Treatment of EBV-Associated Lymphoma

Generally, the approach to the treatment of EBV-associated lymphomas does not specifically target EBV and is similar to the approach to lymphomas that are not associated with EBV. However, there are few special situations in which targeting viral antigens are being used clinically [198]. In bone

marrow and hematopoietic stem cell transplantation, T-cell depletion and other manipulations to prevent graft-versus-host disease are associated with especially high rates of EBV-PTLD. Restoring T-cell immunity with infusion of donor lymphocytes or EBV-specific donor T-cell products is often effective in preventing or treating these tumors [199–206]. Similar adoptive cellular approaches have also been applied in SOT patients, although these have typically involved in vitro expansion and infusion of autologous or third-party EBV-specific cytotoxic T cells. These approaches are also being explored for the treatment of EBV-associated HL. However, since in EBV-associated HL the viral antigens being expressed by tumor cells are more limited than in EBV-associated PTLD, the activated T cells infused are typically targeted against particular viral antigens such as LMP-1 rather than latency viral antigens in general.

7.1 Unresolved Problems

The discovery of EBV in association with endemic BL seemed to provide a simple explanation for the geographic distribution of the tumor. The observation that the virus immortalized lymphocytes in vitro strengthened that conclusion. A half century later, the explanation for the association remains uncertain. While we suspect that both EBV and malaria play a role, another tumor that is similar in its histology and molecular characteristics occurs in the absence of either infection. At the same time, although the list of EBV-associated lymphomas continues to grow, it is not a list that includes every lymphoma, or every B-cell lymphoma, or every lymphoma arising in an immunocompromised patient. And when we sort out the answers to these mysteries, the mysteries of KSHV and the dual infection lymphomas and lymphoproliferative diseases await.

There is still much to be learned about how herpesviruses alter signaling pathways; mimic B-cell biology; drive or skew the production of cytokines, chemokines, and growth factors; influence noninfected cells of the microenvironment; and contribute to epigenetic and genetic changes. Emerging disease entities, such as EBV-positive DLBCL of the elderly, which occurs in patients that have no definable immune dysfunction but are postulated to be vulnerable to virally related lymphomas due to immune senescence of aging, require further investigation to understand the pathogenesis of the disease.

In HIV patients, the incidence of EBV-positive HL is rising despite the use of HAART, and most patients are diagnosed with reasonably robust CD4 counts. The abnormalities in the immune system that place these patients at ongoing risk for lymphoma, despite control of their HIV, are generally thought to relate to chronic B-cell activation and proliferation, but are not well characterized. Additionally, EBV-related T- and NK-cell lymphomas are much more common in Asian countries than in other parts of the world, yet the environmental, genetic, immune, and other factors that modulate this difference in EBV tropism and patterns of disease require further investigation. Insights into the factors that differ in patients that develop these virally related lymphomas may have implications for screening, diagnosis, therapy, and even prevention. Currently, there are no approved therapies specifically indicated for herpesvirus-associated lymphomas. In the research setting, clinical trials using EBV-specific CTLs, vaccines, and other targeted therapies are ongoing. However, the evasiveness of latent herpesvirus infection continues to present many challenges in the development of targeted therapies. There is much interest in the development and validation of EBV-related biomarkers to assess response to therapy, provide prognostic information, and serve predictive functions in the treatment of EBV-positive lymphomas.

Epstein-Barr Virus: Nasopharyngeal Carcinoma and Other Epithelial Tumors

41

Lawrence S. Young, Christopher W. Dawson, and Ciaran B.J. Woodman

1 Introduction

It is estimated that infection contributes to the development of around 20 % of human cancer – some two million cases per year [1]. Understanding the role of infection in cancer continues to provide fundamental insights into the underlying mechanisms responsible for driving the oncogenic process as well as highlighting opportunities for therapeutic and prophylactic intervention. Epstein-Barr virus (EBV) was the first human tumor virus to be discovered and has yielded significant insight into both the pathogenesis of cancer and the natural history of persistent herpesvirus infection.

EBV is one of the most common infections being found as a widespread and largely asymptomatic lifelong infection in all human populations [2, 3]. Early in the course of primary infection, EBV infects B lymphocytes, although it is not known where B lymphocytes are infected and whether this also involves epithelial cells of the upper respiratory tract. To achieve long-term persistence in vivo, EBV colonizes the memory B cell pool where it establishes latent infection, which is characterized by the expression of a limited subset of virus genes, known as the "latent" genes [4]. There are several well-described forms of EBV latency, each of which is utilized by the virus at different stages of the virus life cycle and which are also reflected in the patterns of latency observed in the various EBV-associated malignancies [2, 5]. Furthermore, during its life cycle EBV must periodically enter the replicative cycle in order to generate infectious virus for transmission to other susceptible hosts with epithelial sites in the oropharynx and salivary glands appearing to be the major site for viral replication. Thus, the natural history of persistent EBV infection appears to resemble that of other herpesviruses in requiring distinct cell lineages to manifest the latent and replicative forms of the virus life cycle.

The dual tropism of EBV infection is also reflected in the types of tumor associated with the virus. Colonization of the memory B cell pool in vivo, along with the unique ability of EBV to efficiently transform resting B cells into permanent latently infected lymphoblastoid cell lines (LCLs) in vitro, is mirrored by the various malignancies of B cell origin that are closely associated with EBV infection [2, 3, 5]. However, it is the EBV-associated undifferentiated form of nasopharyngeal carcinoma (NPC) that shows the most consistent worldwide association with EBV. Furthermore, a subset of gastric adenocarcinomas and certain salivary gland carcinomas are also infected with EBV. These tumors demonstrate the ability of epithelial infection with EBV to result in malignant transformation and provide opportunities to consider targeted approaches to preventive and therapeutic intervention.

2 Historical Background

In 1964 Tony Epstein and Yvonne Barr identified herpesvirus-type particles by electron microscopy in a subpopulation of Burkitt lymphoma (BL)-derived tumor cells in vitro. Only 2 years later Lloyd Old and colleagues described antibodies in the serum of African BL patients that recognized antigens prepared from BL cell lines [6]. A surprising observation was that similar BL antigen-specific antibodies were also present in the serum from patients with postnasal space carcinomas and these were found in a high proportion of patients from both Africa and the USA. This led the authors to suggest that "the high frequency of positive sera among patients with carcinoma of the postnasal space indi-

cates the desirability of searching for similar particles in cultures of this class of tumor also." A more specific immunofluorescence assay for detecting antibodies against EBV-encoded replicative antigens was developed by George Klein, Werner and Gertrude Henle, and John H C Ho, and this confirmed the association of elevated antibody titers against EBV-encoded virus capsid antigen (VCA) and membrane antigen (MA) with NPC [7]. In 1970 Harald zur Hausen and colleagues used DNA hybridization technology to demonstrate the presence of EBV DNA in extracts from NPC tumors [8]. Further serological analysis showed an association between EBV antibody titers and NPC tumor stage [9] and identified VCA-specific IgA levels as a potential prognostic indicator [10]. In 1973, EBV DNA was detected by in situ hybridization in the tumor cells of NPC and not infiltrating lymphoid cells [11]. The apparent specificity of the association between VCA IgA levels and NPC led Zeng Yi to embark on a mass serological screening program in Wuzhou City in China where these EBV-specific antibodies were found to be useful in the early detection of NPC and where subsequent prospective analysis revealed the presence of IgA VCA up to 41 months prior to the clinical diagnosis of NPC [12]. Analysis of the terminal repeats (TRs) of the EBV genome in NPCs by Southern blot hybridization demonstrated the monoclonality of the resident viral genomes providing important evidence that EBV infection had taken place before the clonal expansion of the malignant cell population [13].

3 EBV Infection and Nasopharyngeal Carcinoma

The World Health Organization (WHO) has classified NPC into two main histological types – keratinizing squamous cell carcinoma (type I) and nonkeratinizing squamous cell carcinoma (types II and III) – based on the light microscopic appearance of the tumor cells. The nonkeratinizing type is further subdivided into differentiated nonkeratinizing (type II) and undifferentiated carcinomas (type III), and it is these tumors that are predominantly EBV positive [14, 15]. The well-differentiated keratinizing NPC (type I) accounts for less than 20 % of all NPC cases worldwide, and this tumor type is relatively rare in Southern China [15, 16]. However, the association of EBV with the more differentiated WHO type I form of NPC has been found particularly in those geographical regions with a high incidence of undifferentiated NPC [14]. In NPC the virus exists in a latent state, exclusively in the tumor cells and absent from the surrounding lymphoid infiltrate. However, the interaction between the prominent lymphoid stroma found in undifferentiated NPC and adjacent carcinoma cells appears to be crucial for the continued growth of the malignant NPC cells.

Carcinomas with similar features to undifferentiated NPC have been described at other sites including the thymus, tonsils, lungs, stomach, skin, or uterine cervix and are often referred to as undifferentiated carcinomas of nasopharyngeal type (UCNT) or "lymphoepitheliomas." The morphological similarities of UCNTs to undifferentiated NPC prompted several groups to examine such cases for the presence EBV. UCNTs of the stomach are consistently EBV positive [17], whereas the association of the other UCNTs with EBV is less strong. EBV has been demonstrated in thymic epithelial tumors from Chinese but not Western patients [18]. Salivary gland UCNTs are EBV-associated in Greenland Eskimos and Chinese but not in Caucasian patients [19], and several case reports have demonstrated the absence of EBV from UCNTs arising in the uterine cervix and breast [20, 21].

4 Biological Characteristics

4.1 Patterns of EBV Latent Gene Expression in Virus-Associated Tumors

Much of our understanding of the biology of EBV relates to its interaction with B lymphocytes. This is reflected in the ability of EBV to readily infect and transform normal resting B lymphocytes in vitro, a model system which has provided important insights into the biology and behavior of the virus. The lymphoblastoid cell lines (LCLs) generated by in vitro infection of B lymphocytes carry multiple copies of circular extra chromosomal viral DNA (episomes) in every cell and express a limited set of latent proteins, including six nuclear antigens (EBNAs 1, 2, 3A, 3B, and 3C and EBNA-LP) and three latent membrane proteins (LMPs 1, 2A, and 2B) [2, 3, 5]. In addition to the latent proteins, LCLs also show abundant expression of the small non-polyadenylated RNAs, EBERs 1 and 2; these are expressed in all forms of latent EBV infection and have served as excellent targets to detect EBV in tumors. Transcripts, originally referred to as BARTs (BamHI A rightward transcripts), from the *Bam*HI A region (Bam A) of the viral genome are also detected in LCLs and these, along with transcripts from the BHRF1 region, encode microRNAs (miRNAs). This pattern of latent EBV gene expression is referred to as the "latency III" (Lat III) form of EBV infection and is characteristic of the majority of EBV-associated lymphomas arising in immunosuppressed patients.

The examination of EBV latent gene expression in virus-associated tumors and in cell lines derived from Burkitt lymphoma (BL) biopsies identified at least two additional forms of EBV latency. EBNA1 is the only EBV protein consistently observed in EBV-positive BL tumors along with the EBER and *Bam*HIA transcripts; this form of latency is referred to latency I or Lat I [2, 3, 5]. A variant of Lat I is

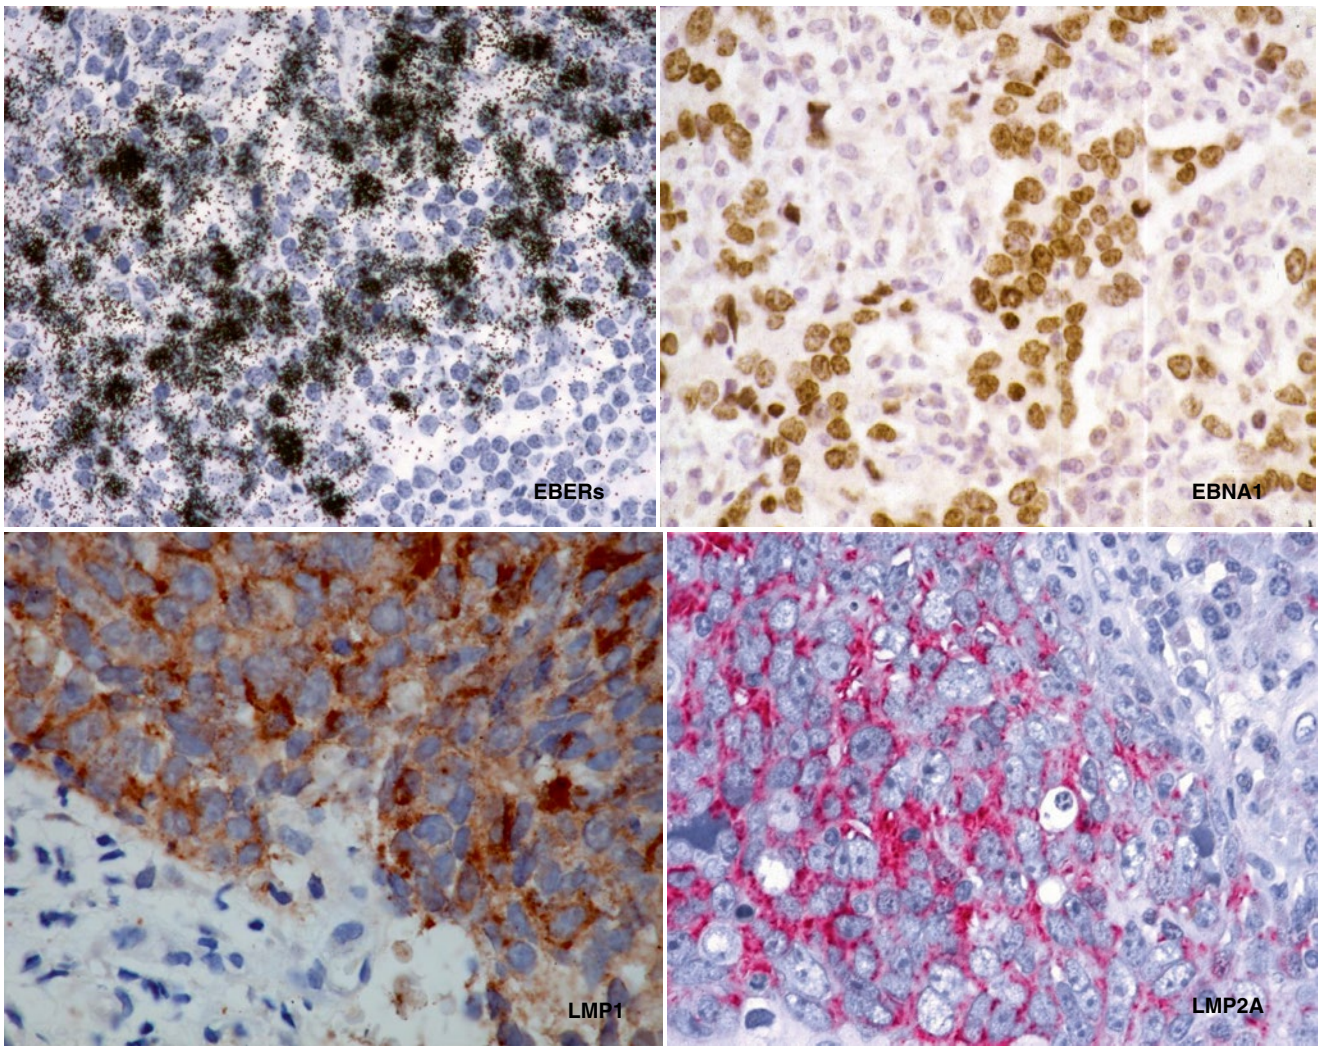

Fig. 41.1 EBV latent gene expression in NPC. In situ hybridization to the abundant EBV-encoded *EBER* transcripts (*left, upper panel*) is the standard approach to detect EBV infection in cells and tissues. Immunohistochemical staining of NPC confirms *EBNA1* expression in every tumor cell (*right, upper panel*). The expression of *LMP1* and *LMP2A* in NPC biopsies (*lower panels*) is more variable. Note the prominent lymphoid infiltrate in NPC, which is believed to contribute to the growth and survival of the tumor cells

observed in around 5–10 % of EBV-positive BL tumors where expression of BHRF1, EBNA3A, EBNA3B, and EBNA3C is observed [22]. It appears that in these tumors the selective pressure to downregulate EBNA2 expression has occurred via deletion of the EBNA2 gene rather than through the switch in viral promoter usage observed in the conventional BL scenario. Another form of EBV latency, Lat II, was originally identified in biopsies of NPC and subsequently found in cases of EBV-associated Hodgkin's lymphoma (HL) (Fig. 41.1) [23–26].

Here, expression of the EBERs, EBNA1, and *Bam*HI A transcripts is accompanied by expression of LMP1 and LMP2A/B. While this Lat II pattern of EBV latent gene expression is a consistent feature of virus-associated HL, LMP1 expression in NPC is variable with only around 20 % of biopsies being unequivocally positive for LMP1 at the protein level [3]. The mechanisms underlying differential LMP1 expression in NPC and the consequent effects on the NPC phenotype remain unknown.

These different forms of EBV latent infection are a reflection of the cellular environment and the complex interplay between host regulatory factors and the viral promoters driving EBV latent gene expression. In Lat III, the different EBNAs are encoded by individual mRNAs generated by differential splicing of the same long (over 100 kb) "rightward" primary transcript expressed from one of two promoters (Cp or Wp) located close together in the *Bam*HI C and W region of the genome [27]. A switch from Wp to Cp occurs early in B cell infection as a consequence of the transactivating effects of both EBNA1 and EBNA2 on Cp. The LMP transcripts are

expressed from separate promoters in the *Bam*HI N region of the EBV genome, with the leftward LMP1 and rightward LMP2B mRNAs apparently controlled by the same bidirectional promoter sequence (ED-L1) which also responds to transactivation by EBNA2 [5, 27]. The LMP2A promoter is also regulated by EBNA2. Both LMP2A and LMP2B transcripts cross the TRs into the U1 region thus requiring the circularization of the genome for transcription. Circularization occurs by homologous recombination of the TRs resulting in fused termini of unique length, and this has been used as a measure of EBV clonality on the assumption that fused TRs with an identical number of repeats denote expansions of a single infected progenitor cell [13]. This contention has been challenged by the observation that EBV clonality postinfection may be a consequence of the selective growth advantage achieved by optimal LMP2A expression over a minimal number of TRs [28]. In the more restricted forms of EBV latency observed in NPC and HL, EBNA1 transcription is driven from the TATA-less Qp promoter [29] and an alternative promoter, L1-TR, located in the terminal repeats is responsible for LMP1 expression [30]. It is widely accepted that these forms of EBV latency reflect the different transcription programs that EBV employs as the virus transits through the germinal center B cell reaction to finally colonize the resting memory B cell compartment [4]. The adoption of these forms of latency in EBV-associated tumors is therefore assumed to represent the aberrant manifestation of inappropriate virus transcription programs as a consequence of both the host cell environment and the selection pressures associated with oncogenic progression.

4.2 The Function of EBV Latent Genes Expressed in NPC

4.2.1 EBNA1

EBNA1 is a DNA-binding protein that is required for the replication and maintenance of the episomal EBV genome; a function that is achieved through the binding of EBNA1 to oriP, the plasmid origin of viral replication [5]. EBNA1 also interacts with two sites downstream of Qp to negatively regulate its own expression [29]. EBNA1 also acts as a transcriptional transactivator and upregulates Cp and the LMP1 promoter [5]. The EBNA1 protein contains a glycine-glycine-alanine (gly-gly-ala) repeat sequence, which varies in size in different EBV isolates. This gly-gly-ala repeat domain is a *cis*-acting inhibitor of MHC class I-restricted presentation and appears to function by inhibiting antigen processing via the ubiquitin-proteosome pathway [31]. While this effect may result in poor presentation of EBNA1-derived epitopes to cytotoxic T lymphocytes (CTLs), it does not prevent the induction of EBNA1-specific CD8+ T cell responses.

Aside from its role in EBV replication, segregation, and transcriptional activation, EBNA1 has recently been found to protect cells from apoptosis, enhance cell survival, and directly contribute to the tumorigenic phenotype [32]. These effects are manifest through a variety of mechanisms including the destabilization of p53, the disruption of PML nuclear bodies, and the modulation of various signaling pathways.

4.2.2 LMP1

LMP1 is the major transforming protein of EBV behaving as a classical oncogene in rodent fibroblast transformation assays and being essential for EBV-induced B cell transformation in vitro [33, 34]. LMP1 has pleiotropic effects when expressed in cells resulting in induction of cell surface adhesion molecules and activation antigens, upregulation of anti-apoptotic proteins (Bcl-2, A20), and stimulation of cytokine production (IL-6, IL-8) [35]. LMP1 functions as a constitutively activated member of the tumor necrosis factor receptor (TNFR) superfamily activating a number of signaling pathways (NF-κB, ERK-MAPK, JNK/AP1, PI3-K) in a ligand-independent manner [36]. Functionally, LMP1 resembles CD40, a member of the TNFR superfamily, and can partially substitute for CD40 in vivo providing both growth and differentiation signals to B cells [37]. The LMP1 protein consists of six hydrophobic transmembrane loops which mediate the self-aggregation of LMP1 into oligomers and a C-terminal cytoplasmic tail which contains two distinct functional domains referred to as C-terminal activation regions 1 and 2 (CTAR1 and CTAR2) originally identified on the basis of their ability to activate the NF-κB transcription factor pathway [35]. This effect contributes to the many phenotypic consequences of LMP1 expression including the induction of various antiapoptotic and cytokine genes. LMP1 is also able to engage the MAP kinase cascade resulting in activation of ERK, JNK, and p38 and to stimulate the JAK/STAT pathway [38–41]. Many of these effects result from the ability of TNFR-associated factors (TRAFs) to interact either directly with CTAR1 or indirectly via the death domain protein TRADD to CTAR2 [42]. LMP1 can also activate the phosphatidylinositol 3-kinase (PI3-K) pathway resulting in a variety of effects including cell survival mediated through the Akt (PKB) kinase, actin polymerization, and cell motility [43]. Expression of LMP1 in epithelial cells is associated with a range of phenotypic effects including hyperproliferation, induction of pro-inflammatory cytokines, resistance to apoptosis, and enhanced motility [35].

The role of LMP1 in the pathogenesis of NPC remains speculative. There is considerable variation in the reported expression of LMP1 in NPC biopsies and a general consensus that around 20–40 % of tumors express LMP1 at the protein level [3]. In one study all six early preinvasive NPC (NPC in situ) lesions analyzed expressed the LMP1 protein,

arguing for a critical role of LMP1 in the early pathogenesis of NPC [44]. The possibility of geographical variation in LMP1 expression in NPC has been suggested and is supported by studies in North Africa where LMP1 has been found to be more prevalent in the juvenile form of NPC [45].

4.2.3 LMP2A/B

The two proteins encoded by the LMP2 gene, LMP2A and LMP2B, share 12 hydrophobic membrane-spanning domains and a short cytoplasmic C-terminus, but it is the unique cytoplasmic N-terminal domain of LMP2A that appears to be responsible for the functional effects of this molecule. This domain contains an immunoreceptor tyrosine-based activation motif (ITAM), similar to that in the B cell antigen receptor (BCR), which interacts with and negatively regulates members of the *src* family of protein tyrosine kinases (PTKs) [46]. The LMP2A ITAM blocks BCR-stimulated calcium mobilization, tyrosine phosphorylation, and activation of the EBV lytic cycle in B cells [47]. Expression of LMP2A in the B cells of transgenic mice abrogates normal B cell development allowing immunoglobulin-negative cells to colonize peripheral lymphoid organs [48]. This suggests that LMP2A can drive the proliferation and survival of B cells in the absence of signaling through the BCR, an effect that may be relevant to the ability of EBV to colonize the memory B cell pool. While LMP2A and LMP2B may share common or overlapping functions, studies suggest that the primary function of LMP2B is to negatively regulate LMP2A signaling [49].

In non-B cells, the LMP2 proteins localize to various intracellular compartments (perinuclear endosomes, the endoplasmic reticulum (ER), the trans-Golgi network (TGN), and CD63-positive lysosomes) [50–52], and LMP2A is also associated with lipid rafts, microdomains that form membrane-associated signaling platforms [53]. While much is known about the so-called LMP2A signalosome in the context of B cells, its role in the epithelial environment is less clear. LMP2A is required for the successful outgrowth of EBV-infected epithelial cells in vitro [28] and can induce anchorage-independent growth, enhance cell adhesion and cell motility, and inhibit epithelial cell differentiation [54–58]. Many of these effects are a consequence of the ability of LMP2A to activate the PI3-K/Akt and β-catenin pathways [55]. LMP2A can also induce an epithelial-mesenchyme transition (EMT) and this is associated with the acquisition of stem cell-like properties [59]. A role of LMP2A and LMP2B in resistance to the antiviral effects of interferons α and β in epithelial cells has been identified [60], and LMP2A is able to modulate NF-κB and STAT signaling in EBV-infected epithelial cells through effects on IL-6 transcription and secretion [61].

Unlike LMP1, LMP2A expression is more consistent in NPC. Studies using RT-PCR confirmed expression of LMP2A mRNA in greater than 98 % of NPC cases, while expression of LMP2B was lower and mirrored that of LMP1 [23, 62]. Immunohistochemical staining has confirmed expression of LMP2A protein in greater than 50 % of NPC cases [59, 63].

Interestingly, this consistent expression of LMP2 in NPC is reflected in serological responses such that the majority of NPC patients have detectable IgG responses to LMP2A/2B [64].

4.2.4 EBERs

Two small non-polyadenylated (noncoding) RNAs, EBERs 1 and 2, are highly expressed in all forms of EBV latency and serve as sensitive targets for detecting EBV infection in cells and tissues [2, 3, 5]. The EBERs assemble into stable ribonucleoprotein particles with the autoantigen La, with ribosomal protein L22, and bind the interferon-inducible, double-stranded RNA-activated protein kinase PKR [65]. The interaction of EBERs with RIG-1 induces type I interferon, an effect that may be counteracted by other viral genes such as LMP1 and LMP2A/B [66]. A role for the EBERs in inducing insulin-like growth factor 1 (IGF-1) in NPC cell lines has been described [67]. This effect is associated with the enhanced growth of NPC cell lines and its relevance to NPC is supported by the frequent expression of IGF-1 in tumor biopsies.

4.2.5 BARTs and BARF1

A group of abundantly expressed RNAs encoded by the BamHIA region of the EBV genome were originally identified in NPC but subsequently found to be expressed in other EBV-associated malignancies as well as in the peripheral blood of healthy individuals [2, 3, 5, 68, 69]. These highly spliced transcripts are commonly referred to as either BARTs (*Bam*HIA rightward transcripts) or complementary strand transcripts (CSTs). It was originally suggested that the BARTs might function as antisense transcripts by interfering with transcription from the complementary DNA strand of the EBV genome thereby inhibiting viral mRNAs associated with the productive cycle of the virus [70]. This possibility was refuted by the discovery of EBV as the first human virus to be found to encode microRNAs (miRNAs) and that the BARTs are a cluster of 22 miRNA precursors that generate 44 mature miRNAs [71]. These miRNAs target and thereby regulate a variety of viral and cellular transcripts [69, 72]. Thus, specific BART miRNAs have been found to protect from apoptosis and to contribute to immune evasion. The BART miRNAs also appear crucial in the regulation of EBV gene expression targeting both latent (LMP1, LMP2A) and lytic genes (BALF5). Because of their stability in serum, miRNAs have been recognized as potential cancer biomarkers and recent studies support the possible use of serum BART miRNAs in the detection and prognosis of NPC [73, 74].

It appears that the BART miRNAs in serum reside in cell-derived exosomes and that these are able to deliver miRNAs to other non-EBV-infected cells [75, 76]. This raises the intriguing possibility that BART miRNAs may be able to contribute to the development of NPC by influencing the behavior of stromal and immune cells.

Another transcript generated from the *Bam*HIA region is BARF1 that encodes a 31 kDa protein originally identified as an early antigen expressed upon induction of the EBV lytic cycle. However, BARF1 is a secreted protein which is expressed as a latent protein in EBV-associated NPC and gastric carcinoma [77, 78]. BARF1 shares limited homology with the human CSF-1 receptor (*c-fms* oncogene) and competes for its natural ligand, macrophage colony-stimulating factor (M-CSF or CSF-1), thereby modulating immune cell growth and function [79]. BARF1 displays oncogenic activity when expressed in rodent fibroblasts and simian primary epithelial cells [80]. Engineered expression of BARF1 in the context of a recombinant EBV enhanced the growth and tumorigenicity of virus-negative NPC cell lines implicating BARF1 in the pathogenesis of NPC [81]. It has been suggested that serum BARF1 could be a useful diagnostic marker for NPC [82].

4.3 EBV Strain Variation

EBV isolates from different regions of the world or from patients with different virus-associated diseases are remarkably similar when their genomes are compared by restriction fragment length polymorphism analysis [3, 5, 83]. However, variations in repeat regions of the EBV genome are observed among different EBV isolates. Analysis of the EBV genome in a number of Burkitt lymphoma (BL) cell lines revealed gross deletions, some of which account for biological differences, i.e., P3HR-1 virus which is non-transforming has a deletion of the EBNA2-encoding gene [3, 5, 83]. Strain variation over the EBNA2-encoding (BamHI WYH) region of the EBV genome permits all virus isolates to be classified as either "type 1" (EBV-1, B95.8-like) or "type 2" (EBV-2, Jijoye-like) [83]. This genomic variation results in the production of two antigenically distinct forms of the EBNA2 protein with only 50 % amino acid homology. Similar allelic polymorphisms (with 50–80 % sequence homology depending on the locus) related to the EBV type occur in a subset of latent genes, namely, those encoding EBNA-LP, EBNA3A, EBNA3B, and EBNA3C [84]. These differences have functional consequences as EBV-2 isolates are less efficient in in vitro B lymphocyte transformation assays compared with EBV-1 isolates [85]. A combination of virus isolation and seroepidemiological studies suggests that type 1 virus isolates are predominant (but not exclusively so) in many Western countries, whereas both types are widespread in equatorial Africa, New Guinea, and perhaps certain other regions [83, 86].

In addition to this broad distinction between EBV types 1 and 2, there is also minor heterogeneity within each virus type. Individual strains have been identified on the basis of changes, compared with B95.8, ranging from single base mutations to extensive deletions [83]. While infection with multiple strains of EBV was originally thought to be confined to immunologically compromised patients, more recent studies demonstrate that normal healthy seropositives can be infected with multiple EBV isolates and that their relative abundance and presence appears to vary over time [87]. Coinfection of the host with multiple virus strains could have evolutionary benefit to EBV enabling the generation of diversity by genetic recombination. Such intertypic recombination has been demonstrated in HIV-infected patients and in the Chinese population and appears to arise via recombination of multiple EBV strains during the intense EBV replication that occurs as a consequence of immunosuppression [88].

The possible contribution of EBV strain variation to virus-associated tumors remains contentious. Many studies have failed to establish an epidemiological association between EBV strains and disease and suggest that the specific EBV gene polymorphisms detected in virus-associated tumors occur with similar frequencies in EBV isolates from healthy virus carriers from the same geographical region [3, 86]. However, this does not exclude the possibility that variation in specific EBV genes is responsible for the distinct geographic distribution of virus-associated malignancies. In this regard, an LMP1 variant containing a 10 amino acid deletion (residues 343–352) was originally identified in Chinese NPC biopsies and has oncogenic and other functional properties distinct from those of the B95.8 LMP1 gene [89–91]. It is therefore likely that variation in LMP1 and other EBV genes can contribute to the risk of developing virus-associated tumors, but more biological studies using well-defined EBV variants are required.

5 Descriptive Epidemiology

NPC has a very distinctive geographic and ethnic distribution. Although the incidence of this cancer is less than 1 per 100,000 person-years in most parts of the world, rates of between 20 and 30 per 100,000 have been reported for populations in Southern China and Southeast Asia with intermediate rates recorded for those living in the Arctic region, North Africa, and parts of the Middle East. However, recent analyses of temporal trends suggest that incidence and

mortality rates from NPC are falling in both high- and low-risk countries [92–96].

5.1 Comparisons Between Low- and High-Incidence Countries

Although only limited comparisons are possible between high- and low-risk countries, because most of the areas at high risk have as yet underdeveloped cancer registration systems, such comparisons as are possible reveal intriguing differences in the age-specific incidence curves of NPC [97]. Whereas in high-risk countries, incidence increases monotonically reaching a peak at around 50 years of age, a bimodal distribution is observed in low-risk populations, irrespective of geographic location. In these countries, the first peak in incidence is seen in late adolescence or early adulthood and is followed by a second peak around the age of 70. Bray et al. [97] suggest that whereas the early peak in incidence point to a role for major susceptibility genes in disease pathogenesis, possibly mediated by other factors including EBV infection, for which age at infection may be critical, the later peak is a consequence of heavy smoking, alcohol consumption, and possibly long-term exposure to occupational carcinogens.

5.2 Immigrant Studies

Studies of immigrant populations have shown that NPC incidence among the Chinese is higher than among African Americans and Caucasians in the USA and is lower in second- and third-generation Chinese immigrants to the USA than in first-generation immigrants while remaining higher than those of other ethnic groups [95]. Compared with the indigenous population, the standardized incidence rate of NPC in Sweden was found to be significantly higher in male (SIR = 35.6) and female (24.6) Southeast Asians, male (12.4) and female (34.7) North Africans, and male (4.9) and female (10.9) Asian Arabs [98]. McDermott et al. commenting on the healthy immigrant effect has pointed out that while immigrants to Canada have a lower overall cancer risk than the indigenous population, they have a significantly higher incidence of nasopharyngeal, liver, and cervical cancer, three cancers which can be related to earlier viral infection in the country of origin [99]. While these immigrant studies suggest that both genetic factors and lifestyle contribute to the etiology of NPC, a recent systematic review has confirmed a decreasing trend in the incidence of NPC in Chinese migrants living in countries with a low risk of the disease, providing further evidence that the excess risk associated with migrant status becomes attenuated over time [100].

5.3 Tobacco Use and Risk of Nasopharyngeal Cancer

Case-control studies have reported an increased risk of NPC related to the duration and intensity of cigarette smoking in both low- and high-incidence regions [101–105]. In those analyses in which cases could be stratified by histological types, the risk associated with smoking behavior was found to be stronger for differentiated as compared to undifferentiated tumors in studies conducted in both low- and high-incidence countries [16, 103, 106]. A fall in the incidence of this histological type have been reported in Singapore, in the Netherlands, and in Chinese men living on the Western seaboard of the USA and has been attributed to a decline in cigarette smoking [94, 95, 107]. In the Netherlands, a low-risk country, the decrease in the incidence of smoking-related keratinizing carcinoma coincided with an increase in the incidence of differentiated nonkeratinizing NPC, a pattern which the authors attribute to recent waves of migration [96].

Compelling evidence of an exposure-disease relationship is provided by cohort studies in which smoking behavior and other risk factors for NPC are ascertained prior to the diagnosis of disease. Such studies have confirmed that prolonged cigarette smoking is associated with an increased risk of developing NPC [108–111]. Consistent with the impression left by earlier cross-sectional and cohort studies, a recent case-control study has shown that not only are cigarette smoking and EBV seropositivity associated with an excess risk of NPC but also that smoking was the only risk factor for NPC associated with elevated titers of VCA IgA antibody in disease-free subjects recruited from both low- and high-incidence areas [102]. The investigators show in vitro that cigarette smoke extract promotes EBV replication, induces the expression of the immediate-early transcriptional activators Zta and Rta, and increases the transcription of BFRF3 and gp350 in the lytic phase. These findings suggest an alternative role for cigarette smoking in the pathogenesis of NPC other than through direct DNA damage.

5.4 Dietary Factors

The consumption of salted fish is an established risk factor for NPC [102, 112]. There is also compelling evidence to suggest that whereas the risk of NPC increases with increasing consumption of preserved foods, it falls with increasing consumption of fresh fruit and Vegetables [101, 112–114]. More recently case-control studies have shown a reduced risk of NPC related to consumption of green tea [113, 115]. Epigallocatechin-3-gallate, the principal polyphenol present in green tea, has been shown to inhibit stemlike characteristics and epithelial-mesenchymal transition in NPC cell lines

when grown in spheres [116]. A meta-analysis of four case-control studies conducted in China revealed a modest but significant excess risk of NPC associated with alcohol consumption [117]. Although these findings are consistent with the results of an earlier systematic review, which concluded that heavy alcohol consumption is associated with an increased risk of NPC, the exposure-disease relationship is complex with some studies revealing a J-shape dose-response trend, with NPC risk decreasing with modest consumption and increasing with higher intake [118].

5.5 Wood Dust and Formaldehyde

At least two million workers are routinely exposed to wood dust in the work environment worldwide. A pooled analysis of cancer mortality among five cohorts of workers in wood-related industries has shown that workers exposed to wood dust may have an excess risk of death from sinonasal cancers and NPC [119]. More recently, case-control studies, which included detailed assessments of occupational exposure, have shown that the risk of NPC is highest for individuals exposed to wood early in life. Consistent with a possible interaction between environmental exposures and genetic predisposition, these studies have shown that the excess risk of NPC associated with wood exposure stronger in families with two or more members already affected by NPC is strongest in those families with early age-onset of disease [120, 121]. However, an association between wood dust and NPC may be more difficult to reveal in low-incidence populations. A recent cohort study with more than 25 years of follow-up did not find an increased risk of NPC in Finnish men in whom estimates of exposure to wood dust had been generated using a job-exposure matrix [122]. There is no compelling evidence of an increased risk of NPC following formaldehyde exposure; a recent meta-analysis of case-control and cohort studies found no excess risk after excluding a single plant with an unexplained cluster of NPC cases [123]. A more recent study which included information on occupational exposure in a cohort of Finnish men also found no evidence to suggest that chronic exposure to formaldehyde increases the risk of NPC [122].

5.6 Genetic Susceptibility

As comprehensively discussed in a recent review [124], there have been many studies exploring the role of genetic polymorphisms in NPC development, but these have been hampered by small cohort sizes, poor study design, and a lack of confirmatory studies. Genome-wide association studies (GWAS) have, however, confirmed previous observations suggesting a strong association of NPC with the MHC locus on chromosome 6p21 [125, 126]. The association of specific HLA alleles with NPC risk implies a possible contribution of differential immune responses to EBV, and this is further supported by linkage of NPC to other immune-related genes. Other studies implicate DNA repair genes, cell cycle control genes, and cell adhesion/migration genes in the development of NPC [124]. It is clear that larger, well-powered, and better coordinated studies are required to confirm these observations and to determine the real impact of gene-environment interactions on the development of NPC.

6 Mechanisms and Routes of Transmission

Transmission of EBV is addressed more extensively in Chap. 38 – EBV and Infectious Mononucleosis. EBV infects the majority of the world's adult population, and following primary infection, the individual remains a lifelong carrier of the virus [2, 3, 5]. In underdeveloped countries, primary infection with EBV usually occurs during the first several months to few years of life and is often asymptomatic. However, in developed populations, primary infection is more frequently delayed until adolescence or adulthood, in many cases producing the characteristic clinical features of infectious mononucleosis (IM). EBV is orally transmitted, and infectious virus can be detected in oropharyngeal secretions from IM patients, from immunosuppressed patients, and at lower levels from healthy EBV seropositive individuals. These observations, together with the fact that EBV-transformed LCLs in vitro tend to be poor producers of the virus and B lymphocytes permissive of viral replication have not been demonstrated in vivo, suggest that EBV replicates and is shed at epithelial sites in the oropharynx and/or salivary glands. This is supported by the demonstration of replicating EBV in the differentiated epithelial cell layers of oral "hairy" leukoplakia, a benign lesion of the tongue found in immunocompromised patients [127]. Replicative EBV infection has been also been found, albeit rarely, in normal squamous epithelial cells at the tongue margin but not in salivary glands (Fig. 41.2) [128]. However, it is also likely that EBV-infected B cells are reactivated within the local mucosal environment and that this contributes to virus shedding at oropharyngeal sites.

The inability to routinely detect EBV in normal epithelial cells and the demonstration that EBV can be completely eradicated by irradiation in bone marrow transplant recipients suggests that B lymphocytes are the main site of EBV persistence [129]. This is supported by the B lymphotropism of EBV that is mediated by the binding of the major viral envelope glycoprotein gp350 to the CR2 receptor on the surface of B cells [130]. Virion penetration of the B cell membrane requires further interactions between

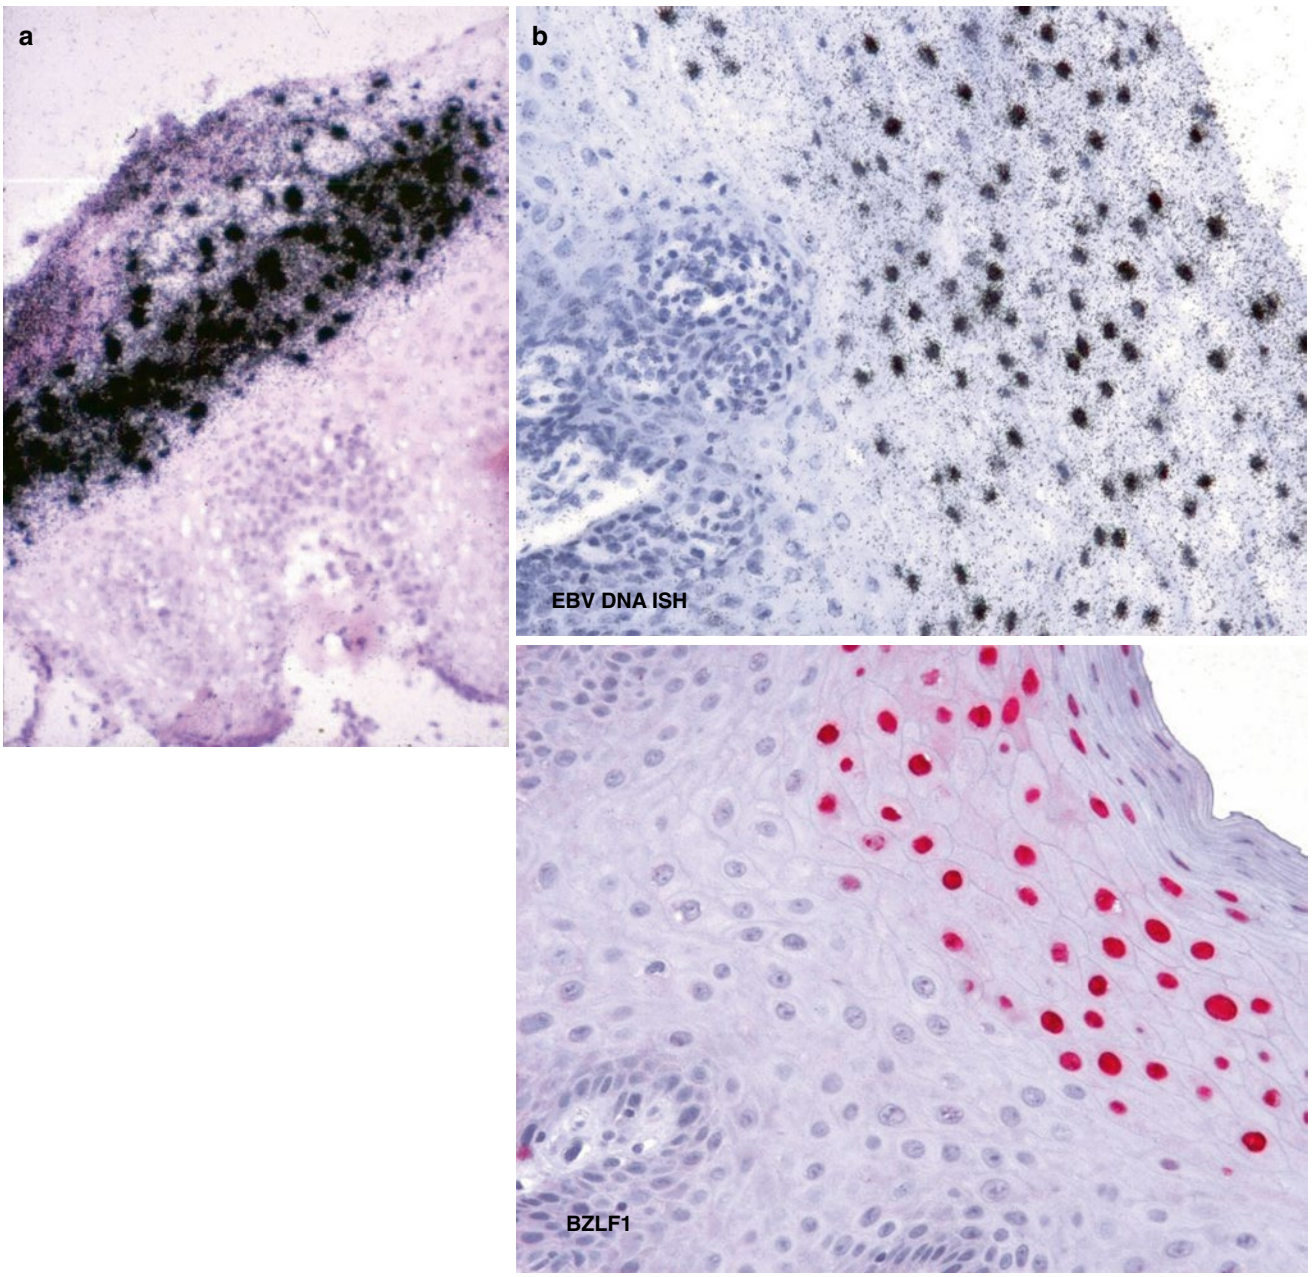

Fig. 41.2 In situ hybridization for EBV DNA reveals rampant virus replication in the differentiating squamous epithelium of oral "hairy" leukoplakia (**a**) and rarely in the epithelial cells of normal tonsil (**b**, upper panel [128]). Staining for the BZLF1 immediate early viral protein confirms EBV replication of EBV in normal tongue epithelium (**b**, lower panel [128])

the EBV glycoprotein gp42 (which forms a ternary complex with gH and gL viral glycoproteins) and HLA class II molecules [130]. It appears that the presence or absence of HLA class II in virus producing cells influences the tropism of EBV for B cells or epithelial cells by affecting the availability of gp42 [131]. Other CR2-independent pathways may be responsible for EBV infection of epithelial cells, including secretory component-mediated IgA transport, integrin interactions with polarized epithelium, and direct cell-to-cell contact, but these are relatively inefficient and of unknown relevance to EBV infection in vivo [130].

7 NPC Pathogenesis

The presence of monoclonal EBV episomes in NPC indicates that virus infection precedes the clonal expansion of the malignant cell population [13]. However, the lack of epithelial EBV infection in tonsils from IM patients and in

normal nasopharyngeal biopsies from individuals at high risk of developing NPC suggests that epithelial infection may not be the initiating event in virus-associated carcinogenesis [2]. EBV infection as detected by in situ hybridization to the abundantly expressed non-polyadenylated EBER RNAs has been demonstrated in high-grade (severe dysplastic and carcinoma in situ) preinvasive lesions in the nasopharynx but not in low-grade disease or histologically normal nasopharyngeal epithelium [44, 132]. Both the high-grade and carcinoma in situ lesions carry monoclonal EBV genomes [44]. Multiple genetic changes have been found in NPC with frequent deletion of regions on chromosomes 3p, 9p, 11q, 13q, and 14q and promoter hypermethylation of specific genes on chromosomes 3p (RASSF1A, RARβ2) and 9p (p16, p15, p14, DAP-kinase) [133, 134]. Both 3p and 9p deletions have been identified in low-grade dysplastic lesions and in normal nasopharyngeal epithelium from individuals at high risk of developing NPC in the absence of EBV infection suggesting that genetic events occur early in the pathogenesis of NPC and that these may predispose to subsequent EBV infection [132, 135]. This possibility is supported by in vitro data demonstrating that stable EBV infection of epithelial cells requires an altered, undifferentiated cellular environment [136] and that cyclin D1 overexpression (a consequence of p16 deletion on chromosome 9p and amplification of the cyclin D1 locus on chromosome 11q) facilitates persistent EBV infection of immortalized nasopharyngeal epithelial cells [137]. Thus, a scheme has been proposed whereby loss of heterozygosity occurs early in the pathogenesis of NPC possibly as a result of exposure to environmental cofactors such as dietary components (i.e., salted fish) creating low-grade preinvasive lesions that after additional genetic and epigenetic events become susceptible to EBV infection (Fig. 41.3). Once infected, EBV latent genes provide growth and survival benefits resulting in the development of NPC. Additional genetic and epigenetic changes occur after EBV infection.

8 Immunity and Patterns of Host Response

As mentioned previously, the association of EBV infection with NPC was originally identified as a consequence of the observation that these patients had significantly elevated antibody responses to EBV-encoded antigens associated with virus replication. The serological response to EBV infection is manifest in all virus-positive individuals and targets both latent and lytic antigens. In healthy individuals these antibody titers are stable, consistent with the nature of asymptomatic persistent EBV infection. However, immune suppression (e.g., HIV, immunosuppressive drugs) or chronic inflammatory conditions (e.g., rheumatoid arthritis, multiple sclerosis) can result in elevated antibody levels to EBV, and this can sometimes confuse the etiological contribution of EBV infection to various diseases. Unique to NPC and other EBV-associated carcinomas is a robust mucosal (IgA) immune response to certain lytic antigens (VCA, EA, MA); these can be seen several years prior to the development of NPC and correlate with tumor burden, remission, and recurrence [3, 138].

Primary EBV infection elicits strong cellular immune responses that then bring the infection under control. Thus the lymphocytosis typifying acute IM reflects the hyperexpansion of cytotoxic CD8+ T lymphocytes (CTLs). The majority of these CTLs are specific for epitopes derived from immediate-early and early antigens of the lytic cycle, while some are specific for latent antigens, particularly to epitopes drawn from the immunodominant EBNA3A, EBNA3B, and EBNA3C proteins [139]. Both sets of reactivities are subsequently maintained in CD8+ T cell memory at levels that, collectively, may constitute up to 5 % of the total circulating CD8 T cell pool. This level of commitment to a single virus, apparent even in EBV carriers with no prior history of IM, implies a crucial role for CD8+ T cell memory in controlling persistent EBV infection. EBV-induced CD4+ T cell responses are also detectable both in acute IM patients and in long-term virus carriers but at much lower levels than their CD8 counterparts. The role of these CD4+ T cells, whether in maintenance of effective CD8 immunity or possibly as antiviral effectors in their own right, remains to be determined. NPC patients are not immunosuppressed and maintain robust EBV-specific T cell responses suggesting that the tumor cells are able to evade immune recognition. This is likely to reflect the poor immunogenicity of the latent antigens expressed in NPC (EBNA1, LMP1, LMP2) and the immune milieu in the tumor microenvironment [139].

9 Control and Prevention

9.1 Molecular Biomarkers

While EBV-specific IgA antibodies are useful in the early detection and prognostic monitoring of NPC, the circulating levels of cell-free EBV DNA in the peripheral blood of NPC patients have been found to be a more sensitive and specific marker [140–142]. The pre-therapy levels of plasma EBV DNA are able to identify prognostically distinct subsets of patients and thus contribute to the staging and subsequent management of NPC. Other studies have highlighted the potential of analyzing nasal swabs for EBV DNA or methylated tumor suppressor genes (TSGs) for the diagnosis and local monitoring of NPC [143, 144]. More recent work has identified serum EBV miRNAs as diagnostic biomarkers in

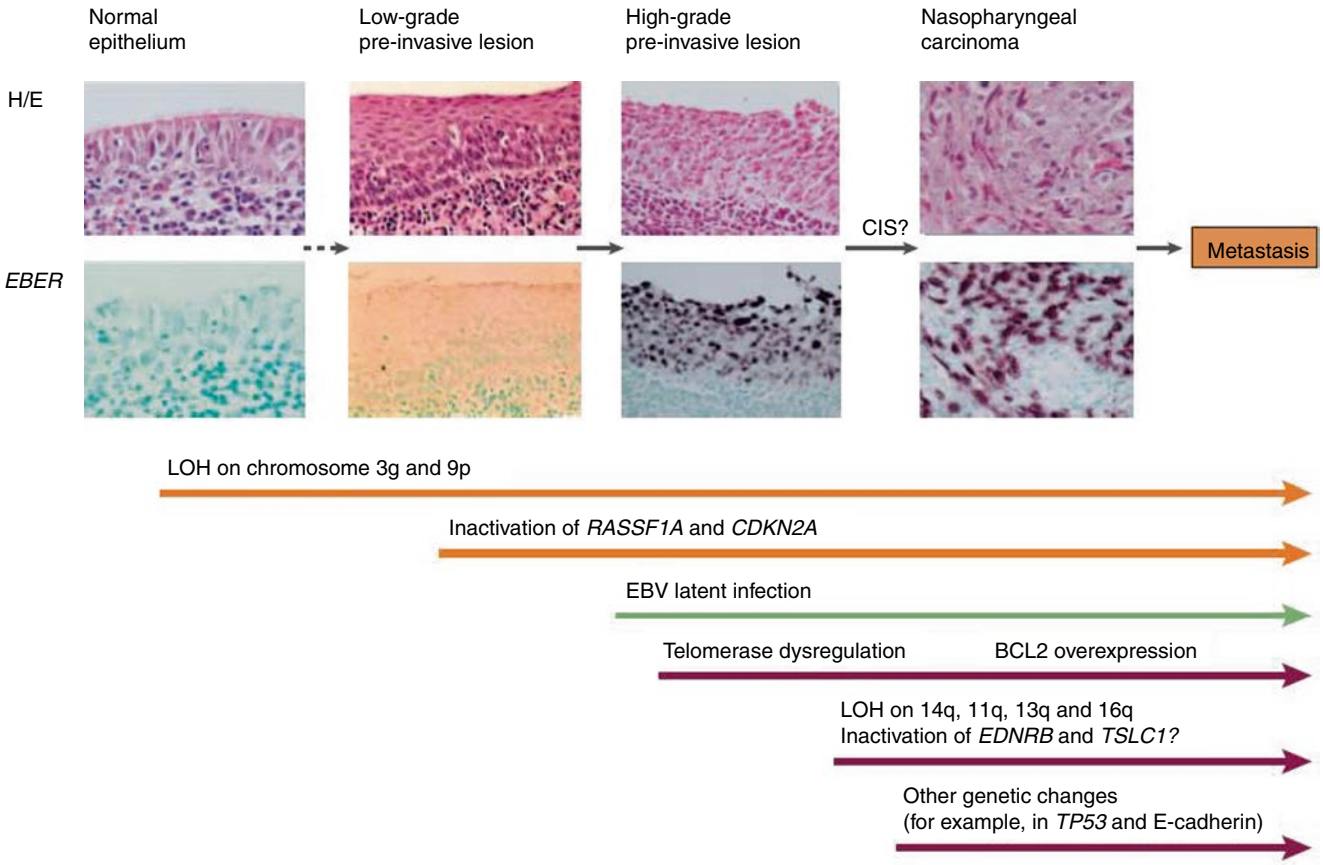

Fig. 41.3 Schematic representation of the pathogenesis of NPC. This model proposes that loss of heterozygosity (*LOH*) occurs early in the pathogenesis of NPC, possibly as a result of exposure to environmental cofactors such as dietary components (such as salted fish). This results in low-grade preinvasive lesions that, after additional genetic and epigenetic events, become susceptible to EBV infection. Once cells have become infected, EBV latent genes provide growth and survival benefits, resulting in the development of NPC. Additional genetic and epigenetic changes occur after EBV infection

NPC [73, 145]. As with other cancers, the advent of technologies to provide more detailed molecular classification of NPC tumors will provide opportunities to develop more personalized approaches to managing this disease [146].

9.2 Conventional Treatment

Early stage NPC is highly sensitive to radiotherapy (so-called intensity modulated radiation therapy), and locally advanced disease responds well to platinum-based chemotherapy in conjunction with radiotherapy [140]. Locally advanced recurrent NPC is more difficult to manage, but nasopharyngectomy has yielded excellent outcomes [147]. While there have been significant improvements in the primary treatment of NPC, 30 % of patients with locoregionally advanced disease will subsequently succumb to distant metastasis [140]. While first-line therapy with cisplatin-based chemotherapy is effective in some of these patients, novel approaches using targeted drugs and antibodies in conjunction with conventional radiochemotherapy are providing encouraging results [148].

9.3 EBV-Targeted Therapy

The success of the adoptive transfer of EBV-specific CTLs for the treatment of virus-driven posttransplant B cell lymphomas has led to a number of clinical trials using this same approach in the context of NPC. While these studies have demonstrated some limited clinical efficacy in patients with locoregional disease, the response in patients with metastatic tumors has been disappointing [149]. This likely reflects: (a) the broad specificity of the CTLs which are polyclonal populations containing low frequencies of T cells specific to the EBV latent antigens expressed in NPC and (b) the tumor microenvironment which is likely to suppress CTL activity. Approaches are being developed to enhance the generation of LMP1- and LMP2-specific CTLs [150] and to modify the cytokine milieu by using modified EBV-specific T cells [151, 152].

Alternative approaches to the treatment of NPC that target either the function of EBV-encoded proteins or exploit the transcriptional regulation of the virus are being developed. One approach is the use of gene therapy to deliver either cytotoxic proteins or proteins that interfere with EBV latent gene function. Selective expression of cytotoxic proteins (e.g., FasL) or wild-type p53 exploiting the ability of EBNA1 to activate transcription downstream of OriP has been demonstrated in in vitro and in vivo models of NPC [153, 154]. Induction of the EBV lytic cycle by either pharmacologic agents or delivery of EBV immediate-early genes results in the expression of virus-encoded kinases (EBV-TK, BGLF4) that phosphorylate ganciclovir (GCV) into its active cytotoxic form [155]. The ability of chemotherapy to confer sensitivity to GCV has been demonstrated in in vitro and in vivo NPC models [156] and was more recently shown to have therapeutic benefit in patients with recurrent and metastatic NPC [157]. Demethylating agents such as 5-azacytidine are also able to induce lytic EBV infection as well as expression of the immunodominant EBNAs (EBNAs 2, 3A, 3B, 3C) in EBV-associated tumors [158]. Such demethylation of EBV latent and lytic genes has been demonstrated in vivo in a clinical trial of 5-azacytidine therapy in patients with NPC [159].

More specific targeted approaches to inhibit the EBV transforming proteins, particularly LMP1, have also been investigated. Inhibiting the downstream consequences of LMP1 expression such as NF-κB activation by either genetic or pharmacologic approaches also has the potential to be effective in the management of LMP1-positive NPC [160]. Given the central role of EBNA1 in supporting EBV genome replication, the use of dominant-negative forms of EBNA1 to directly inhibit interaction of the wild-type protein with OriP may prove useful in eradicating EBV infection from tumor cells. This approach has been tested in various experimental systems using a recombinant adenovirus to deliver a dominant-negative version of EBNA1 [161]. OriP function has also been exploited to generate a conditionally replicating oncolytic adenovirus that, in conjunction with local radiotherapy, was able to eradicate established NPC tumors in an in vivo model [162].

9.4 Prophylactic and Therapeutic Vaccines

A vaccine to either protect from primary EBV infection or boost existing antiviral immunity in patients with NPC is an obvious approach that has been explored for over 40 years. The major EBV envelope glycoprotein gp340 is a target for neutralizing antibody responses and, when delivered as purified protein, has been shown to prevent lymphomagenesis in animal models. This approach has also been tested in phase I and phase II clinical trials and shown to be safe and well tolerated in EBV seronegative individuals [163, 164]. Whether such vaccination results in long-term sterilizing immunity and will prevent NPC is questionable. Therapeutic vaccines aimed at boosting EBV-specific T cell responses are being developed that use either peptides or viruses (adenovirus, vaccinia) expressing intact or modified (polyepitopes, fusion proteins).

9.4.1 Is EBV Associated with Other Common Epithelial Malignancies?

A number of other more common carcinomas such as breast cancer [165] and liver cancer [166] have been reported to be infected with EBV. Difficulties in confirming these associations have raised concerns about the use of PCR analysis alone to define EBV association and about the specificity of certain monoclonal antibody reagents. Definitive designation of a tumor as "EBV-associated" should require unequivocal demonstration of the EBV genome or virus gene products within the majority of the tumor cell population. This is not the case with breast cancer where it is clear that a small and extremely variable proportion of tumor cells are susceptible to EBV infection in vivo resulting in a low level lytic EBV infection [167, 168]. It is possible that a subset of EBV-infected breast carcinoma cells undergoing the virus lytic cycle produce soluble factors that are able to influence the growth and survival of surrounding EBV-negative tumor cells, but this remains to be demonstrated. The association of EBV with liver cancer, which was originally described in Japanese cases, has not been confirmed in cases from Europe and the USA raising the possibility of geographical variation [169].

Gastric Cancer

Gastric cancer remains the second leading cause of death from cancer (Global Cancer Statistics 2007). Although incidence and mortality rates have been falling for over 50 years, the number of deaths from this tumor will inevitably continue to increase globally because of population growth and aging in high-risk countries. As approximately 10 % of gastric carcinomas comprise cells latently infected with EBV, EBV-associated gastric cancers (EBV-GC) may represent the most common form of EBV-associated malignancy [170, 171]. These EBV-GC tumors display a restricted pattern of EBV latent gene expression (EBERs, EBNA1, LMP2A, the BART miRNAs, BARF1) similar to that observed in NPC [78, 172]. There is significant geographical variation in the association of EBV with GC that may be attributed to ethnic and genetic differences [170, 171]. EBV-GCs have distinct phenotypic and clinical characteristics compared to EBV-negative GC tumors including loss of p16 expression, p73 promoter methylation, wild-type p53, a different pattern of allelic loss, and improved patient survival [173–176]. As in NPC, the precise role of EBV in the pathogenesis of gastric carcinoma remains to be determined, but the absence of EBV

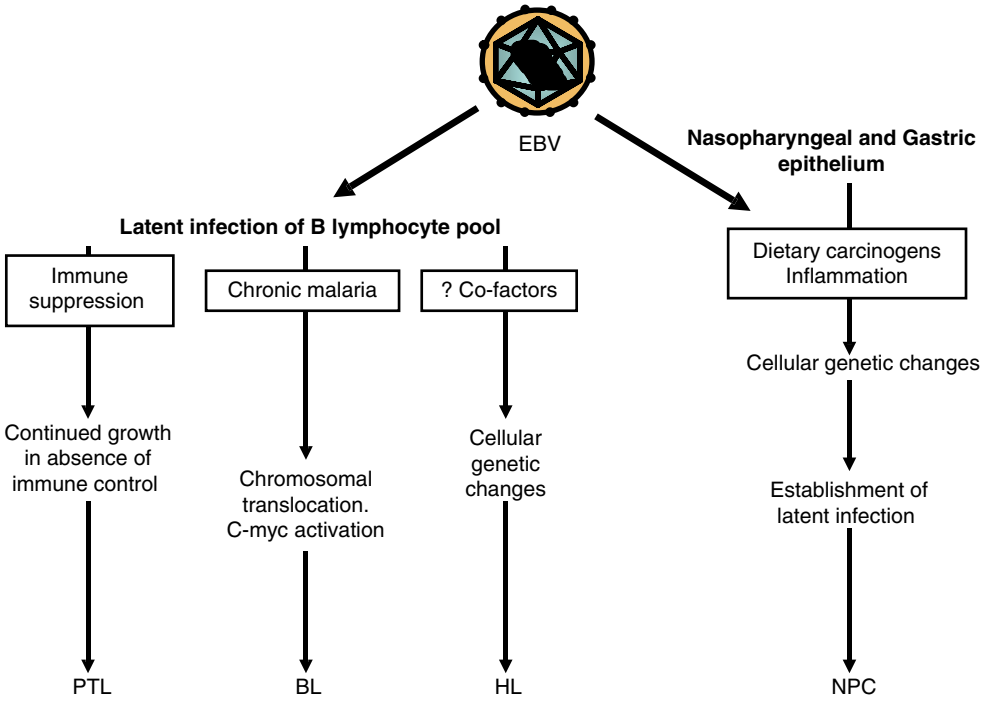

Fig. 41.4 This schematic representation highlights the different role of EBV infection in the pathogenesis of B cell-derived lymphomas as compared to carcinomas arising in the nasopharynx and stomach. It is proposed that latently infected B cells, arising from the persistent infection of the memory B cell pool, are influenced by immunosuppression and/or various cofactors to develop into either posttransplant lymphomas (*PTL*), Burkitt lymphoma (*BL*), or Hodgkin's lymphoma (*HL*). By contrast, stable latent EBV infection can only be sustained in epithelial cells of the nasopharynx or stomach once genetic and/or epigenetic changes have created a conducive cellular environment. These changes may be induced by dietary carcinogens along with a chronic inflammatory milieu

infection in premalignant gastric lesions supports the contention that virus infection is a relatively late event in gastric carcinogenesis [177]. Epidemiological studies have suggested that EBV-GC is related to birth order, high salt intake, and exposure to metal dust, but likely geographical variation in these factors (e.g., between Japan and Colombia) supports the need for more detailed investigation [170, 171]. It has been suggested that distinct EBV strains contribute to the development of EBV-GC, although this could reflect geographical variation in the prevalence of different EBV strains in the population [178].

10 Future Perspectives

EBV was discovered almost 50 years ago and its DNA was fully sequenced in 1984. It remains the most common persistent virus infection in humans with over 95 % of the population sustaining an asymptomatic lifelong infection – testimony to the intimate interaction between EBV and the immune host. This relationship relies on the ability of EBV to persist in the memory B cell pool of normal healthy individuals, and perturbation of this interaction results in virus-associated B cell tumors. Much work has contributed to the unequivocal identification of EBV as oncogenic in humans, but the precise role of EBV in the pathogenesis of NPC and EBV-GC remains unclear.

Little is known about the replicative life cycle of EBV in vivo particularly with regard to the relative role of B cells versus epithelial cells in this process. The impact of EBV infection on the development of NPC and EBV-GC may be a consequence of the aberrant establishment of virus latency in epithelial cells that have already undergone premalignant genetic changes. This appears to be a distinct pathogenic process from that associated with EBV-induced lymphomagenesis where the virus appears to be the initiating driver (Fig. 41.4).

The development of more efficient in vitro systems for studying EBV infection and replication in different cell types is helping to unravel the complex interplay between the virus and the cell. The use of EBV recombinants continues to shed light on the role of latent genes in the transformation process, on the requirements for the efficient production of progeny virus, and on the role of membrane glycoproteins in the infection process. Understanding the host cell–virus interaction will be dependent on the generation of appropriate in

vitro and in vivo models, particularly systems which allow a more detailed understanding of the tumor microenvironment and the role of the local cytokine milieu.

Whatever the precise role of EBV in the carcinogenic process, there is clearly the opportunity to exploit this association for the clinical benefit of patients. EBV is the ultimate biomarker and routine application of serum testing for virus DNA not only provides invaluable prognostic information in NPC patients but will also facilitate the implementation of mass screening programs to identify patients with the early stages of NPC. This approach will be further enhanced by the development of additional adjunctive tests (e.g., EBV miRNAs, methylated TSGs). Novel therapeutic approaches using targeted drugs, gene therapy [60], or therapeutic vaccination [61] augur well for our ability to effectively target the clinically challenging aspects of locally recurrent and metastatic disease. Alongside these therapies, the advent of personalized medicine raises the possibility of using molecular classification to subdivide NPC and EBV-GC and thereby improve patient management and outcomes. Our growing understanding of EBV-associated oncogenesis provides paradigms for the development of targeted cancer therapies and diagnostics and further confirms the far-reaching value of tumor virology to the whole cancer field.

Human Herpesviruses: Varicella and Herpes Zoster

42

John W. Gnann Jr.

1 Introduction

Varicella-zoster virus (VZV) causes two clinically distinct diseases in humans [1]. Varicella (or chickenpox), which results from primary infection of a susceptible individual, is a common, extremely contagious, and usually benign acute illness that occurs in seasonal epidemics and is characterized by a generalized vesicular rash. Like all herpesviruses, VZV establishes latency following primary infection. Reactivation of latent VZV results in herpes zoster (or shingles), a localized cutaneous eruption in a dermatomal distribution that occurs most commonly among elderly individuals. Thus, varicella results from primary exogenous contact with VZV, while herpes zoster represents reactivation of latent VZV that usually occurs decades after the primary infection. Both varicella and herpes zoster can cause serious morbidity and mortality in immunocompromised populations. Both manifestations of VZV can now be prevented through the use of vaccines containing live, attenuated virus [2].

2 Historical Background

Varicella has been recognized as a distinct disease since at least the ninth century AD when the Persian physician Rhazes described a vesicular rash that was not protective against smallpox. However, confusion of varicella with other pustular skin diseases persisted into the nineteenth century. Indeed, the name "varicella" is a diminutive form of the term "variola," or smallpox, indicating that the two diseases were formerly thought to be etiologically related. The common term "chickenpox" has been variously attributed either to the old English word *gican* which means "to itch" or "to scratch" or to the old French word *chiche-pois* which likens the appearance of a vesicle to a chickpea.

Because of its distinctive dermatologic distribution, herpes zoster has been recognized as a unique entity since antiquity, although the observation that varicella and herpes zoster were etiologically related was not made until the nineteenth century. *Herpes* is derived from the Greek word meaning "to creep." *Zoster* and *shingles* are derived from the Greek and Latin terms, respectively, for "girdle," referring to the band-like distribution of lesions.

Heberden was among the first to definitively distinguish varicella from smallpox in 1767. In 1875, Steiner demonstrated the infectious nature of varicella when he was able to transmit the disease to volunteers by inoculating them with vesicular fluid from patients with chickenpox. The relationship between varicella and herpes zoster began to be elucidated by von Bokay in 1888 when he observed that susceptible children acquired varicella after contact with patients with herpes zoster. In 1925 Kundratitz was able to produce varicella-like lesions in volunteers by experimentally inoculating them with fluid from patients with herpes zoster. The careful work of Tyzzer in 1908 and Lipschüv in 1921 demonstrated that the histopathologic characteristics of varicella and herpes zoster lesions were identical. The important intuitive leap that herpes zoster represented a reactivation of latent varicella virus was made by Garland in 1943. In the 1950s, Weller and colleagues were able to propagate the etiologic agent in vitro and provide final definitive proof that varicella and herpes zoster are caused by the same viral pathogen. Hope-Simpson is credited with theorizing that declining immunity allowed latent VZV to reactivate, producing herpes zoster, as reviewed [3, 4].

3 Methodology Involved in Epidemiologic Analysis

Varicella has been added to and deleted from the nationally notifiable disease list several times since 1972 [5]. Most recently, varicella deaths became nationally notifiable in 1999.

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_42,

To track varicella incidence after implementation of the varicella vaccine in 1995, the CDC established sentinel sites for active surveillance in California and Pennsylvania [5]. With the success of varicella vaccination and reduction in the number of cases, the sentinel sites were no longer able to provide sufficient incidence data. In 2003, case-based surveillance for varicella was reestablished in all states via the National Notifiable Disease Surveillance System (NNDSS). By 2010, a total of 39 states required reporting of varicella cases, and 38 states were conducting passive case-based surveillance [5].

Vaccination data are collected via the National Immunization Survey (NIS), which is a random telephone survey that gathers vaccination coverage data from households with children age 19–35 months in all 50 states and in selected urban areas. Additional data on vaccination are available from the Vaccine Adverse Event Reporting System and from the Vaccine Safety Data Link.

Herpes zoster has never been a reportable disease. Data regarding the incidence of herpes zoster are gathered from several sources including large managed care databases such as the Keiser Permanente System [6] and the US Department of Veterans Affairs databases [7]. Insurance company databases (both private and federally sponsored insurers such as Medicare) are also a key source of incidence data [8]. Valuable data have been derived from studies of large population-based cohorts such as the Rochester Epidemiology Project [9] and the Olmsted County cohort [10]. Other methodologies include searches of electronic hospital diagnosis codes and prescription records for evidence of herpes zoster encounters [11]. Ongoing surveillance systems that can provide disease incidence data include the National Hospital Discharge Survey, the National Ambulatory Medical care Survey, and the National Hospital Ambulatory Care Survey.

4 Biological Characteristics of the Virus That Affect the Epidemiologic Pattern

Varicella-zoster virus (human herpesvirus 3), along with herpes simplex viruses type I and type II, makes up the human alpha herpesvirus group. Sequencing analysis demonstrates genetic differences among VZV strains isolated in different epidemiologic situations. These strains can be grouped into clades, but there is only a single VZV serotype [12–14]. At least 5 (and perhaps as many as 9) genotypically distinct clades of VZV have been identified and used for epidemiologic mapping [15].

The alpha herpesviruses are characterized by short replication cycles, rapid spread in tissue culture, destruction of host cells during replication, and latency in sensory nerve ganglia (including cranial nerve, dorsal root, and autonomic ganglia) [16]. VZV shares structural characteristics with other members of the family *Herpesviridae*. Complete VZV virions are pleomorphic and measure approximately 180–200 nm in diameter. The nucleocapsid measures about 100 nm in diameter and is composed of 162 capsomeres arranged in icosahedral symmetry. An amorphous tegument layer surrounds the capsid. The virion is enclosed in a lipid-containing laminated envelope with external glycoprotein spikes, which are key antigenic determinants. The VZV genome consists of a linear, double-stranded DNA molecule containing about 125,000 base pairs with a guanosine-plus-cytosine content of about 46 %. The genome is organized in a manner similar to that of other herpesviruses, having unique long (UL; 104.5 kb) and unique short (US; 5.2 kb) regions flanked by inverted terminal repeat sequences. VZV encodes about 70 genes, including 7 that encode glycoproteins [17, 18]. VZV can be propagated in vitro in a limited number of continuous and discontinuous cell culture monolayers, mostly of human or simian origin. In human embryonic fibroblasts, cytopathic effects begin as a focal process with subsequent cell-to-cell spread. Approximately 8–10 h after infection, virus-specific immunofluorescence can be detected in cells adjacent to the initial focus of infection. Viral cytopathic effects are visible after about 3 days. In vitro, VZV replication is highly cell associated, with very limited release of infectious virions into the fluid medium.

5 Descriptive Epidemiology

5.1 Epidemiology of Varicella

In temperate climates such as that of the USA, varicella epidemics occur annually in the late winter and early spring, with peak numbers of cases reported in March. Before the availability of the varicella vaccine, approximately 3.8 million cases of chickenpox occurred each year in the USA (about 15 cases per 1,000 population), which approximately equaled the annual birth cohort. In the absence of a systematic vaccination program, varicella is predominantly a disease of school-aged children. Historically, in the USA, about 50–60 % of varicella cases occurred in children between 5 and 9 years of age; over 90 % of cases occurred in persons younger than 15 years. Previous surveys indicated that greater than 90 % of the US. population was VZV seropositive by age 20 years [19–22]. Sex and race have no apparent impact on the incidence of varicella in susceptible populations. Mortality estimates among children (ages 1–14 years) with varicella were 1.4 deaths per 100,000 cases. In temperate countries where routine varicella vaccination has not been adopted, this epidemiologic pattern continues (Fig. 42.1) [23]. In countries such as the USA, widespread use of the varicella vaccine has produced dramatic changes in the epidemiology of varicella and varicella-related mortality, as discussed in detail below.

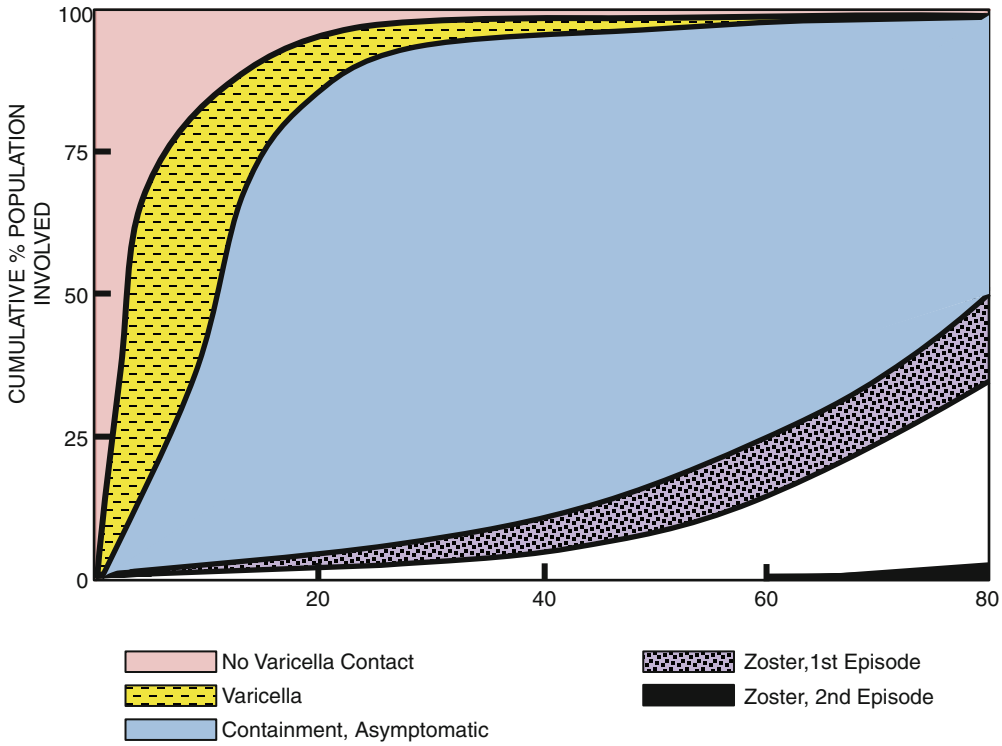

Fig. 42.1 Age-related occurrence of VZV disease in a population in a temperate climate without varicella or herpes zoster vaccination [302]

An interesting observation regarding the geographic distribution of varicella is the lower incidence of chickenpox among children in tropical areas of the world. This phenomenon is not yet fully understood, although it may be related to decreased transmission efficiency of VZV due to climate (temperature, humidity, etc.) or sociological factors [24]. The consequence is that a higher proportion of persons growing up in tropical areas may remain VZV seronegative after reaching adulthood. When those susceptible individuals subsequently travel to areas with higher rates of VZV transmission (e.g., young adults from Puerto Rico reporting to mainland USA for military training), they are at increased risk to acquire chickenpox. This has significant consequences, because the morbidity of varicella is much higher in adolescence and adults than it is in young children.

6 Epidemiology of Herpes Zoster

Herpes zoster results from reactivation of latent VZV [25–27]. Over 90 % of adults in the USA have serologic evidence of prior VZV infection and are at risk for herpes zoster. In the general population (including individuals of all ages), the annual incidence rate for herpes zoster is about 3.6 cases per 1,000 population, with a range of 3.2–5.2 cases per 1,000 person-years in various studies (Fig. 42.2) [6, 8, 10, 28–38]. This incidence rate would predict about one million cases of herpes zoster annually in the USA [6, 10, 27].

Increasing age is a well-defined risk factor for herpes zoster. Herpes zoster is not a rare disease in young adults, but the incidence clearly begins to increase in individuals over 55 years of age. The median age of patients with herpes zoster is estimated to be 64 years [39]. By decades, the risk for herpes zoster is about 7, 9.5, and 11 cases per 1,000 person-years for populations aged 60–69, 70–79, and >80 years, respectively [6, 28–30]. In the prospective Shingles Prevention Study that evaluated the efficacy of the herpes zoster vaccine, the incidence of shingles was 11.8 cases per 1,000 person-years among the 18,357 placebo recipients ≥60 years of age who completed the study [40].

A key component of Hope-Simpson's original hypothesis regarding the pathogenesis of herpes zoster was that intermittent reexposure of adults to VZV (primarily via children with chickenpox) resulted in the boosting of VZV-specific immunity and immune containment of latent virus. While attractive, this hypothesis has been difficult to support with observation. For example, the hypothesis would predict that adults who are not intermittently exposed to VZV should have earlier onset and perhaps increased incidence of herpes zoster. However, studies of individuals who are members of cloistered monastic orders have not shown that they have an increased risk or earlier onset of herpes zoster compared to the general population [41]. While studies suggest that the incidence of herpes zoster in adults has increased since the implementation of varicella vaccination, a causal relationship has been difficult to establish [7, 8, 42]. For example, age-standardized surveys conducted in the states of Washington (1997–2002) and

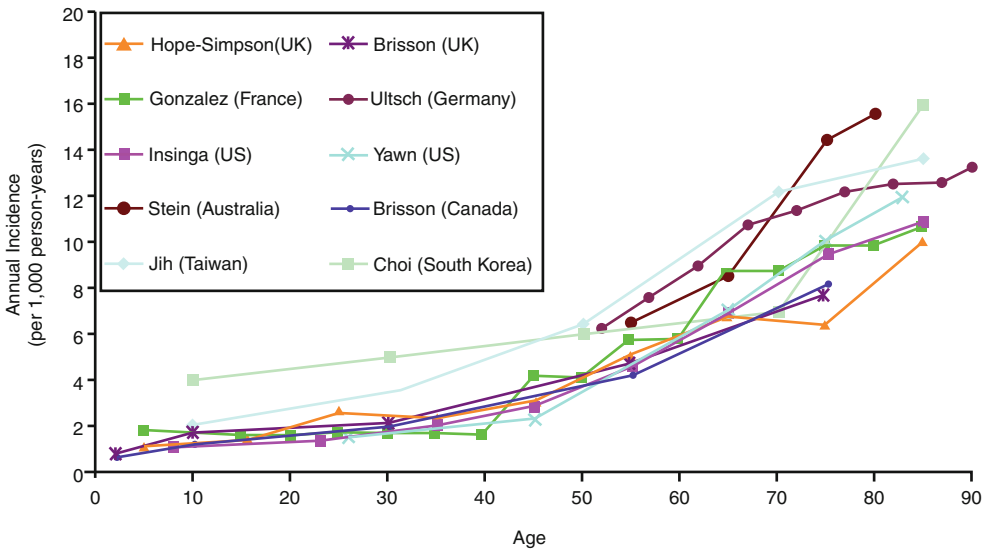

Fig. 42.2 Increasing age has a positive correlation with incidence of herpes zoster. Data displayed from 10 incidence studies conducted in 8 countries (compiled by Eddie Bresnitz, M.D., Merck and Co., Inc.) [10, 28, 32, 38, 297–301, 303]

Minnesota (1996–2005) demonstrated increases in herpes zoster incidence over the surveillance periods from 3.28 to 4.29 cases and from 3.2 to 4.1 cases per 1,000 person-years, respectively [6, 10]. An analysis of large medical claim databases for the period 1993–2006 showed an increase in herpes zoster incidence as well as herpes zoster-related hospital discharges [8, 43]. However, herpes zoster incidence did not vary by state on the basis of varicella vaccination coverage [8]. Similar studies in Australia demonstrated an increase in herpes zoster incidence [44], while herpes zoster incidence in Canada appeared to be stable [45]. In neither case was it possible to attribute observed trends in herpes zoster incidence to the varicella immunization program. Thus, while there is compelling evidence that the incidence of herpes zoster is increasing among adults, it has not been possible to link this observation to increased varicella vaccine coverage [46]. Contributing factors to the increasing incidence may be the growing proportion of the population in the developing world that is over 65 years of age and the steadily increasing numbers of persons who are immunocompromised due to disease or medical interventions. The complex epidemiologic interactions between pediatric varicella vaccination and incidence of adult herpes zoster remain to be fully elucidated [47]. Notably, the incidence of herpes zoster among children covered by varicella vaccination has declined substantially [48]. In a cohort of California children monitored from 2000 to 2006, the incidence of herpes zoster in children under 10 years of age declined by 55 %, from 42 cases reported in 2000 to 2018 reported in 2006 [49]. The authors estimated that children aged 10 years who had received varicella vaccination had a 4–12 times lower risk for developing herpes zoster compared with children who had experienced varicella disease [49].

In addition to age, the other well-described risk factor for herpes zoster is immunodeficiency, specifically depressed cell-mediated immune responses. Groups clearly identified as being at high risk for herpes zoster include patients taking immunosuppressive medications (e.g., high-dose corticosteroids), organ transplant recipients receiving immunosuppressive antirejection therapy, and patients with lymphoproliferative malignancies or HIV infection. For example, 15–30 % of patients with Hodgkin disease experience herpes zoster compared to 2 % of patients with non-hematologic solid tumor malignancies. However, the converse is not true: herpes zoster is not a sensitive enough marker for malignancy that it warrants a search for underlying cancer [50]. Shingles occurs in 3–10 % of renal transplant recipients, 20–25 % of cardiac transplant recipients, and 20–50 % of allogeneic hematopoietic stem-cell transplant recipients [51–54]. In a recent US study using the Department of Veterans Affairs databases, the incidence of herpes zoster among solid organ transplant recipients was 22.2 cases per 1,000 person-years [55]. Herpes zoster also occurs with increased frequency among patients with immunologically mediated connective tissue diseases, including rheumatoid arthritis and systemic lupus erythematosus [56–59]. The zoster risk may be further increased when these patients are treated with biological therapies such as anti-TNF-alpha drugs [60, 61]. In surveillance studies conducted in the USA, Europe, and Africa, the incidence of herpes zoster among HIV-seropositive patients was shown to be approximately 30–50 cases per 1,000 person-years, with a cumulative incidence over 10 years of approximately 30–40 %. In contrast, the shingles incidence among HIV-seronegative controls was two to three cases per 1,000 person-years, with a 10-year cumulative incidence of about 3 %. These observations confirm that the incidence of herpes zoster is approximately 15-fold higher among HIV-infected individuals than among age-matched HIV-seronegative controls. From a clinical perspective, the possibility of HIV infection should be considered in otherwise healthy younger patients who present with herpes zoster. In

African populations where the prevalence of HIV infection is high, more than 90 % of patients presenting with a new diagnosis of herpes zoster were found to be HIV infected [62]. The incidence of herpes zoster in HIV-infected children and adults has declined substantially since the availability of effective antiretroviral therapy and varicella vaccination [63, 64], but shingles continues to occur at higher frequency, even among patients with well-controlled HIV infection [65].

Unlike varicella, there is no seasonal predilection for herpes zoster. In age-adjusted cohorts, female sex and Caucasian race appeared to be risk factors for slightly increased incidence of herpes zoster [8, 66]. Investigations of a possible familial or genetic predisposition to herpes zoster have yielded conflicting results. In studies conducted in the USA, case patients were more likely to report blood relatives with a history of herpes zoster than controls (43.5 % vs. 10.5 %; $p<0.001$), with evidence of a dose-dependent effect (risk was increased with multiple blood relatives) [67, 68]. A study in Italy, however, found no evidence of family history as a risk factor for herpes zoster [69]. Larger prospective cohort studies will be needed to definitely determine whether family history is a risk factor for herpes zoster.

The lifetime risk of herpes zoster is estimated to be 10–20 %. The frequency of second episodes of herpes zoster in immunocompetent persons is not well defined, but appears to be low (≤5 %) [70]. Persons who experience a first episode at a relatively young age may have a second episode as older adults. In contrast, multiple recurrences of herpes zoster are frequently observed in HIV-seropositive patients.

7 Mechanisms and Routes of Transmission

7.1 Varicella

Chickenpox is acquired by person-to-person transmission of VZV from an infected individual to a susceptible host. The incubation period is about 14 days with a range of 10–21 days. Patients with chickenpox are capable of transmitting virus from 48 to 72 h before the onset of rash until all cutaneous lesions have crusted. The fact that transmission has been documented to occur during the incubation period prior to rash onset suggests that respiratory secretions are an important source of viral transmission. While VZV can be difficult to recover from respiratory secretions by culture during the incubation period, the presence of virus is readily demonstrated by polymerase chain reaction (PCR). Virus is present in high concentrations in vesicular cutaneous lesions, and aerosolized virus from vesicular fluid is also a likely mechanism for transmission. Varicella is a highly contagious infection, and attack rates of 60–90 % have been observed among susceptible household contacts of chickenpox patients.

Herpes zoster can also serve as a source for viral transmission [71]. Exposure of a susceptible host to a patient with active vesicular herpes zoster can result in VZV transmission and development of chickenpox. The source of virus is not completely clear. Aerosolization of vesicular fluid seems the most obvious mechanism. Studies using PCR methodology have clearly demonstrated the presence of VZV DNA (and presumably infectious virus) in the air from a room where a patient with herpes zoster is housed. However, VZV DNA can also be detected in the saliva of patients with acute dermatomal herpes zoster, suggesting that transmission via respiratory secretions might be possible [72, 73]. Because vaccination has resulted in such a dramatic decline in varicella incidence in the USA, herpes zoster may prove to be an increasingly important source of VZV transmission and new infections [74].

Another unusual route of VZV infection is organ transplantation. Rare cases of transmission of VZV via the donor organ have been reported when the donor had a very recent history of chickenpox [75].

Varicella occurring during pregnancy can result in congenital or neonatal infections. Development of maternal chickenpox during the first half of pregnancy introduces the risk of the rare congenital varicella syndrome (CVS), which results from viremic intrauterine transmission and VZV infection of the fetus [76]. VZV infection of neonates may result from either vertical or horizontal transmission [77–79]. If maternal varicella develops during the time window from 4 to 5 days before until 2 days after delivery, the baby is exposed to VZV (usually by transplacental viremia) without the benefit of transplacental maternal anti-VZV Immune globulin indicates a drug G (IgG). In this situation, varicella will develop in an estimated 17–48 % of neonates. Conversely, infants who have varicella lesions present at birth or within the first 5 days following delivery (thus having received transplacental maternal anti-VZV IgG prepartum) are unlikely to develop severe disease. In addition, infants (particularly low-birth-weight babies) born to VZV-seronegative mothers are at high risk for severe varicella if infected during their first few days of life (e.g., in the nursery).

7.2 Herpes Zoster

Shingles always results from reactivation of endogenous latent VZV. Thus, there is no transmission of herpes zoster from one individual to another (although exposure to herpes zoster can result in chickenpox in a susceptible host, as described above). Despite frequent anecdotal reports, there is no convincing evidence that exogenous exposure to VZV (e.g., contact with a person with varicella) can serve as a trigger for reactivation of latent VZV resulting in herpes zoster.

8 Pathogenesis and Immunity

8.1 Pathogenesis of Varicella

Humans are the only known reservoir for VZV. Primary infection occurs when a susceptible individual is exposed to airborne virus, presumably via the respiratory route. Since there is no easily manipulated animal model for varicella, much of the pathogenesis story is based on clinical observations and analogies with other exanthamatous viral pathogens. Varicella is most often acquired following exposure to another person with active chickenpox, but infection can also result from close exposure to a patient with herpes zoster. Virus and airborne droplets enter the susceptible host via mucosal surfaces of the conjunctiva, oropharynx, or upper respiratory tract. Like HSV, VZV demonstrates tropism for epithelial cells of mucosal and cutaneous surfaces as well as for neural tissues. VZV undergoes an initial round of replication, presumably in tonsillar or cervical lymph nodes. Studies have demonstrated that subpopulations of activated memory T lymphocytes in tonsils are readily infected by VZV [80]. According to the long-held theory, when local immune responses are overcome, a primary round of viremia occurs with widespread dissemination of VZV to the reticuloendothelial system. Following additional cycles of replication, a second viremic phase occurs approximately 1 week after the initial viremia and is accompanied by the onset of clinical symptoms. A newly proposed hypothesis is that VZV may be transported to the skin primarily via infected peripheral blood mononuclear cells (PBMCs), particularly infected T lymphocytes. T cell subpopulations that express the cutaneous homing antigen and chemokine receptor CCR4 are highly permissive for VZV infection and may serve to deliver virus to the cutaneous epithelial cells. VZV initially localizes to endothelial cells of cutaneous capillaries and then extends to epithelial cells of the epidermis. Innate immune mechanisms appear to establish early control of viral replication. Cell-to-cell spread of virus is contained for the first week by production of interferon-alpha in adjacent epithelial cells [81]. Localized viral replication in epithelial cells is subsequently facilitated by VZV-mediated downregulation of interferon-alpha within the infected cells and failure of induction of inflammatory adhesion molecules [80, 81]. Eventually, the virus overcomes the innate immune defenses and undergoes epithelial replication with the appearance of cutaneous vesicles. The production of cytokines and upregulation of capillary endothelial adhesion factors attract activated T cells that may become infected by VZV and serve to further spread infection before replication is eventually contained [82]. In the normal host, viremia and new vesicle formation continue for 3–5 days until suppressed by developing humoral and cellular immune responses. Cutaneous vesicles contain cell-free infectious virus. Sensory nerve exons that terminate in the dermis may be infected with VZV, allowing viral transport to sensory ganglia and subsequent establishment of latent infection [83]. VZV may also reach neurons via hematogenous spread.

VZV replication in the skin results in ballooning degeneration of epithelial cells in the prickle cell layer (stratum spinosum) of the epidermis. Local collections of extracellular edema fluid result in acantholysis, with elevation of the stratum corneum to form a clear vesicle. Multinucleated giant cells are found at the base of the lesion. Infected cells contain eosinophilic intranuclear inclusion bodies (Cowdry type A inclusions) surrounded by a clear zone [84]. Perivascular infiltration of mononuclear cells is seen around cutaneous vessels. The vesicular fluid becomes cloudy as it accumulates inflammatory cells and desquamated epidermal cells. Vesicular fluid is resorbed, resulting in drying and crusting of the lesion. Healing occurs with regeneration of the epithelial cell layers.

8.2 Immune Responses in Varicella

Control of VZV replication in the early stages of primary infection is mediated by innate immune responses, including production of interferon-alpha by epidermal cells [81]. VZV-specific IgM and IgG can be detected in serum as early as 1–3 days after the appearance of skin lesions. Antibodies induced during primary infection are directed against nucleic capsid proteins and glycoproteins and have viral neutralizing activity. Humoral immune responses are thought to contribute to recovery from primary VZV infection, but are not essential. This is supported by the observation that children with humoral immune deficiency syndromes tend to have uncomplicated courses of varicella. On the other hand, passive immunotherapy with immunoglobulin preparations containing high titers of anti-VZV IgG within 96 h of VZV exposure clearly ameliorates the clinical symptoms of varicella in immunocompromised patients. The roles of humoral and cellular immunity have been demonstrated in the simian varicella virus (SVV) animal model. Animals depleted of CD4+ cells had higher viral load, prolonged viremia, and disseminated SVV infection, while B cell-depleted animals demonstrated no alteration in disease severity [85]. In humans, adaptive cell-mediated immune (CMI) responses appear to be essential for resolving primary VZV replication. This is demonstrated by the severe and potentially life-threatening clinical courses of varicella in children with congenital or acquired T cell immunodeficiency syndromes. VZV-specific T cell proliferative responses are detectable in most healthy children within a week of appearance of rash. The CMI response consists of both CD4+ and CD8+ effector cells as well as memory T cells. T cell proliferation results in elaboration of cytokines with both direct and indirect

antiviral activity, including interferon-gamma. The termination of VZV replication in varicella is marked by upregulation of human leukocyte antigen (HLA) class II expression, permitting lysis of VZV-infected cells by CD4+ CTLs as well as interferon-gamma-enhanced HLA class I-restricted cellular cytotoxicity mediated by CD8+ T lymphocytes [86–88]. These memory T cell responses are also important contributors to protection following reexposure to VZV [87]. Adaptive cell-mediated immune responses can be boosted by exposure to endogenous (reactivation of latent virus) or exogenous (environmental exposure) VZV, which is thought to be important in long-term immune suppression of latent virus in the ganglia.

8.3 Pathogenesis of Herpes Zoster

In many ways, VZV should be considered a neurotropic virus [89]. As VZV replicates in the skin during acute varicella, virions are transported via sensory nerves to the corresponding sensory ganglia. In the ganglion, the virus establishes a latent infection within neurons and probably also in satellite cells [90]. An alternative explanation is that VZV may reach the ganglion by viremic spread [91, 92].

Difficulty in obtaining large quantities of cell-free virus and the lack of suitable small animal models for varicella and herpes zoster have complicated investigations of mechanisms of latency. Recently developed rodent models allow study of some aspects of VZV latency [90]. Latent VZV is located predominately in human ganglionic neurons where VZV DNA is found in a circular or concatameric (end-to-end) configuration at a copy frequency of 2–9 genomic copies per neuron. In situ hybridization studies have shown the latent VZV genome to be present in 1–7 % of the sensory ganglia neurons [93–96]. Animal model experiments have demonstrated the presence of VZV genomic DNA, viral proteins, and virion production in both neurons and satellite cells [97]. Transcription of VZV genes during latency is restricted to expression of 6 genes (4, 21, 29, 62, 63, and 66), with expression of gene 63 the most prevalent and considered to be the marker for latency [98–100]. A recently developed model of SVV infection in rhesus macaques appears to simulate human varicella and results in latent ganglionic infection with expression of ORF63 protein [101]. The complex mechanisms that control latency and virus reactivation in ganglia remain incompletely understood.

Following reactivation and replication in the ganglion, virus is transported along the sensory nerve at a rate estimated to be 13 cm/day to the skin where it again replicates in epithelial cells, producing the dermatomal vesicular rash characteristic of shingles [102, 103]. Unlike the lesions of varicella, in which different stages are seen simultaneously, most herpes zoster lesions are in the same stage of development. Replication of VZV in the sensory ganglion results in intense inflammation, neuronal destruction, and focal hemorrhagic necrosis. Less severe inflammatory changes often occur in adjacent ganglia. Occasionally, inflammation and necrosis also extend to the anterior nerve root, resulting in localized motor neuropathy. These changes are accompanied by lymphocytic pleocytosis and virus may be detectible in the CSF. Movement of VZV from the ganglion down to the sensory nerve to the skin produces acute inflammation in the nerve. Inflammatory changes in the sensory nerve persist for months and may result in demyelination, Wallerian degeneration, and sclerosis. Virus reaching the skin replicates in epithelial cells of the epidermis, producing pathologic changes identical to those described for varicella above. Viremia occurs during most episodes of herpes zoster. VZV can be demonstrated both in plasma and PBMCs during acute shingles and can, in some cases, persist for weeks [104, 105].

8.4 Immune Responses in Herpes Zoster

The specific immune responses that limit reactivation of VZV from the sensory ganglia are poorly understood, although the role of VZV-specific memory T lymphocytes is critical [86, 87]. VZV may periodically reactivate and undergo limited replication, but replication is suppressed by the immune response before any clinical symptoms result. The most important factor that predisposes to the development of herpes zoster is decline or suppression of VZV-specific cellular immunity [106]. Lower frequency of circulating VZV-specific responder T cells characterizes all conditions associated with increased incidence of VZV reactivation, while levels of humoral immunity are well maintained, even in the elderly [107]. VZV responder cell frequency peaks in early adulthood and then begins to decline [87]. Elderly individuals and renal transplant recipients have lower frequency of VZV-reactive effector memory T cells when compared with controls [108]. Specificity of these responder T cells in latently infected individuals is directed against VZV glycoproteins (E, H, B, and I) as well as against transcriptional activators encoded by ORF 4, 10, 62, and 63. Currently, there is no assay available that identifies an exact immunologic correlate of protection for herpes zoster.

Following reactivation of latent VZV and clinical herpes zoster, patients demonstrate enhanced levels of VZV-specific humoral and CMI responses [107, 109]. The observation that second episodes of herpes zoster are rare in immunocompetent individuals suggest that this boosting of immunity that accompanies clinical herpes zoster is sufficient to maintain the virus in its latent state and prevent subsequent reactivation for at least several years.

9 Patterns of Host Response

9.1 Clinical Presentation of Varicella

Symptoms of varicella develop after an incubation period that averages about 15 days (range 10–21 days). Varicella is generally a benign disease in healthy children, but symptoms are often more severe in adolescents and adults. Symptomatic visceral organ infection (pneumonia, encephalitis, hepatitis, etc.) is rare in immunocompetent patients, but occurs at much higher frequency in the setting of immune suppression, especially in children with hematologic malignancies or organ transplant recipients. Fewer than 5 % of primary VZV infections are asymptomatic or subclinical. A prodrome of fever, malaise, headache, and anorexia is variably present, occurring more commonly among older children and adults and lasting 1–2 days. A transient scarlatina-like rash is occasionally noted just before or coincident with the appearance of the varicella lesions. Lesions begin as pink macules that quickly evolve into fragile vesicles 1–4 mm in diameter surrounded by a zone of erythema. The lesions first appear on the face and scalp, then on the trunk, and finally on the extremities, with the greatest concentration of lesions seen on the trunk and proximal extremities. Vesicles also appear on mucosal surfaces and rapidly evolve into shallow ulcerations. The rash of chickenpox is characterized by a rapid evolution of lesions over 8–12 h and by successive crops of new lesions. Consequently, lesions of all stages are present simultaneously on the involved skin surfaces. New lesion formation continues for 2–4 days, accompanied by pruritus, fever, headache, malaise, and anorexia. The rash peaks on about the fifth day with an average lesion count of 250–500 lesions. Fewer lesions are seen in children younger than 5 years. Older children and adults, as well as secondary cases within a household, tend to have more severe disease (higher lesion counts and higher fever) and a higher frequency of complications [110]. As inflammatory cells migrate into the vesicular fluid, the lesions become pustules that are often centrally umbilicated. The pustules become crusted and the scabs detach after 1–3 weeks, usually healing without scarring.

9.2 Complications of Varicella

9.2.1 Skin and Soft Tissue Infections

The most common complication of pediatric varicella is cellulitis. The bacterial superinfection is most often caused by *Staphylococcus aureus* or *Streptococcus pyogenes* (group A streptococcus) and is attributed to scratching [111]. The skin infection can range from simple cellulitis (which is common) to more severe manifestations, including necrotizing fasciitis (which is rare) [112]. In the prevaccine era, it was reported that up to one-third of all cases of group A streptococcal cellulitis in children were temporally associated with chickenpox. Toxin-induced diseases (scalded skin and toxic shock syndromes) have been reported as a consequence of bacterial skin infections in children with varicella [113].

9.2.2 Varicella Pneumonia

Pneumonitis caused by VZV is rare in children with chickenpox but occurs with increased frequency in adolescents and adults [114]. In studies of military recruits with chickenpox, 15–20 % showed pulmonary infiltrates on chest radiograph, although most did not have clinical signs or symptoms of pneumonia. Women who contract varicella while pregnant have an estimated 10–20 % risk of developing symptomatic VZV pneumonia, which is a much higher rate than observed in nonpregnant women [115]. Some studies have suggested that both the frequency and the severity of VZV pneumonia are higher when chickenpox is acquired during the third trimester of pregnancy. Before the availability of acyclovir, mortality among pregnant women with severe VZV pneumonia (those requiring mechanical ventilation) was about 40 %, but is now less than 15 % with the availability of effective antiviral therapy and improved supportive care [77].

9.2.3 Neurologic Complications

The CNS manifestations most frequently associated with chickenpox are cerebellar ataxia and encephalitis [116, 117]. Uncommon neurologic complications include transverse myelitis, aseptic meningitis, vasculopathy syndromes, and Guillain-Barré syndrome. Optic neuritis has been reported as a rare complication of varicella in both pediatric and adult patients with good visual recovery expected in most cases. Reye syndrome, a triad of acute hepatic failure, encephalopathy, and hypoglycemia, previously associated with varicella and other viral infections, is now known to be more specifically related to salicylate therapy in febrile children.

Cerebellitis with ataxia, the most common neurologic abnormality associated with chickenpox, is diagnosed in approximately 1:4,000 cases of varicella. Children can develop ataxia from a few days before to 2 weeks after the onset of the rash, although neurologic symptoms most often occur simultaneously with the rash. Symptoms include vomiting, headache, and lethargy accompanied by ataxia. Chickenpox-associated cerebellar ataxia is usually self-limited, and most abnormalities resolve completely within 1–3 weeks. Mortality is essentially zero.

Encephalitis is a less common but more severe complication of chickenpox. The incidence of encephalitis is estimated to be one to two cases per 10,000 cases of varicella. The largest number of cases of encephalitis occurs in children, but the incidence is highest in adults and young infants. Neurologic symptoms most often appear about 1 week after the onset of the varicella rash (but may actually precede the

rash or follow much later in some cases). The usual presenting symptoms are headache, fever, vomiting, and altered sensorium. Seizures occur in 29–52 % of patients. The reported mortality for varicella encephalitis has ranged from 5 to 35 %, but is probably less than 10 %, with complete or near-complete recovery expected in most cases. Long-term sequelae may be present in 10–20 % of survivors.

Recent studies have emphasized that large- and small-vessel vasculitis is a pathologic hallmark of CNS VZV infection. Arterial ischemic stroke syndromes can occur in children (and adults) following varicella [118, 119]. By some estimations, young children with arterial ischemic strokes are threefold more likely than controls to have recently had varicella [120, 121]. The syndrome typically occurs in otherwise healthy children, average age 5 years, who present with hemiplegia. The median interval between varicella infection and the onset of neurologic deficits is 2 months [122, 123]. Angiography reveals vasculopathy of the branches of the middle cerebral artery. In one fatal case, histopathologic examination demonstrated active granulomatous arteritis of the middle cerebral artery with lymphocytic inflammatory infiltrates and VZV antigens in the smooth muscle layer [123]. Most children with hemiplegia following varicella have a good neurologic outcome.

9.2.4 Congenital and Neonatal Varicella

As noted above, varicella infection early in pregnancy may result in CVS [76], a syndrome characterized by limb hypoplasia, ocular and neurologic abnormalities, and distinctive cicatricial skin scarring in a dermatomal pattern [124]. Thirty percent of babies born with CVS will die during the first few months of life. The pathogenesis of the syndrome is thought to be invasion of the fetal nervous system by VZV during a critical state of development. The risk of CVS with maternal chickenpox occurring during gestational weeks 2–12 is 0.4–0.6 % and weeks 13–28 is 1.4–2.0 %, and the risk beyond 28 weeks is essentially zero [125, 126]. The period of highest risk appears to be gestational weeks 13–20. When maternal varicella occurs during the third trimester, fetal infection can occur despite passively acquired maternal antibody, but the outcome is usually good with no associated birth defects.

VZV infection of neonates may result from either vertical or horizontal transmission [77]. If maternal varicella develops during the time window from 4 to 5 days before until 2 days after delivery, the baby is exposed to VZV via transplacental viremia without the benefit of transplacental maternal anti-VZV immunoglobulin G. In this situation, varicella will develop in approximately 17–48 % of neonates. The babies seem healthy at birth but develop signs and symptoms of varicella 5–10 days postpartum. Historically the mortality rate for neonatal varicella was about 30 %, but the availability of VZV immune globulin, antiviral therapy, and intensive supportive care has reduced the mortality to about 7 %. Conversely, infants who have varicella lesions at birth or within the first 5 days of life (thus having received transplacental maternal anti-VZV antibody before delivery) are unlikely to have severe disease. In addition, infants (particularly low-birth-weight babies) born to VZV-seronegative mothers are at risk for severe varicella if infected during the first few days of life (e.g., in the nursery). Infants born to seropositive mothers who experience chickenpox early in life tend to have mild disease (perhaps due to partial protection from maternally acquired antibody), but are at increased risk to develop childhood herpes zoster [127].

9.3 Diagnosis of Varicella

The appearance of varicella is quite distinctive, and a clinical diagnosis made by an experienced healthcare provider is usually accurate and reliable. The presentation of an unvaccinated child with mild constitutional symptoms, a diffuse vesicular rash, and no history of chickenpox is strongly suggestive of the diagnosis, especially if there has been a documented exposure within the previous 2 weeks. However, with the dramatic decline of varicella in the American pediatric population, new medical trainees have much less experience with clinical diagnosis of chickenpox. Furthermore, cases of chickenpox in immunocompromised patients or "breakthrough" varicella in vaccinated patients may have an atypical appearance, necessitating laboratory confirmation.

In the past, viral culture has been the benchmark method for laboratory diagnosis of active VZV infections. VZV can be cultured by inoculating vesicular fluid onto monolayers of human fetal diploid kidney or lung cells. Unlike HSV, VZV is extremely labile and every effort should be made to minimize the time spent in specimen transport and storage. Ideally, fluid should be aspirated from clear vesicles into a tuberculin syringe containing 0.2 ml of viral transport medium, inoculated directly into tissue culture at the bedside (or taken directly to the laboratory).. If no vesicles or pustules are available for aspiration, the clinician should carefully remove overlying crusts from the freshest lesions available, swab the underlying ulcer, and place the swab directly into viral transport medium for rapid delivery on ice to the laboratory. Characteristic cytopathic effects are usually seen in tissue culture in 3–7 days, although cultures should be held for 14 days before they are declared negative. The culture process can be accelerated by using centrifugation cultures in shell vials. Identification of the isolate can be confirmed by staining the cell monolayer with VZV-specific monoclonal antibodies. In general, viral culture for VZV is highly specific but slow, insensitive, and expensive. However, culture remains essential if in vitro testing of susceptibility of the VZV isolate to antiviral drugs is desired.

The use of the PCR to detect VZV nucleic acids in clinical specimens has emerged as an important diagnostic tool and has replaced viral culture in many settings [128–131]. PCR overcomes the difficulties inherent in culturing labile VZV and has been used successfully to detect viral DNA not only from cutaneous lesions but also in cerebrospinal fluid from patients with CNS infection and in ocular fluids and tissues from VZV retinitis cases [132, 133]. Unlike HSV or CMV, VZV is not known to be shed asymptomatically (except possibly in saliva). Therefore, identification of VZV nucleic acids from cutaneous lesions or tissue biopsies is diagnostic of active infection. PCR is a reliable diagnostic tool for cases with atypical or vaccine-modified skin lesions [131]. PCR of blood is likely the diagnostic method of choice for patients with visceral VZV disease (e.g., pneumonia, hepatitis, etc.) without cutaneous involvement [134–136]. In addition, the use of PCR methods makes it possible to distinguish between diseases caused by wild-type VZV or by the VZV vaccine virus, which is not routinely possible using viral culture.

VZV can be identified in infected tissues by histopathology or electron microscopy, but visualization of multinucleated giant cells with inclusion bodies or herpesvirus virions does not distinguish between HSV and VZV. Immunohistochemical staining of viral antigens can provide a more specific diagnosis. Directly fluorescent antigen (DFA) staining using fluorescein-conjugated monoclonal antibodies to detect VZV glycoproteins in infected epithelial cells is especially helpful for making a rapid diagnosis when the clinical presentation is atypical [137]. This simple, rapid technique is more sensitive than viral culture (especially in later stages of VZV infection when virus isolation becomes more difficult) and can be performed more rapidly than PCR. To perform the DFA assay, epithelial cells are gently scraped from the base of a vesicle or ulcer with a scalpel blade, smeared on a glass slide, fixed with cold acetone, stained with fluorescein-conjugated monoclonal antibodies, and then examined using a fluorescent microscope. By using virus-specific monoclonal antibodies, HSV can be readily distinguished from VZV; DFA staining is therefore a much more powerful technique than a conventional Tzanck preparation.

Serologic assays are helpful for determining susceptibility to VZV but are not generally useful for diagnosing acute infections. VZV-specific serum IgG becomes detectible several days after the onset of varicella, with titers peaking at 2–3 weeks, so routine serologic tests provide only a retrospective diagnosis. The detection of VZV-specific serum IgM does not reliably distinguish among primary infection, reinfection, or reactivation. A variety of techniques have been used to detect VZV IgG antibodies, but most laboratories have now adopted an ELISA or latex agglutination (LA) assay for VZV serodiagnosis [130, 138]. The ELISA is capable of detecting IgG or IgM responses, is a reliable indicator of immune status following natural infection, and is readily automated. However, the ELISA may not be sufficiently sensitive to measure vaccine-induced immunity [139]. The LA is rapid, simple, inexpensive, and highly sensitive, but cannot be automated or used to detect IgM. The fluorescent antibody to membrane antigen (FAMA) test is also highly sensitive, but not widely available. The best tests for documenting vaccine-induced protection against varicella appear to be FAMA or a purified VZV glycoprotein ELISA (gpELISA), although further validation is necessary [130].

9.4 Clinical Presentation of Herpes Zoster

Herpes zoster classically presents as a painful cutaneous eruption in a dermatomal distribution [140, 141]. The inflammatory changes that occur when latent VZV reactivates in the sensory ganglion produce discomfort in the corresponding dermatome. The patient may report unpleasant prodromal sensations that range from mild itching or tingling to severe pain that precede the development of the skin lesions by 1–5 days (or occasionally longer) [142]. The cutaneous eruption appears in the skin segment innovated by a single sensory ganglion, is unilateral, and does not cross the midline. Overlap of lesions into ipsilateral adjacent dermatomes occurs in at least 20 % of cases. The most common sites for herpes zoster are the thoracic dermatomes (50 % of cases), followed by cranial nerve (15 %), cervical (15 %), lumbar (15 %), and sacral (5 %) dermatomes. During the acute phase of herpes zoster, most patients experience dermatomal pruritus and pain, which can be quite severe. Patients may also complain of headache, photophobia, and malaise, but significant fever is uncommon. Skin changes begin with an erythematous maculopapular rash followed by the appearance of clear vesicles (Fig. 42.3).

New vesicle formation typically continues for 3–5 days, followed by lesion pustulation and scabbing. The extent of cutaneous involvement can range from a few vesicles to a confluent eruption filling the entire dermatome. Skin necrosis in the involved dermatome can occur but is more commonly encountered in immunocompromised patients. Skin lesions heal within 2–4 weeks, often leaving scarring and permanent pigmentation changes. Immunocompetent children and young adults with herpes zoster tend to have less extensive cutaneous eruptions, less severe pain, and a much lower risk for chronic pain compared with elderly adults. Disseminated VZV infection with visceral involvement is extremely rare in immunocompetent patients with herpes zoster, although occasional cases of encephalitis and myelitis have been reported. In contrast, immunocompromised patients (especially organ transplant recipients and those receiving myeloablative chemotherapy) are at significant

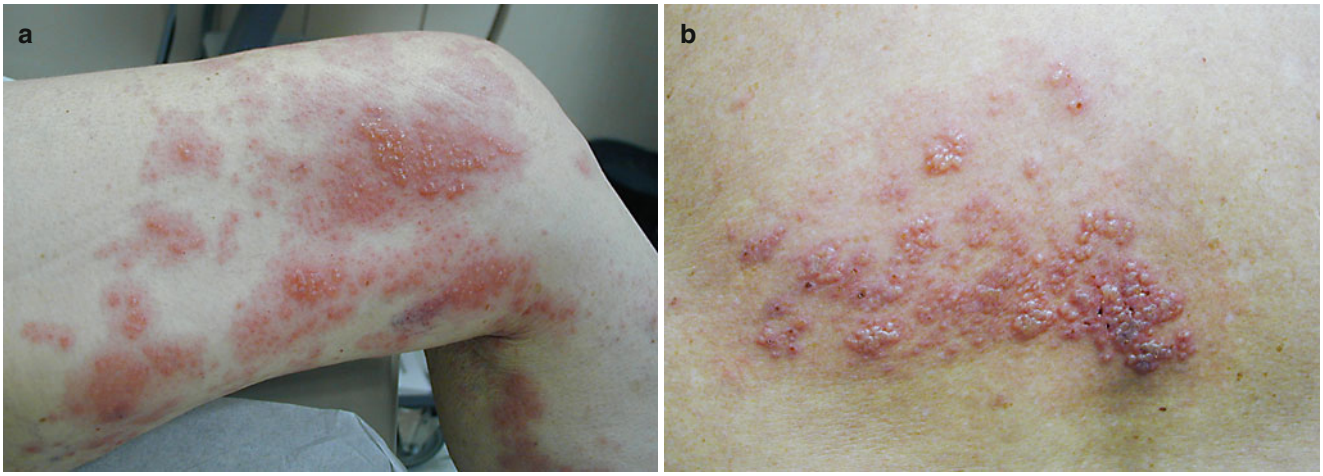

Fig. 42.3 Clinical presentation of herpes zoster. (**a**) Acute herpes zoster involving the L3 dematome. (**b**) Clusters of vesicles characteristic of acute herpes zoster

risk for cutaneous and visceral dissemination complicating dermatomal herpes zoster. In unusual cases, patients develop typical dermatomal neuralgic pain or even focal neurologic syndromes but do not progress to the typical cutaneous eruption, a condition termed "zoster sine herpete."

9.5 Complications of Herpes Zoster

9.5.1 Acute Pain

While the cutaneous manifestations of herpes zoster are unpleasant, pain is the defining symptom for most patients with shingles. As the virus replicates within the ganglion and travels down the afferent sensory nerve, the resulting intense inflammation and neuronal necrosis produce pain and related symptoms that can be very severe. The range of symptoms can vary from numbness or tingling, to a deep aching discomfort, to sharp stabbing or burning sensations. A significant number of patients also report prominent itching which may occur along with or instead of pain [143].

9.5.2 Postherpetic Neuralgia

Pain that persists after healing of the skin lesions, termed postherpetic neuralgia (PHN), is the most feared complication of herpes zoster. The quality and severity of the pain varies among patients, with common descriptions of constant deep aching or burning pain, or intermittent sharp stabbing pain or electric shock sensations, or severe itching [39, 144]. The precise incidence of PHN is difficult to state with certainty because of the wide variety of definitions employed by various investigators. In an analysis that combined data from several large clinical trials of antiviral therapy for herpes zoster in outpatients >50 years of age, 68 % of placebo recipients had pain 30 days after rash onset, 46 % had pain at 120 days, and 35–40 % had pain at 180 days [145]. Analyses of the severity and duration of pain in herpes zoster patients enrolled in clinical trials demonstrate three distinct phases of pain. Acute pain can last as long as 30 days after rash onset, followed by subacute neuralgia that lasts 30–120 days after rash onset and PHN which is defined as pain that persists for at least 120 days after rash onset [146, 147]. The implication is that these different stages of pain may be induced by different pathophysiologic mechanisms. Most pain experts favor a theory of altered excitability of the ganglionic or spinal cord neurons as the etiology of persistent zoster-associated pain [39, 148]. Other investigators have suggested persistent ganglionitis caused by ongoing low-level viral replication [149].

The strongest risk factor for development of long-term postherpetic pain is age [150]. Just as older adults are at increased risk for development of herpes zoster, older adults demonstrate a much higher incidence of PHN [151]. In a study conducted in Iceland, postherpetic pain of >3 months duration was documented in 1 % of patients aged 0–49 years, 13 % of persons 60–69 years of age, and 29 % in those ≥70 years of age [152]. In addition to older age, other well-defined risk factors for PHN include the presence and severity of prodromal pain preceding the rash, greater severity of acute pain, and greater severity of the rash (as measured by lesion surface area) [145, 147, 153, 154]. Like other chronic pain syndromes, PHN is a potentially debilitating and expensive affliction that can have a long-term impact on the quality of life of elderly patients [155–157].

9.5.3 Central Nervous System Complications

CNS involvement with VZV may occur simultaneously with the cutaneous shingles eruption or follow the acute episode by weeks or months. A variety of neurologic syndromes attributed to VZV infection have been described including encephalitis, myelitis, cranial and peripheral nerve palsies,

and vasculopathies, including a syndrome of delayed contralateral hemiparesis [133]. VZV neurologic disease has also been described in patients with no history of VZV cutaneous lesions [158]. Large- and small-vessel vasculitis is now recognized as the pathologic mechanism underlying most CNS manifestations of VZV infection.

Acute VZV encephalitis is a rare complication of herpes zoster that develops a few days after the onset of rash and occurs most frequently in immunocompromised patients. Herpes zoster involving a cranial nerve dermatome and the presence of cutaneous VZV dissemination are other markers for increased risk of encephalitis. The clinical presentation is most often an acute or subacute delirium accompanied by few focal neurologic signs. The mortality rate due to herpes zoster-associated acute encephalitis is around 10 % and may be higher in more severely immunocompromised patients. A chronic form of multifocal VZV encephalitis is seen almost exclusively in immunocompromised patients, especially AIDS patients with low levels of CD4+ T cells, and is thought to be due to small-vessel vasculitis. The onset of chronic encephalitis may occur months after an episode of herpes zoster and up to 40 % of these patients have no recognized history of shingles. The clinical presentation is usually subacute with headache, fever, mental status changes, and seizures. Patients may have focal neurologic defects including, aphasia, hemiplegic, and visual field cuts. The clinical course is often one of progressive deterioration and death, but responses to intravenous acyclovir therapy have been reported [159, 160].

Herpes zoster-associated myelitis is thought to result from direction invasion of the spinal cord by VZV, with virus spreading along the central axons of infected primary sensory neurons. The most severe forms are seen in immunocompromised patients, especially those with AIDS. Myelitis usually follows herpes zoster involving thoracic dermatomes, with weakness developing in the same spinal cord segment as the rash. Neurologic symptoms begin to develop an average of 12 days after the onset of rash. The most common initial manifestations are bladder dysfunction, lower extremity weakness, asymmetrical reflexes, and sensory disturbances [161]. In severe cases, myelopathy can progress to a partial Brown-Séquard syndrome or total cord transection.

When herpes zoster involves the seventh cranial nerve (geniculate) ganglion, the result is weakness of ipsilateral facial muscles with rash in the external auditory canal and sometimes on the ipsilateral anterior two-thirds of the tongue or hard palate. This clinical presentation of peripheral facial weakness with zoster oticus is termed the Ramsay-Hunt syndrome. Some patients also report nausea and vomiting, nystagmus, tinnitus, diminished hearing, and vertigo, indicating involvement of the eighth cranial nerve as well [162].

Delayed contralateral hemiparesis following herpes zoster ophthalmicus (HZO; shingles involving the first division of the trigeminal nerve) is a rare but devastating vasculopathy syndrome that has been reported in both immunocompetent and immunocompromised patients [163]. The pathogenesis of this unusual disorder is thought to be direct VZV invasion of large cerebral arteries by extension of virus from smaller vessels that transverse the trigeminal-innovated meninges. This produces a necrotizing arteritis that can result in vascular thrombosis or hemorrhage [164]. The most frequently described presentation is headache and contralateral hemiplegia that follow herpes zoster ophthalmicus by an average of 7 weeks. The mortality rate among adults is 20–25 %, with a high probability of permanent neurologic sequelae among survivors. In some studies, the overall risk for strokes was increased in the 1-year interval following an episode of herpes zoster [165].

9.5.4 Ocular Complications

HZO can be associated with several potentially sight-threatening conditions. While not all patients with shingles involving the first division of the trigeminal nerve develop ocular complications, the consequences are so serious that ophthalmologic consultation and close follow-up are warranted. VZV infection of ocular structures can range from conjunctivitis (which is extremely common) to serious forms of keratitis, iridocyclitis, glaucoma, and palsies of cranial nerves III, IV, and VI [166].

Syndromes of acute retinal necrosis (ARN) caused by VZV have occasionally been described in immunocompetent patients, but more aggressive variants of this infection are now recognized in immunocompromised patients, especially those with AIDS. These syndromes, termed "progressive outer retinal necrosis" (PORN) or "rapidly progressive herpetic retinal necrosis" (RPHRN), occur most frequently in AIDS patients with CD4+ T lymphocyte counts of <100 cells/mm^3 [167]. This syndrome of necrotizing VZV retinitis may occur concurrently with active herpes zoster or, more frequently, develop weeks or months after the acute episode of herpes zoster has resolved. The retinitis begins with multifocal necrotizing lesions involving the peripheral retina. Most patients present with unilateral involvement, but progression to bilateral disease occurs frequently. PORN rapidly progresses to confluent full-thickness retinal necrosis and results in blindness in 75–80 % of involved eyes. The prognosis for preservation of vision is better when ARN occurs in immunocompetent patients.

The etiologic role of VZV in PORN occurring in immunocompromised patients has been established by demonstrating the virus by culture or PCR from ocular fluids or tissues (although HSV occasionally causes an identical syndrome) [168]. PORN can follow either HZO or herpes zoster in a remote dermatome. Furthermore, retinal involvement is bilateral in more than half of cases, suggesting that VZV reaches the retina via hematogenous spread, possibly with extension along nerve pathways within the anterior visual system.

9.5.5 Pregnancy

CVS is not observed after herpes zoster during pregnancy, possibly due to preexisting maternal anti-VZV immunity that limits viremia and protects the fetus. Similarly, development of maternal herpes zoster in the peripartum period does not put the healthy infant at increased risk for neonatal varicella [169].

9.6 Diagnosis of Herpes Zoster

The appearance of a classic case of herpes zoster is sufficiently distinctive that a clinical diagnosis is usually accurate. Characteristic features include pain (or other abnormal sensations) and clustered vesicular lesions in a dermatomal distribution that does not cross the midline (Fig. 42.4).

One important alternative diagnosis to be considered is "zosteriform" HSV rash appearing in a pseudodermatomal distribution, most commonly in the sacral area. However, many presentations of herpes zoster are not "classic" and may require laboratory confirmation. Patients may have very few cutaneous lesions, or the lesions may have an atypical appearance (which is especially common in immunocompromised patients). The laboratory diagnostic methods discussed above with varicella also apply to the diagnosis of herpes zoster. The DFA and PCR assays are especially useful [170]. Most patients will demonstrate an increase in VZV-specific antibody titers following an episode of herpes zoster, which is occasionally useful for retrospective confirmation, but not very helpful for real-time diagnosis.

10 Control and Prevention

10.1 Treatment of Varicella

In healthy children, chickenpox is generally a benign disease associated with low rates of morbidity and mortality. For most children, supportive care is sufficient. Astringent soaks, antipruritics, and antipyretics (preferably acetaminophen rather than aspirin) provide symptomatic relief. Trimming the fingernails closely helps prevent bacterial superinfections related to scratching. If bacterial cellulitis develops (especially infection caused by group A streptococcus), antibiotic therapy may be necessary.

As antiviral therapy, oral acyclovir has been evaluated for treatment of uncomplicated varicella in immunocompetent children (Table 42.1)

When initiated within 24 h of rash onset, acyclovir results in shorter duration of fever, fewer skin lesions, and accelerated lesion healing. Oral acyclovir is well tolerated and reduces the overall duration of symptomatic illness by about 24 h. The populations that have been studied in clinical trials were not sufficiently large to assess the impact of acyclovir therapy on the incidence of varicella complications such as pneumonitis or encephalitis. Unlike acyclovir, valacyclovir and famciclovir have not been as extensively evaluated as therapy for varicella in children but should be efficacious. Many pediatricians still view antiviral therapy as optional for otherwise-healthy children with chickenpox.

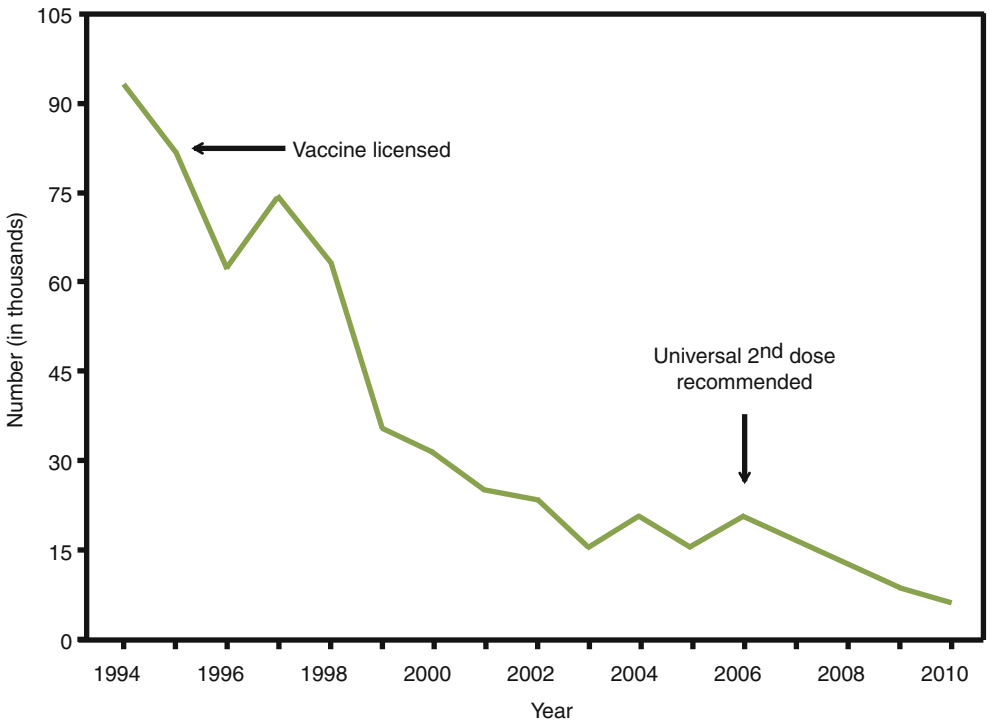

Fig. 42.4 Decline in chickenpox in the U.S. after institution of vaccination. Number of reported cases from the states of Illinois, Michigan, Texas, and West Virginia, 1994–2010 (Centers for Disease Control and Prevention, Summary of Notifiable Diseases-United States, 2010. MMWR 59 (No. 53): 89, June 1, 2012)

Table 42.1 Recommended antiviral therapy for VZV infections

	Drug	Route and dose[a]	Major toxicities
Immunocompetent patients			
Varicella	Acyclovir	20 mg/kg (800 mg max.) po five times daily × 5 days[b]	None, minor nausea or headache
Herpes zoster	Acyclovir	800 mg po five times daily × 7–10 days	As above
	Valacyclovir	1,000 mg po every 8 h × 7 days	None, minor nausea or headache
	Famciclovir	500 mg po every 8 h × 7 days	None, minor nausea or headache
	Brivudin[c]	125 mg po once daily × 7 days	Potentially serious interaction with fluoropyrimidines (e.g., 5-fluorouracil)
Immunocompromised patients			
Varicella	Acyclovir	10–15 mg/kg (or 500 mg/m^2) intravenously every 8 h for ≥7 days	Nephrotoxicity (rare), CNS disturbances (rare)
Herpes zoster	Acyclovir	IV (dose as above)[d]	As above
Disseminated VZV syndromes (e.g., encephalitis, pneumonitis)	Acyclovir	IV (dose as above)	As above
Infection caused by acyclovir-resistant VZV	Foscarnet	60–90 mg/kg intravenously every 12 h until healed (≥10 days)[e]	Nephrotoxicity (common): electrolyte disturbances (common), seizures, arrhythmias, anemia, genital ulcers

[a]Doses given are for adults with normal renal function
[b]Famciclovir and valacyclovir will also likely be effective
[c]Not licensed for use in the United States
[d]Mildly to moderately immunocompromised patients, including most AIDS patients, can be treated with oral therapy
[e]Alternative – intravenous cidofovir

On the other hand, adolescents and adults with varicella can be seriously ill, with high fever, hundreds of skin lesions, debilitating constitutional symptoms, and a higher risk of complications (especially VZV pneumonia) [171]. Given the risk of significant morbidity and resultant absenteeism from school or work, therapy that will reduce the severity and duration of the acute illness is warranted. In clinical trials enrolling adolescents and adults with varicella, oral acyclovir therapy was shown to reduce the duration of new lesion formation, reduce the maximum number of lesions, accelerate cutaneous healing, and shorten the duration of fever. In these studies, the benefit of acyclovir administration was minimal when therapy was initiated later than 24 h after rash onset. Overall, acyclovir reduced the duration of symptomatic illness of about 2 days. Valacyclovir and famciclovir are also likely to be effective for chickenpox in adolescents and adults, but data from controlled clinical trials are limited. The decision whether to initiate antiviral therapy in a patient with chickenpox will be influenced by the patient's age, the underlying medical conditions, and the risk of complications [172]. While antiviral therapy is considered optional for healthy children with chickenpox, the higher potential for morbidity clearly favors treatment in adolescents and adults.

10.1.1 Pregnant Women

Although based more on case reports than on prospectively acquired data, the evidence that varicella in pregnancy is associated with enhanced morbidity, especially pneumonia, is compelling [78]. Any pregnant woman who presents with signs and symptoms suggestive of chickenpox should be started immediately on oral acyclovir (800 mg five times daily) or valacyclovir (1 g three times daily) and undergo further evaluation with chest radiograph and blood oxygen saturation measurement. If she has significant respiratory symptoms (including cough or dyspnea), pulmonary infiltrates on chest radiograph, or low oxygen saturation, hospitalization for therapy with intravenous acyclovir (10 mg/kg every 8 h) should be strongly considered. No data are available to indicate whether treating the mother will alter the risk of the congenital varicella syndrome [77, 126].

10.1.2 Immunocompromised Patients

The availability of safe and effective antiviral drugs has greatly reduced the high mortality rate previously associated with varicella in immunocompromised patients. Populations at high risk include organ transplant recipients, patients with cancer (especially hematologic malignancies), and other patients receiving immunosuppressive medications (including high-dose corticosteroids). Small studies of intravenous acyclovir in immunocompromised children with varicella demonstrated a dramatic reduction in the frequency of VZV complications, especially pneumonitis. In this setting, therapy with intravenous acyclovir (10 mg/kg or 500 mg/m^2 every 8 h for 7–10 days) should be initiated at the first sign of infection. A switch to oral antiviral therapy (acyclovir, valacyclovir, or famciclovir) can be considered when the

patient is afebrile and new lesion formation has ceased. Initial treatment with oral therapy may be efficacious in modestly immunocompromised patients (e.g., those with solid tumor malignancies or taking low-dose corticosteroids), but prospectively acquired data are limited. Because of the high frequency of visceral involvement in immunocompromised children or adults with chickenpox, antiviral therapy should be considered mandatory.

Varicella does not appear to be especially severe in most HIV-seropositive children, although some investigators have reported a longer duration of new lesion formation and higher median lesion counts. Deaths attributable to chickenpox in children with HIV infection are rare and are usually due to pneumonitis. Most clinicians prescribed oral antiviral therapy for chickenpox in HIV-infected children, reserving intravenous acyclovir for patients with unusually severe or complicated infections.

10.2 Varicella Postexposure Prophylaxis

10.2.1 Postexposure Vaccination

The administration of varicella vaccine within the first few days after exposure to VZV will produce a protective (or partially protective) immune response in VZV-seronegative individuals [173–175]. About 20 % of patients receiving postexposure immunization within 3 days of exposure may still develop some signs and symptoms of chickenpox, but the disease manifestations are usually very mild (<50 skin lesions) [176]. Postexposure vaccination appears to be more effective and less expensive than preemptive therapy with antiviral drugs. This postexposure vaccination approach is useful for managing VZV exposures that occur in a family, in the workplace, or in a medical care setting.

10.2.2 Passive Immunotherapy

Advisory committees have recommended the administration of varicella-zoster immune globulin (VariZIG™) to VZV-susceptible immunocompromised patients, pregnant women, or neonates who have been exposed to a patient with active chickenpox or herpes zoster [177]. In many cases, varicella-zoster immune globulin administration will not prevent infection in the susceptible host, but will significantly reduce the severity of the resulting illness [178]. Placebo-controlled trials in immunocompromised children have clearly demonstrated that varicella-zoster immune globulin ameliorates the severity of chickenpox and significantly reduces the risk of disseminated infection. A single treatment will reduce the risk of disseminated infection by about 75 % and will provide 4 weeks of passive immunity. No controlled clinical trials of VZV immune globulin prophylaxis have been conducted in populations of pregnant women. The primary rationale for immunoprophylaxis in pregnant women is to prevent varicella complications in the mother, although there are some data to suggest that timely administration of varicella-zoster immune globulin may also reduce the risk of CVS [179].

For maximal efficacy, varicella-zoster immune globulin must be administered as soon as possible after exposure. The window for administration has traditionally been 96 h (4 days), but this was recently extended by the FDA to 10 days [180]. Unfortunately, in this time-critical scenario, the true serologic status of the immunocompromised patient or pregnant woman with a negative history of varicella is often not known. The clinician may be faced with the decision to initiate passive immunoprophylaxis empirically or to wait for the results of serologic testing. Given the time pressure to administer varicella-zoster immune globulin as soon as possible after exposure, it may not be feasible to await serologic test results. In that situation, the recommended course is to proceed with varicella-zoster immune globulin administration after first obtaining a blood specimen for VZV serologic testing. Administration of varicella-zoster immune globulin to an individual who is subsequently shown to be immune will result in no adverse consequences (other than unnecessary expense). If varicella-zoster immune globulin cannot be obtained in a timely fashion, administration of standard intravenous immunoglobulin (IVIG) at a dose of 400–600 mg/kg is an option. Most IVIG contain significant titers of anti-VZV IgG, but the amount varies from lot to lot and may decline in the coming years as more plasma contributions come from younger donors who never had chickenpox.

The VZV immune globulin product available in the USA since 2006 is VariZIG™ (Cangene Corporation, Winnipeg, Canada) [181]. It is available on a patient-specific basis under an FDA-approved expanded access protocol from FFF Enterprises (Temecula, CA; 24-h hotline 1-800-843-7477). VariZIG™ is a lyophilized preparation of purified human immunoglobulin made from plasma containing high levels of anti-VZV IgG. Each vial of VariZIG™ contains 125 units and must be reconstituted to a concentration of 5 % IgG and then administered intramuscularly. The recommended dose of VariZIG™ is 125 units/10 kg of body weight (with a minimum dose of 125 units and a maximum dose of 625 units).

10.2.3 Varicella Chemoprophylaxis

Studies in healthy children have shown that oral acyclovir administration during the latter half of the varicella incubation period (i.e., 7–14 days after exposure) successfully protects 80–90 % of recipients from clinical disease [182]. About 80 % of subjects receiving prophylactic acyclovir demonstrate a humoral immune response, indicating that acyclovir prophylaxis does not reliably prevent infection but does significantly ameliorate symptomatic disease. For healthy children and healthy nonpregnant adults,

most authorities consider postexposure vaccination to be a more effective approach and chemoprophylaxis has not been widely used. Acyclovir and valacyclovir seem to be safe for use in pregnancy, and antiviral chemoprophylaxis in pregnant women can be considered if VZV immune globulin immunotherapy is not available or not feasible. However, this approach has not been adequately studied and is not routinely recommended [183].

10.3 Prevention of Varicella by Vaccination

A live, attenuated varicella vaccine was developed in Japan in 1974 by serial passage of a clinical isolate by Takahashi and colleagues [184]. The genetic differences between wild-type VZV and the vaccine strain (called VZV_{oka}) that account for the attenuation are relatively minor [185, 186]. As a result, the vaccine-strain virus is replication competent and relatively immunogenic [187]. However, VZV_{oka} can still be readily distinguished from wild-type virus using molecular methods [188]. In 1995, the USA became the first country to adopt a universal one-dose childhood varicella vaccination program [46] which was changed to a routine two-dose childhood immunization schedule in 2006 [189]. In the USA, the CDC Advisory Committee on Immunization Practices (ACIP) currently recommends that all immunocompetent children receive their first dose of varicella vaccine at age 12–15 months, followed by a second dose at age 4–6 years before entering school [177]. For adolescents and adults (≥13 years) without evidence of varicella immunity, varicella vaccine should be administered as 2 doses given 4–8 weeks apart. Adolescents who received only a single dose in childhood should receive a second "catch-up" vaccination. The varicella vaccine has proven to be very safe and effective in children, and its widespread use has resulted in substantial reduction in the incidence of varicella and varicella-related complications in the USA (Fig. 42.4) [177].

By 2011, varicella vaccine coverage (receiving at least one dose of vaccine) for children aged 19–35 months was 90.8 % [190], according to the National Immunization Survey (NIS). Between 1995 and 2005, varicella incidence in the USA declined 90.4 % according to the data from the NIS [191] and the CDC Varicella Active Surveillance Project. According to the data from the NNDSS, the national incidence of varicella decreased 43 % between 2000 and 2005 (the one-dose era) and declined another 72 % between 2006 and 2010 (the two-dose era) [5]. Between 2000 and 2010, the national incidence of varicella declined from 43 cases to 9 cases per 100,000 population, a decline of 79 % [5]. The single dose of varicella vaccine has been estimated to be about 84 % effective in preventing varicella disease and 100 % effective for preventing severe varicella [46, 175, 192]. The vaccine is well tolerated and has an excellent safety profile.

However, the decline in numbers of varicella cases plateaued between 2003 and 2006; outbreaks continued to occur even among highly vaccinated school populations [46]. Testing using the highly sensitive FAMA assay indicated that only about 76 % of vaccinees seroconverted after a single dose of varicella vaccine [193]. Multiple studies showed that a single dose of vaccine elicited low humoral and CMI responses that might not be protective [194]. It became apparent that many new cases of varicella occurred in recipients of a single vaccine dose, likely due to primary vaccine failure.

By 2005, 57–64 % of varicella cases occurred in vaccinated patients [191]. About 20 % of children vaccinated with a single dose of varicella vaccine may develop breakthrough varicella if exposed to the virus [195]. It should be emphasized that "breakthrough varicella" is caused by a wild-type virus, not by VZV_{oka} vaccine virus [196]. Among vaccinated children aged 1–14 years, breakthrough varicella is a modified disease and typically very mild; 75 % of patients had <50 lesions [195]. However, these children were able to transmit virus to other susceptible individuals and so outbreaks of varicella continue to occur, although dramatically less frequently than in the prevaccine era [197, 198]. Surveillance in Oregon public schools in 2000–2007 showed that breakthrough varicella was occurring in 0.2–0.3 % of public elementary school students annually [199]. While single-dose vaccination produced an impressive reduction in varicella incidence, the regimen was not sufficiently effective to provide population immunity to prevent continuing transmission, even in highly vaccinated populations [46, 192].

Multiple studies demonstrated that, compared to a single-dose, a two-dose regimen was more efficacious and resulted in a higher proportion of vaccinees with protective antibody titers [46, 194]. Humoral and CMI responses seen after two doses of varicella vaccine approximate those seen after wild-type infection [194]. Compared to single-dose vaccinees, children receiving two doses were 95 % less likely to develop breakthrough varicella [46, 200]. The CDC ACIP changed their recommendation to a two-dose vaccination regimen for varicella prevention in 2006. As of the school year 2011–2012, all 50 states require at least one dose of varicella vaccine before beginning childcare or elementary school. Two doses of varicella vaccine prior to school entry are required by 36 states and District of Columbia. Audit of the Kaiser Permanente database in southern California demonstrated that coverage with the second dose of the varicella vaccine increased from 42.1 % in 2007 to 74.6 % in 2009 [201]. Addition of the second dose has significantly reduced the problem of breakthrough infection and resulted in a continuing decline in varicella incidence [202]. Occasional chickenpox outbreaks continue to be reported, even among vaccinees who received two doses [203].

The declining incidence of varicella has produced benefits even for populations not actively vaccinated. Between 1995 and 2008, the incidence of varicella in infants aged 0–11 months fell 89.7 %, even though this age group is not routinely vaccinated [204]. Similar declines in congenital and neonatal varicella have been reported from Australia following introduction of universal vaccination [205]. Adults also benefited from herd immunity with a 74 % decline in the incidence of varicella between 1995 and 2005, despite a very low frequency of vaccination in adults [110].

Widespread adoption of varicella vaccination in the USA has resulted in a decrease in varicella-related outpatient visits, hospitalizations, and deaths [46, 206, 207]. Comparing the prevaccine era (1988–1995) with the single-dose vaccine era (2000–2006), the frequency of varicella-related hospitalizations in the USA declined from 0.42 per 10,000 population to 0.12 per 10,000 population [208]. This 65 % reduction in hospitalization was seen across all age groups (but was highest in the 0–4-year group) and predicts that varicella vaccination prevented approximately 50,000 varicella-related hospitalizations in the USA between 2000 and 2006 [206, 208]. Similar reductions in hospitalization rates following institution of a varicella vaccine program have been described in other countries including Canada [209] and Australia [210]. In the USA, deaths due to varicella have been nearly eliminated by wide adoption of varicella vaccination. The varicella death rate fell from 0.41 deaths to 0.05 deaths per million population between 1990 and 1994 and 2005–2007 [211]. This represents a reduction in deaths of 97 and 96 % for patients less than 20 years of age and less than 50 years of age, respectively [211]. The decline in the incidence of chickenpox and its complications has resulted in substantial reductions in medical expenditures for chickenpox [46]. Compared with no varicella vaccination, both the single-dose and two-dose vaccination regimens are estimated to result in substantial cost savings from the societal prospective [212].

Post-marketing surveillance studies have demonstrated that the VZV_{oka} varicella vaccine is generally safe and well tolerated [213]. The most common adverse effect is a mild vesicular rash seen in 2–3 % of recipients. Vesicular rashes occurring within 2 weeks after vaccination are usually caused by wild-type virus, while vesicular rashes seen 14–42 days post vaccination are usually caused by VZV_{oka} [214]. VZV_{oka} shed from these lesions is potentially infectious, and rare cases of secondary transmission of VZV_{oka} to susceptible household contacts have been reported [214]. In addition, rare cases of disseminated VZV_{oka} disease have been described in immunocompromised patients. The vaccine virus is markedly less neurovirulent than wild-type VZV [103]. Retrospective database reviews have not demonstrated any association between varicella vaccination and neurologic complications such as ischemic stroke or encephalitis in children [214, 215]. Rare cases of herpes zoster caused by VZV_{oka} have been observed, sometimes involving the same arm where the vaccine was administered [103, 216]. This demonstrates that VZV_{oka} is capable of establishing latency. Furthermore, cases of herpes zoster caused by VZV_{oka} occurring in remote (non-C5) dermatomes are consistent with viremic delivery of vaccine virus to multiple ganglia [92]. There have been occasional reports of the onset of wild-type herpes zoster temporally associated with varicella vaccination [217, 218]. It is not currently clear whether this is coincidence or whether induction of reactivation of latent wild-type virus may occur after exposure to VZV_{oka}.

A data registry of women exposed to VZV_{oka} during pregnancy has not documented any occurrence of fetal varicella syndrome or other birth defects linked to vaccine virus [219]. VZV-susceptible children living in a household with a susceptible pregnant woman should be vaccinated. If the pregnant woman is known to be VZV susceptible and if the vaccinee develops a rash, it may be prudent to separate the vaccinee and the pregnant woman until the rash resolves [177]. The risk of having a susceptible child in the household who might acquire wild-type varicella in the community almost certain exceeds the risk of transmission of attenuated vaccine virus.

VZV_{oka} varicella vaccine has been combined with measles, mumps, and rubella vaccine (MMR) to constitute a quadrivalent vaccine (MMRV) that has been generally safe and effective [220]. Based on reports of increased risk of fever and febrile seizures (eight cases per 10,000 vaccinations, occurring 5–12 days after vaccine administration) when MMRV is used as the first vaccination at 12–15 months, some guidelines recommend that MMR and varicella vaccine be administered separately for the first vaccination [221]. The risk of febrile seizures does not seem to occur among older children, and MMRV can be used for the second vaccination at age 4–6 years [222, 223].

Since varicella vaccine contains replicating virus, it is generally contraindicated in immunocompromised patients, including pregnant women. Concerns about the use of live attenuated vaccines in immunocompromised patients have focused on the potential for vaccine virus to cause disease and on the possibility that immunocompromised patients will fail to mount a protective immune response [224]. However, there are scenarios where varicella vaccine can be safely and effectively used in patients with impaired immunity [225]. Varicella vaccine is recommended for susceptible HIV-seropositive children and adults with CD4-positive T lymphocyte counts of >200 cells/mm^3 (or >15 %) [226] and is safe and well tolerated in this population [227]. Prospective studies have demonstrated that 11.8 % of HIV-seropositive children with preserved CD4+ T lymphocyte counts seroconverted after the first dose of varicella vaccine and 79.4 % seroconverted after the second dose [228]. Retrospective

case reviews suggest that varicella vaccine is about 82 % effective for preventing chickenpox and 100 % effective for preventing herpes zoster when administered to HIV-seropositive children [229].

Other clinical situations where varicella vaccine is being tested on an investigational basis include children with leukemias and other malignancies and children undergoing hematopoietic stem-cell transplant or solid organ transplantation [230, 231]. Multiple studies have demonstrated that varicella vaccine is safe and effective when given to solid organ transplant candidates prior to transplantation [232–235]. Small studies have demonstrated that varicella vaccine can be safely administered after organ or bone marrow transplantation in selected clinical settings, although much larger clinical trials will be required to fully validate the safety and efficacy of this approach [236–238]. Compared with the expense of varicella-zoster immune globulin or treatment of varicella, immunization would be highly cost-effective if shown to be safe and effective [239]. An alternative approach being taken by other investigators is development ofnon-replication competent subunit vaccines (e.g., a glycoprotein E vaccine) that will be highly immunogenic, yet safe to use in seriously immunocompromised populations [240].

10.4 Treatment of Herpes Zoster

The therapeutic goals for herpes zoster in immunocompetent adults are to accelerate the events of cutaneous healing, to reduce the severity of acute neuritis, and, most importantly, to reduce the incidence, severity, and duration of chronic pain [1]. Ganglionic and neuronal inflammation and necrosis begin well before the appearance of skin lesions; thus, the observation of suboptimal response to antiviral therapy initiated after onset of rash is not surprising. Even without antiviral therapy, the cutaneous lesions of herpes zoster almost always resolve within a month. However, chronic pain can persist for months or even years and is the most significant clinical manifestation of herpes zoster in the normal host [241]. In the USA, three oral antiviral drugs (acyclovir, valacyclovir, and famciclovir) are approved and have been demonstrated to reduce the duration of viral shedding, promote resolution of skin lesions, and limit the duration of pain when therapy is initiated within 72 h of lesion onset [242, 243] (Table 42.1). In prospective controlled clinical trials, these antiviral drugs reduced the duration of new vesicle formation by about 1.5 days and reduced the time to 50 % lesion healing by about 2.5 days. The percentage of patients still experiencing pain at 6 months after the onset of shingles was reduced from about 25–35 % in placebo groups to 15–20 % in groups receiving antiviral therapy. It should be noted that, even with appropriate and timely antiviral therapy, some patients will still develop PHN. Acyclovir, valacyclovir, and famciclovir are all well tolerated and appear to be approximately comparable in clinical efficacy for managing herpes zoster in the immunocompetent host. Because their enhanced pharmacokinetic properties allow simpler dosing regimens, valacyclovir and famciclovir are preferred over acyclovir for this indication. Another potent antiviral drug, brivudin, has also been demonstrated to be effective for reducing the duration of new lesion formation and improving pain outcome [244, 245]. Brivudin is commercially available in several countries but has not been approved in the USA because of concerns about potential drug-related toxicities [246]. There is currently no role for topically applied antiviral medications in management of herpes zoster.

Characteristics have been defined which identify immunocompetent patients at highest risk for complications of shingles and thus most likely to benefit from antiviral therapy. Several studies have clearly shown that older age, greater skin surface area involved with rash, and severity of pain at the time of clinical presentation are all predictors of more severe and longer-lasting pain. Patients meeting these criteria should be targeted with therapy with antiviral drugs and potent analgesics. Conversely, patients under 50 years of age are at lower risk for severe or prolonged pain and an argument can be made that antiviral therapy in this group is optional.

Available efficacy data from published clinical trials describe patients who present within 72 h of lesion onset, although, in practice, patients frequently present for medical care well beyond that window. The presence of new vesicles correlates with recent viral replication and may be a marker for patients who would benefit from antiviral therapy, even beyond 72 h. In addition, patients presenting with the high-risk clinical characteristics described above should be considered for antiviral treatment, even when presenting beyond 72 h after lesion onset. However, patients whose lesions have all begun to crust are unlikely to derive benefit from antiviral treatment.

Symptomatic measures should be suggested to keep the patient with herpes zoster more comfortable. Patients should keep the cutaneous lesions clean and dry to reduce the risk of bacterial superinfection. Patients may wash the skin lesions with soap and water in the shower and then carefully pat the skin dry with a clean towel. Some patients find warm or cool astringent soaks to be soothing. A sterile nonocclusive, nonadherent dressing placed over the involved skin will protect the lesions from contact with clothing, which may be especially helpful for patients with increased skin sensitivity (i.e., allodynia). Pain is the most important symptom of herpes zoster and should be managed aggressively. Short-acting narcotic analgesics should be prescribed on a scheduled (rather than as-needed) basis [247]. Prospective clinical trials have demonstrated that corticosteroid administration within 72 h of lesion onset leads to a reduction of pain during the acute phase of herpes zoster, but does not impact the risk of PHN. This modest benefit is balanced against the potential

adverse effects of high-dose corticosteroids in elderly patients, and most physicians do not routinely prescribed steroids for herpes zoster. In patients with severe neuralgic pain unresponsive to oral analgesics, sympathetic nerve blocks can provide rapid but temporary relief [248].

10.4.1 Postherpetic Neuralgia

Medical management of established PHN is complex and often requires a multifaceted approach [140, 247, 249–251]. Opioid analgesics are the mainstay of therapy during the early phase of neuralgic pain. Treatment of PHN may require combinations of analgesics, anticonvulsants (e.g., gabapentin or pregabalin), antidepressants (e.g., nortriptyline or duloxetine), and topical anesthetics (e.g., lidocaine patches) [252]. Patients with severe or prolonged PHN may benefit from referral to a pain management specialist. Most experts do not think that prolonged administration of antiviral drugs has any role for treatment of established PHN [253], although some small studies have suggested benefit [254].

10.4.2 Herpes Zoster Ophthalmicus

Because of the high potential for ocular complications, special emphasis should be given to patients presenting with herpes zoster involving the first division of the trigeminal nerve. Without antiviral therapy, 50 % of patients with HZO will develop significant ocular complications (which can include neurotropic keratopathy, episcleritis, iritis, and epithelial or stromal keratitis). Controlled prospective clinical trials have clearly demonstrated that oral antiviral therapy with acyclovir, valacyclovir, or famciclovir reduces the frequency of late ocular inflammatory complications of HZO from 50–60 % to 20–30 % [255–257]. Some experts favor intravenous acyclovir as initial therapy for selected patients (especially immunocompromised patients) with severe HZO. Systemic antiviral therapy has largely replaced topical antiviral preparations for treatment of the ocular complications of HZO [258, 259]. Referral to an experienced ophthalmologist to assist with management of HZO is recommended.

10.4.3 Herpes Zoster in Immunocompromised Patients

Patients with disorders of CMI are at increased risk for development of herpes zoster and zoster-related complications. Patients with the most significant immunosuppression (such as hematopoietic stem-cell transplant recipients or patients with lymphoproliferative malignancies) are at highest risk for VZV dissemination and visceral organ involvement. Clinical trials with intravenous acyclovir for treatment of herpes zoster in immunocompromised patients clearly demonstrated that treatment resulted in more rapid viral clearance, halted disease progression, and reduced the risk of disseminated infection. In addition, intravenous acyclovir is considered the drug of choice for treating VZV dissemination when it occurs, although efficacy data from prospective studies are limited. Patients with less severe immunosuppression (e.g., patients with solid tumor malignancies or HIV-infected individuals with preserved CD4+ T lymphocyte counts) can, in most cases, be safely and effectively treated with oral antiviral therapy.

10.4.4 VZV Retinal Necrosis

PORN occurs most frequently in immunocompromised patients, with the highest frequency in patients with AIDS. Responses to intravenous acyclovir or ganciclovir have been inconsistent and disappointing. Anecdotal evidence and expert opinion favor a combination of intravenous and intravitreal ganciclovir, with or without intravenous foscarnet [260, 261]. The optimal duration of induction therapy and options for long-term maintenance therapy for PORN in HIV-seropositive patients have not been established [262]. When ARN occurs in immunocompetent patients, the clinical outcome is clearly more favorable, with a good response seen to intravenous acyclovir therapy.

10.4.5 Management of Acyclovir-Resistant VZV Infections

Most cases of infection caused by acyclovir-resistant VZV have been described in AIDS patients with very low CD4+ T lymphocyte counts; most patients had previously been treated with acyclovir. The most common mutations causing acyclovir resistance result in absent or truncated expression of viral thymidine kinase [263]. With this mutation, the isolate will also be resistant to valacyclovir, famciclovir, penciclovir, and ganciclovir, all of which depend upon viral thymidine kinase for phosphorylation and activation. On the basis of anecdotal experience and expert opinion, the drug recommended for treatment of acyclovir-resistant VZV disease is foscarnet, a viral DNA polymerase inhibitor that is not dependent on viral thymidine kinase for activation. Most cases of disease caused by acyclovir-resistant VZV have been limited to cutaneous involvement, although a few instances of visceral infection have been documented. In addition, several reports emphasize that the appearance of the cutaneous lesions caused by acyclovir-resistant VZV may be atypical. In a situation where acyclovir-resistant VZV is suspected and foscarnet therapy is not a viable option, treatment with cidofovir would be considered the next alternative.

10.5 Prevention of Herpes Zoster by Vaccination

Immunologic studies have documented a positive correlation between the risk of herpes zoster and the declining frequency of circulating VZV-specific responder cells, occurring as a consequence of either natural aging or immunosuppressive disease or medical therapy. The hypothesis behind the zoster

vaccine was that administering VZV antigens via vaccination would boost VZV-specific immune responses, allowing the immune system to keep latent VZV in check and prevent reactivation [40, 264]. This would be the first vaccine licensed to prevent disease in patients already infected with the pathogen [265]. The zoster vaccine selected for testing contained live attenuated VZV_{oka}, the same attenuated VZV strain found in the varicella vaccine (although zoster vaccine has over 14-fold more plaque-forming units of virus per dose, thus the two vaccines are not interchangeable).

In a placebo-controlled clinical study of 38,546 subjects 60 years of age or older, the herpes zoster vaccine was shown to be effective by reducing the herpes zoster "burden of illness" (an index of disease severity and duration) by 61 % compared with placebo [40]. A total of 957 cases of herpes zoster were documented among 38,456 adult subjects, with 315 cases occurring in the vaccine group, compared with 642 cases among placebo recipients. Vaccine efficacy for reducing the incidence of herpes zoster was 51.3 % ($p<0.001$), with 5.42 versus 11.12 cases per 1,000 person-years seen in the vaccine and placebo groups, respectively (Fig. 42.5) [40]. The reduction of zoster incidence was significantly greater in the recipients aged 60–69 (63.9 %) than in those aged ≥70 years (37.6 %).

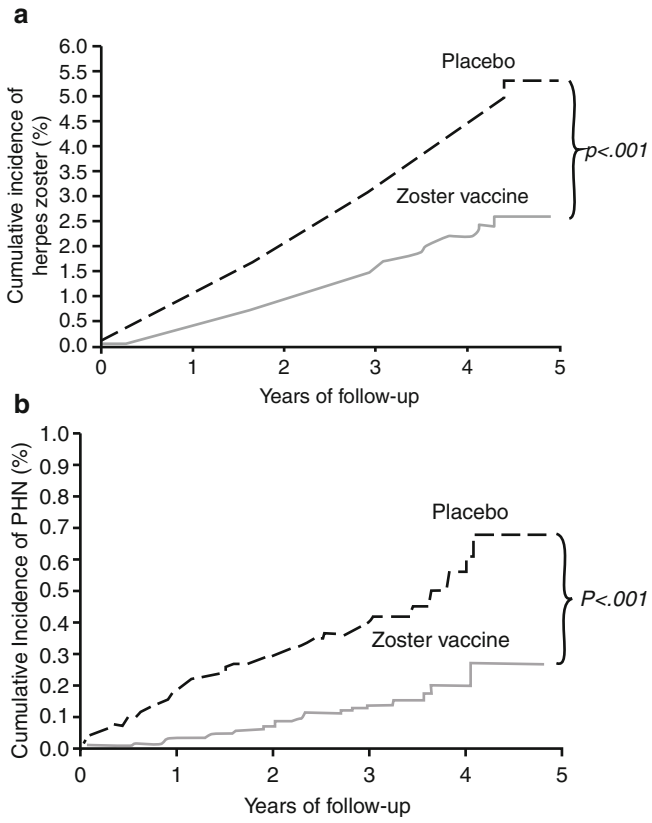

Fig. 42.5 Time-to-event estimates of the effect of the herpes zoster vaccine on the cumulative incidence of herpes zoster (**a**) and postherpetic neuralgia (**b**) [304]

Zoster vaccine resulted in a 66.5 % reduction in the incidence of PHN ($p<0.001$), largely through reduction in incident herpes zoster cases. The duration of protection of the zoster vaccine has not yet been firmly established, but follow-up studies to date have suggested that the duration of protection is at least 7 years [266]. Assuming vaccine efficacy of 63 % and sustained duration of protection, the number of 65-year-old individuals needed to vaccinate to prevent a case of herpes zoster, to prevent a case of PHN, or for a quality-adjusted life-year (QALY) is estimated to be 11, 43, and 165 individuals, respectively [267].

The most common adverse event observed in patients receiving the zoster vaccine was injection site reactogenicity (i.e., erythema, tenderness, and swelling) that occurred in 48 % of vaccine recipients versus 16 % of placebo recipients [268]. Inoculation site adverse events were more common in the 60–69-year-old population than in those 70 years of age and older. The zoster vaccine is equally well tolerated in patients who report a prior history of herpes zoster [269]. Post-licensure surveillance has not documented any significant safety concerns [270]. Neither the safety nor the efficacy of the herpes zoster vaccine is altered when it is coadministered with pneumococcal vaccine in older adults [271, 272]. A theoretical concern was raised that the zoster vaccine could induce cases of herpes zoster in patients with impaired immunity. In a review of a large Medicare database, receipt of zoster vaccine was not associated with any short-term increase in herpes zoster in a population of patients with autoimmune disorders [273]; indeed, vaccination was associated with a decreased incidence of herpes zoster over 2 years of follow-up.

A subsequent clinical trial of zoster vaccine in 22,439 individuals aged 50–59 years demonstrated an even higher degree of efficacy. In the vaccine cohort, 30 cases of zoster were observed for a zoster incidence of 1.99 per 1,000 person-years. In the placebo group, 99 cases of zoster were observed, yielding an incidence of 6.57 cases per 1,000 person-years [274]. Vaccine efficacy for preventing herpes zoster was 69.8 %. As noted in the previous study, a higher frequency of injection site adverse events was observed in vaccine recipients. The only commonly observed systemic adverse event was mild headache.

In prospectively followed subjects, VZV-specific CMI and antibody responses were shown to significantly increase 6 weeks after vaccine administration, with greater increases seen in persons aged 60–69 compared with those 70 years of age or older [230]. The CMI boost persisted over 3 years of follow-up, although the magnitude declined over time. In elderly adults <75 years of age, the zoster vaccine induced peak VZV-specific responder cell frequency higher than that induced by wild-type infection [87]. Vaccine virus has been recovered from saliva of patients following zoster vaccination, presumably reflecting active replication and

asymptomatic dissemination [275]. Other studies have examined potential benefits of a two-dose regimen. Compared with one injection, two doses of zoster vaccine were well tolerated, but did not result in any further significant increase in VZV-specific immune responses [276, 277].

The herpes zoster vaccine received FDA approval for administration to individuals 60 years of age and older in 2006 [278]. The vaccine is currently FDA approved for use in immunocompetent adults 50 years of age or older, although recommendations from advisory panels have maintained a recommended vaccination age of 60 years and older. Uptake of zoster vaccine among eligible older adults has been slow. In 2008, a National Health Interview Survey found that only 6.7 % of eligible adults had received zoster vaccine [279]. Surveys have suggested that barriers to uptake include vaccine cost, insurance reimbursement issues, and the requirement for a vaccine freezer in providers' offices [280–283]. Solutions to these issues will have to be implemented in order for the zoster vaccine to receive the appropriate level of coverage in the targeted population of adults 60 years of age and older.

As the zoster vaccine is a live virus vaccine, use is not generally recommended in immunocompromised patients. Zoster vaccine has been studied in HIV-seropositive adults with well-preserved CD4+ T lymphocyte counts. In small studies, herpes zoster vaccine was well tolerated, but measurements of VZV-specific CMI responses showed no significant increases [284].

It is estimated that the annual cost of providing medical care for herpes zoster patients in the USA is about $1.1 billion [285]. Healthcare expenditures are not limited to care of acute herpes zoster, but include management of chronic pain and hospitalization for zoster-related complications [155, 286]. Cost-effectiveness calculations are complex; variables include the age of vaccination, vaccine costs, herpes zoster incidence, incidence and duration of PHN, and duration of vaccine protection [287]. Overall, however, analyses have suggested that zoster vaccine will likely be cost-effective when given at age 65 if the duration of immune protection is >10 years [288, 289].

10.6 Herpes Zoster Prophylaxis

Controlled clinical trials in organ transplant recipients have clearly shown the benefit of prophylactic antiviral therapy for reducing the incidence of herpes zoster. Studies in HSCT patients have demonstrated that prophylactic oral therapy with acyclovir or valacyclovir can essentially eliminate herpes zoster occurrences in the posttransplant period [290–292]. Twelve months of acyclovir prophylaxis does not impair bone marrow engraftment or reconstitution of VZV-specific immune responses [290]. The frequency of herpes zoster increases after antiviral prophylaxis is discontinued, but the use of prophylaxis prevents herpes zoster during the early posttransplant period when patients are most severely immunosuppressed and are at highest risk for VZV-related complications [290, 293]. Three to six months of antiviral prophylaxis is the standard of care in most bone marrow transplant centers, with some centers extending prophylaxis to 12 months [294–296]. Because VZV reactivation occurs late and with lower frequency in solid organ transplant patients, many experts elect not to offer VZV-specific antiviral prophylaxis for this population [296]. However, prophylactic drug regimens designed to prevent HSV or CMV recurrences in SOT patients will also effectively prevent herpes zoster.

11 Unresolved Problems

While varicella vaccine coverage in the USA is very good, there are still substantial numbers of children (particularly immigrant children) who have not received vaccine. While varicella is not a top priority for international health authorities, efforts should continue to be made to find ways to make varicella vaccine available in countries where health resources are limited. It will not be possible to consider elimination of chickenpox in the foreseeable future, since most of the world's children remain unvaccinated. Even if effective universal childhood vaccination was accomplished worldwide, there will be continued exposure to VZV from naturally infected adults who subsequently develop herpes zoster.

It will be important to continue to monitor the epidemiology of both varicella and herpes zoster. Epidemiologists need more data to assess the impact of universal varicella vaccination as practiced in the USA on the incidence of herpes zoster, both in vaccinated children and naturally infected adults. It is also essential to monitor incidence rates to assess the duration of protection provided by each vaccine.

Means must be found to promote the broader use of the imperfect but still effective herpes zoster vaccine, which is currently greatly under-prescribed. Developing a laboratory marker that accurately predicts risk of herpes zoster in immunocompetent older adults could guide targeted vaccination. While the herpes zoster vaccine is certainly a major advance in our efforts to prevent shingles, the 50 % efficacy of the current vaccine for preventing incident herpes zoster is suboptimal. Improvements in the vaccine might include a modified vaccine virus, an inactivated vaccine containing immunogenic VZV proteins, a modified injection schedule, or use of adjuvants.

Treatment of herpes zoster also remains inadequate. Given that VZV reactivation causes extensive ganglionitis and nerve inflammation prior to appearance of skin lesions,

administering effective antiviral therapy early enough to make a real difference is a challenge. The currently available antiviral drugs are quite potent, but the natural history of herpes zoster dictates that drug therapy is usually started relatively late in the course of disease. Laboratory methods that provide much earlier diagnosis, such as PCR of blood or saliva, could be helpful. In addition, managing chronic neuropathic pain in patients who have had herpes zoster is a difficult and challenging problem. Improved therapeutic approaches to PHN represent a significant clinical need.

Human Immunodeficiency Viruses Types 1 and 2

43

Richard A. Kaslow, Emily J. Erbelding, and Paul A. Goepfert

1 Introduction

Human immunodeficiency virus type 1 (HIV-1) is a retrovirus that may produce an acute, usually self-limited mononucleosis-like syndrome but more inevitably causes a broad array of progressive clinical manifestations, widely known as the acquired immunodeficiency syndrome (AIDS). HIV type 2 (HIV-2) causes a similar but far less widespread infection and a generally more indolent chronic disease. This chapter emphasizes HIV-1 and selectively covers the more distinctive aspects of HIV-2.

For centuries pandemic influenza and smallpox have decimated the inhabitants of whole countries, often surging through in a matter of weeks or months, then virtually disappearing almost as fast. HIV/AIDS insinuated itself into human populations over years, and its less dramatic appearance and its chronicity have posed a different but no less formidable threat. Since its recognition in 1981, AIDS has had a profound impact not simply on the health of nearly all nations of the world but on their economic, social, ethical, legal, and political structures. During those three decades, more resources have probably been invested in research on and care of individuals with HIV-1 infection than for any other infectious disease in history. Cumulative expenditures on research alone exceed the equivalent of tens of billions of US dollars. In terms of the information generated, as a crude comparison, for the period from late 1981 through 2012, the National Center for Biotechnology Information bibliographic resource PubMed lists more than 250,000 publications under the terms "AIDS" or "HIV," compared with about 100,000 for "tuberculosis" and 55,000 for "influenza," the two infectious diseases probably commanding the next highest levels of interest and support for research.

In the years since the initial recognition of AIDS, teams of epidemiologists, virologists, immunologists, and scientists from many other disciplines have assembled an exquisitely detailed and comprehensive understanding of the two etiologic agents and their simian cousins, the complex biological and behavioral responses made by humans and primates and the factors in the physical, biological, and social environment that have driven this infection so relentlessly to pandemic proportions. Despite what has often seemed like painfully slow progress against the onslaught of HIV, multiple effective therapeutic agents have been developed, programs for treatment and prevention continue to be implemented on a global scale; and disappointments in the pursuit of an efficacious vaccine have not slowed efforts in that direction.

In retrospect, considering the unique nature of this infectious disease, the relatively modest insight into human retrovirology at the time the struggle began, and the depth of prejudice and anxiety about individual human sexual and other behavioral preferences, the accumulation of knowledge has enabled remarkable progress toward the goal of understanding and controlling the infection. What follows is an attempt to summarize that vast body of knowledge—documenting both the great distance traveled toward that goal as well as the critical shortfalls in the quest for effective prevention and treatment on a population scale. However, even this lengthy chapter cannot amply depict the viciously circular impact HIV/AIDS has had on the entire world—how 30 years of pandemic HIV-1 infection has profoundly altered

fundamental socioeconomic and demographic characteristics of so many of the countries it has touched and vice versa.

2 Historical Background

During the three decades since the discovery of AIDS, for the first time in human history, the world witnessed a previously unknown infection leap from an obscure zoonosis into a full-scale pandemic in human populations around the globe. The virus was probably introduced into humans in the first half of the twentieth century [1, 2]. It became detectable at low frequency in stored samples of blood available from certain high-risk groups prior to 1980 [3]. From that time forward, one country after another experienced an oft-repeated pattern of silent introduction among a core transmission group followed by a usually insidious but occasionally more explosive spread of infection. The gradual but highly variable disease progression (with a median of 8–10 years from initial sexual transmission of infection to clinical diagnosis of AIDS) meant that the virus had usually penetrated deeply into a population before health-care providers and/or government officials grasped the extent of spread and its public health implications.

The earliest harbinger of the eventual worldwide pandemic consisted of a handful of cases of pneumonia among men who have sex with men (MSM) in Los Angeles, California, and New York City; this disease was due to *Pneumocystis carinii*, a relatively unusual agent now classified as the fungus *P. jirovecii*, which had not previously been known to occur in such a cluster [4]. Soon thereafter an equally unusual parallel epidemic of Kaposi's sarcoma (KS) was reported. Two things were common to these initial reports: both of these conditions had been seen sporadically in the past among immunosuppressed hosts in the developed world, and both were occurring simultaneously in MSM. From clinical and immunologic assessments of the earliest cases, it was clear that the common thread was cell-mediated immune deficiency characterized by profound reduction in the number of circulating T-helper lymphocytes.

Various alternative causal theories were proposed to account for the emerging pattern of the disease (e.g., immune exhaustion from constant stimulation and behavioral factors such as atypical sexual practices or the intense use of recreational drugs), but within less than a year, it seemed inescapable that an infectious agent was centrally involved. From the time these cases were first reported, less than 2 years elapsed before several groups of retrovirologists, through a series of elegant technical accomplishments, converged on the etiologic agent—the novel retrovirus that would come to be known as human immunodeficiency virus, type 1 (HIV-1).

Although the earliest work on RNA-based oncogenic retroviruses began in chickens more than a century ago [5], it was the discovery and elucidation of the properties of reverse transcriptase, the virally encoded enzyme-mediating synthesis of a proviral DNA from a viral RNA template in the 1970s, that led to the detection of the first human retrovirus, human T-lymphotropic virus type I (HTLV-I) in 1979 [6]. The close similarities between the known effects of HTLV-I (T-cell tropism, pathogenicity, and modes of transmission) and the new immunodeficiency identified in 1981 led laboratory scientists to postulate a novel retrovirus as its etiology [7]. The lymphadenopathy-associated virus (LAV) was discovered and reported as the likely cause of AIDS by Montagnier in 1983 [7]. In the following year, Gallo and his co-workers confirmed that the virus initially called LAV or HTLV-III but subsequently renamed HIV-1 was indeed the etiologic agent of AIDS [7–9].

After the initial recognition of AIDS, its definition rapidly expanded beyond the two sentinel conditions (*Pneumocystis* pneumonia and KS) to include a variety of other opportunistic infections [10]. Between 1981 and 1983, risk groups were defined for surveillance purposes in anticipation that an infectious agent was involved and transmitted by sexual routes, blood transfusion, and injection drug use and from mother to infant [11, 12]. Between 1983 and 1984, the etiologic agent was isolated and proven to be the cause of AIDS. Prospective studies in high-risk populations confirmed the causal temporal relationship between HIV-1 seroconversion and the development of AIDS as well as estimates of risk attributable to the various modes of viral transmission [13–15]. Over the next 5 years, rapid progress was made in developing an accurate blood screening test, characterizing the virus molecularly, defining certain aspects of pathogenesis, and determining the positive benefits of nucleotide analog antivirals and prophylactic therapies for prolonging the life of those with severe immunodeficiency and opportunistic infections.

Identification of the cause of AIDS opened the door to deeper inquiry into the origins and evolution of the virus and into the provenance of the infection in humans. The first documented case of AIDS occurred in a British seaman who died of *P. carinii* pneumonia in Manchester, England, in 1959 and was subsequently found to have had HIV-1 infection [16]. A very small proportion of serum samples taken in Zaire about that time contained antibodies suggestive of HIV-1 infection [17], and it has been postulated that UNESCO's exchange of educational technicians and perhaps military personnel between Zaire (Congo, at that time) and Haiti beginning in 1960 accounts for the early spread of the infection into the Caribbean [18].

Not long after HIV-1 was discovered, the related but less pathogenic HIV, type 2 (HIV-2), was linked to a milder form of the clinical syndrome occurring predominantly in West Africa [19, 20]. The earliest apparent cases of Africans with AIDS or pre-AIDs who were serologically positive for HIV-2 included a person who died in 1978 [21, 22] and a Portuguese family whose infections displayed several epidemiologic

features of HIV-2 infection: the propensity for heterosexual transmission, the low perinatal transmission rate, and the apparent long latency for disease. This virus was more closely related to a nonhuman primate virus, simian immunodeficiency virus (SIV) [23], and found in conjunction with AIDS-like illness in some primate species. Although there was fear that the spread of HIV-2 infection would lead to a parallel or overlapping epidemic of similar proportions, that concern was to prove largely unfounded.

In the decade after the discovery of HIV-1, great progress was made in understanding the origins of the virus itself. Phylogenetic relationships between human and simian immunodeficiency viruses raised the possibility of a nonhuman primate origin of HIV-1 [23]. Investigators isolated strains from chimpanzees, the only other species susceptible to HIV-1 infection, which appeared to bear a close phylogenetic relationship to the human virus [24], and to a new strain of HIV-2 from a West African that was more closely related to one found in sooty mangabeys (SIV_{SM}) than to prototype human isolates. This work suggested that HIV-2 has been transmitted from monkey to human and is a member of closely related primate virus family. The nonhuman primate-to-human hypothesis was further supported by reports of SIV infection in laboratory workers [25] and HIV-2 infection in women from Guinea-Bissau who prepared primate meat for human consumption (with potential blood exposure) [26].

Other observations in primates provided insight into viral evolution. SIV_{AGM} infection causes no disease in African green monkeys, its presumed natural host [27]. SIV_{SM} is nonpathogenic in the sooty mangabey, its apparent natural host, but may cause AIDS-like illness in other primate species [28]. SIV_{SM} was linked to epizootic AIDS-like disease resulting from cross-species infection of captive macaques (a nonnatural host) in US primate research centers [29]. These observations illustrate that slow adaptation between a virus and its host may have minimal pathologic consequences, but when the virus leaps to a new species, it often becomes much more pathogenic. In 1999 a group of researchers reported the discovery that a particular type of chimpanzee, once common in West Central Africa, was the source of HIV; they suggested that HIV-1 was introduced into the human population when hunters became exposed to an infected blood [30].

Throughout the latter half of the 1980s and early 1990s, as HIV/AIDS exploded into a pandemic, bad news generally outweighed the good. From 1993 onward, the CDC used an expanded definition of AIDS [31], but even before that, it had become increasingly clear that the numbers of people and places affected would continue to rise. By WHO estimates for 1992–1993, some 2.5 million cases of AIDS had occurred in adults and more than 14 million adults were infected. The single antiretroviral agent, the nucleoside reverse transcriptase inhibitor azidothymidine (AZT, now zidovudine), alone or in combination with other related drugs, offered the hope of interrupting the inexorable course of infection, but these agents turned out to be limited in the potency and duration of their effects. The following year, however, witnessed a major breakthrough with the success of AZT in reducing the rate of mother-to-child transmission by two-thirds [32]. At that point world health leaders began to realize that programs for prevention had been implemented in different countries with varying degrees of support and success, but many heavily affected countries still lacked a sense of unity and common purpose about the messages and strategies for reversing the trends. The United Nations announced the establishment of a new Joint United Nations Programme on AIDS (now called UNAIDS) to be cosponsored by a number of its components, with coordinated resources and forceful leadership [33]. By the end of 1995, it was estimated that 4.7 million new HIV infections occurred, 500,000 of them in newborn infants [34].

Advances in treatment during the next several years were encouraging. A second class of promising drugs (protease inhibitors) approved for clinical use was succeeded by a third, the nonnucleoside reverse transcriptase inhibitors (NNRTIs). One of these drugs, nevirapine, proved highly effective at preventing peripartum mother-to-child transmission (MTCT) [35], and although controversy over drug resistance and its longer term benefit arose, it has retained a prominent role in prevention of MTCT [36]. Trials of NNRTIs more broadly continued to demonstrate substantial and sustained decline in morbidity and mortality, and combinations of these drugs (termed "highly active antiretroviral therapy," HAART, and now "combination ART," cART) began to be used on a large scale in the USA and other countries where the regimens were more affordable.

This major advance was accompanied by another when the US Food and Drug Administration approved the introduction of a quantitative measure of burden of infection. Having undergone successive refinements since the original demonstration of its prognostic value [37], a test for the number of copies of viral RNA (i.e., viral load) has remained the single most critical clinical indicator of disease control.

As evidence for the effectiveness of cART continued to mount, a debate turned to whether, when, where, and how infected people should be treated. What was initially a cautious implementation of programs for treatment in less developed regions of Asia and Africa and elsewhere soon evolved into more ambitious plans and investments in drugs, infrastructure, monitoring, and evaluation on a global scale. Numerous clinical trials of derivatives of the approved classes of drugs were completed, and entirely new products were beginning to show promise. By 2002 a clinical trial of T-20 (later, enfuvirtide), a member of a new class of AIDS drugs called fusion inhibitors, had demonstrated its efficacy; in the next year it was approved for parenteral use in patients with drug-resistant HIV-1 infection. In the next few years, two other agents, maraviroc (a co-receptor antagonist) and raltegravir (an integrase inhibitor), also became available for

drug-resistant infection (see Sect. 9). However, the limited indications for their use and their higher cost precluded their incorporation into global treatment programs.

By the turn of the millennium, there were 34.3 million people infected with HIV worldwide, with 1.3 million under age 15. It was predicted that AIDS would cause early death in as many as half of the teenagers living in the hardest hit countries of southern Africa, causing population imbalances. In the midst of this raging epidemic 15 years after HIV-1 was established as the etiologic agent, South African President Thabo Mbeki was publicly doubting the viral origin of AIDS. For that entire period since AIDS first came to public attention, the superstition that surrounded it and the stigma haunting those who succumbed to it had proved to be as refractory an impediment to progress in preventing the infection as the novel viral biology itself. An entire parallel history of the social, cultural, and economic impact of HIV/AIDS has been documented in countless forms. The reader is referred [38] as one source of information on these historical aspects.

For approximately 15 years, from the mid-1990s until about 2010, as efforts to achieve universal access to treatment of HIV/AIDS accelerated, progress in prevention moved forward at a slower pace, reached fewer new milestones, and experienced some significant setbacks. Most frustrating of all has been the minimal success at producing an efficacious vaccine to prevent infection. Those who fully understand the virologic and immunologic obstacles to producing a new vaccine against *any* disease had no illusions about how quickly or easily those barriers could be surmounted. Indeed, experts at one extreme have considered the prospect nearly hopeless, while most others have scoured the information collected during the series of unsuccessful vaccine trials that have been conducted for any useful insight. The unfulfilled quest for a vaccine has not been the only disappointment in the area of prevention. Randomized controlled trials evaluating treatment of genital herpes and other genital infections have failed to demonstrate meaningful reductions in incidence of HIV-1 infection [39], despite every indication from studies of MSM, sex workers, and others that genital inflammatory conditions predisposed to new HIV-1 infection (see Sect. 5). It was only in 2010 that the first apparent success of topical prophylaxis with an antiretroviral agent was reported [40], and the full implications of this finding remains to be assessed.

On the more positive side, by 2004, teams in Uganda reported that reduction of sexual partners and other prevention measures in local communities was capable of lowering HIV-1 seroprevalence to half a million people compared with 1.5 million a decade earlier [41]. More recently, excitement was generated by the findings in clinical trials of circumcision that documented an approximately 50 % reduction of female-to-male heterosexual transmission (Sect. 9). The enthusiasm for promoting the practice more widely has been high, albeit tempered by the recognition that implementation on a wide scale faces a number of issues. Even more promising have been the clinical trials demonstrating the efficacy of preexposure prophylaxis and the proof of the principle of "treatment as prevention"—that early therapy of an infected individual can prevent transmission to the uninfected partner (Sect. 9). Finally, optimism has risen – some argue too high – with the apparent proof of principle that infection in one or more individuals might have been cured through bone marrow transplantation.

In 2007 for the first time in the history of HIV/AIDS, a report from UNAIDS announced the "stabilization of the global epidemic," estimating that 33 million people were living with HIV-1 worldwide (down from the 39.5 million estimate from 2006). Part of that reduction was attributed to better surveillance techniques in many countries, but another substantial part represented a real decline in HIV-1 prevalence in certain areas, including sub-Saharan Africa. The report also concluded that the decline in AIDS deaths from 2.2 million in 2005 to 2 million in 2007 reflected an increase in the number of people receiving antiretroviral drugs. In subsequent years, UNAIDS data have verified this "reversal" of the previous, ever-upward trends in the statistics that characterized the first 25 years of AIDS (Ref. [42] and Sect. 5).

During the past decade, medical and public health advances have been accompanied by significant advances in the commitment of social and economic resources to the battle against HIV/AIDS. In 2001 the United Nations Secretary-General called for a tenfold increase in spending on AIDS in developing countries—$7–10 billion to be spent under the auspices of a new entity called The Global Fund to Fight AIDS, Tuberculosis and Malaria [43]. The actual amount initially offered by donor countries was less than 25 % of that figure, and the Fund struggled during its early years. However, between 2001 and 2013 paid pledges to the Global Fund have actually totaled nearly $24 billion, and that did not include the numerous other public and private investments in treatment and prevention programs. Still, in 2011, even after 10 years of collaboration, the vulnerability of the global effort was again highlighted by the failure donors to honor pledges to the Fund. This prompted a promulgation of a new model of funding [44].

Clearly, chapters of the history of HIV/AIDS are still being actively updated. Only time will tell whether the insights thus far gained into host/agent molecular interactions and into individual and social behavior have been sufficient to overcome one of the greatest threats to humans ever posed by an infectious agent.

3 Methods of Epidemiologic Analysis

3.1 Sources of Mortality Data

3.1.1 HIV-1

USA

In the 15 years before effective therapy became widely available, the median time from initiation of infection (seroconversion) to clinically defined AIDS was about 9 years,

although it became clear that this interval varied greatly according to the mode of transmission of infection as well as several rather carefully documented host and viral determinants (Sect. 5). In contrast, the median time from onset of untreated AIDS to death was more predictably about 2 years, varying relatively little by specific clinical diagnosis [45]. In the USA the two primary sources of mortality data have been the vital statistics of all-cause mortality recorded by the National Center for Health Statistics (NCHS) and the National AIDS Surveillance. Both are managed by the Centers for Disease Control and Prevention (CDC) and depend on reporting of deaths due to AIDS by state health departments.

Even in such well-organized systems for gathering mortality statistics in the USA and other parts of the developed world, particularly in the early years of the epidemic, difficulties in attributing death to AIDS were due to diagnostic imprecision around a range of causes of immunodeficiency or to the absence of health services for disadvantaged populations. There was also often reluctance to diagnose and/or code socially stigmatizing AIDS-defining conditions [46]. Over time, as those barriers fell and the AIDS definition was refined, the attribution of cause of death evolved. By 1993 the definition had been expanded to require documentation of both HIV-1 infection and diminished CD4+ cell numbers [31], improving diagnostic sensitivity and specificity and thereby the accuracy of mortality data. In the years that followed, use of the Social Security Administration Death Master File has accounted for some additional improvement in ascertainment of AIDS deaths [47].

Global

As individual countries began to experience the impact of AIDS, they adapted surveillance systems for mortality and morbidity to their individual circumstances, which varied greatly with the resources available for diagnostic testing and delivery of health care. Efforts made by the UN Global Program on AIDS and its successor, UNAIDS, helped to centralize the documentation of deaths and death rates, but heterogeneity in the primary data continued to limit their usefulness. The heavy burden of coincident tuberculosis and HIV-1 infection and the difficulty of teasing apart their respective contributions to the cause of death are just two examples of the obstacles faced more by resource-poor regions. AIDS mortality statistics have also been less consistently reliable from country to country as a result of the different points in time when HIV-1 was introduced, the varying trajectories with which it spread, the use of prophylaxis for opportunistic infections, and the penetration of ART. The difficulty in arriving at a definitive mortality estimates is illustrated in the steadily changing proportions surviving in the years after the introduction of HAART in the USA (Fig. 43.1).

Mortality has also been less informative because it has represented a lagging indicator of the actual burden of HIV-1 infection in a population [49].

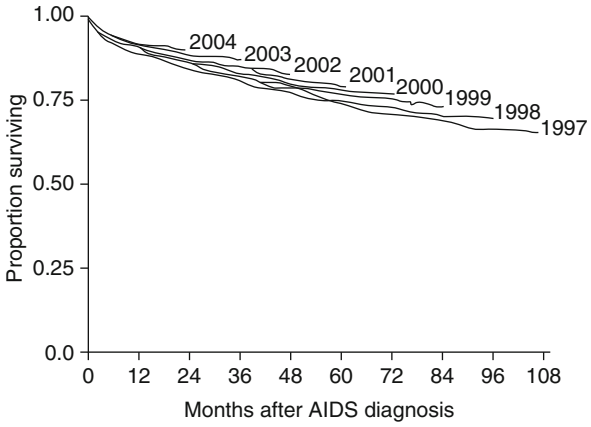

Fig. 43.1 Cumulative proportion of patients surviving by months after the first diagnosis of an AIDS-defining opportunistic infection 1997–2004 (Reproduced from CDC [48])

3.1.2 HIV-2

HIV-2 presumably originated in West Africa and has remained largely confined to residents of that region, to travelers or immigrants from there, and to their contacts. Accordingly, the main sources of epidemiologic information are the uneven descriptive studies in former colonies of Portugal (e.g., Guinea-Bissau, Cape Verde, Goa, and Brazil) or other neighboring West African countries (e.g., Senegal and the Gambia).

Mortality experience with HIV-2 has not been well documented because of the strong geographic influence on its occurrence as well as its frequent dual occurrence with HIV-1 and its lower pathogenicity than that of HIV-1. The largest and most reliable estimates of mortality probably come from a study of deaths due to serologically confirmed HIV-1, HIV-2, and HTLV-I infections among more than 5,000 residents of a rural area in northwestern Guinea-Bissau [50]. The study spanned the 18-year period before ART became available in 2007. Although there are concentrations of immigrants from different West African countries throughout the USA and other regions, systematic studies of HIV-2 mortality in these places have not been published.

3.2 Sources of Morbidity Data

3.2.1 HIV-1

USA

CDC established a nationwide surveillance for AIDS soon after the initial cases were reported. In a matter of months, insights emerging from rapidly accumulating cases in the different risk groups supported an infectious etiology. In 1983 CDC adopted a surveillance definition of AIDS based on a collection of clinical conditions reflecting an underlying immunodeficiency unexplained by known causes [51]. By 1987 when the viral etiology had been discovered and

serologic testing for HIV-1 antibody had revealed that AIDS represented an even wider spectrum of sequelae related to immunodeficiency, the CDC revised the definition [52]. Beginning in 1993 the agency made a major revision that substantially broadened the criteria [31] and then several successive minor changes to arrive at the current (2008) AIDS definition and HIV-1 classification system for adults and adolescents. In addition to the medical conditions defined as AIDS in 1993 (Table 43.1), the 2008 definition established three stages of infection based on CD4 cell measurements (Table 43.2), with stage 3 (AIDS) defined as the occurrence of HIV-1 infection accompanied by a CD4 count <200 cells per μL or a percentage of CD4 lymphocytes <14 [54]. The definition of AIDS in infants and children was also updated in 2008.

The earlier modifications of the AIDS case definition produced significant increases in case numbers [55]. By including cases based on a laboratory marker of an outcome (CD4 cell count) preceding end-stage clinical immunodeficiency, the 1993 revision accounted for a 111 % increase in reported AIDS cases, most notably among women, minorities, and those infected through heterosexual contact. In the 20 years since this last major revision, fluctuations of disease occurrence in the USA and other developed countries have diminished, but opportunities for misclassification still occur. For example, persons experiencing a transiently high viremia and low CD4 cell count during acute HIV-1 infection (see Sect. 5) could be erroneously classified as having reached a later stage of infection than would be revealed once viral load set point has been reached. In the USA, a parallel scheme for surveillance by source of HIV-1 infection classifies patients hierarchically according to their membership in a risk group [54]. However, misclassification can occur in this system too because a case with multiple risk factors can only be classified as belonging to a single (the highest) risk group. Thus, in areas where injecting drug use is common, preferential assignment to that risk group could exaggerate its role as the primary risk factor among women also highly likely to acquire HIV-1 through heterosexual transmission.

Table 43.1 1993 Revised classification system for HIV infection and expanded AIDS surveillance case definition for adolescents and adults

	Clinical categories		
$CD4^+$ T-cell categories	(A) Asymptomatic, acute (primary) HIV or PGL	(B) Symptomatic, not (A) or (C) conditions	(C) AIDS-indicator conditions
1. ≥500/μL 2. 200–499/μL 3. <200/μL AIDS-	Asymptomatic HIV infection; persistent generalized lymphadenopathy (PGL); acute (primary) HIV infection with accompanying illness or history of acute HIV infection	Bacillary angiomatosis; candidiasis, oropharyngeal (inrush); candidiasis (thrush); candidiasis, vulvovaginal; persistent, frequent, or poorly responsive to therapy; cervical dysplasia (moderate or severe)/ cervical carcinoma in situ; constitutional symptoms, such as fever (38.5 °C) or diarrhea lasting >1 month; hairy leukoplakia; oral herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome; idiopathic thrombocytopenic purpura; listeriosis; pelvic inflammatory disease, particularly if complicated by tubo-ovarian abscess; peripheral neuropathy	Candidiasis of the bronchi, trachea, or lungs; candidiasis, esophageal; cervical cancer, invasive; coccidioidomycosis, disseminated or extrapulmonary; cryptococcosis, extrapulmonary; cryptosporidiosis, chronic intestinal (>1-month duration); cytomegalovirus disease (other than the liver, spleen, or nodes); cytomegalovirus retinitis (with loss of vision); encephalopathy, HIV related; herpes simplex, chronic ulcer(s) (>1-month duration); bronchitis, pneumonitis, or esophagitis; histoplasmosis, disseminated or extrapulmonary; isosporiasis, chronic intestinal (>1-month duration); Kaposi's sarcoma; lymphoma, Burkitt's (or equivalent term); lymphoma, immunoblastic (or equivalent term); lymphoma, primary, of the brain; *Mycobacterium avium* complex or *M. kansasii*, disseminated (or extrapulmonary); *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary; *Pneumocystis carinii* pneumonia; pneumonia, recurrent; progressive multifocal leukoencephalopathy; salmonella septicemia, recurrent; toxoplasmosis of the brain; wasting syndrome due to HIV

Table 43.2 Surveillance case definition for human immunodeficiency virus (HIV) infection among adults and adolescents (aged ≥13 years)—USA, 2008

Stage	Laboratory evidence	Clinical evidence
Stage 1	Laboratory confirmation of HIV infection *and* CD4+T-lymphocyte count of ≥500 cells/μL *or* CD4+ T-lymphocyte percentage of ≥ 29	None required (but no AIDS-defining condition)
Stage 2	Laboratory confirmation of HIV infection *and* CD4+ T-lymphocyte count of 200–499cells/μL *or* CD4+ T-lymphocyte percentage of 14–28	None required (but no AIDS-defining condition)
Stage 3 (AIDS)	Laboratory confirmation of HIV infection *and* CD4+ T-lymphocyte count of < 200cells/μL *or* CD4+ T-lymphocyte percentage of < 14	*or* documentation of an AIDS-defining condition (with laboratory confirmation of HIV infection)
Stage unknown	Laboratory confirmation of HIV infection *and* no information on CD4+ T-lymphocyte count or percentage	*and* no information on presence of AIDS-defining conditions

Adapted from Refs. [31, 54]

During the early years of the epidemic in the USA and other advanced countries, underreporting in the numbers and distribution of AIDS was suspected due to fear of the deadly consequences of the disease that led those affected to deny it and to the stigma attached to it that drove those affected and their caretakers to conceal it. Even health authorities found themselves uncomfortably joining groups who resisted standard surveillance approaches and demanded anonymity with screening for HIV-1 because of concerns about confidentiality and discrimination. Those counterproductive responses were gradually converted to more constructive ones, especially once counseling, serologic testing, and effective antiretroviral therapy became more widely available.

With regard to AIDS in children, CDC established a pediatric surveillance case definition in 1987 and updated it periodically thereafter its current, comprehensive 2008 revision [54]. It covers both children aged 18 months to 13 years and children <18 months old. In the younger group, the latest laboratory criteria for an AIDS diagnosis are exacting; and only those babies with a compatible clinical condition who were born to an HIV-infected mother meet the case definition in the absence of a positive serologic test.

Global

In the decade that followed the recognition of AIDS, the World Health Organization (WHO) assumed major responsibility for monitoring the pandemic. Although its surveillance activities and definitions have been modeled broadly on those of the CDC and other advanced countries, the approach has accommodated the inadequacy of resources to diagnose infection or disease in many other areas. As UNAIDS became operational in the mid-1990s and financial support began to increase significantly, the surveillance systems in the developing world improved dramatically. In 2007 UNAIDS added laboratory confirmation as a criterion for the surveillance case definition for HIV infection. By 2012 there were 186 countries maintaining and reporting AIDS statistics and, in turn, submitting the data summarized in a remarkably comprehensive annual report [56]. These sources of data along with the methods used to curate, report, and analyze them have been refined by a reference group of epidemiologists, demographers, and other experts on HIV and described in a series of articles [57–59]. Using these and other resources, UNAIDS has provided comprehensive guidance to national AIDS programs and other groups on the application of core indicators for reporting their data, their national response, and their progress toward 2015 global HIV/AIDS targets [60].

Despite this immensely successful global effort to increase awareness of HIV/AIDS and document epidemiologically important features of its occurrence, of the risk factors for acquiring it, and of the benefits of treatment, some countries have remained unable to counter entirely the forces of poverty, ignorance, and stigma that have prevented them from gathering and reporting the data needed to characterize their national epidemic.

3.2.2 HIV-2

As with mortality, systematic studies of the nature, frequency, and course of disease manifestations of HIV-2 are sparse. In addition to the population-based cohort in Guinea-Bissau described above, sources include Senegalese sex workers [61] and another cohort in the Gambia [62].

3.3 Serologic Surveys: Sources of Prevalence and Incidence Data

3.3.1 HIV-1

Prevalence

Soon after the virus was discovered, the first generation of serologic test systems was created for biological research and epidemiologic and clinical purposes. These and successive generations have utilized the enzyme immunoassay (EIA) technique to detect antibody to HIV proteins or peptides encoded by the conserved regions of the genomes of HIV-1 and HIV-2. The assays include combinations of viral

core, polymerase and envelope proteins; technical details of their composition, performance, and application are discussed in Sect. 3.4. Because both viral replication and antibody production at some level are considered lifelong in humans, the extremely sensitive and specific assays developed immediately after the initial isolation of the virus are highly reliable at documenting past or present infection in population surveys [3.463, 64].

In the USA and other developed areas, serologic testing increased steadily since the assays first became available. In recent years, with the increased emphasis on earlier intervention both for its own sake and as part of prevention strategy aimed at infected persons, many health-care systems around the world have implemented testing programs. In more socioeconomically advanced countries, testing is now increasingly a routine [65]. In 2009, for example, the US Department of Veterans Affairs adopted recommendation that an HIV-1 test be performed on all patients under care in its health-care facilities at least once during their lifetime [66], and the data on testing in that population are updated annually as part of the Federal government comprehensive update of the status of testing. Numerous prevalence surveys have been conducted in the subpopulations at higher behavioral or demographic risk—hemophiliacs, blood transfusion recipients, prostitutes, injection drug users (IDUs), patients with sexually transmitted infections (STI) and tuberculosis, Latino and black patients in communities with high seroprevalence, and those attending prenatal and mental health clinics. Estimates of seroprevalence in lower risk populations still rely on testing of anonymized samples from blood donors, hospital patients without HIV-associated conditions, pregnant women, applicants for military service, and other special populations (e.g., prison inmates).

Incidence

In contrast to prevalence, which can be measured more straightforwardly, incidence of HIV-1 infection has been more difficult to document for several reasons. The earliest estimates of incidence relied on indirect techniques of back calculation from statistics on AIDS mortality and morbidity [67]. Because rates of infection by definition can change more rapidly than rates of disease, estimates across population subgroups were subject to substantial variation in accuracy because of differential access to care and intensity of surveillance. Although more direct observation of incident infection was possible in certain fixed cohort studies during in the years soon after follow-up began [68–70], estimates in those cohorts inevitably grew more biased as behavior changed; screening and other measures protected blood product supplies; early seroconversions removed the most vulnerable members from the pool of susceptibles; and effective treatment became widely available [71]. Increasingly effective prevention and treatment brought an end to large-scale unbiased longitudinal surveillance in these and other samples of individuals who were representative of their high-risk target populations.72

In Africa and Asia current estimates of incident HIV-1 infection have been available from various cohorts of subjects assembled for the purposes of studying various prevention measures—behavioral interventions, vaccines, male circumcision, and antimicrobial treatment of predisposing STIs. Examples of these sources include serodiscordant couples receiving counseling and serologic testing in Zambia and participants in a vaccine preparedness study in Tanzania [72].

The dearth of opportunities to measure incidence directly led to the development of approach involving detection of biological markers (e.g., p24 antigen) to gauge the timing or maturity (i.e., duration) of a prevalent infection [73]. However, the brevity of antigenemia and the cost of testing large number of specimens rendered this approach less suitable than originally hoped.

Another alternative strategy for incidence estimation was also devised in the late 1990s; it is known as the serologic testing algorithm for recent HIV seroconversion (STARHS) [74]. This approach depended on measurement of differential titer of HIV-1 antibodies between recent and long-term infection. Once initial shortcomings were overcome, the algorithm was more widely adopted for incidence estimation in conjunction with a simple enzyme immunoassay (EIA) that could quantify a gradual increase of HIV-1-specific IgG against immunodominant sequences of gp41 from HIV-1 B, E, and D. Evaluation in longitudinal specimens taken from 139 incident infections in the USA and Thailand documented the improvement in performance [75]. Further refinements culminated in the first direct estimates of HIV-1 incidence in the USA in representative serum samples from newly diagnosed HIV-positive patients in 22 states who were >13 years of age in 2006 [76]. This BED HIV-1 capture EIA classified recent or long-standing infection, with statistical adjustment for testing frequency and extrapolation to the entire country.

The accuracy of incidence estimates based on this assay continues to be evaluated [77], and still other approaches, for example, based on antigen avidity maturation are under investigation [78]. However, once the STAHRS and BED methods were judged conceptually valid tools for wider application, CDC proceeded to establish and fund efforts at HIV incidence surveillance in conjunction with the National HIV Surveillance System (NHSS), in which state and local jurisdictions with moderate-to-high morbidity conduct surveillance using those methods to identify incident HIV-1 infection. Details on the strategy for estimating incidence can be found at reference [79].

Lately, strategies have been proposed for estimating HIV incidence using multiple biomarkers measured in samples obtained from cross-sectional surveys. By combining data from BED, antibody avidity, viral load, and CD4 assays, algorithms can be optimized for accuracy, feasibility, and

cost individually and jointly to support surveillance and research in a variety of settings [80, 81].

Another strategy, especially in regions where laboratory-based approaches were infeasible, has been to model HIV-1 incidence by inferring it from prevalence estimates, under assumptions about average survival of and effects of ART of infected individuals [82]. Despite the uncertainty and instability of current HIV-1 incidence estimates, the fervor around the potential preventive impact of early ART has led statistical modelers to begin exploring the magnitude of the reduction in *future* incidence that might be projected under different intervention scenarios [83]. Such projections in suboptimally resourced countries must obviously depend on often dubious inferences about numbers of infected individuals, their stage of infection, their likelihood of receiving effective treatment, the transmissibility of their infection, and other features.

Unfortunately, the lingering stigma attached to the infection as well as AIDS itself remains another barrier to HIV testing and reporting of new or newly recognized infection. In some places this may still account for a significant discrepancy between the estimates of actual occurrence and reported new infections.

3.3.2 HIV-2

Estimates of HIV-2 seropositivity have also come mainly from the countries mentioned above, although more deliberate efforts to detect infection with this virus as well as HIV-1 have been made in places where risk groups are concentrated—the New York City vicinity, other parts of the northeastern USA, and certain other countries where appreciable numbers of residents have West African connections.

3.4 Laboratory Diagnosis of HIV-1 and HIV-2

3.4.1 Virus Isolation

Historically, a major challenge in the detection and isolation of HIV-1 was its propensity to lyse the target CD4 cell. Unlike HTLV-I, which promotes the growth of CD4 cells, HIV cell cultures result in the death of these cells. Initial laboratory techniques developed to isolate the virus involved serial propagation in tissue culture by continually coculturing with normal peripheral blood lymphocytes or cord blood lymphocytes [84]. Detection of virus relied on assays for virally associated reverse transcriptase in culture media, detection of viral antigen, and electron microscopy, as shown in Fig. 43.2.

A major breakthrough occurred when Popovic and colleagues grew the virus in continuous mature T-cell lines derived from leukemic patients [86]. Virus grown in these lysis-resistant cell lines could be purified and its antigens studied as the basis for subsequent development of serologic assays. It is noteworthy that in this first paper describing the growth characteristics of the virus, there was marked variation from patient to patient and from cell line subclone to subclone in virus growth and cytopathic effects [86]. Since these early breakthroughs, refinements in culture techniques have provided insights about the protean variables that define virus growth characteristics and cell trophism. While cellular trophism of HIV-1 has been classified on the basis of growth in CD4/T cells versus macrophages, these characteristics are not absolute; most strains of HIV-1 will grow in either cell type but manifest a strong predilection for one or the other. The methods used for HIV-2 viral isolation are essentially the same as for HIV-1.

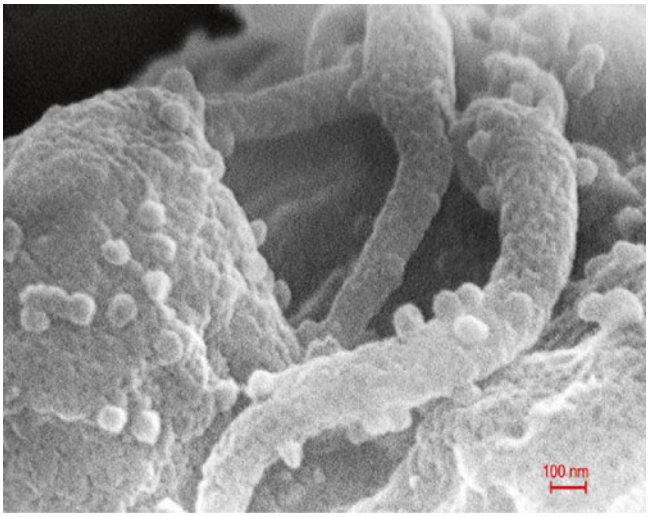

Fig. 43.2 Electron micrograph of HIV-1 virions budding off the membrane of an infected cell (Electron microscopic image courtesy of Cynthia Goldsmith, Centers for Disease Control and Prevention (CDC) Goldsmith et al. [85].

3.4.2 Serologic Diagnostic Methods

During primary infection with HIV-1, the initial buildup of virus in the plasma is followed by the appearance of HIV-1 antibodies. Concomitant with this early phase of infection, there is a decline in CD4 cells that can be modest or quite dramatic; immune activation markers such as neopterin and β_2-microglobulin also increase with HIV-1 infection. Measurements of all of these markers [viral antigen (p24 antigen), viral antibody, lymphocyte subset count (especially CD4 cells and other markers of immune activation)] have been used in epidemiologic studies to detect infection and define predictors of endpoints such as AIDS and death [87–90].

The HIV Western blot identifies antibodies to individual HIV-1 proteins (Fig. 43.3) and is considered more specific

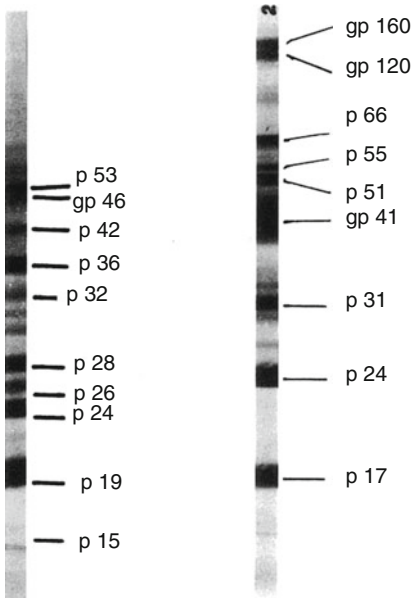

Fig. 43.3 Western blot of major antigenic proteins of HIV-1 (Photograph courtesy of Dr. Steven Alexander)

than EIA for diagnosis. It is therefore widely used to confirm the diagnosis of HIV-1 when the EIA is repeatedly positive. The abbreviations for the Western blot proteins include "p" for protein or "gp" for glycoprotein followed by the number indicating its molecular weight. The major bands used to diagnose HIV-1 include envelope protein (gp160, gp120, gp41), the gag core proteins (p55, p24, p17), and polymerase proteins (p66, p51, p31). Other smaller HIV-1 protein bands may also be seen but are not used for diagnosis. There are several criteria for a diagnosis of HIV-1 by Western blot, but the WHO one includes two envelope bands with or without gag or pol proteins [91]. The algorithm developed for testing requires the presence of a repeatedly reactive EIA and a positive Western blot test for confirmation (Fig. 43.3).

The mainstay of HIV-1 detection is testing for antibody to the virus. HIV-1 antibody testing is highly predictive of infection [92] except when antibody is passively transferred at birth [93–95] or lost during late-stage infection [96]. In view of the short time from initial propagation of the virus in continuous T-cell lines to assay licensure, first-generation HIV-1 whole virus lysate tests achieved remarkable sensitivity and specificity [63, 64]. Second- and third-generation enzyme immunoassays (EIA) have replaced viral lysates with recombinant proteins or peptides from conserved regions in HIV-1 and HIV-2. Many have also included modifications to the detect outlier (O) group of HIV-1. While these modifications have increased the sensitivity and specificity of the assay, there are still situations where false-positive and false-negative tests occur. False-positive tests can occur as part of procedural mistakes or as a result of hypergammaglobulinemia, autoimmunity, or acute or chronic inflammatory states [97–99]. False-negative tests can also be due to procedural mistakes but are more commonly due to early infection when the antibody response has yet to develop to detectable levels [100, 101]. Fourth-generation EIA assays are now including p24 antigen detection to decrease the number of false positives [102, 103]. HIV-1 viral antigenemia may occur early in infection or at the end stage of disease, and serologic assays can detect the 24,000 molecular weight, p24, viral nucleocapsid antigen. The antigen-capture assay is relatively insensitive compared to techniques such as RNA PCR assays; sensitivity can be enhanced by acid dissociation, which frees the p24 antigen from its complexing antibody [104].

Because HIV-1 and HIV-2 differ antigenically, HIV-1 screening tests are unreliable for detecting HIV-2. The methods for serologic diagnosis for HIV-2 infection are complicated because HIV-1 and HIV-2 have a nucleotide sequence homology of about 60 % for the *gag* and *pol* glycoproteins and about 40 % for *env* [105, 106]. The amount of cross-reactivity varies between assays and between areas. It also decreases concurrently with the level of immunosuppression, so that HIV-2-associated AIDS cases are less likely to be detected by an HIV-1 assay than are healthy carriers. HIV-2 screening tests have been developed and now include combination tests with antigens representing both virus types. Confirmatory testing for HIV-2 also requires HIV-2-specific assays to distinguish the two infections, since HIV-2-infected persons may test positive, indeterminant, or negative by HIV-1 Western blot. Although many early reports of apparent dual infection with HIV-1 and HIV-2 simply represent cross-reactivity, true dual infection confirmed by PCR and viral culture does occur [107].

In the USA blood donors have been screened for HIV-2 antibodies since June 1992 with licensed combination enzyme immunoassays (EIAs). Persons from HIV-2-endemic areas have also been asked to refrain from donating blood. These actions have reduced the probability of transfusion-acquired HIV-2 infection to essentially zero [106]. Although routine screening outside of blood centers is not recommended, according to CDC guidelines, HIV-2 testing should be included for individuals who are specifically at risk of that infection, either by nationality, by sexual exposure to a person from an endemic area, or by birth from an infected mother [105]. The reported performance of the HIV-1/HIV-2 combination assays licensed by the US Food and Drug Administration (FDA) for detection of HIV-2 infection is quite high, with >99 % sensitivity.

In recent years, the FDA has approved several rapid HIV antibody tests, by providing results within an hour of sample collection. Depending on the rapid test, analysis can be performed on the whole blood, serum, plasma, or even oral fluids or urine. Most of these rapid tests achieve the sensitivity and specificity that are equivalent to those of standard

EIA and Western blot assays; however, all rapid tests should have a confirmatory testing via Western blot regardless of the EIA result [108]. Rapid tests are now routinely used for initial diagnosis of HIV in many emergency departments in all patients who have not had recent testing. These tests are also useful in situations where decisions on using combination antiretroviral therapy (cART) for HIV-1 prevention are urgently needed—in the setting of needle exposure or at the time of delivery in pregnant women who had not had routine HIV testing as part of their maternal care.

3.4.3 Nucleic Acid Amplification Diagnostic Methods

A variety of advanced molecular techniques involving amplification of HIV-1 viral RNA or proviral DNA have been developed. The most widely used is PCR, but approaches such as ligase chain reaction [109] and branch chain amplification are also available [110]. During the past 15 years, advances in viral RNA detection and quantification by PCR have significantly improved their sensitivity and specificity. Both quantitative and qualitative tests are commercially available. The current version of the quantitative PCR assay has a lower limit of detection of 20 copies of viral RNA per ml of plasma and is routinely used for assessing prognosis, guiding decisions about initiation of cART, and monitoring patients after therapy has begun (see Sect. 9.3) [111, 112]. Quantitative viral RNA by PCR is also routinely used to diagnose primary HIV-1 infection because serologic methods are insufficient to detect the presence of virus during this "window" period before HIV-1 antibodies have had time to develop [98, 111, 113, 114]. Plasma viral RNA measurements during primary HIV infection are generally very high (10^4–10^7 copies/ml) prior to the appearance of antibodies [112, 114, 115].

Qualitative plasma RNA or peripheral blood mononuclear cell (PBMC) DNA detection methods using PCR are routinely used for diagnosis in infants following mother to child transmission [116–122]. In this situation antibody testing would yield false-positive results due to the presence of maternal HIV-1 antibodies passively transferred during gestation. Qualitative RNA/DNA PCR analysis is also used for blood donor screening in addition to the previously described serologic methods [123–125]. Because viral RNA or DNA assessment by PCR is associated with false-positive results (especially when copy numbers are low), all positive results should be confirmed by eventual HIV-1 seroconversion for a definitive diagnosis.

3.4.4 Markers of Immunologic Status

Both HIV-1 and HIV-2 are trophic for the CD4 cells, and perturbation of the CD4 lymphocyte count is a sine qua non of infection. Early in the AIDS epidemic before the discovery of the etiologic agent, the CD4 count was used as a surrogate for infection [126]. Since the discovery of HIV-1, the CD4 count has been widely used clinically as an intermediate marker of disease and epidemiologically as a staging tool [127, 128]. In epidemiologic studies, CD4 count has been used to estimate the duration of disease following seroconversion [129–131] and to predict AIDS onset [13]. The number of CD4 cells is also used for defining AIDS in the 1993 CDC AIDS definition [31]. Since the use of cART has become a standard practice, the CD4 count is routinely used to measure immune reconstitution during administration of the drugs. Clinical decisions regarding the discontinuation of prevention and treatment medications for opportunistic infections are also based on CD4 count measurements following cART administration.

The CD4 lymphocyte count is measured most reliably on a fluorescence-activated cell counter that uses a laser to activate chemiluminescent-tagged antibodies specific for cell surface markers such as CD4 (T helper) or CD8 (T suppressor). Because of its critical value in clinical and research settings, considerable attention has been paid to issues of quality control of these measurements [132]. Over the years, various alternative parameters related to CD4 cell numbers (e.g., the % of total lymphocyte count, logarithmic transformation) have been proposed [133], but none has been deemed to improve upon the clinical utility of the count itself enough to gain acceptance as a staging measure or as a prognostic indicator. Other immunologic markers (e.g., soluble CD4 measurements and markers of immune activation, such as neopterin, β_2-microglobulin, and interferon [89, 132, 134–136]) also appeared to have some value in predicting disease outcome; however, as with the alternatives to CD4 cell number, none has been accepted as clinically advantageous, either on its own or as an adjunct to CD4 count.

3.4.5 HIV Diagnostic Testing Recommendations

In 2006, the CDC revised their recommendations on individuals who should receive HIV testing [137]. All individuals aged 13–64 should receive an HIV test unless the patient declines testing. Patients at high risk for HIV should be tested at least once per year. Pregnant women should be tested as part of routine prenatal screening, and repeat screening is considered in certain areas with elevated rates of HIV infection among pregnant women. Ideally, screening should be part of the general consent for medical care and should not require a separate written consent. These changes were motivated by several factors including the concern about the estimated 250,000 individuals in the USA who are unaware of their HIV diagnosis, the importance of early and effective treatment, the potential reduction in behaviors associated with HIV transmission, and the possible reduction in stigma associated with HIV testing.

In the past few years, the availability of reliable rapid HIV testing procedures has increased interest in testing at the point of contact (POC) and providing results to the patient at the time of the initial evaluation. The algorithms recom-

mended by the Association of Public Health Laboratories and CDC for screening for HIV-1, for HIV-2, and for both can be found in a joint report [138]. In brief, they involve the use of combinations of standard EIA tests, Western blot assays, and supplementary nucleic acid amplification tests, with the choices depending on whether the testing is performed in a laboratory or at the POC and which of the two viruses testing is aimed at detecting.

4 Biological Characteristics of HIV

Much of the basic HIV structure and its replicatory processes were elucidated during the first 15 years after the discovery of HIV. More recent research has expanded our knowledge of the interactions of the virus with various host elements deployed with varying success to control the infection. Three classes of human retroviruses—oncornaviruses, lentiviruses, and spumaviruses—are enveloped RNA viruses. HIV-1 and HIV-2 are lentiviruses with a single-stranded RNA genome that replicates through a double-stranded DNA proviral intermediate (cDNA) (Fig. 43.4) [139, 140]. Reverse transcriptase, a viral enzyme, catalyzes the unique life cycle of these viruses by converting genomic RNA into cDNA; viral integrase incorporates cDNA into the host genome [140]. Integration of retroviruses into the human genome facilitates lifelong infection and may explain the propensity of human retroviruses to cause diseases of long latency [139].

Morphologically, HIV-1 is approximately 110 nm in diameter with a thin electron-dense outer envelope and an electron-dense, roughly cone-shaped cylindrical core (Fig. 43.5). In the production of new HIV particles, retroviral genes are expressed as large overlapping polyproteins that are later processed into functional peptide products by the viral-encoded and cellular proteases [140].

HIV-1 long terminal repeats (LTR) at the 5′ and 3′ ends of the genome contain regulatory elements that promote virion production [141]. The genomic structure of HIV-1 and HIV-2 (Fig. 43.6) contains the following genes: *gag* (group-specific antigen), whose products form the skeleton for the virion; *pol* (polymerase/integrase), whose products are involved in enzymatic functions of the virus; *env* (envelope), which codes for the external and transmembrane outer envelope

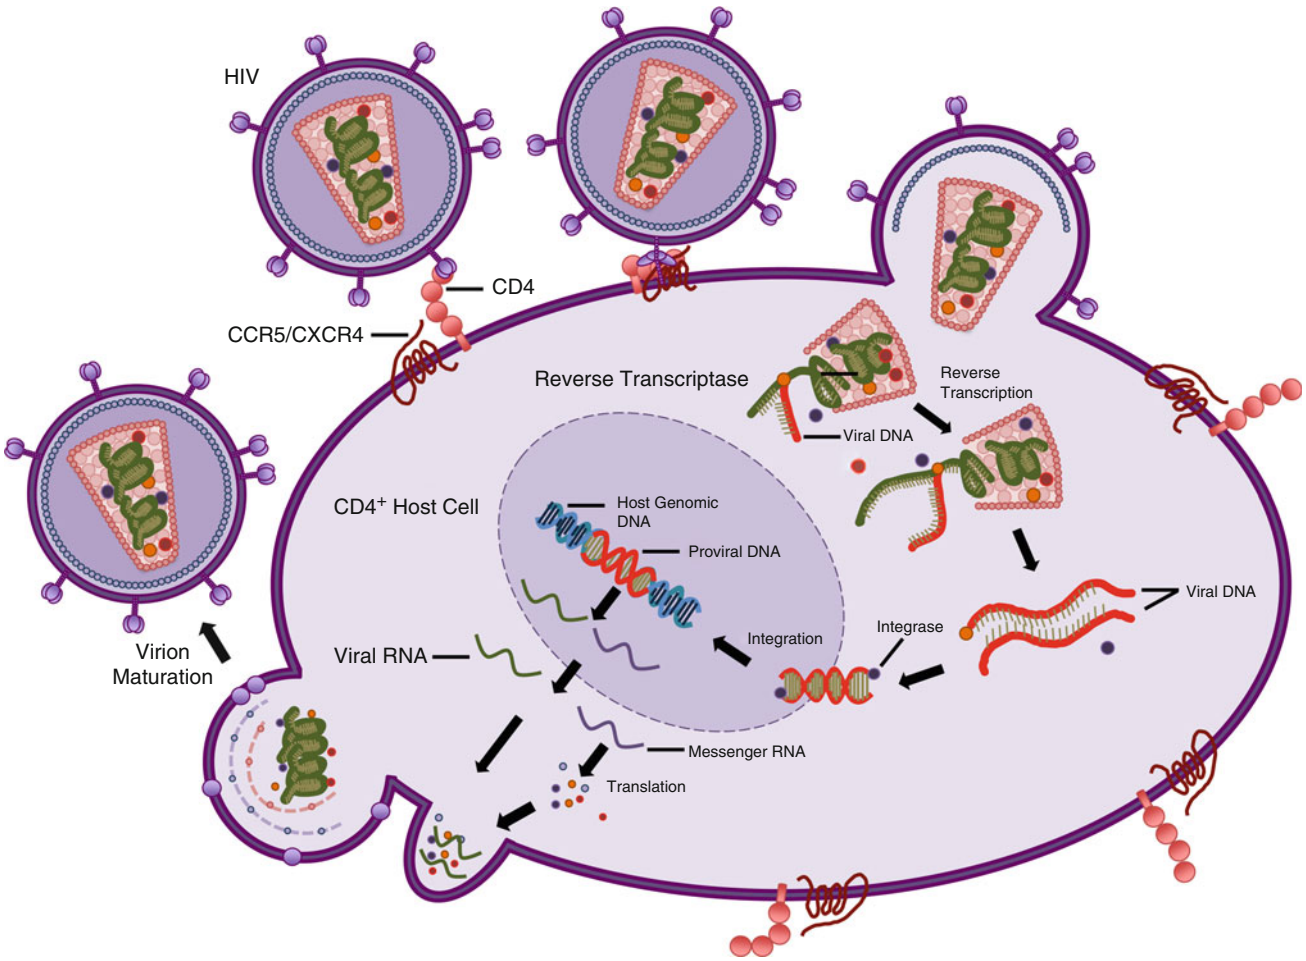

Fig. 43.4 HIV-1 replication cycle (Diagram, courtesy of Nilesh Amatya)

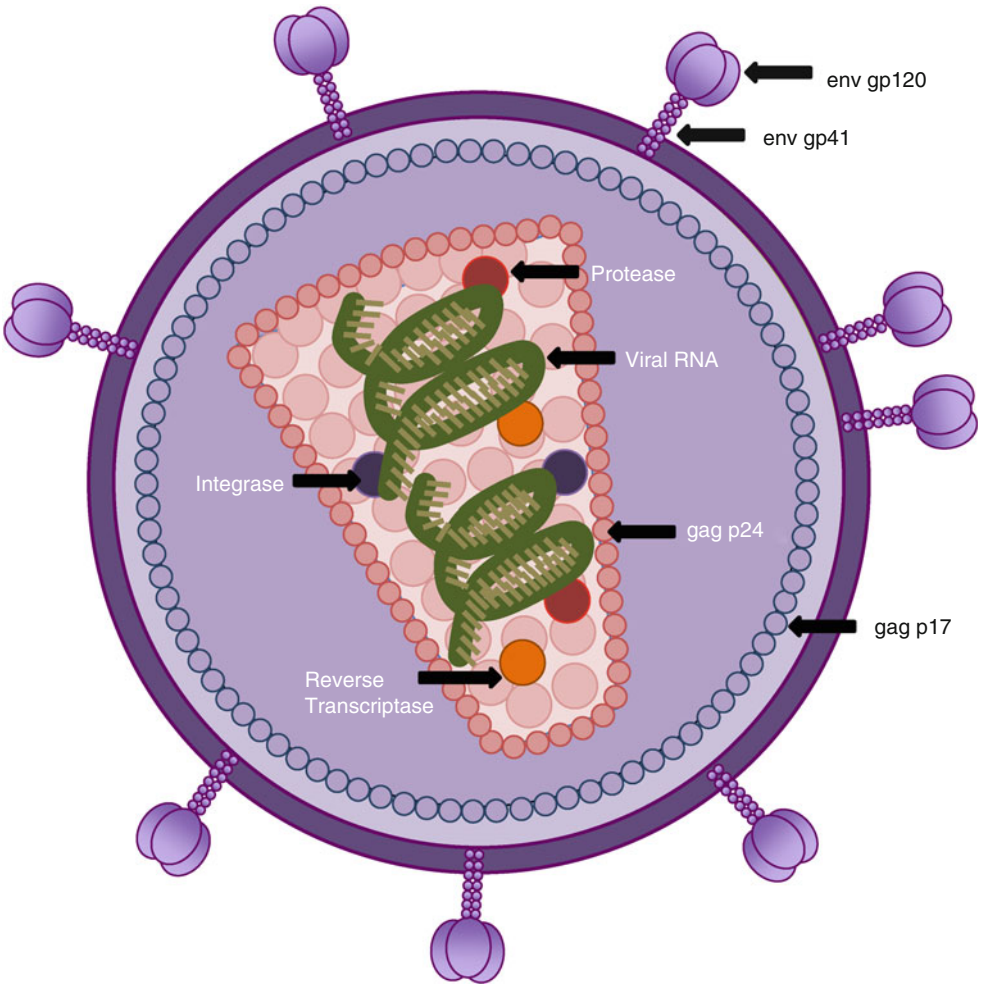

Fig. 43.5 HIV-1 virion structure (Diagram, courtesy of Nilesh Amatya)

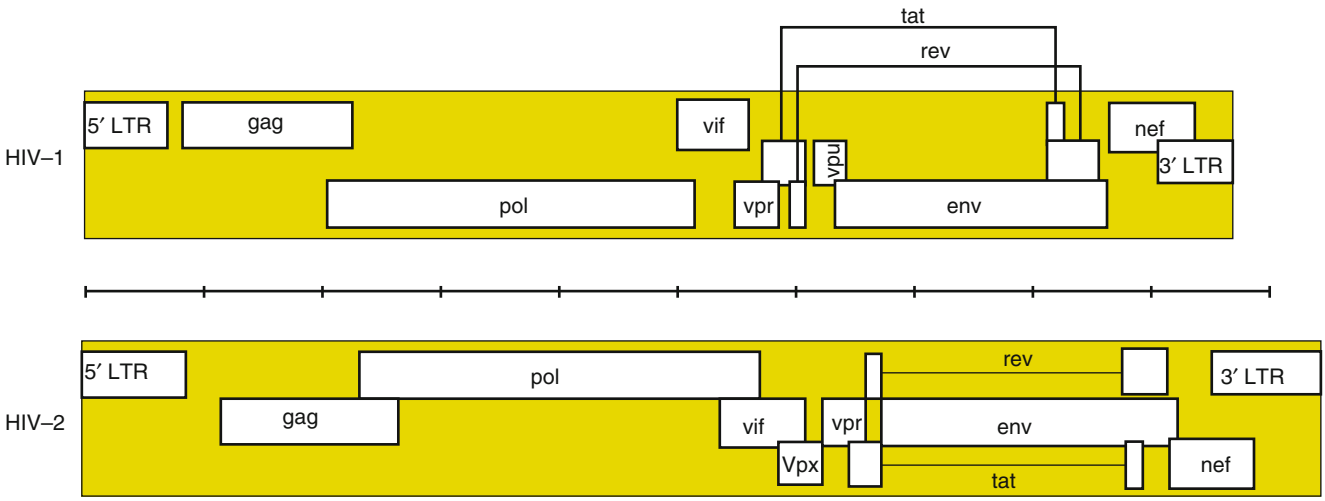

Fig. 43.6 Genomic organization of HIV-1 and HIV-2. In their approximately 10,000 base-pair sequence, HIV particles have a complex array of structural and regulatory genes: *gag* (coding for the viral capsid proteins), *pol* (coding for *reverse transcriptase*), *env* (coding for HIV's envelope-associated proteins). Regulatory genes: *tat*, *rev*, *nef*, *vif*, *vpr*, *vpu* (not in HIV-2), *vpx* (not in HIV-1) (Adapted from Ref. [142, 143])

elements involved in virus binding; and a series of accessory genes that regulate virus expression [7, 139, 144]. The *gag* gene products are synthesized from a single message, and the functional proteins are formed through enzymatic cleavage using the viral-encoded protease [145]. These structural elements are the matrix protein of 17,000 Da (p17), the capsid of 24,000 Da (p24), the nucleocapsid of 9,000 Da (p9), and the nucleic acid-binding protein of

6,000 Da (p6) [146]. On Western blot these proteins (except for p6) are strongly antigenic and appear as distinct bands with additional bands representing precursor intermediates. The *pol* gene codes for several enzymes: reverse transcriptase (involved in RNA to DNA transcription), endonuclease (ribonuclease-H), and integrase, which functions for viral integration [147]. The *env* gene encodes the major components of the viral coat: the surface glycoprotein of 120,000 Da (gp120), the transmembrane component of 41,000 Da (gp41), and the precursor called gp160 [148].

HIV-1 virion production and propagation involves a complex process controlled by genes encoding a series of multiple spliced mRNAs encoding a sequence of early and late regulatory proteins. The early regulatory genes are *tat*, *rev*, and *nef*, and the late regulatory genes are *vif* and (for HIV-1 only) *vpu*; accessory proteins are encoded by additional genes, *vpr* and (for HIV-2 only) *vpx*, which influence replication efficiency [149, 150]. HIV *tat* is responsible for enhanced transcription of viral gene products and also has a transactivating repressor function for some genes in the major histocompatibility complex [150, 151]. Free *tat* molecules released by the infected cell are able to activate uninfected CD4 T cells [152, 153]. Rev (regulator for HIV) modulates the complex transport of virion components and the translation of viral messages containing the *rev* responsive element (RRE); Rev thereby switches the production of regulatory proteins dominant early in the replication cycle to mainly structural proteins [151, 154]. Nef modulates CD4 receptor and human leukocyte antigen A and B expression and facilitates in vivo viral replication and pathogenesis [155–157]. Nef also plays a role in CD4 T-cell depletion by inducing apoptosis of uninfected bystander cells [158, 159]. Additionally, Nef activates resting T cells and has been shown to promote AIDS in transgenic mice even without the expression of any other HIV-1 gene [160, 161]. Vif prevents the inactivation of HIV-1 by the host protein, APOBEC3G, which is an innate immunity factor that resists HIV-1 through cytidine deamination of proviral DNA [162, 163]. Vpu influences virion maturation and release by antagonizing the action of tetherin, a molecule that prevents the release of virions from the infected cell [164–166]. Vpr induces cell cycle arrest in G2, enhances replication in macrophages, binds cyclophilin A, and contributes to apoptosis [167–169].

The life cycle of HIV involves an infection phase (including viral attachment, entry, reverse transcription, and proviral integration) and an expression phase (including transcription, translation, assembly, and budding of the virion) (Fig. 43.4) [140]. The initial stage of infection involves the binding of either HIV-1 or HIV-2 to cell surface structures that determine viral trophism. Many of the pathogenic effects of the virus result from immune dysfunction, which compromises the ability of the immune system to perform its myriad surveillance and regulatory processes. The HIV-1 envelope has a high-affinity binding site specific for the CD4 molecule. The CD4 molecule occurs on mature T-helper lymphocytes and on other cells of the immune system, particularly circulating and fixed tissue (dendritic) monocytes, macrophages, and microglia [86, 170–172]. The virus also attaches to other cells: follicular dendritic cells in the lymph nodes, M cells on the Peyers patches, and galactosylcerebroside-positive cells in the brain and gut.

A second co-receptor is also necessary for viral infection, and for this purpose HIV-1 uses either of the two chemokine receptors, C-C chemokine receptor 5 (CCR5) or C-X-C chemokine receptor 4 (CXCR4) [173–175]. Both receptors are important for chemotactic activity in lymphocytes and are generally expressed on cells that also express CD4. HIV-1 viral isolates vary in their use of the co-receptor, but the majority of viral strains establishing acute infection use CCR5, while a greater proportion of viral isolates from chronically infected individuals use CXCR4 [176, 177]. Although most HIV-1 isolates bind to one or the other co-receptor, so-called dual tropic viruses can utilize both [178].

Following attachment, a fusogenic domain on the gp41 appears to be involved in the uncoating and release of virion genetic material into the cell. The viral reverse transcriptase synthesizes a cDNA copy of the virus that is transported to the nucleus; viral integrase is then involved in proviral integration. Integration of HIV-1 appears to be random but may be influenced by host factors [179]. Once integrated into the host chromosome, the virus is replicated like a cellular gene and incorporated into the progeny cells. The proviral genome is the template for new virus production, and the expression of new virus production is controlled by viral and host cellular regulatory elements. The first elements produced are the regulatory elements, which then modulate the production of genomic RNA and mRNA necessary for production of virion structural proteins. The process is orchestrated by the regulatory elements discussed above, with the *rev* protein playing a key role in the switch to virion production.

The morphology, life cycle, and genomic structure of HIV-2 are quite similar to that of the HIV-1, but the regulatory genes of HIV-2 differ from those of HIV-1: in the former *vpx* appears in place of *vpu*, as noted above. The *env* gene encodes a gp120 membrane and a gp32–40 transmembrane glycoproteins. The *gag* gene encodes a p55 precursor to p24–26 and p15. The *pol* gene products include the p64 and the p53 of reverse transcriptase, p34 of integrase, and p11 of protease [180].

5 Descriptive Epidemiology of HIV/AIDS

HIV-1 has propagated from one risk group to another in different places and times, evolving into a pandemic with myriad patterns of occurrence, transmission, and modulating influences that stretch beyond the scope of this section. The statistics

in this section very briefly depict the force of mortality, morbidity, and infection caused by the virus. Where differences seem informative, the picture is presented first in global terms; then in the more developed world as represented by the USA and other countries in North America, Europe, or Australia; and then in regions lacking robust epidemiologic capabilities, most notably southern Africa or Southeast and East Asia. The section next addresses the contagiousness of the infection and the distinctive modes and patterns of its transmission. Finally, it summarizes the various behavioral and biological factors believed to modify the rate of disease progression. Except for host genetic factors, several of which have been implicated in acquisition of HIV-1 infection as well as disease progression, factors that more directly alter the risk of transmission or acquisition of infection are reviewed in Sect. 6.

5.1 Mortality

5.1.1 Global

The series of illustrations below provide the most current mortality estimates for the pandemic. The estimated annual numbers of deaths from AIDS peaked during the first few years of the new millennium and declined steadily since then to 1.7 million in 2011 (Table 43.3). An estimated 86 % of deaths were in adults.

5.1.2 USA and Other Regions of the Developed World

Rates of mortality due to AIDS in the USA climbed steadily during the first decade of the epidemic and peaked in the early 1990s. By 2010 it is estimated that 619,000 persons had died of AIDS since the epidemic began. In 1992 HIV-related conditions were the leading cause of death in men between 25 and 44 years of age and the fourth leading cause in women of that age (Fig. 43.7). Their place among the most frequent causes of death then steadily declined after the introduction of HAART, and by 2010, AIDS was the seventh and tenth leading cause in 25–44-year-old men and women, respectively. In 2011 only 28,000 deaths occurred in all of North America and Western and Central Europe (Table 43.3).

After 1996 striking changes began to occur in most places where HAART became available. In one analysis of nearly 10,000 patients seen in 70 European centers, in just the 8-year interval (1994–2002) spanning the pre-, early post-, and later post-HAART periods, deaths among the most immunodeficient declined by half from the early to the later HAART period [181]. A similar conclusion was drawn by the HIV-CAUSAL Collaboration in a recent analysis of nearly 63,000 individuals with HIV-1 infection who were followed for an average of 3.3 years with or without treatment. Compared with untreated patients, those who initiated combined ART

Table 43.3 Regional HIV and AIDS statistics and features 2012

	Adults and children living with HIV	Adults and children newly Infected with HIV	Adult prevalence (15–49) [%]	Adult and child deaths due to AIDS
Sub-Saharan Africa	25.0 million	1.6 million	4.7 %	1.2 million
	[23.5–26.6 million]	[1.4–1.8 million]	[4.4–5.0 %]	[1.1–1.3 million]

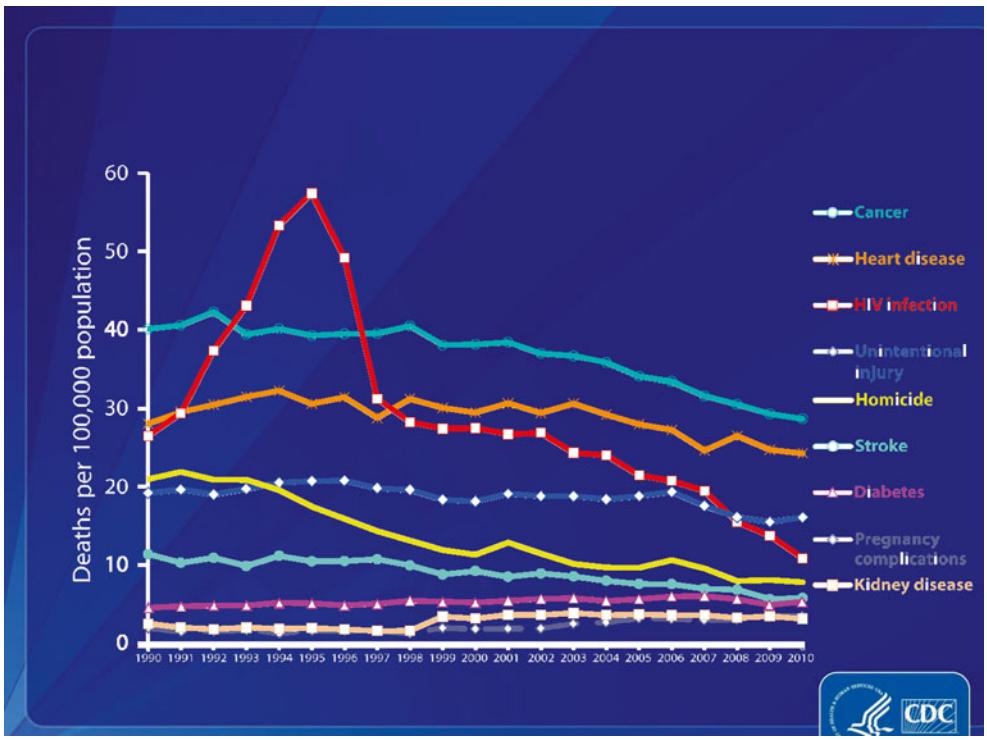

Fig. 43.7 Trends in annual rates of deaths due to the 9 leading causes among persons 25–44 years old, USA, 1987–2010. Data were compiled from death certificates from all 50 states and the District of Columbia by the National Center for Health Statistics (NCHS) (Reproduced from Centers for Disease Control and Prevention, http://www.cdc.gov/hiv/pdf/statistics_surveillance_HIV_mortality.pdf)

had a 0.48 mortality hazard ratio, with those whose prognosis was worse at the beginning of the follow-up period showing the greater reduction in mortality [182].

Even where treatment is readily accessible, however, it has not had uniformly dramatic results or an equal impact in reducing deaths from all of the AIDS-defining conditions. For example, a study of 30,000 European and North American patients treated with ART reported that the adjusted hazard ratio for death from high-mortality conditions like non-Hodgkin's lymphoma and progressive multifocal leukoencephalopathy (7.3) is higher than for such complications as cryptococcosis, cerebral toxoplasmosis, AIDS dementia complex, and disseminated *Mycobacterium avium* complex (2.4) and other milder conditions (1.5) [183].

5.1.3 Regions of the Developing World

Of the 1.7 million deaths from AIDS worldwide in 2011, approximately 70 % occurred in sub-Saharan Africa, and another 15 % in South and Southeast Asia (Table 43.3). However, programs for distributing effective and affordable treatment have had significant impact on mortality in many of the poorer countries of the world, and in half-dozen years between 2005 and 2011, gains in those places have been almost as impressive as those where far greater resources have been committed [56].

In sub-Saharan Africa deaths dropped 32 % overall and 50–70 % in various other African countries. Cambodia and Thailand experienced 77 and 49 % reductions in mortality, respectively. One of the most frequent causes of death in HIV-1-infected persons in many poorer parts of the world is tuberculosis (TB), and the expansion of treatment for HIV-1 during the past few years has led to a reduction in annual AIDS-related TB deaths from 600,000 to 450,000 (25 %). As encouraging as these gains are, they represent relative reductions from very high mortality rates, and reaching levels comparable to those achievable under optimal treatment conditions will require sustained aggressive effort.

5.2 Morbidity

5.2.1 Acute Retroviral Syndrome

The initial weeks of infection are frequently characterized by an acute syndrome, which in US and other populations in the developed world closely resembles that of the Epstein–Barr virus-induced mononucleosis (see Sect. 8) [184]. Data on the overall frequency of this syndrome have not been systematically collected in large populations of prospectively identified seroconverters. However, only a minority of seroconverting individuals experience these acute symptoms, and it may differ by host characteristics in different settings [185]. The syndrome may be associated with higher levels of viremia, but neither the mode of transmission nor various

other factors examined appear to explain why or when the syndrome is likely to occur.

5.2.2 Pre-AIDS

Beginning a few months after the acute seroconversion phase, the vast majority of recent HIV-1 infections quiesce for months or years before classic AIDS-defining conditions develop. During that long variable period, an intermediate stage may be punctuated with one or more minor conditions (e.g., localized zoster, hairy leukoplakia, and other dermatologic lesions) (Table 43.1), but the frequency, patterns of occurrence, and determinants of those conditions have not been well studied.

5.2.3 AIDS

From the time the outbreak began and for the years prior to the introduction of HAART, the primary metric of morbidity and mortality was the annual or cumulative number of AIDS cases—OIs and cancers in the absence of known causes of natural or iatrogenic immunodeficiency. However, ironically, as a result of the huge impact of treatment, in recent years in the USA, simple total or annual numbers of AIDS cases are now seldom reported as such. Rather, disease is staged, and according to CDC figures for 2010, the number of persons with stage 3 disease (AIDS) at the time of diagnosis of HIV-1 infection (11,898) represented 27.7 % of all persons with newly diagnosed HIV infection (42,901) [186]. The reason for reporting the data in this form is that a concerted effort to reduce the number of infections diagnosed at this late stage is a goal of the 2010 National HIV/AIDS Strategy for the United States (NHAS) (see Sect. 9.1).

Data on the individual AIDS-defining conditions are even more difficult to find and interpret. Their frequencies have varied according the place, time, risk group, and other features, as well as the diagnostic capabilities in the specific populations under surveillance. For example, from the inception of the epidemic, the striking excess of Kaposi's sarcoma before the advent of HAART was inexplicably confined almost exclusively to MSM. In contrast, IDUs were more frequently affected by bacterial and other agents known to contaminate drug injection paraphernalia. Other pathogen distributions have usually mirrored their distinctive prevalence in different geographic areas. Thus, in a review of multiple observational studies and trials conducted in southern Africa just before the advent of treatment, OIs included not only those seen commonly in the populations of North America, Europe, and Australia but also those more common with immunodeficiency in less developed areas: *Streptococcus pneumoniae*, *Salmonella* species, *Cryptococcus neoformans*, *Cryptosporidium parvum*, *Microsporidium* species, and *Isospora belli* [187].

As with mortality, in the past 15 years, the incidence of these late complications has steadily diminished. In the developed world, the OIs and AIDS-defining cancers that were formerly frequent occurrences in the severely immunodeficient have declined sharply; among carefully treated individuals, some have almost disappeared. Still, current overall morbidity due to HIV-1 is by no means negligible. For instance, rates of hospitalization during the HAART era in Australia were 50–300 % higher in a cohort of treated individuals who were comparable in age and sex to the general population, and the rates were higher for those who were older, had been infected longer, or had been treated with more antiretroviral drugs [188].

5.2.4 Non-AIDS-Defining Comorbidity

Among those HIV-1-infected people living longer as a result of treatment, such non-AIDS diseases as other neoplasms (skin, anus, liver, etc.) appeared to occur at incidence rates above background [189]. However, two other major chronic infectious diseases (tuberculosis and hepatitis C) have flourished disproportionally where prevalence of coinfection with these agents is high. In 2011, of the estimated 8.7 million people who developed TB worldwide, people living with HIV-1 accounted for 1.1 million (13 %); nearly one-quarter of people with TB who were tested were positive for HIV-1 [190].

Comorbidity with HIV-1 and hepatitis C virus (HCV) coinfection is also significant. Some four to five million persons worldwide are infected with both viruses; the prevalence of HCV is 72–95 % in IDUs, 1–12 % in MSM, and 9–27 % in heterosexuals who are HIV-1 positive in the USA and Western Europe [191]. A meta-analysis covering 30 studies and more than 100,000 patients coinfected with HCV documented increased overall mortality, but from non-AIDS-defining conditions rather than AIDS itself [192]. A number of studies of dually infected patients have shown 2–3-fold higher rates of progression to chronic hepatitis, severe fibrosis, cirrhosis, or death in IDUs and other groups compared with HCV-monoinfected patients [193].

5.3 Prevalence

5.3.1 Global

As noted earlier, uneven surveillance efforts as well as actual variation in the pattern of occurrence of HIV-1 infection from place to place account for substantial differences in reported prevalence around the world. Data collected and assembled relatively uniformly by the United Nations between 1990 and 2012 document a steady rise in prevalence until about 2000, an inflection in the trajectory, followed by

a slower rise. By 2012 the number of adults and children totaled 35 million, broken down by continent and major subdivision in Fig. 43.8.

Sub-Saharan Africa again accounts for about 70 % of the total, and South and Southeast Asia for about 12 %. Of course, these figures include infection present at any stage in living individuals, treated or untreated.

5.3.2 USA

Based on back calculation from the latest available state- and area-level HIV-1 and AIDS data [186], in the USA at the end of 2009, an estimated 1,148,200 persons aged 13 and older were living with HIV-1 infection. That figure represented approximately 0.45 % of the adolescent and adult population, with clear heterogeneity by age, sex, and race. Overall about 18 % of these infections are estimated to remain undiagnosed. In Western and Central European countries, the overall 0.2 % prevalence is lower than in the USA.

5.3.3 Regions of the Developing World

Eastern Europe and Central Asia experienced more rapid increases in prevalence in the 1990s, with the most recent overall figure reaching 0.8 % [42]. Elsewhere the figures range from 0.1 % in East Asia to 1.0 % in the Caribbean; however, prevalence remains exceptionally high (4.9 %) in sub-Saharan Africa.

5.4 Incidence

5.4.1 Global

Worldwide, 2.3 million infections (7 % of the total) are estimated to be new or incident (Fig. 43.9). This aggregate figure belies the striking heterogeneity by age, sex, race, geography, risk category, and other factors whose roles are examined in greater detail below. Encouragingly, estimates from UNAIDS have shown a steady decline in global incidence rates from a peak of about three million per year in the mid-1990s to about 2.5 million in 2012 [56].

5.4.2 USA and Other Developed Regions

Incidence estimates have been based on increasingly more sophisticated back calculation coupled with other estimation techniques described in Sect. 3. Estimates have been extrapolated from a study of 6,864 diagnostic specimens taken in 2006 [76]. In 2133 (31 %) results were indicative of recent infection. These data translate to 56,300 new infections or an incidence rate of 22.8 per 100,000 in the entire USA in that year. The incidence was compared closely with incidence estimates for 2003–2006 based on back calculation from HIV diagnoses and AIDS incidence. More than half were among men who have sex with men, and nearly half were among black individuals. The overall incidence increased in the mid-1990s, declined slightly after 1999, then stabilized.

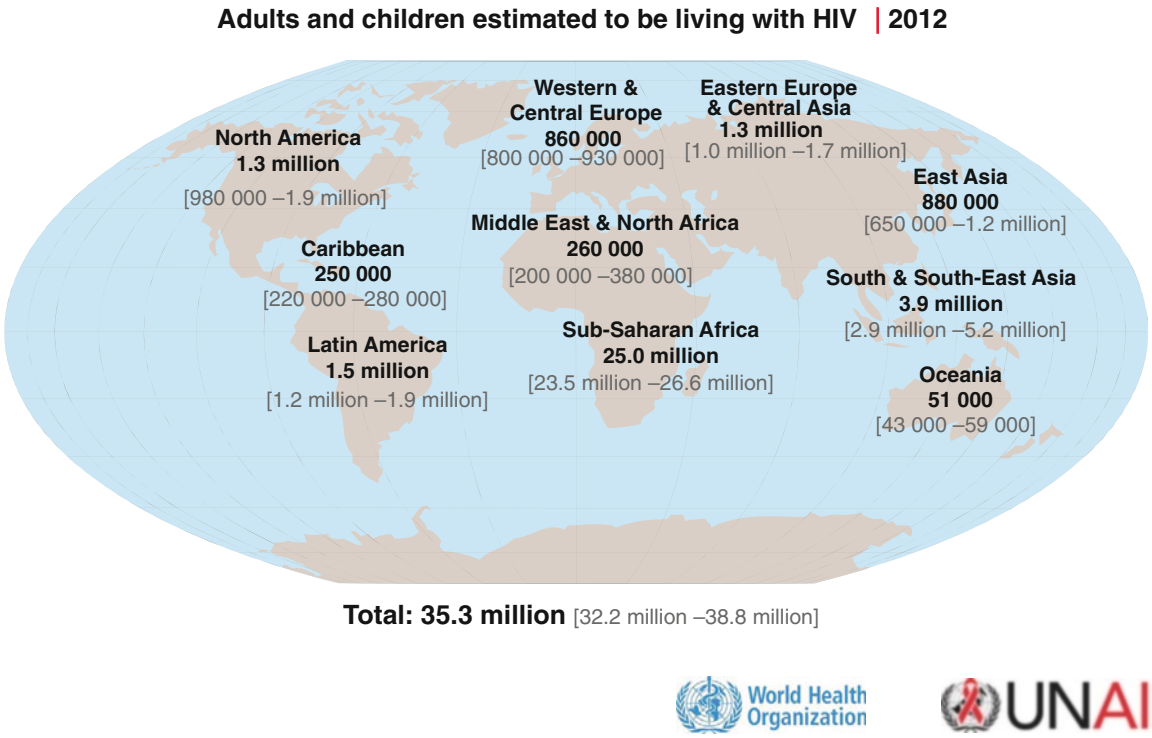

Fig. 43.8 Adults and children estimated to be living with AIDS, 2012 {UNAIDS, September 2013}, http://www.unaids.org/en/media/unaids/contentassets/documents/epidemiology/2013/gr2013/201309_epi_core_en.pdf

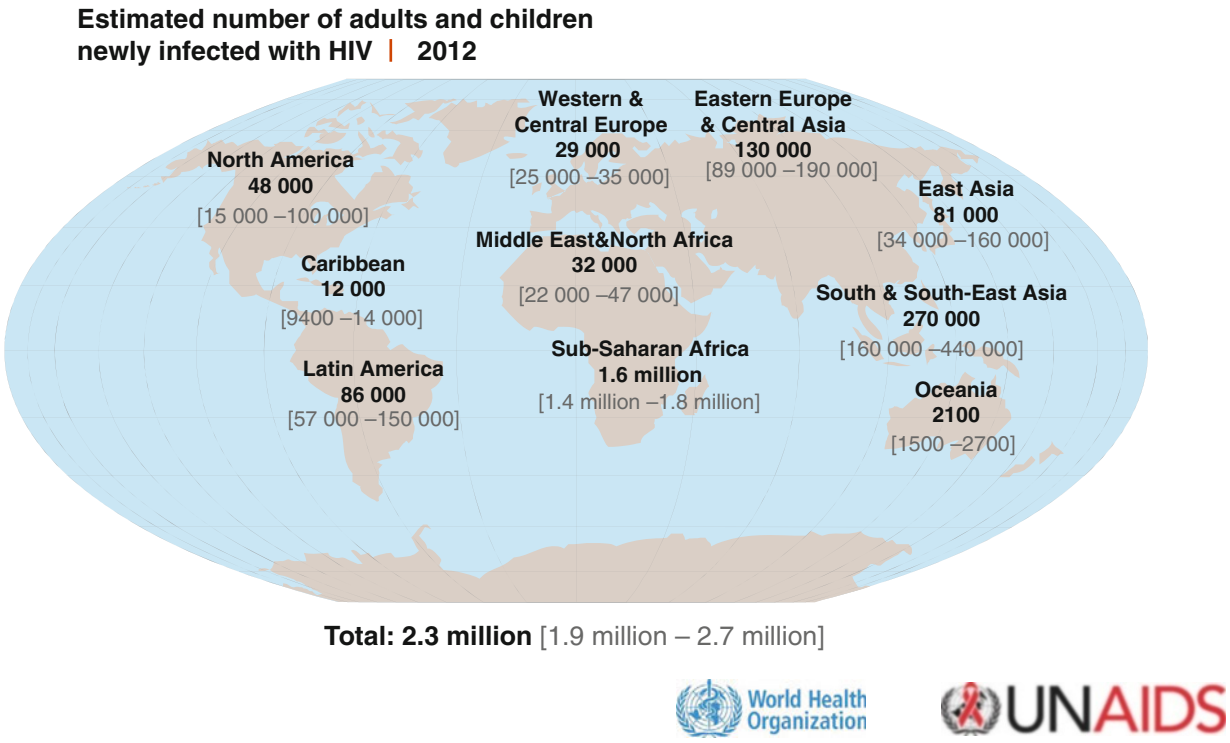

Fig. 43.9 Estimated number of adults and children newly infected with HIV, 2012 {UNAIDS, September 2013}, http://www.unaids.org/en/media/unaids/contentassets/documents/epidemiology/2013/gr2013/201309_epi_core_en.pdf

National HIV Surveillance System figures have confirmed the overall stability in incidence rates after 2006, but they have also reemphasized the concern about disproportional increases among young MSM in general (accounting for 61 % of new infections) and young African–American MSM in particular, who accounted for one-quarter of all new infections in 2010 (Figs. 43.10 and 43.11) [196].

5.5 Epidemic Behavior and Contagiousness

In the 30 years since HIV-1 was first discovered, one of its most prominent characteristics has been its capacity for epidemic spread. However, to summarize the nature and extent of this epidemic behavior would be to recapitulate the Introduction, Historical Background, and much of the material in Sect. 6. The focus here is on contagiousness, which despite the relatively low intrinsic capability of the virus has proved high enough to enable it to propagate from person to person in epidemic fashion.

HIV-1 replicates efficiently in certain human lymphoid cells and far less so in most other human cell types. Contagiousness depends mostly on the quantity and quality of free virus passing from those infected cells into the bodily fluids and tissues that can, in turn, make direct physical contact with the appropriate mucosal surface or blood of a new susceptible host.

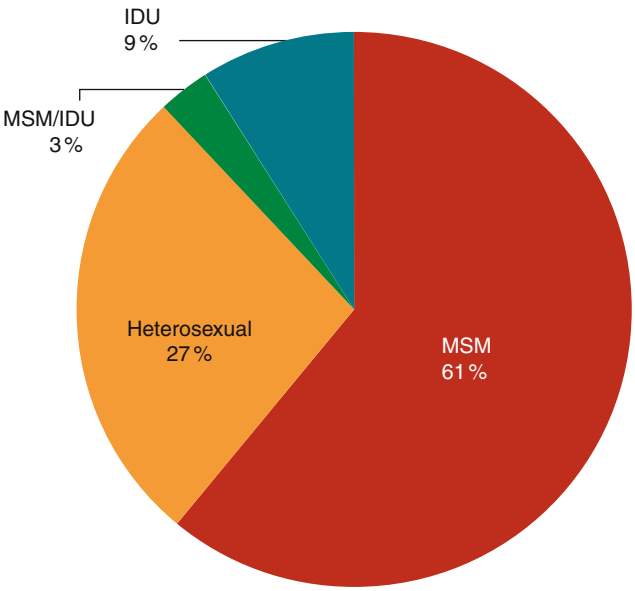

Fig. 43.10 Estimates of new HIV infections in the USA, 2009, by transmission category (Reproduced from Ref. [194] as adapted from Prejean et al. [195])

The likelihood of that sequence of events is determined by both the transmissibility of the virus from the infected host and the susceptibility of the uninfected host. The level of virus in the plasma or genital secretions of the infected host appears to be the strongest determinant of transmissibility.

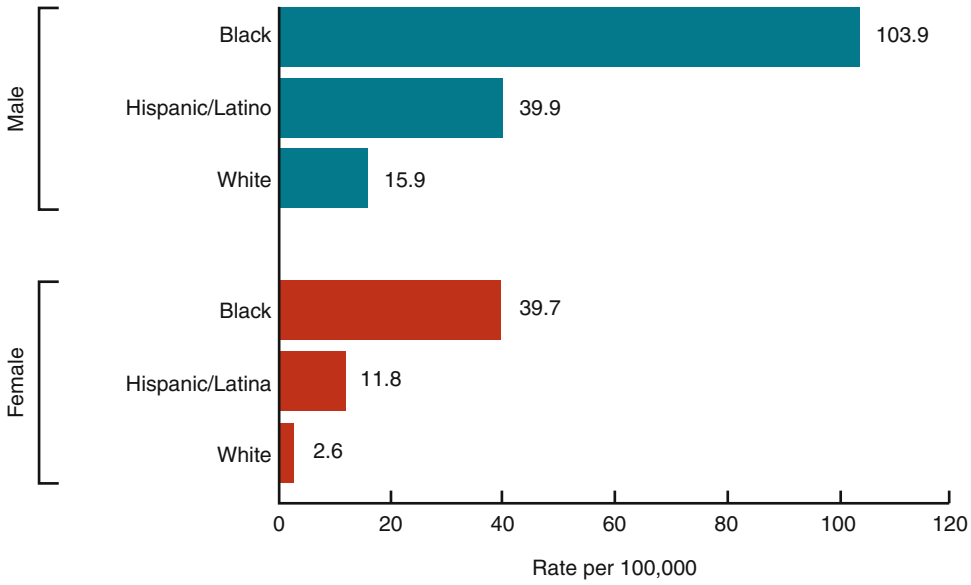

Fig. 43.11 Estimated Rate of New HIV Infections, 2009, by Gender and Race/Ethnicity (Reproduced from Ref. [194] as adapted from Prejean et al. [195])

Table 43.4 Estimates of infectivity due to sexual and parenteral exposure

Transmission probability from a single contact with an infected partner	
Heterosexual transmission	
Male to female (California Partner Study)	0.001–0.03
Male to female (Transfusion Partner Study)	0.001–0.189
Female to male (STD patients, Kenya)	0.082
Female to male (Thailand military recruits)	0.025–0.075
Homosexual transmission	0.008–0.032
Per partnership transmission probability from a relationship with an infected partner	
Heterosexual transmission	
Male to female	0.10, 0.18, 0.20, 0.22, 0.27, 0.28
Female to male	0.01–0.12
Homosexual transmission	
San Francisco Men's Health Study	0.10
Transmission probability from single contact in nonsexual setting	
Blood transfusion	0.60–0.72
Needle stick, health-care worker	0.0046–0.009
Laboratory worker	0.0048–0.023
Perinatal transmission	0.12–0.30

Adapted from Brookmeyer and Gail [200]

Other modifying characteristics of the source virus are its lack of ability to induce syncytium formation and its trophism for cells of the monocyte–macrophage lineage [197]. Contagiousness may also be higher at the earliest and latest stages of the disease when viral load (VL) tends to be higher and when the number and duration of partnerships at the time of acute infection is greater [198, 199]. As for susceptibility to HIV-1 infection, in addition to source virus characteristics, a number of host factors have been well documented to increase or reduce the probability of acquiring infection, while other associations remain unproved. They are described in the broader context of cofactors for transmission (Sect. 6). The remainder of this section summarizes the approaches that have been taken to estimating contagiousness, based on transmission rates irrespective of viral and host determinants.

Early partner and cohort studies attempted to quantify the contagiousness of HIV-1 from a single sexual or parenteral exposure (Table 43.4) before the advent of ART. Estimates of the frequency of transmission following a single sexual or parenteral exposure depend on such variables as the type of exposure, the gender of the infected partner, and the viral and host factors described elsewhere.

High probabilities of infection occurred with transfusion, where follow-back studies indicated that two-thirds or more of recipients who received a positive unit became seropositive [201–203]. In one study, 200,000 screened samples

yielded 124 transfusion recipients with no other risk factor and 111 (89 %) were seropositive [202]. HIV-1 can be efficiently transmitted in whole blood, lymphocytes, packed red cells, platelets, and plasma. None of the products purified from donated blood (e.g., albumin or immune globulin) have proved infectious for HIV-1.

Transmission from HIV-1-positive mothers to their infants occurred in approximately 10–30 % of their pregnancies in the absence of prophylactic intervention [12, 204].

The estimated risk of acquiring HIV-1 as an IDU is about 7 per 1,000 per event, as reported earlier in the epidemic and in a recent study in Thailand [205]. HIV-1 transmission between IDUs occurs by injection with a needle that is contaminated by residual virus as a consequence of sharing contaminated injection equipment [206]. In many cross-sectional studies, duration of drug use and older age are the predominant risk factors, probably reflecting cumulative risk over time [207–210]. In incidence-based studies, in contrast, younger age appears to predispose to HIV-1 infection, possibly because the risk for acquiring new infection may be highest at the onset of drug use when experimentation with new networks may occur and patterns of self-protective behaviors, such as accessing equipment exchange programs, have not yet formed [206]. The risk for infection from a single injection will vary not only by individual injection practices but also by the average HIV-1 viral load in the community network of needle/syringe users. The per-contact risk is obviously high in settings such as "shooting galleries," where exposure to contaminated equipment is likely. Individual practices may further amplify the likelihood of exposure to higher levels of HIV viral particles. Repeated flushing of the syringe ("booting") and other practices also increase the risk by increasing the quantity of blood exchanged between individuals. Although once promoted as decreasing risk, bleach treatment for disinfecting injection equipment has not been fully effective in prevention HIV transmission [211, 212].

Sexual transmission of HIV-1 may also be an important independent source of HIV-1 infection among drug users. In one prospective analysis, subjects with a history of sexual exposure to an HIV-1-infected partner had a fourfold increased risk of HIV infection, independent of needle or syringe sharing [206]. Similar to other studies of heterosexual transmission of HIV, this risk was higher for women than for men.

In the early work on sexual transmission, although risks from sexual contact overall were comparatively low, the risk per contact of male-to-female transmission was similar to the risk for male to male but higher than for female to male. Based on more recent direct observations in prospective studies of untreated HIV-1-discordant couples in Africa, heterosexual transmission in either direction on a per single contact or per act basis now appears closer to the lower ends of those shown in Table 43.4 [213]. MTF and FTM risks unadjusted for age, prior infection with HSV-2, or source partner VL were 0.0019 and 0.001, respectively, but converged to a relative risk of nearly unity after adjustment. As noted above, lower VL in women explained much of their apparently lower transmissibility. Other comparable studies have differed in their estimates, possibly due in part to inclusion or exclusion of virologically linked seroconverting partners [198, 214, 215].

Those with needle-stick injuries or accidents in clinical settings or in laboratories where exposure was known to occur have had lower risks, similar to those following sexual contact (see Sect. 6) [216]. As for casual skin or mucous membrane exposure, the risk has been estimated to be extremely low [217].

Because most of the transmission has involved direct contact, the epidemic has often tended to propagate primarily within and more haphazardly between groups. For example, female sex workers in urban areas of Africa and Asia represented core transmission groups who passed the virus to customers such as itinerant laborers or truck drivers traveling a distance from their rural homes. High prevalence in the sex workers meant high rates of transmission to their male customers and, in turn, high levels of secondary spread when those men returned to their spouses and other sexual partners. In Southeast Asia and India, injection drug use and sex work combined to augment secondary spread into the community. In Thailand parallel epidemics were produced by two distinct viral subtypes, a clade B-related virus spread largely among IDUs in Bangkok [218, 219] and a clade E virus spread heterosexually among a network of female sex workers, their male military clients, and the sexual partners of those men.

The growing body of information about the virus and host characteristics influencing transmission has stimulated a number of efforts to construct models of HIV-1 contagiousness and individual evolving epidemic. One example, a multi-compartmental model (Fig. 43.12) depicts the interrelationships of the compartmentalized risk groups and the likelihood of sexual and parenteral exposure. Other more theoretical and quantitative models ultimately rely on the rather sparse data and wide-ranging parameter estimates for each of the included variables.

As details of viral dynamics have become clearer, so has a more empirically based insight into the contagiousness and evolution of microepidemics in the main risk groups. For example, in a study of the epidemic among heterosexuals in the United Kingdom, sequencing of regions of the viral protease and reverse transcriptase in a large number of non-subtype B viruses isolated from more than 11,000 individuals, phylogenetic analyses revealed a much lower degree of clustering of heterosexuals than previously estimated for MSM [220]. These analyses also suggested a longer maximum transmission interval for heterosexuals (median—27 months) than for MSM (median—14 months). Likewise in an outbreak in IDUs in Sweden in 2006, investigators capitalized on

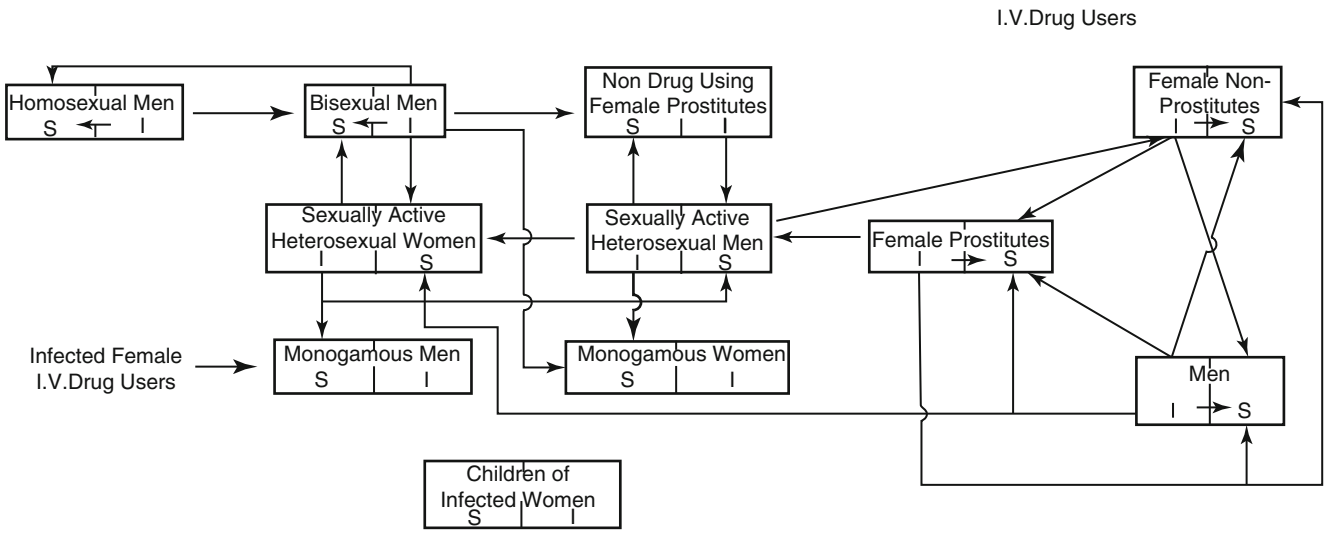

Fig. 43.12 Compartmental model for spread of AIDS (Reproduced with permission from Brookmeyer and Gail [200])

epidemiologic and phylogenetic data on the highly variable sequence of the gene for the V3 domain of the HIV-1 envelope [221]. The new viral strain, imported into Sweden from Finland, did not appear more virulent or more transmissible than the form already circulating; rather the work suggested that the availability of a network of uninfected IDUs led to an abrupt 12-fold increased incidence once the new virus was introduced. Other approaches to modeling of the contagiousness and transmission of HIV-1 are summarized and assessed elsewhere [222]. Finally, effective and especially early treatment of infected individuals has begun to show impressive effects on viral transmissibility, as described in Sect. 9.

5.6 Geographic Distribution

The broad patterns of occurrence throughout the world have been addressed in Sect. 5.1. covering the magnitude of the current pandemic. As apparent from that summary, the occurrence in any particular place has usually been most strongly determined by its peculiar mix of high-risk subpopulations. At the global level, the disproportional intensity of HIV-1 infection and disease at the epicenter in sub-Saharan Africa cannot be overstated. But peculiarities of the southern African geography do not explain this phenomenon. Rather, it appears to have been the combination of multiple sexual partnerships and practices coupled with ineffective early responses to the impending epidemic that fueled its rapid expansion from one place to the next. In comparison, the concentration of commercial sex workers, risk-prone heterosexual men, and IDUs in Thailand and other parts of Southeast Asia in the early 1990s led to projections that region would soon surpass all others in the world in incidence. Indeed, the numbers of new infections in Thailand were then increasing steeply. However, concerted efforts to reverse that rise began to pay off soon thereafter, and although the incidence rate did not decline as sharply as it rose, an epidemic equal to or worse than the one in South Africa did not materialize.

At the other extreme, areas reporting the lowest prevalence estimates have usually been predictable based on their sociobehavioral characteristics. For example, although data from the Middle East and North Africa are not equally reliable for every nation, the burden of HIV-1 infection in those regions is not nearly as onerous as in others (Fig. 43.8), ostensibly because the high-risk activities leading to rapid spread of infection elsewhere have been less common in the more traditionally conservative cultural and religious environments.

Even within a single country or city, variations in behavior have often accounted for large differences among its subpopulations. The epidemic in the USA began in east and west coast cities and quickly spread to other metropolitan areas in the USA, while it simultaneously disseminated in the cities of Western Europe, reflecting the concentrations of MSM. However, the geographic distribution has evolved considerably in the ensuing years, and HIV-1 infection shows similar concentration in many parts of the southeastern USA (Fig. 43.13), reflecting more intense spread across the major transmission risk groups within the African–American community.

HIV-1 in IDUs and commercial sex workers in the USA initially followed the same coastal pattern, but elsewhere in the world, the broader distribution of those risk groups and their connections with each other and with other risk groups in many locations facilitated global spread of HIV-1 among them. As an especially compelling example of how personal behavior has been the primary determinant of the geography of HIV-1 infection, prevalence of infection in numerous places around the world rose rapidly in locations along routes

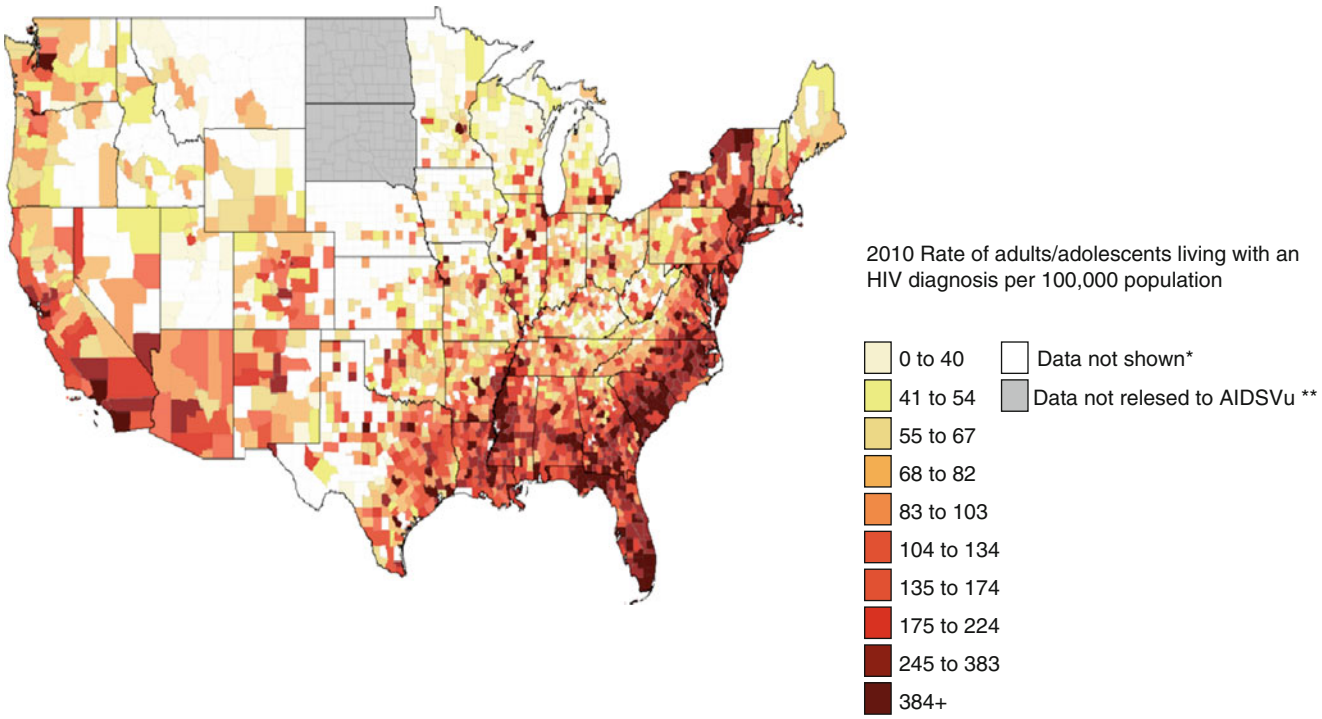

Fig. 43.13 Rates of persons living with an HIV diagnosis, by county, 2010 (Reproduced from Source: AIDSVu [223]; #1798}). This map shows the estimated county-level rates (per 100,000 population) of adults and adolescents living with an HIV diagnosis at the end of 2010. Data include adults and adolescents living with a diagnosis of HIV infection, regardless of the stage of the disease at diagnosis, and have been statistically adjusted to account for reporting delays and missing risk-factor information, but not for incomplete reporting. All displayed data are estimates based upon actual data reported to CDC through June 2012. Persons living with an HIV diagnosis are classified as adult or adolescent based on age at end of 2010

where long-distance truck drivers traveled and where other migrant workers congregated; this distribution was soon accompanied by secondary spread to the rural areas when these workers, upon returning home, infected their spouses and other sexual partners.

5.7 Temporal Distribution

Unlike many acute viral infections, HIV-1 does not display predictable seasonality, nor has it sporadically surged and subsided in the form of an epidemic of weeks or months. Unlike other chronic viral infections and their sequelae, HIV/AIDS did not become endemic throughout much of the world long before it was discovered. Rather, HIV-1 infection has proved unique in its temporality in that, except for perhaps a few dozen occurrences during the several decades before its discovery, it produced a pandemic that evolved almost entirely in plain view of clinicians, public health officials, biological and social scientists, politicians, and the rest of humankind (Sect. 2). Therefore, unlike any other viral infection, many facets of its occurrence, diagnosis, treatment, and prevention have changed so radically in the years since its discovery that the temporal distribution of HIV/AIDS cannot be easily examined without reference to those changes. Rather than reiterating here how each of those various developments has affected its temporality, the reader is referred to the sections above and below that cover them.

5.8 Age

Age enters the epidemiologic picture of HIV/AIDS in various ways. With regard to morbidity and mortality in the early years of the epidemic, it was clear that AIDS incidence (and death rates) showed an age distribution pattern typical of infections transmitted by the sexual and blood-borne routes. Cases clustered primarily among the most sexually active groups (20–40 years of age). This primary mode in the age distribution of AIDS was apparent for homosexual men and heterosexually active populations throughout the world [224, 225, 92, 226] It also characterized IDUs, in whom a peak of AIDS at the lower end of that age range probably reflected the shorter latency between infection on disease onset due to their more intense exposure (i.e., higher inoculum size).

Among military recruits, blood donors, NHANES, and other relatively representative populations in the USA, the highest prevalence of seropositivity has been found in the

group 20–30 years of age (Fig. 43.14) [224, 227–230]. On a global basis, the pattern of HIV-1 prevalence in Uganda typifies the age-specific patterns of most developing countries with a peak among men 20–30 years old and among women 5–10 years younger [20, 231]. For the most part this pattern probably reflects the usual age differential in male–female partnerships; it has also been observed for the incidence of infection in studies of transmission among HIV-1-discordant heterosexual couples [232].

During the first years of the epidemic, a minor mode in the age distribution was formed by pediatric AIDS cases. About 20 % of infants with MTCT of HIV-1 infection became symptomatic in the first year of life, most likely due to intrauterine transmission. In the remainder the incidence of AIDS was about 8 % per year [233]. This longer interval from infection to AIDS more closely resembles the latency period in adults and suggests transmission during the trauma of birth or thereafter through breastfeeding [234].

More recently, this bimodal distribution has changed for several reasons, most dramatically in the developed world. Drug treatment of primary HIV-1 infection and prophylaxis against opportunistic infections have significantly prolonged the AIDS-free period after initial infection. In places where these medications are readily available, adults and children infected at or after birth now live much longer. In countries providing optimal perinatal care, the original pediatric age mode has all but disappeared.

Besides its influence on the peak periods of risk for infection, age exerts its biological effects independently on morbidity and mortality rates as it does with most other chronic diseases. Not long after AIDS was recognized, it became clear that when the time to AIDS and death among older children and adults was stratified by age, older individuals showed progressively shorter intervals from infection to AIDS and from AIDS to death. The strong age effect was especially apparent in hemophiliacs, virtually all of whom received contaminated blood products within a very short period of time but succumbed at rates that differed substantially with their age at the time of infection. Many other studies have confirmed this pattern.

5.9 Sex

As the epidemic first unfolded, MSM, IDUs, and hemophiliacs were the groups most heavily affected. Soon the infection had spread to female commercial sex workers, sex partners of those in the groups initially affected, and transfusion recipients; within just a few years, among the subset of patients who immigrated to Europe from sub-Saharan Africa, proportions of men and women with AIDS were nearly equal [225]. Men with AIDS continued to outnumber the women in a gradually declining ratio, but the sex ratio of new infections in groups other than MSM approached unity. Thus, despite the evidence that male to female is more efficient than female-to-male transmission on a per sex act basis (Sect. 6), such contributing factors as the type and number of partners, coinfection with genital tract pathogen,

absence of circumcision of a susceptible ultimately seem to offset that differential risk in determining sex-specific incidence rates.

One well-established difference between men and women is the lower level of viremia among women in the early stages of HIV-1 infection. The approximately one-log lower concentration of virus in copies/ml plasma has been consistently documented in various populations but remains unexplained [235]. Intriguingly, the levels of viremia in untreated men and women gradually converge over the course of infection; and with comparable follow-up, the two sexes experience overall similar disease courses and ultimately equal hazards of AIDS and death [236].

5.10 Race and Ethnic Group

Once the AIDS epidemic had emerged and spread beyond MSM, the racial and ethnic disparities in cases grew increasingly apparent. By the early 1990s, African–Americans in the USA already accounted for 36 % of all AIDS cases and Hispanics for 17 % compared with their proportions of the US population, 12 and 6 %, respectively. The particular vulnerability of heterosexual minority adolescents and young men was also becoming apparent [237]. In very large serosurveys among the prospectively followed military cohorts, the incidence of new infections was 3–4 times higher in African–Americans and Hispanics compared with troops of European ancestry [238]. This ominous trend in black men has continued [239].

As the pandemic expanded into populations of different ancestry and from developed to less developed areas of the world, it became clear that higher rates of disease in one or another race or ethnic group reflected the higher rate of infection rather than the underlying host differences between the groups in their ability to control the disease. As uncertain as international comparisons may be, at least in adults the course of HIV-1 infection appears to be roughly comparable across the major racial groups. What racial and ethnic differences have been observed in disease progression have been modest and largely attributable to factors other than race or ethnicity. In African settings where more rapid development of AIDS has been observed, it has usually been attributed to poor nutrition or other immunocompromising conditions rather than race per se [240, 241]. Still, although the data are thin, some direct racial comparisons suggest that real differences may exist. In an earlier study of the natural history of the infection, including MSM of different racial and ethnic backgrounds, and in more recent analyses of European cohorts, individuals of African descent have appeared to be at a slight advantage as measured by slower decline in CD4 cell count or lower viral load [242–244]. No similar direct comparisons including Asians have been made.

5.11 Genetics

A number of genetic influences on progression of HIV-1 infection have been proposed, but relatively few have been confirmed [245]. For the several gene systems discussed here, the epidemiologic and experimental evidence is more consistent and compelling. The first heritable effect on the course of disease to be convincingly documented was that of the gene, now known as *CCR5*, which encodes the major co-receptor for HIV-1 on the surface of target cells [246]. About 1–2 % of persons of European ancestry are homozygous for a loss-of-function deletion in that gene that renders their cells incapable of being infected by the form of the virus that is most often transmitted. Elegant laboratory experiments along with numerous population studies have confirmed that virtually all of these individuals are completely protected from acquiring the infection [247]. Furthermore, heterozygotes, whose risk of HIV-1 infection is little if any lower than those carrying two copies of the fully functional gene, show modestly prolonged AIDS-free times and lower viral load set points [248]. Other polymorphisms in the coding and promoter regions, and its neighbor, *CCR2*, appear to confer different degrees of risk on their carriers [247, 249]. In addition, research on the loci encoding several chemokines, the natural ligands of this co-receptor, has generated more controversial evidence that polymorphic alteration in their gene structure or their copy number affects both the risk and course of HIV-1 infection. For *CCL3L1* in particular, despite elaborate epidemiologic and biological studies as well as a meta-analysis indicating that relatively low numbers of copies of this gene confer a slightly higher risk and less favorable outcome of infection, methodologic concerns and inconsistency in the results have left uncertainty about its role [250–252].

A second major gene system also exerts considerable influence on the course of infection and very likely on its acquisition as well. The major histocompatibility complex, known in humans as the human leukocyte antigen (HLA) system, is a cluster of genes encoding proteins with clefts that bind small antigenic peptides derived from the host or foreign biological material including viruses. Two principal classes of HLA molecules (HLA-I and HLA-II), complexed with their bound peptides, migrate to the surface of antigen-presenting cells, where they may be recognized and destroyed by effector (CD4 or CD8 T lymphocytes). The HLA genes are extraordinarily polymorphic, and some of the innumerable allelic variants encoded by class I genes are more or less efficient than others at stimulating a strong CD8 cytolytic T-lymphocyte (CTL) response. Certain HLA-I alleles, most notably HLA-B*57 but others as well, have been conclusively shown to alter the rate of disease progression differentially, and the preponderance of evidence indicates that they do so by exercising variable control of viremia beginning

soon after infection occurs [253, 254–256]. Each of at least a half-dozen HLA-I variants has been associated with up to a 0.5 log difference in the virus copies/ml of plasma, and they may operate additively [256, 257]. The involvement of HLA-I polymorphisms in the control and evolution of HIV-1 infection has been extensively corroborated in comprehensive population studies and in experimental work demonstrating highly HLA-I sequence-specific cytotoxicity for epitopes in regions of the virus that tend to be more essential to its fitness for replication [258–260].*257*

Further studies of polymorphisms in HLA-I and in HLA-II genes have suggested, albeit not yet so persuasively as for the HLA-I effects described above, that they exert other influences on susceptiblility to or control of infection [261–263].

Strong evidence has been emerging for involvement of a third, even more complex system of genes encoding natural killer cell receptors—the killer cell immunoglobulin-like receptor (KIR) loci. Different combinations of KIR genes are present or absent in each individual, and the genes themselves show considerable sequence polymorphism. In aggregate they may enhance or diminish the overall effects of the natural killer cells. KIR gene polymorphism may have its own independent effect, but HLA-I molecules also serve as ligands for KIRs, and the two systems likely act in close concert. Both population and functional studies have suggested that at least one such gene combination (*KIR3DS1*/*KIR3DL1*), and even more likely certain products of the latter gene, in conjunction with particular HLA-I alleles, confers a more favorable disease prognosis [264]. The intricate HLA and KIR systems and their interactions have just begun to be explored in the depth that will be required to unravel their full contributions to HIV-1 infection and disease control.

Epidemiologic associations of DNA sequence polymorphisms in a number of other candidate genes have been reported with HIV-1 viremia or disease progression. However, these associations generally lack definitive replication at the population level along with unambiguous evidence that the variations lead to meaningful differences in gene function. It is also worth mentioning that, even for the firmly established genetic relationships with disease course, their prognostic value has not been considered high enough to justify the addition of genotyping to the measurements already being used (i.e., viral load and CD4 cell count) for management of patients in clinical practice or as stratification variables in context of treatment trials.

At the dawn of the genomics era, high-throughput genotyping technology with assays for hundreds of thousands of human single nucleotide polymorphisms (SNPs) to cohorts of HIV-1-susceptible and HIV-1-infected individuals held early promise of detecting previously unrecognized key genetic determinants. However, these genome-wide association studies (GWASs) have been surprisingly unenlightening [245]. Few if any new variants beyond those already discovered in and near the HLA genes have withstood rigorous confirmatory analysis, probably for any of several reasons. To date GWASs have incorporated neither the sample sizes needed to detect key but infrequent variants nor the technology needed to detect key structural differences nor the bioinformatics needed to recognize transcription factor binding or mRNA splice sites. Deeper insights into genetic influences on HIV-1 infection may have to await the application of newer, even more powerful study designs, laboratory methods, and analytical approaches.

5.12 Coinfection

A large body of research has addressed the role of coinfecting agents in altering the course of the disease among HIV-1-infected individuals. It was natural to suspect that other retroviruses (HIV-2 and HTLV-I and HTLV-II) would enhance the pathogenetic processes initiated by HIV-1; however, evidence is meager and potentially conflicting. In some studies, those coinfected with HTLV-I have experienced poorer clinical outcomes, especially neurologic complications [265–267], while another study demonstrated a survival benefit with HIV-1/HTLV-II coinfection [268].

In West African countries impacted by HIV-2, up to 1 % of HIV-2-infected persons may be infected by HIV-1 as well. In these dually infected patients, the evidence for their mutual impact has been somewhat inconsistent. Similar rates of mortality from dual and HIV-1 monoinfection corroborate the greater virulence of HIV-1 as a pathogen [269, 270]. However, a report from a cohort in Guinea-Bissau whose participants had known times of HIV-1 acquisition suggested that the small number who had antecedent HIV-2 infection had a slower rate of disease progression than those with HIV-1 infection alone [271].

Because HIV-2 represents a less virulent pathogen, there has been great interest in investigating whether HIV-2 can either protect against HIV-1 acquisition or attenuate the natural history of HIV-1 progression in dually infected individuals, thus providing lessons for design of either preventive or therapeutic vaccines. However, these questions have been difficult to answer conclusively through epidemiologic studies. In the case of protection against HIV-1 acquisition, it is difficult to ascertain or control for level of sexual exposure to HIV-1 and investigators have reported mixed findings [272]. With regard to the question of whether HIV-2 attenuates the pathogenicity of HIV-1 by retarding disease progression, it is often difficult to ascertain which virus was acquired first in dually infected individuals through serologic surveys alone. Furthermore, the availability of effective antiretroviral therapy in West African countries obligates researchers to

provide access to care and treatment at the time of HIV-1 diagnosis, thus altering the natural history of dual infection.

The devastating impact of infection with HIV-1 and *Mycobacterium tuberculosis* on individuals and whole populations—a so-called syndemic in regions with high dual prevalence—has generated intense concern [56, 273, 274]. By every epidemiologic, clinical and experimental measure, HIV-1 and TB are a deadly combination. By the end of the first year of HIV-1 infection, the risk of active TB doubles. The case–fatality ratio for incident TB in HIV-1-positive people appears to be more than twice the ratio in HIV-1 negatives—due to a faulty immune response to mycobacteria, delayed diagnosis of either HIV-1 or TB, and delayed or ineffective treatment of one or both of the infections. On the other hand, the effect of latent or clinically apparent TB on the course of HIV-1 infection is far less certain. Carefully analyzed observational population studies are quite sparse, and reports that TB alters isolated immunologic or virologic responses relevant to the control of HIV-1 have been difficult to interpret or remain unconfirmed. Furthermore, treatment of active TB in 111 coinfected and prospectively followed South African patients did not significantly improve their viral loads or CD4 counts [275].

For coinfection with hepatitis C virus (HCV), the experience is much the same as for TB. Dually infected individuals with immune deficiency due to HIV-1 have intractably higher and more sustained HCV viremia (even with ordinarily more effective HCV treatment [276, 277]), and they follow an accelerated course of hepatocellular destruction and death. This rapid decline may be due to the adverse effects of microbial translocation on hepatic inflammation and fibrosis [278, 279]. In contrast, although certain studies have suggested that HCV coinfection hastens the development of AIDS or is associated with less robust response to cART [280], other work including a meta-analysis casts doubt on those findings [281].

The most noteworthy if not yet conclusive evidence for an effect of coinfection on the outcome of HIV-1 infection comes from a series of reports about the favorable influence of a virus called GBV-C—a flavivirus (formerly known as hepatitis G virus) that replicates primarily in lymphocytes but is not known to cause disease in humans. In 1998 the first of a number of investigations documented a protective effect among HIV-1-positive subjects, among whom up to 40 % of some subgroups have been coinfected with GBV-C [282, 283]. A meta-analysis has indicated that rates of progression were about 2-fold slower in dually infected individuals compared with those without GBV-C infection in the period beginning 2 years after the onset of HIV-1 infection [284]. Numerous experiments have suggested several mechanisms by which GBV-C may interfere with fusion and entry of HIV-1 into target cells or suppress T-cell activation required for HIV-1 replication. Findings in different populations have not been uniformly positive, and laboratory experiments have not yielded definitive biological explanation of the protective effect, but supportive evidence continues to accumulate [285, 286].

Investigation into the potential impact of various other coinfecting agents (e.g., herpesviruses, hepatitis B virus, HTLV-II, and agents of malaria) on the pathogenesis and course of HIV-1 infection has been less convincing.

5.13 Recreational Drugs, Alcohol, and Tobacco

Many of the substances used for recreational (i.e., nonmedicinal) purposes were implicated as risk factors for sexually transmitted infections (STIs) even before HIV/AIDS appeared. In light of their documented capability of stimulating or disinhibiting high-risk behavior, it has not been necessary or even possible to invoke additional biological activity to explain their associations with high rates of STIs.

In contrast, there have been many efforts to link the use of various chemicals to an atypical (usually a more rapid) course of HIV-1 infection or to other complications. For any of several reasons, these efforts have generally fallen short of their goal. The research has shown inconsistent or insignificant effects; the observed associations could be relatively easily explained by biased selection of subjects (e.g., individuals who may have changed their pattern substance use after developing HIV-1 infection or symptoms of advancing disease) or experimental work has failed to confer biological plausibility on the observed effects. Considerable attention has also been devoted to how these substances might disrupt immunobiological pathways involved in resistance to the pathogens causing AIDS-defining OIs [287]. Here the data are somewhat more persuasive, but still inconclusive.

Results of studies on alcohol use and disease progression typify the findings relating substance use to HIV-1 infection. Population and clinical studies have more often than not yielded equivocal or no evidence of an association, whereas experiments on animal or human biological material have suggested perturbation of some features of the immune system [288]. Work on associations of amphetamines, opiates, and other classes of recreational drugs with HIV-1 disease progression itself has likewise been inconclusive; on the other hand, experimental and clinical studies of these substances specifically on the pathogenesis of neurologic manifestations of the infection are more noteworthy. With regard to tobacco use, although smoking has long been known to predispose to respiratory tract infection (e.g., *Pneumocystis* pneumonia) and may alter certain immune system functions along with lung microanatomy, those effects have not translated into acceleration of HIV-1 disease at the clinical level.

5.14 Nutrition

Vitamins and micronutrients have deservedly received considerable attention because dietary supplementation has previously been credited with success in reducing morbidity and mortality from various childhood infections, and it is relatively simple and an inexpensive intervention to provide. While observational studies have found that low vitamin A levels are associated with increased MTCT, randomized trials have actually demonstrated increased risk with vitamin A supplementation [289]. Differences in stage of maternal HIV-1 disease may account in part for these contradictory observations. Fortunately, consistency in the salutary effect of vitamin A on disease progression in infants and children has been more reassuring.

Multivitamin supplementation (specifically with vitamins B, C, and E) has also been widely promoted as protective, although the evidence is uneven. Overall nutritional status has received much attention in the underdeveloped regions of Africa and Asia. In these impoverished areas, close concurrence of malnutrition with generally poorer health as well as other potential cofactors (e.g., vitamin deficiency, TB, malaria) and with systematic problems of diagnosis and management of HIV-1 infection has made it difficult to isolate the independent contribution of nutritional deficiency to a more ominous disease course.

5.15 Sex Hormones

The role of sex hormones, particularly those used by women for contraception, has also received attention. In brief, there is evidence that they prevent MTCT, but in a carefully analyzed prospective study in African women, neither oral nor injectable contraceptive hormones accelerated HIV-1 disease progression [290]. Sparse findings with male hormones as used by MSM have not suggested that they confer any excess risk.

5.16 Occupational, Physical, and Sociobehavioral Factors

Factors such as occupational and environmental exposures, physical exertion and trauma, psychological stress, and others have also been proposed as determinants of HIV-1 infection or disease progression. As already discussed, workers in the commercial sex and health-care industries are at higher risk of acquiring infection than those in most other occupations for obvious reasons. By the same token, it is difficult to envision how a factor as nonspecific as stress could be dissociated from behaviors that increase the risk of HIV-1 infection well enough to establish its independent causal relationship in an observational study. Likewise with regard to disease progression, the associations reported almost invariably have more plausible explanations. At best, the supporting data are usually equivocal; more generally the findings remain confounded, unconfirmed, and/or unaccompanied by strong biological plausibility.

5.17 HIV-2

5.17.1 Mortality

As suggested above (Sect. 3), the most reliable mortality statistics probably come from Guinea-Bissau, where median survival with HIV-2 infection during the 18-year period before ART became available in 2007 was significantly decreased compared with survival of uninfected individuals but approximately twice as long as in individuals with HIV-1 infection [50]. More on the reciprocal influences can be found in Sect. 5.12.

5.17.2 Morbidity

As implied by the longer survival among persons infected with HIV-2 than those infected with HIV-1, the course of infection with the former is more indolent. The distribution of clinical complications would also be expected to be more characteristic of the opportunistic infections seen in West African populations.

5.17.3 Prevalence and Incidence

Seroprevalence surveys conducted in the mid-1980s documented the presence of a second distinct retroviral infection (HTLV-IV, subsequently renamed HIV-2) in a cluster of cases identified in Senegalese prostitutes in 1987. Serosurveys conducted in other African countries documented that HIV-2 was highly concentrated in West African countries, including Guinea-Bissau, the Gambia, Cape Verde, Mali, and Sierra Leone, with cases few or nonexistent in countries of central, eastern, or southern Africa.

Although initial fears that the epidemic of HIV-2 could quickly expand to the rest of the continent, these fears were somewhat allayed by several early reports from suggesting that HIV-2 may be less transmissible compared to HIV-1. The first observation came from a community-based prevalence survey in Guinea-Bissau showing that the highest prevalence of HIV-2 infection occurred in the oldest (>40 years) age stratum, evidence that either HIV-2 exposure or transmission efficiency in that community might have been decreasing [291]. The overall prevalence in adults was 8.9 %. A follow-up population-based study in the same region documented an incidence rate of 1 per 100 person-years [292]. Another report from the West African region focused on a dynamic cohort of high-risk group, Senegalese female sex

workers, and followed them for an average of 3.2 years during the period from 1985 through 1992. The overall incidence rate for both HIV-2 and HIV-1 infections was the same (1.1 per 100 person-years). However, the HIV-1 incidence rate showed an increasing trend, while for HIV-2 it remained stable during that study period [[293]. From all of these data together, it was reasonable to infer that HIV-2 had been present in the Senegalese population for a relatively long time and that the HIV-2 epidemic was either reaching a steady state condition or waning. These reports further suggested that the level of infectiousness of HIV-1 may have been greater, because its incidence was increasing despite its lower prevalence relative to HIV-2.

HIV-2 has been detected in many places outside of West Africa, although the infection can usually be connected to that region in some way. From a summary of nationwide surveillance statistics for the period 2000–2009, newly recognized instances of HIV-2 infection in the USA have averaged 12 per year [294]. Over 80 % of those have a connection to West Africa, and about half of them were reported from New York City. The total number reported is likely to be an underestimate because nearly 60 % were initially misclassified as HIV-1 by the Western blot, and other undoubtedly go unrecognized.

5.17.4 Epidemic Behavior and Contagiousness of HIV-2

Epidemiologic data have demonstrated that the modes of transmission of HIV-2 infection are the same as those of HIV-1 (sexual, maternal to child, and blood borne), although lower rates of transmission for HIV-2 suggest reduced capacity for spread [293, 295, 296]. This reduced risk of transmission for HIV-2 for a given mode likely reflects the presence of fewer viral particles of HIV-2 than HIV-1 at comparable stages of infection [297]. While of HIV-1 has moved rapidly throughout sub-Saharan Africa to cause devastating generalized epidemics in much of the continent, epidemics of HIV-2 have remained focused in West Africa near the epicenter of its initial introduction into the human population or among groups who have migrated directly from those locations. Some reports have indicated either a plateau in prevalence of HIV-2 or modest waning of the epidemic, but simultaneously increasing prevalence of HIV-1. That increase in HIV-1 prevalence raises doubts that implementation of public health strategies to prevent HIV-2 transmission is the principal reason for its decline.

5.17.5 Geographic Distribution

As noted, several decades after the initial reports of this distinct retrovirus, HIV-2 has remained relatively confined to West African countries with only limited spread even to countries that have historic ties to this region and therefore migration. Clusters of infection with HIV-2 have been reported in Portugal (historically linked to Cape Verde), in North America among immigrants from West Africa, and in regions of India linked to Portugal during its colonial era [297]. This relatively focused epidemic contrasts with the HIV-1 pandemic, which spread rapidly throughout the African continent during the same time frame.

5.17.6 Temporal Distribution

Epidemiologic reports that have focused on HIV-1 and HIV-2 surveillance in relatively consistent populations over time have documented either stable or waning prevalence. In an STI clinic in the Gambia, the prevalence of HIV-2 decreased from 7 to 4 % with each sequential serosurvey performed between 1988 and 2003. In contrast, HIV-1 prevalence rose significantly from 4.2 to 17.5 % with each successive wave of sampling, despite relatively constant average CD4 cell counts at time of diagnosis [298]. These reports are consistent with very early predictions of epidemic trends discussed in Sect. 5.2.3.

5.17.7 Other Factors Influencing Acquisition and Control of Infection

In view of the unequivocal influence of HLA-I polymorphism on the control and course of HIV-1 infection (see Sect. 5.11), it would be surprising if it were not involved in the control of HIV-2 infection. However, given the exquisite specificity in the peptide-binding properties of HLA molecules, the class I alleles implicated in HIV-2 infection have, predictably, been distinct from those consistently implicated in control of HIV-1 [299]. Indeed, differences between HIV-1 and HIV-2, not only in their interaction with HLA molecules and KIR ligands but in other gene systems as well, may help explain the more benign course of the latter infection.

6 Mechanisms and Routes of Transmission

HIV-1 is transmitted by blood and other biological fluid, especially genital secretions, which may be cell-free or contain infected cells. Major routes of transmission involve sexual (anal, vaginal, or oral) contact with an infected person, sharing of needles or other injection paraphernalia with an infected person, or perinatal (transplacental, intrapartum, or postpartum from breastfeeding). Transfusion of blood products from infected individuals in locations where those products are not properly screened and removed from the supply is now, fortunately, a relatively uncommon to rare mode of transmission throughout most of the world. Although the virus can be found in saliva, the circumstances under which it may be transmitted by the oral route remain controversial. Despite sparsely documented claims to the contrary in the early years of the epidemic, the virus does not naturally reproduce outside of humans. It does not spread by the airborne, waterborne, or animal vectorborne routes; and transmission is not known to occur through an insect bite, saliva,

tears, sweat, casual contact (e.g., shaking hands or sharing tooth brushes, razors, or dishes), or closed-mouth or social kissing [299–302].

6.1 Men Who Have Sex with Men (MSM)

AIDS was first recognized in MSM, and they accounted for the intense transmission that spread the infection through the urban areas of the USA and both Europe and Caribbean (e.g., Haiti) during the early stage of the epidemic [303–305]. In the first dozen years, this risk group dominated as the source of cases in the USA as well as in other more developed countries of Latin America, Northern and Western Europe, Australia, and New Zealand.*302*

By back calculation from cases and deaths occurring in the 1990s, the incidence of HIV-1 infection in MSM peaked a decade earlier [45]. Then, presumably because of the catastrophic increase in the numbers of deaths and modification of high-risk behaviors, infection rates gradually began to fall. They were followed by a decline in AIDS diagnoses and deaths with a lag corresponding to the 8–10-year median latency period before the advent of effective ART.

Although morbidity and mortality has declined in all groups with access to HAART (Sect. 5), unfortunately, the earlier downward trajectory of new infections in MSM has not been sustained. Prevalence in MSM remains at 10–30 % in parts of the world with both lower and higher incomes; for example, in 2008 estimates in six West African countries ranged from 10 to 25 % [306]. In the USA annual incidence in this risk group has reached a plateau of 2–3 %, and MSM represented nearly two-thirds of the 47,500 new infections in 2010 (Fig. 43.10). As an example of how refractory this group is to prevention efforts even in the most advanced countries, as recently as 2008 nearly one-quarter of the 20–29-year-old African–American MSM around the USA were infected, yet far too few were aware of it [307]. Concern now focuses on overcoming the particular barriers to enrolling MSM, in both advantaged and disadvantaged populations, into health systems where they can receive treatment effective at both controlling the disease and preventing the infection [308].

6.2 Heterosexuals

Transmission between men and women is now the dominant mode in most regions and countries of the world. However, the intensity and pattern of heterosexual transmission differs greatly from one place to another depending on the number and nature of partnerships to which infected individuals tend to belong, the intensity of prevention efforts, access to ART, and other factors.

6.2.1 Global

Although connections between cases in the USA and Haiti at the onset of the epidemic involved predominantly MSM, bisexual and heterosexual spread in Haiti was also documented soon after AIDS was recognized [309]. Almost simultaneously it appeared in heterosexuals living in and emigrating from francophone countries of central and eastern Africa. Over the next decade, rampant spread, particularly concentrated in the less developed areas of the world, transformed the numerous separate introductions into a pandemic of 20 million infected, with a sizable majority of those infections occurring in heterosexual men and women in nearly equal proportions. The multiplicity of partnerships and certain distinctive sexual practices in regions of sub-Saharan Africa intensified transmission there, in contrast to the more circumscribed occurrence in Asia, where relatively fewer infections were transmitted heterosexually. The intensity of exposure among commercial sex workers and their high risk is well documented [310].

Paradoxically, there is a subset of sex workers in Kenya and other heavily exposed sex partners who have remained seronegative for inordinately long intervals [311, 312]. The mechanism(s) of their protection would be especially important to discover and has been the focus of attention. However, it remains controversial whether these sex workers and other exposed seronegatives were protected by effective T-cell-mediated immune responses typical of long-term controllers or by some as yet unknown form of immunity; careful study of CTL and humoral responses in different groups of these exceptional individuals have yielded inconsistent results [313, 314].

From the statistics cited in Sect. 5, there are clearly whole countries where, until implementation of massive intervention programs began, the health impact and socioeconomic consequences of heterosexual HIV-1 transmission represented an existential crisis. Lately, the delivery of critical health services under the auspices of large-scale enterprises like The Global Fund for AIDS, Tuberculosis and Malaria and the President's Emergency Plan for AIDS Relief has reversed some of the more ominous trends in heterosexual transmission (see Sect. 9). Nevertheless, the existing burden of morbidity and prevalent infection and the socioeconomic obstacles to effective delivery of resources are still formidable.

6.2.2 USA and Other Developed Regions

In the initial stages of the epidemic in the USA, relationships between women and MSM or IDUs accounted for most of the heterosexual transmissions. Not unlike the situation in urban Africa and Asia, commercial sex work served as another pathway for movement of the virus into the general population—in much the same way as it did in those regions (see Sect. 5). In the ethnic and other subcultures where

"drugs for sex" was a common nexus, it has also been a particularly powerful amplifier of heterosexual transmission. Expansion of HIV/AIDS into the heterosexual populations in the more developed regions of North and South America, Europe, Australia, and New Zealand proceeded at a pace that was less alarming than some observers predicted. Nevertheless, the burden for the health and social systems of these populations remains serious. In 2010 one-quarter of all new infections in the USA were heterosexually transmitted (Fig. 43.10).

6.3 Parenterally Exposed

6.3.1 Injection Drug Use

Accurate population-based estimates of occurrence of HIV/AIDS in IDUs have always been difficult to obtain because of the uncertain numbers at risk and because injection as the mode of transmission may be confounded by the extensive drug use among members of high-risk sexual networks. It was nevertheless clear as soon as epidemics took hold in individual countries of the developed world that, relative to the general populations of most countries, IDUs would be the most severely affected by HIV-1 infection.

As noted above cross-sectional studies during the first 15 years of the epidemic established relationships of HIV-1 risk with a variety of injection-related activities including older age, duration of drug use, and geographic proximity to a high-transmission area, frequency of syringe sharing, and use of "shooting galleries" (places to buy drugs and rent injection equipment) [206–208, 210]. Many of these predisposing factors were and still are intertwined with high-risk sexual practices (e.g., sex in anonymous venues, transactional sex) and involve multiple partners. In a prospective analysis, subjects reporting sexual exposure to an HIV-1-infected partner had a fourfold increased risk of infection, independent of needle or syringe sharing [206]. Similar to other studies of heterosexual transmission of HIV-1, this risk was higher for women than for men.

Prevalence in IDUs rose rapidly during the 1980s, and new infections continued to occur throughout the 1990s particularly in Spain, Portugal, and Italy, followed by countries in Eastern Europe and states in the western part of the former Soviet Union at the beginning of the new millennium. In some of these countries, increases have continued at an alarming pace (Fig. 43.15). Thus, the pattern of HIV-1 infection in IDUs worldwide now varies markedly, depending on the prevalence of injection drug use in a given region as well as the uptake and penetration of public health countermeasures to minimize transmission risk (Sect. 9).

Beginning in the late 1980s, there was an explosive rise in new HIV-1 infections among IDUs in South and Southeast Asia. In Thailand within a matter of 5–7 years, prevalence reached at least 40 % in some communities. Following efforts to implement more aggressive prevention policies for all risk groups, the rapid increase infection ceased rather abruptly. Even so, the experience in Thailand illustrates the difficulty of uniformly sustaining or reversing established trends in every risk group and every location. Despite a decline in new IDU-associated infections in the northern

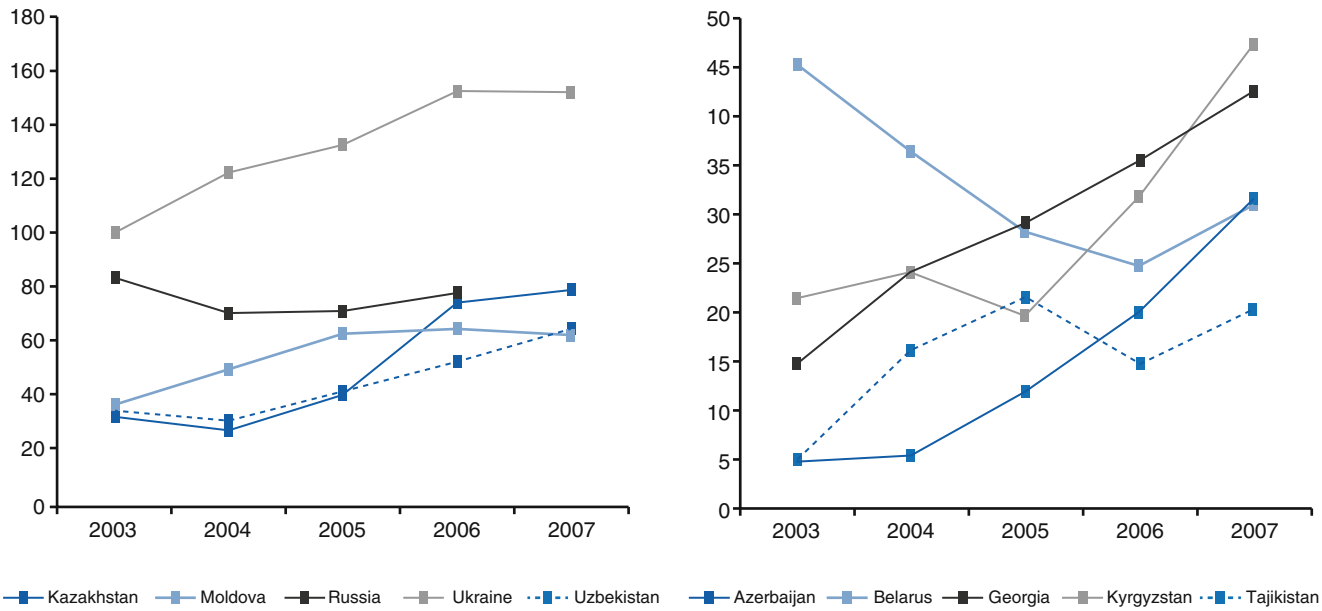

Fig. 43.15 Newly diagnosed reported HIV infections among injecting drug users, rate per million population, no EU/EFTA countries in the eastern part of the WHO European region, 2003–2007 (Reproduced with permission from Wiessing et al. [315])

Thai provinces, overall prevalence remained high because that improvement was offset by increases in the central region and Bangkok. Thus, overall prevalence peaked in the 1999–2001 period and has fluctuated in the 25–50 % range in more recent surveys [226]. Moreover, those consistently high proportions contrast sharply with the remarkable reversal of trends in other risk groups, where the 2008 prevalence figures of 2.5–5 % represent two- to fivefold reductions during the preceding 13 years.

In 2007 the number of people worldwide who inject drugs was estimated at 16 million [316], of whom approximately three million were infected with HIV-1. The largest numbers of IDUs living with HIV-1 were in Eastern Europe, East and Southeast Asia, and Latin America. In most of the 49 countries reporting 2012 data to UNAIDS, the prevalence of infection in IDUs was above 2 %, and in 11 of them it was at least 50-fold higher than in the general population [56]. Further perspective on this particularly refractory population can be found in Reference [308].

6.3.2 Contaminated Blood Products

The hazard associated with continual exposure to the factor concentrate between 1981 and 1984 was extremely high. Soon after testing for HIV-1 antibodies became available, 20–90 % of hemophiliacs who had received commercial factor VIII concentrate preparations in the USA between 1978 and 1984 were discovered to be seropositive (Fig. 43.16). Prevalence depended on severity of the disease and amount of concentrate used [317]. It also depended on the source of the concentrate. Hemophilia A patients for whom commercially available products were used had HIV-1 prevalence of 60–90 %; in contrast, hemophiliacs in countries that made their own products from non-risk donor populations had much lower prevalence [318].

At the peak of transfusion transmission, before the implementation of donor deferral procedures, as many as 1 % of all donations in San Francisco were HIV-1 contaminated [203]. From 1984 onward rigorous screening of the donated blood products and exclusion of contaminated units from the supply in most countries where testing was readily affordable, the prevalence and incidence in hemophiliacs, and other less susceptible transfusion recipients declined precipitously. Lately, recombinant DNA technology has been used to produce clotting factors for treatment of coagulation deficiencies, thus eliminating the risk of blood-borne pathogen exposure altogether.

Further precautions in the form of nucleic acid testing (NAT) added to standard serology were introduced beginning in 2000 in the USA, Europe, and many other countries. An example of the impact can be seen in the report from 93 Italian transfusion centers where NAT screening of more than ten million units of blood between 2001 and 2006 eliminated the already rare event of an HIV RNA-positive but still

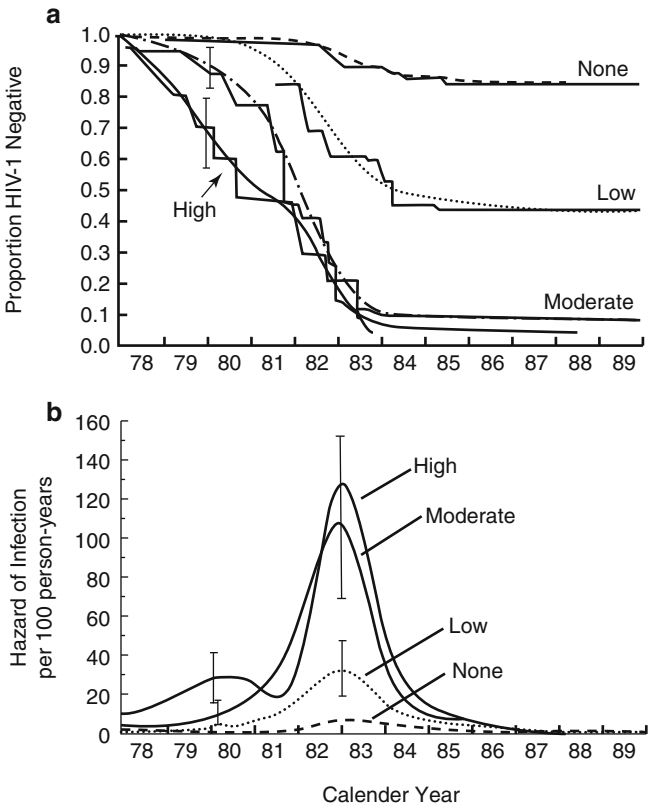

Fig. 43.16 Hazard of HIV prevalence in hemophiliacs. Estimates of (**a**) the HIV-1-free survival curve and (**b**) the corresponding hazard rate for members of the five-center cohort with type A hemophilia, grouped by mean annual dose of factor VIII concentrate used between 1978 and 1984 (Reproduced with permission from Kroner et al. [317])

seronegative donor. NAT excluded an additional 1.8 RNA-positive units per million units screened seronegative [319].

In economically challenged areas, introduction of screening of blood products and precautions for eliminating iatrogenic and related transmission by reused infusion equipment have been far more gradual and variable. A particularly egregious disregard of hygienic practices occurred between 1990 and 1994 in at least one province of China (Henan) and has probably occurred elsewhere. Pooling of plasma from multiple donors during collection, re-infusion of red blood cells, and reuse of tubing at innumerable commercial plasmapheresis centers were responsible for thousands of HIV-1 infections before public health authorities intervened [320].

6.3.3 Contaminated Injection Equipment

HIV-infected blood on needles, syringes, and other medical equipment can survive for up to 2 h outside of the body. WHO recently estimated the overall worldwide probability of acquiring HIV-1 infection by a medical injection at 1.2 %; other estimates have varied from 0.1 to 6.9 % [321]. The absence of training, new equipment, and sterilization resources in developing countries has accounted for gross hygienic

failures reported from such places as Kazakhstan [322] and Romania, where both contaminated injections and unscreened blood transfusions accounted for thousands of new infections. Recent efforts to eliminate such unsafe practices have been more successful when support has come from the international aid groups focusing on this issue (see Sect. 9).

6.3.4 Needle-Stick Injury

At the initial stages of the epidemic, the potential for transmission from relatively casual exposure to biological fluids raised fear among those caring for AIDS patients in the health-care systems around the world and in laboratories handling infected biological materials [216]. Early estimates of risk per contact partially relieved the fear (Sect. 5). However, percutaneous injuries from hollow-bore needles that had penetrated an artery or vein, shown blood on the device or contacted an AIDS patient, continued to pose appreciable risk of transmission [323]. In successive publications, most recently in 2005, CDC reported attempts to quantify the risk of occupational transmission of HIV in the USA (approximately 0.3 % after percutaneous exposure to HIV-infected blood and 0.09 % after mucous membrane exposure) and to update recommendations for postexposure prophylaxis (PEP) in health-care settings [324]. This latest guidance also reiterated that the risk for transmission after non-intact skin or mucous membrane exposure or from fluids or tissues other than HIV-infected blood is unknown but probably considerably lower than for blood exposures. In developed countries, incidence of infection has dropped as the prevalence of unrecognized and untreated infection has declined and guidelines for PEP have evolved, although its acceptance by health-care workers and first responders has varied greatly not simply by the degree of risk but also by occupational, setting, gender, and temporal factors [325, 326]. Current figures for transmission by needle stick in high prevalence, poorly resourced areas like sub-Saharan Africa and Asia are difficult to obtain, although rates of infection are undoubtedly higher than in developed countries.

Fortunately, in the USA and other developed countries, despite their close care of HIV/AIDS patients and/or high frequency of documented needle-stick, surgical exposures or other accidents, health-care and laboratory workers have experienced low seroconversion rates, which declined further after the widespread adoption of blood/secretions precautions [327].

6.4 Perinatally Exposed

Vertical or mother-to-child transmission (MTCT) of HIV-1 infection may occur antepartum (in utero), intrapartum (at delivery), or postpartum (via breastfeeding). The first probable cases of perinatal transmission of HIV-1 infection in the USA were reported within months after AIDS was recognized [328]. During the first decade of the epidemic in the USA, case numbers rose steadily, peaking at nearly 1,000 in 1992, and then declined rapidly following implementation of testing and preventive interventions (Fig. 43.17). By 2002 CDC estimated that 144–236 HIV-infected infants were born

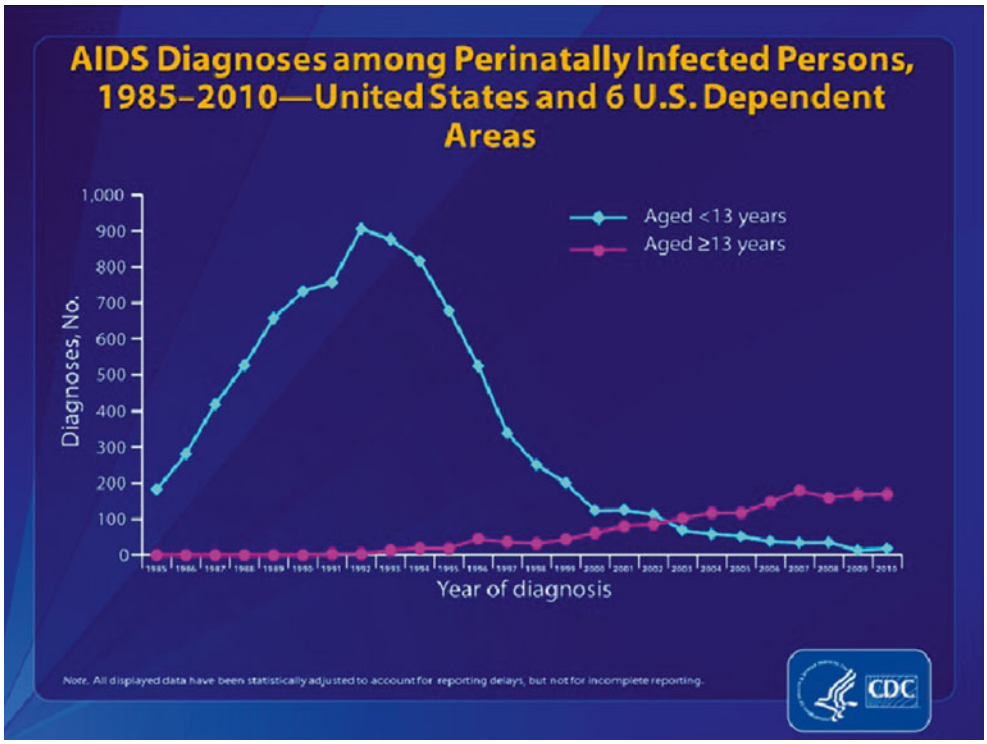

Fig. 43.17 AIDS diagnoses among perinatally infected person, 1985–2010 – United States and 6 U.S. Dependent Areas [329]. Data adjusted for reporting delays and for estimated proportional redistribution of cases in persons reported without an identified risk factor

in the USA, and the numbers continued to fall to a very few each year. The USA has implemented detailed recommendations for interventions in pregnant women to prevent all but a small number of MTCTs, and comparable approaches have led to similar success in most other developed countries [330, 331].

At the international level, the progress has been less favorable. Unfortunately, overall no more than half of pregnant women and probably considerably fewer have been receiving appropriate treatment for their own health, and even in the southern regions of sub-Saharan Africa, where prevention programs have been promoted aggressively, perinatal transmission has only dropped from 35 to 20 %. In economically marginalized regions, MTCT has occurred almost 2.5 times more frequently than in the general population.

Several factors modulate the likelihood of vertical transmission. Maternal plasma viral load is probably the most important determinant of whether transmission will occur, but other factors also play a role [332, 333]. Advanced maternal immunodeficiency, concomitant genital infection, and chorioamnionitis may be independent risk factors. Delivery by elective Caesarian section has been shown to reduce intrapartum transmission, although the availability of that option has been limited in resource-poor regions.

Breastfeeding increases the risk of postpartum transmission and accounts for perhaps one-third of all perinatal HIV-1 transmission. However, because breastfeeding is widely accepted as improving overall health of the infant, recommendations against its use in places lacking access to effective prophylactic drug regimens have been one of the biggest challenges. In 2006 WHO recommended that infected mothers be counseled individually and decide between options including breastfeeding or not. Soon thereafter, several ART trials of breastfeeding mothers or their infants demonstrated the capacity of treatment to reduce total MTCT rates to 1–5 % at age 6 months. As a result in 2010 WHO began emphasizing either breastfeeding with an established ART regimen or none at all.

6.5 Other

There are rather rare anecdotes of cutaneous or mucous membrane exposure that may have led to HIV-1 infection in home settings [334, 335]. More systematic household studies covering more than 1,700 person-years of follow-up revealed no infections (95 % confidence interval: 0–0.2 infections per 100 person-years) [336, 337].

6.6 Host Cofactors for Transmission or Acquisition

Much work on contagiousness has been done in the context of sexual transmission. Early epidemiologic studies demonstrated that ulcerative or other inflammatory genital infection coincided with or antedated HIV-1 infection among MSM and heterosexuals [338–341]. Whether these relationships with transmission and/or acquisition of HIV-1 infection represent predispositions due entirely to biological properties of the coinfecting etiologic agents themselves, to the mucosal disruption or attraction of inflammatory cells, or to other coincident host characteristics has not been definitively established for all of these agents.

Most of the evidence favors the second mechanism. Loss of integrity of the genital tract lining or skin due to ulcerative genital infections [e.g., syphilis, herpes simplex virus type 2 (HSV-2), or chancroid] provides a clear path whereby HIV-1 can reach its subepithelial target cells. In addition to the agents causing genital ulcers, chronic infection with other organisms responsible for disrupting the genital mucosal surfaces (e.g., *Trichomonas vaginalis* and bacterial vaginosis) has been associated with acquisition of HIV-1 infection [342, 343]. Alternatively, the concentration of HIV-1 in semen is much higher in men who have both HIV-1 infection and an STI (e.g., with *N. gonorrhoeae* or herpes simplex virus) than in men with HIV-1 alone [344]. Inflammatory genital infections may lead to increased risk of HIV-1 transmission by raising the concentrations of those target cells in genital fluid [345, 346].

Trials of antimicrobial agents known to suppress or cure these infections (e.g., HSV-2, *Trichomonas*) have achieved some suppression of target pathogens and may decrease genital shedding of HIV-1. Nevertheless, treatments for HSV-2 and other STIs have disappointingly failed to reduce the incidence of HIV-1 infection [347].

The evidence for relative protection of circumcised men (but not their female partners) has come largely from clinical trials in Africa. The reductions in acquisition achieved in those trials have been the basis for the inclusion of circumcision in prevention strategies described in Sect. 9.

The host genetic factors known or thought most likely to modify HIV-1 transmission from an infected host or its acquisition by a susceptible host are discussed in Sect. 5.

HIV-2 is spread by the same routes as HIV-1, although in the case of heterosexual transmission, probably at a lower rate. This lower level of contagiousness is likely due to the lower level of free HIV-2 virions in the plasma compartment for a given disease stage. Because HIV-2 is less easily transmitted and has been largely confined to West Africans and

those in contact with them, epidemiologic research on HIV-2 transmission between discordant partners has not received the same attention accorded HIV-1. As a result, event-level risk estimates of transmission and investigation into cofactors have not been as systematic or refined. In a report from rural Guinea-Bissau, the level of provirus in HIV-2-infected male partners was associated with concordant serology in wives, and older women appeared to be more susceptible [348]. In cross-sectional analysis, ulcerative genital disease has also been associated with an elevated risk of HIV-2 infection, as observed with HIV-1 transmission [349].

7 Pathogenesis and Immunity

7.1 HIV-1

Our understanding of exactly how HIV-1 induces AIDS remains incomplete despite substantial insights gained over 30 years of intense genetic, molecular biological, and immunologic research. The schematic portrayal (Fig. 43.18) of the interrelationship between expression of HIV-1 and the decline in CD4 lymphocytes oversimplifies the broad interpersonal variability of the process [128, 350–352]. In vitro HIV-1 mimics, in a crude way, the in vivo natural history of the virus in that HIV-1 targets and infects the CD4 cell and causes cell lysis [139]. AIDS pathogenesis involves complex interactions of the virus with an organ whose very core functions that would ordinarily defend against that virus are subverted to promote virus replication. Sophisticated molecular approaches often coupled to epidemiologically well-defined populations have gradually expanded our understanding of the pathogenic process from infection to end-stage failure of the immune system [353–358].

HIV-1 exists and can be transmitted as cell-free and cell-associated virus in the semen, vaginal fluids, blood, and plasma [359, 360]. HIV-1 cannot survive outside of the bloodstream or lymphatic system and quickly dies when outside of this environment. As such HIV-1 is only transmitted in situations where infected blood or secretions

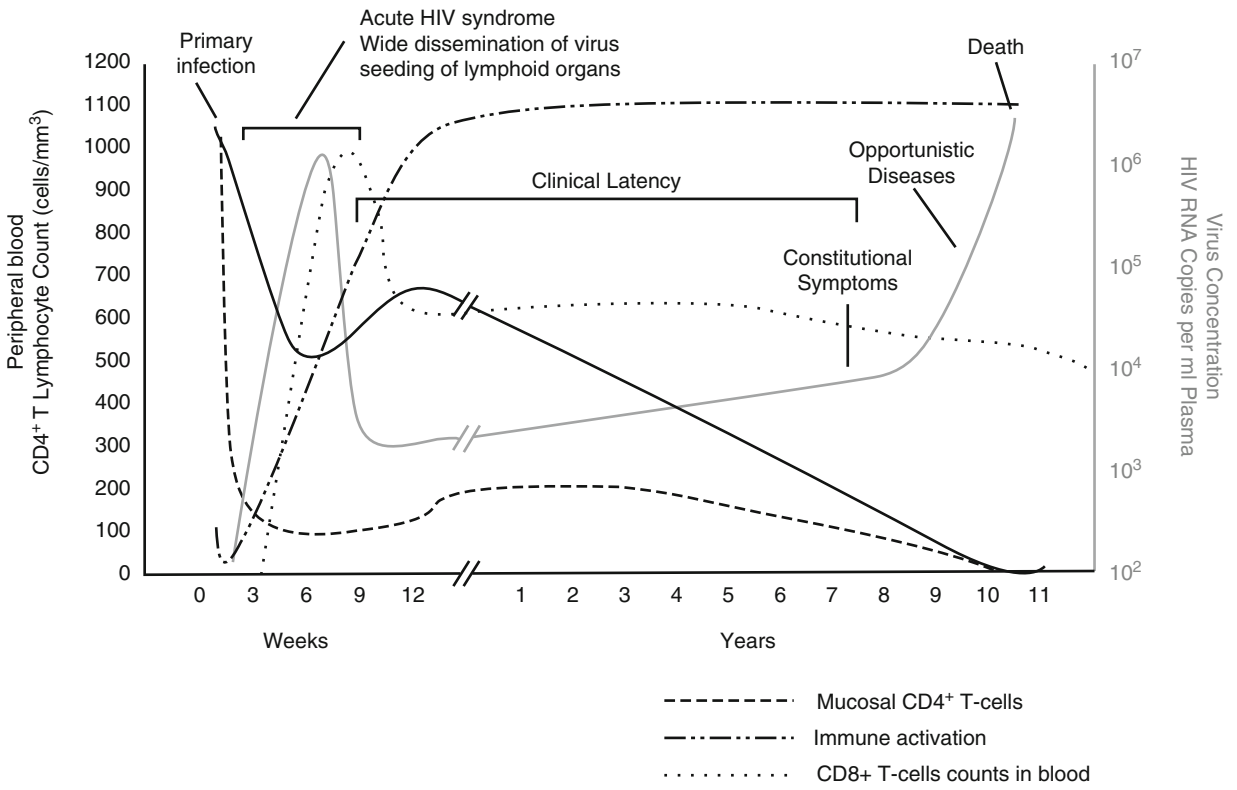

Fig. 43.18 Typical course of HIV infection. During the early period after primary infection, there is widespread dissemination of virus and a sharp decrease in the number of CD4 T cells in peripheral blood. An adaptive immune response to HIV ensues with the induction of antibodies and cell-mediated immunity. This stage is followed by a decrease in detectable viremia and a prolonged period of clinical latency. Immune activation that is both HIV-1 specific and nonspecific develops following acute infection and persists thereafter. The CD4 T-cell count continues to decrease with varying speed during these years, until it reaches a critical level below which there is a substantial risk of opportunistic infections and neoplasms typical of AIDS (Diagram is courtesy of Nilesh Amatya and LaTonya Williams)

come into contact with mucosal tissue or damaged skin (e.g., via abrasions from needles or sexual intercourse). Depending on the route of infection, the initial target of infection is either the tissue dendritic cell, the CD4 lymphocyte, or the monocyte–macrophage [361]. Recent data suggest that HIV-1 replication first occurs in a small number of resting CD4 T cells in the genital mucosa [362]. No matter the route of infection, the vast majority of transmitted HIV-1 viral isolates that have been characterized use CCR5 rather than CXCR4 as their co-receptor [363]. As noted earlier, the 1–2 % of persons of European ancestry who lack expression of CCR5 are highly resistant to HIV-1 infection; if they acquire infection, it is with a virus using CXCR4 [364, 365]. In different circumstances the differential trophism of the virus for either lymphocytes or macrophage-related cells may be important because the number and availability of different target cells may vary; however, much of the evidence suggests that CD4 T cells represent the dominantly infected cell type early during infection [362, 366]. As indicated earlier, the virus load in a potential transmitter may determine the success of an infection as well; epidemiologic studies have consistently associated the presence of antigenemia and high viral loads with increased risk for infection [256, 367, 368]. Also, ulcerative genital infections may increase the risk of infection by disrupting normal protective barriers and enhancing inflammatory cell exudation, thus increasing numbers of susceptible target cells.

HIV-1 diversity in a population and even in a single patient with chronic infection can be an enormous, yet remarkably, establishment of infection following heterosexual transmission usually occurs with a single viral strain [363, 369]. Even in transmission in MSM and IDUs, the median number of viral strains establishing infection is relatively low [370, 371]. Within 72 h of establishment of viral infection, HIV-1 infects the site of infection and the draining lymph nodes [372]. Within the first week, the infection becomes systemic and the virus disseminates to other lymph node compartments in addition to infecting a number of different tissues including the brain and kidney; however, most of the early replication takes place in the lymph nodes [373, 374]. Virus is generally detectable in the blood by day 8 following infection and demonstrates a doubling time of about 0.3 day during the first 2–3 weeks of infection [113, 372–379].

Since the GI tract has the largest concentrations of lymph nodes, early infection is characterized by extensive viral replication in this tissue [355, 380]. Furthermore, data in both humans and rhesus macaques point to the rapid depletion of CD4 T cells in the gut as a major factor in disease pathogenesis [355, 380–382]. Because CD4 T cells are rapidly depleted in the gut following acute HIV-1 infection, the host is left with a relatively impaired immune system unable to properly contain gut pathogens from undergoing persistent microbial translocation [383]. This process in turn likely leads to chronic immune activation contributing to immune pathogenesis from the onset of infection and continuing even when viral replication is controlled with cART [353, 384]. In fact, major research effort in the era of cART has been devoted to understanding the causes and treatment of persistent immune activation that is likely contributing to early immunosenescence and cardiovascular, kidney, and liver disease in addition to higher rates of diabetes in patients whose HIV-1 is controlled on treatment [385, 386]. As disease becomes more severe and CD4 cells become increasingly depleted, there is increasing disruption of lymph node architecture and destruction of the follicles. Thus, the pathogenesis of HIV-1 disease involves not only destruction of large numbers of circulating lymphocytes, especially CD4 cells, but also destruction of the lymphoid organ itself, i.e., stromal tissues and those with specific functional responsibilities for regeneration and immunologic diversity [387].

Figure 43.18 represents a typical disease course for the vast majority of those infected with HIV-1. Following acute HIV-1 infection, rapidly replicating virus achieves very high copy numbers within 2–3 weeks following infection, with viral load usually above one million copies/ml. It is during this viremic phase that the acute seroconversion syndrome described below occurs [388]. Concomitantly, CD4 T cells in the peripheral blood also decline, with the rate and level of decline varying markedly between individuals [387, 389]. It is interesting that the decline of mucosal CD4 T cells is more profound initially and remains so during the entire disease course. As discussed previously, this gut depletion of CD4 T cells likely contributes to the onset of immune activation, which persists throughout infection [353, 354, 380]. During the first month of infection, long-lived viral reservoirs become established [390] with large numbers of viral particles being sequestered in follicular dendritic cells, where HIV-1 is protected from destruction [391]. In smaller numbers, HIV-1 integrates into resting CD4 T cells that serve as a latently infected viral reservoir [392, 393] with a long life span (about 44 month half-life). The latter process is one of the main reasons that current cART is not likely to achieve a cure [390, 391].

The viral load begins to decline within 4–6 weeks following infection associated with an increase in the host responses of CD8 T cells and antibodies [113, 373, 379, 394–402]. Neutralizing antibody responses generally takes longer to appear (8–24 weeks) but likely plays a role, along with other arms of the immune system, in establishing the viral load set

point that takes place during this time period [403, 404]. At this point the CD4 T cells partially recover but never achieve their preinfection levels. In most untreated individuals, a period of clinical latency ensues during which no symptoms attributable to HIV-1 infection occur. This latent period lasts around 8–10 years on average but varies greatly [405, 406]. During this long latency, however, while there is persistent viral replication and CD4 T-cell turnover, the host is able to maintain at least some level of viral control [407, 408]. Nevertheless, in the vast majority of situations, sooner or later the host immune system fails, and untreated patients develop AIDS and die.

The process by which HIV-1 causes the progressive destruction of CD4 T cells and the immune system is not entirely known but is likely multifaceted. Mechanisms include the direct lytic destruction of cells by the virus, immune killing of virally infected cells, cellular apoptosis, innocent bystander killing, and possibly destruction of the stem cells [354, 382, 409–415]. The principal markers that have been used to predict disease progression include viral loads, CD4 T-cell counts, and measures of immune activation [37, 416–419]. There is some evidence that CD8 T-cell immune activation is the best predictor of disease progression [420], although this measurement has not been adopted for clinical use. In general terms, viral load measurements are used to predict progression to AIDS with the higher loads correlating directly with disease progression. Absolute CD4 T-cell counts are more often used to determine the stage of disease but also correlate with outcome. Disease progression is also reflected in increasing virus load in lymph nodes and the disruption of lymph node cytoarchitecture, particularly the destruction of the follicular dendritic cell network [350, 357].

The determinants of virus control are poorly understood but certainly involve host genetic determinants of immune response, especially those in the human leukocyte antigen type I (HLA-I) system [253, 255], as well as characteristics of the virus phenotype [421]. As noted in Sect. 5, genetic epidemiologic investigations including genome-wide association studies of clinical outcomes or with viral load set point have consistently demonstrated that certain HLA-I alleles, most notably HLA-B*57, are associated with a favorable response [253, 255, 422]. This particular HLA allele occurs at high frequency in patients who maintain an undetectable plasma viral load far longer than others in the absence of cART (so-called elite controllers). The data on these protective effects of HLA-I suggest that CD8 T cells play a vital role in HIV-1 control since HLA-I molecules present epitopes to these cells. Additionally, CD8 T cells force extensive mutation in the virus as it attempts to escape recognition [394, 423–426]. The evidence from humans along with nonhuman primate models of HIV-1 infection [402, 427] all points to an essential role for CD8 T cells in viral control. It is equally clear that innate host factors are playing a role in HIV-1 control; among the important factors recognized to date are CCR5 (the viral co-receptor) [246, 247], TRIM5α (blocks HIV-1 capsid uncoating) [428–430], APOBEC3G (cytosine deaminase countered by HIV-1 vif) [431], and cyclophilin A (proline isomerase important for HIV-1 infection) [432]. Indeed, nearly every major arm of the immune system studied now appears to be working in concert to control HIV-1.

For disease progression of HIV-1 acquired neonatally, a more complex pattern reflects factors associated with timing of infection, e.g., parturient versus prenatal. Children who progress to AIDS in weeks to months (median, 4.1 months) are thought to have acquired infection in utero [433, 434]. For the remainder (median, approximately 6.1 years [435]), infection appears to have occurred later in the perinatal period. Besides timing of infection, additional determinants presumably include viral load and viral strain [435]. Among children and adolescents infected after birth, the natural history of infection also differs from that seen in adults. For example, the time from exposure to CD4 lymphocyte count <200/mm^3 occurs more slowly in children, adolescents, and young adults than in those over 30 years of age [436, 437]; likewise, once a CD4 count falls below 200/mm^3, disease progresses more rapidly in older than in younger individuals [12, 438]. The young immune system may mount a more effective initial response or a more robust recovery.

7.2 HIV-2

HIV-2 is less pathogenic than HIV-1; it causes slower CD4 T-cell decline and a 1.5- to 3.5-fold higher than normal mortality rate compared with a 5- to 10-fold excess rate seen with HIV-1 infection in Africans [439]. Other studies have demonstrated that disease progression can be very heterogeneous with some individuals actually progressing fairly rapidly to AIDS following HIV-2 infection. At high CD4 T-cell counts, there is a clear survival advantage in HIV-2-infected individuals, but this advantage tends to wane in older age groups and when immune suppression is matched with that seen in HIV-1 patients [269, 440]. Interestingly, plasma viral load set points are about 30-fold lower in HIV-2-infected patients than in their HIV-1 counterparts [441, 442], and most asymptomatic HIV-2 patients have undetectable plasma viral load [443, 444]. Nevertheless, baseline plasma viral load appears to be a good predictor of survival [440, 443, 445], and when baseline viral loads are matched, the median

rate of CD4 T-cell decline is similar for both infections [446]. Markers of immune activation also seem to predict disease progression with HIV-2 infection [447], but levels of these markers are generally lower when compared to HIV-1 [448]. Furthermore, the manifestations of AIDS due to HIV-2 mirror those due to HIV-1 except that rates of Kaposi's sarcoma may be lower [449].

The mechanism behind the slower rates of disease progression seen with HIV-2 infection is not clear but is likely multifactorial. This virus has appeared less fit in vitro [450], and replication kinetics of the virus seem slower in HIV-2 than in HIV-1 aviremic controllers [451]. Furthermore, the immune responses made by both CD4 and CD8 T cells to specific viral antigens tend to be stronger in patients with HIV-2 infection [452–455], and neutralizing antibody responses measured in one small study were also more robust in HIV-2 infection [456–458]. Finally, innate factors involved in HIV-1 control (e.g., TRIM5α [459] and APOBEC [460, 461]) have been implicated in control of HIV-2 infection as well.

8 Patterns of Host Response

8.1 HIV-1

8.1.1 Primary Infection

An acute viral syndrome, characterized as a "flulike" syndrome with fever, rash, myalgias, mouth sores, and occasionally reversible encephalitis, has been reported among persons undergoing seroconversion [462]. Up to 2/3 of persons with primary HIV-1 infection make an acute clinical response while the rest remain asymptomatic [463–467]. It is difficult to determine the percentage of persons who exhibit the clinical syndrome of primary HIV-1 infection because many of the signs and symptoms are nonspecific. Fever (up to 40 °C) occurs in the majority (80–90 %) of symptomatic patients; malaise, anorexia or weight loss, myalgias, and arthralgias occur in about half. Fewer than half of acutely ill patients complain of headache, pharyngitis, or rash; and complaints of diarrhea or mucosal ulcers are even less common. Meningeal signs may be present, but more specific neurologic findings are rarely observed. The nonspecificity of the symptoms makes the acute retroviral syndrome difficult to distinguish from various other acute viral syndromes. They may or may not bring patients to medical attention [468]. Laboratory findings include general leukopenia with CD4 lymphopenia, atypical lymphocytosis, and thrombocytopenia in addition to abnormal liver function tests [469, 470]. Symptoms of acute HIV-1 infection generally resolve after 2 weeks; however, the number and duration of these symptoms directly correlate with worsening disease prognosis [396, 471–473]. Recently highlighted beneficial immune effects of starting early ART has provided new incentive to pursue early diagnosis of acute HIV infection [474–478].

8.1.2 Chronic Infection

While HIV-1-infected persons may remain free of serious clinical sequelae for an extended period of chronic infection, the virus is not quiescent but rather continues to replicate in the lymph nodes [361, 387]. The persistent generalized lymphadenopathy often found in a sizable percentage of HIV-infected persons relatively early in their course [479] may reflect the role of the lymph node as a harbor for HIV-1, but lymphadenopathy does not predict the rate at which opportunistic infections or HIV-associated malignancies will develop. The resolution of lymphadenopathy has been suggested as an ominous prognostic sign by some investigators [480] but not others [481].

Depletion of CD4 lymphocytes occurs throughout the course of HIV-1 infection, but the rate of CD4 lymphocyte loss varies dramatically between individuals [482]. This deficiency in CD4 cells is the primary mechanism by which HIV-1 infection leaves an individual vulnerable to life-threatening opportunistic infections and cancers. However, because the CD4 lymphocytes play such a central role in maintaining cell-mediated immunity [483], their loss may also be a more direct cause of some of the conditions seen with HIV/AIDS.

8.1.3 End-Stage Disease

Opportunistic Infections

Persons with HIV-induced immunodeficiency are more susceptible to diseases caused by a large number of commonly encountered parasites, fungi, bacteria, and viruses. In the USA, serious common opportunistic infections include *Pneumocystis jirovecii* pneumonia (formerly known as *P. carinii*), pulmonary or disseminated *Mycobacterium tuberculosis* infection, disseminated *M. avium* complex infection, meningitis caused by *Cryptococcus neoformans*, toxoplasmic encephalitis, chorioretinitis due to cytomegalovirus infection, and many others (Table 43.1). Life-threatening infections generally do not develop until an HIV-infected person has suffered considerable loss of $CD4^+$ lymphocytes (<200 total $CD4^+$ lymphocytes per microliter), but less serious conditions, including oral candidiasis (thrush), persistent herpes simplex virus infection, and herpes zoster (shingles), may present earlier in the course of HIV infection [97, 463, 467].

The incidence of specific HIV-associated opportunistic infections varies by HIV-risk group, geographic location, and time. Injection drug users are more likely to suffer *M. tuberculosis* infection than are MSM [484], while the incidence of disseminated *M. avium* complex infection does not vary by risk group [485]. Diseases such as tuberculosis

and toxoplasmosis are common in HIV-1-infected persons throughout Africa [486]. *P. jirovecii* pneumonia, originally thought to be rare in Africa, also appears to be common there [487]. The incidence of endemic mycoses (e.g., histoplasmosis, coccidiomycosis) varies geographically within the USA in association with the known geographic distribution of these infections [488]. Other mycoses are endemic in different geographic locations: *Penicillium marneffei* in Southeast Asia and *Paracoccidioides brasiliensis* in South America [489, 490]. Since cART became more widely available, the incidence of all opportunistic infections has declined significantly, but *P. jirovecii* pneumonia still remains the most common of them [491–494].

Neoplasia

Kaposi's sarcoma (KS) and non-Hodgkin's lymphoma (NHL) are strongly associated with advanced HIV-1 infection; both are AIDS-defining illnesses. In the USA, KS signaled the beginning of the AIDS epidemic among MSM and became the most common cancer occurring in HIV-1-infected patients. KS tends to appear earlier in the course of HIV-1 infection than serious opportunistic infections or NHL, and the hazard for development of KS is less strongly related to the time since infection or degree of immunosuppression [495]. The incidence rate of NHL, especially high-grade B-cell lymphoma, is markedly higher in HIV-1-infected persons [496, 497] and increases with age as it does in with non-AIDS-associated NHL [498]. Compared to KS, NHL is distributed more uniformly among all risk groups and appears later in the course of HIV-1 infection. HIV-1 infection may lead to NHL primarily because of decreased immunosurveillance, but evidence suggests that in some instances, HIV-1 may cause NHL by insertional activation of an oncogene [499]. AIDS-defining cancers have declined precipitously since cART became widely available [500]. See Chaps. 39 and 40 or more on AIDS- associated cancer.

As AIDS-defining cancers were disappearing in cART-treated HIV-1 patients, certain non-AIDS-defining cancers were increasing in incidence. The explanation for this relationship is unclear, but reactivation of infection with other viruses may be partly responsible. Hodgkin's lymphoma (due to Epstein–Barr virus), cervical or anal cancer (due to human papillomavirus), and hepatocellular carcinoma (due to hepatitis B or C) all occur at higher rates in HIV-1-infected patients [312, 501–503]. They may emerge because of HIV-1-induced immune system defects that persist despite substantial immune reconstitution with cART. In particular, when treated individuals are compared with HIV-1 seronegative controls, they exhibit a higher level of chronic immune activation, leading in turn to T-cell exhaustion and immunosenescence. Those phenomena likely contribute to the increased risk of cancer in HIV-1-infected patients just as happens with aging in persons without HIV-1 infection [504–506].

8.1.4 Healthy Long-Term Nonprogressors and Elite Controllers

A small minority (probably <1 %) of patients with HIV-1 infection can control viral replication and/or disease progression in the absence of cART [482]. Originally recognized as maintaining stable CD4 T-cell counts for ≤15 years following infection, these untreated individuals were later shown to have low levels of viremia as well [507]. A "viremic controller" group can maintain plasma viral loads at <2,000 copies/ml [367, 508], a level associated with both decreased transmission and slower rate of disease progression. An "elite controller" group can maintain plasma viral load at <50 copies/ml, the lower limit of detection in the assay used at the time this cohort was originally defined. More recently, with a detection limit at <20 copies/ml, of plasma, an even smaller subset would be categorized as having an "undetectable" viral load. Even in elite controllers, however, certain characteristics of their HIV-1 infection (e.g., immune activation) suggest progression, albeit at much slower rates [509, 510].

After intense study, although much is still unknown about why these individuals are so effective at suppressing the virus, it is clear that both viral and host characteristics contribute to this exquisite control. A fascinating, inherently defective virus with a deletion of the gene for nef generated great interest when it initially appeared that it might account for slow disease progression [511, 512]; however, most of the individuals infected with this virus eventually progressed to later stages of infection, and further research has failed to demonstrate significant viral deletions leading to replication deficits in HIV-1 controller patients [513]. In contrast, numerous studies have demonstrated the importance of different facets of the immune response in viral control. Innate factors (APOBEC3B and Trim5α), NK cells, antibodies, and T cells have all been associated with disease progression; however, the most convincing evidence for immune control in chronic HIV-1 infection has been assembled for CD8 T cells [514]. HIV-1-specific CD8 T cells from controllers tend to proliferate better, express their functional capacity more strongly, and target distinct proteins of HIV-1 [515–518]. Furthermore, CD8 T cells induce many of the mutations seen in viral proteins other than envelope, in an attempt by the virus to escape these CD8 responses. This immune pressure by CD8 cells on key viral proteins further reflects their importance in controlling viral replication [258, 423, 426]. Finally, studies show that HLA-I is strongly associated with disease progression, more so than any other human gene [253, 255]. Since a cardinal function of HLA-I is to present HIV-1 peptides to CD8 T cells for immune recognition and

control, the HLA-I associations corroborate the importance of this cell subtype in viral control.

8.2 HIV-2

As previously noted, disease in patients infected with HIV-2 progresses at a slower rate than in those infected with HIV-1 [439]; however, progression rates for both infections are similar for individuals with similar plasma viral load [446]. Furthermore, the clinical manifestations of HIV-2-associated AIDS do not appear distinctive [519–521].

Not surprisingly, a greater percentage of individuals with HIV-2 infection are able to control virus without therapy, and most asymptomatic patients have undetectable viral load [443, 444]. The reasons for this enhanced viral control seen in HIV-2-infected patients are poorly understood; however, their numbers of CD4 and CD8 T cells tend to remain higher for longer, and the function of those cells remains more intact. Moreover, HIV-2 appears to generate enhanced neutralizing antibody responses [452–458].

9 Control and Prevention

Buoyed by recent progress through simplified treatment regimens and the success of treatment as prevention, some have raised prospects of "the end of AIDS," while others emphasize the unique and formidable challenges to reaching that goal. One of the greatest challenges is the etiologic agent itself. Although other retroviral infections affect humans, no other has been so pernicious and pervasive as HIV-1. It not merely evades many of the usual immune mechanisms but actually infects and destroys the very cells vital to coordinating an effective response. In addition, eradicating HIV-1 in individuals presents an especially high hurdle compared with other chronic viral infections (e.g., hepatitis B or herpes viruses) because the former establishes latency by integrating into the host genome of these key cells so tightly as to defy complete displacement or destruction by any technique. An assault on the virus in this critical and sensitive location must be mounted cautiously. Finally, HIV-1 mutates extensively with tolerable loss in replication capacity, readily adapting to the natural immune pressure applied by successive new hosts and, in some measure, to the drugs and immunizing agents developed to date. All the more remarkable then is the steady stream of success at developing increasingly safe, effective, and affordable pharmaceuticals, and the application of these drugs on a population scale was unimaginable less than a decade ago. However, there are no illusions that the approaches to treatment currently in use will likely prove feasible or desirable as a long-range solution. Other promising breakthroughs have involved new insight into viral persistence and strategies for shrinking the reservoir virus or infected cells, as well as an ostensible proof-of-principle "cure" of HIV infection by bone marrow transplantation or extremely early antiretroviral treatment [522–524].

Those successes have impelled the US National Institutes of Health to commit substantial resources to cure research [525].

No less challenging than the biological barriers to effective control are the behavioral and social ones. Campaigns for abstention from high-risk practices and more promising risk reduction strategies have yielded mixed success at achieving and maintaining lower rates of incident HIV-1 infection: gains have been documented in certain populations (e.g., heterosexual couples), while relapses have occurred in others (e.g., young MSM). In the developed world, much of the stigma and prejudice that accompanied the original expansion of the epidemic through and beyond the MSM populations has dissipated, although it has not disappeared entirely. In less advantaged regions, the ignorance, denial, fear, ostracism, and taboos that so often shadow poverty have continued to retard prevention efforts tied to sexuality and gender. Even in the USA and some other advanced countries, it is the social, political, and legal issues that are the stubborn impediments to manifestly effective the needle exchange paradigm.

The following, in more concrete terms, is a summary of the approaches and accomplishments in dealing with these challenges at the public health level.

9.1 Public Health Approaches

The HIV/AIDS was and still is an unprecedented worldwide public health threat of HIV/AIDS has required unprecedented global public health responses. The world was unprepared to deal with the impending pandemic during its early years, but the global effort now represents an extraordinarily comprehensive, collaborative, and costly array of public health programs. Because HIV affects numerous risk groups and uses several alternative routes of transmission, it has required the multipronged attack described below.

9.1.1 Prevention of Parenteral Transmission

Screening of Blood Products

With the availability of serologic testing for HIV in 1985, widespread screening of the blood supply was added to behavioral screening of volunteer blood donors. In 1999 the USA instituted the use of nucleic acid tests (NATs) on pooled donor samples. This strategy improved detection of HIV during the so-called seronegative window, a period usually lasting weeks during which a donor may be infected but may not produce antibodies. With NATs, the risk of HIV transmission related to blood product transfusion in the USA decreased from 1 in approximately 500,000 donated units (1995) to 1 in

1.5 million donated units (2007–2008). Similar screening approaches have been adopted by most other countries with sufficient resources. For a decade, the US President's Emergency Plan for AIDS Relief (PEPFAR) has been assisting national blood transfusion services in countries with the greatest need for prevention of transfusion-transmitted HIV. From 2007 forward, varying numbers of these countries have implemented or planned safe blood collection policies, increased the numbers of whole blood units collected from voluntary uncompensated donors, decreased the proportions of HIV-reactive units [294].

Needle and Syringe Programs (NSPs)

As a measure to prevent HIV transmission among IDUs, public health programs focusing on the exchange of used for unused needles and syringes have been introduced in a few countries (e.g., the United Kingdom and Australia), often in connection with other harm reduction services. In Australia, early widespread coverage of the IDU population with NSPs has been credited with preventing a significant HIV epidemic among this risk group, despite the continuing parallel HIV epidemic due to sexual transmission in that country [526]. In 2004 a WHO panel reviewing the experience with NSPs up to that time concluded that the evidence for the efficacy, safety, and cost-effectiveness of NSPs for HIV prevention was compelling [527]. Contrary to this forceful endorsement, throughout many countries including the USA, the illegality and stigmatizing nature of injection drug use and the challenges inherent in reaching this marginalized population, along with political opposition to NSPs, have precluded the implementation or limited the impact of these programs in some of the most vulnerable populations.

Medical Injection Safety

Until very recently, many health-care facilities lacked the resources to ensure adherence to optimal medical injection practices. In recent years this gap has been addressed by programs like the WHO effort called "The Safe Injection Global Network" (SIGN) alliance, a voluntary coalition of stakeholders aiming to achieve safe and appropriate use of injections [528], and another called "Making Medical Injections Safer" (MMIS) funded in a dozen less developed countries by PEPFAR through the service and training organization John Snow, Inc [529]. These programs have been aggressively assisting governments in the training and education of health-care providers and in promoting proper use and disposal of medical injection equipment along with introduction of single dose, prefilled auto-disable syringes.

9.1.2 Prevention of Sexual Transmission

Condoms

Although research on the efficacy of condom use has varied according to subject selection, advice conveyed, methods of measurement, and other features of study design and execution, multiple studies have demonstrated that consistent and correct use of male latex condoms provide significant protection against infection with most sexually transmitted agents, including HIV. In one analysis of heterosexual HIV-1-discordant couples who reported consistent use of condoms, the HIV-negative partner was 80 % less likely to acquire HIV than persons in similar relationships not reporting condoms use [530]. Based upon this and other similarly persuasive reports, promotion of condom use and widespread distribution of condoms at sites where HIV prevention and care are delivered have been common since risk factors for HIV infection were first identified.

HIV Testing and Counseling

Once serologic screening became widely available in the mid-1980s, HIV testing was targeted to those whose behaviors increased their risk for acquiring HIV (MSM, IDUs, commercial sex workers, and others, with high-risk sexual contact) through publicly funded testing programs. Serologic testing was often linked to client-centered risk reduction counseling so that, in the event of a negative HIV test, the experience of the counseling process would promote risk-reducing behavioral change. Specialized consent procedures for HIV testing were also often required by law. Multiple diverse behavior modification approaches, combining the provision of educational information along with theory-based behavior change counseling, demonstrated some level of efficacy in clinical trials [531], but reports on their effectiveness in "real world" settings were mixed [532]. Nevertheless, public HIV testing programs focused on linking HIV testing to counseling to reduce sexual risk and increasing condom use.

As highly effective antiretroviral drugs were developed in the mid-1990s and ARV therapy became widely available in the developed world, the opportunity cost of a missed case of HIV detection became greater, because it was clear that HAART was increasingly successful in restoring health when initiated before an AIDS-defining clinical condition occurred. Over time, it also became clear in the USA that public health policies based upon targeting specific risk groups (MSM, IDU) led to many HIV-1 infections going undetected. At a practical level for various reasons, individuals often did not perceive their own HIV risk and seek testing, or staff in public HIV testing sites simply could not recognize risk status. In 2006, as noted earlier, the CDC announced a significant shift in HIV testing guidelines—to a policy of "opt out" as the standard approach to testing in clinical settings [137]. These guidelines recommended against any statute or regulation that prescribed special consent procedures for HIV testing. The guidelines did endorse counseling for those who had identifiable behaviors that put them at higher risk for HIV acquisition, but they did not link specialized risk reduction counseling to the administration of a diagnostic HIV test to an individual. Technological

advances in reliable point-of-care HIV serologic tests, which could yield results in less than 15 min, have further facilitated the public health approach of streamlined and widespread HIV testing, both in the USA and globally.

Adult Male Circumcision

Although the benefit of circumcision had been suspected previously, three well-designed and executed randomized controlled trials have demonstrated unequivocally that adult male circumcision reduces risk of heterosexual acquisition of HIV by 55–60 % [533–535]. Thus, implementation and scale up of voluntary male circumcision has become a major public health focus in parts of the world where heterosexual HIV transmission predominates and where medical circumcision of males is uncommon. Reports of long-term follow-up of cohorts who participated in circumcision trials show a very durable protective effect of circumcision [536]. However, formidable cultural and economic barriers must be overcome: variable acceptability, resource limitations, complicating infection, and potential overconfidence among susceptible men about its degree of protection.

9.1.3 Prevention with Antimicrobial Agents

Prevention of Maternal-to-Child Transmission (PMTCT)

The first clear demonstration that antiretroviral drugs could be successfully deployed to reduce HIV transmission came in 1994, when a randomized controlled trial demonstrated a 67 % reduction in HIV transmission from HIV-1-infected mothers to their infants with maternal antepartum and intrapartum use of zidovudine along with administration of zidovudine to the exposed infant during the first 6 weeks of life [32]. This landmark observation coupled with the subsequent demonstration of the safety and efficacy of combination maternal antenatal ARVs provided the impetus for routine prenatal screening for HIV-1 and the recommendation of cART for PMTCT [537]. In settings where breastfeeding is encouraged both for its nutritional advantage and for prevention of other neonatal infections, effective prophylaxis requires continuation of maternal cART along with infant ARV throughout the course of breastfeeding. When optimally implemented in the clinical trial setting, these approaches have resulted in PMTCT rates as low as 1–2 %, raising hope for its elimination under the most favorable socioeconomic conditions [538]. In fact, several international organizations have in turn set the optimistic goal of "virtual elimination" of pediatric HIV-1 infection (i.e., MTCT <5 %) in the foreseeable future [539]. The most recent available UNAIDS report on progress through the Global Plan [540] is relatively optimistic: new HIV infections have declined by an average of 38 % in 21 target countries with progress accelerating in several vulnerable ones, and new recommendations for women and children should lead to improved delivery of HIV prevention and treatment services, earlier initiation of HIV treatment, and harmonization of eligibility and regimens among various populations. Unfortunately, MTCT may persist in less developed countries at far higher rates than it should at this stage of knowledge and capacity [541] if access to cART in those places remains in adequate.

Postexposure Prophylaxis (PEP)

An early case–control study among health-care workers with occupational percutaneous injury resulting in known HIV-1 exposure showed that zidovudine given in the postexposure period was associated with a lower odds of seroconversion (OR 0.19; 95 % CI 0.06, 0.52) [323]. The safety and tolerability of combination ARV as PEP for occupational exposures has also been documented more recently. Based upon these observations, as well as animal data showing its benefits, PEP is recommended within 72 h of occupational HIV-1 exposure as well as other discrete exposure events, such as sexual assaults.

Treatment as Prevention

The strong log-linear relationship between plasma HIV-1 viral load and lower risk of heterosexual HIV transmission was noted previously [368]. Furthermore, ARV therapy in the infected partners of serodiscordant couples resulted in virologic suppression and lower transmission risk [542]. This work culminated in a landmark randomized controlled clinical trial that documented a 96 % reduction in HIV-1 transmission to the uninfected partner of a serodiscordant couple when the HIV-1-infected partner was treated early (i.e., before significant clinical outcomes or damage to the immune system was evident) [543]. This pivotal trial provided compelling justification for early identification of individuals with HIV-1 accompanied by direct linkage to early treatment. This "test-and-treat" strategy has rapidly become the cornerstone of a global public health approach to control the spread of HIV-1 and ultimately reversing the AIDS epidemic [544]. Population-level models based on this strategy predict that the widespread implementation and scale up of combinations of interventions with proven benefit—HIV testing, PMTCT, voluntary male circumcision, early treatment of HIV-infected persons—can lead to reduction of HIV incidence [545]. Widespread implementation of combination prevention packages, along with evaluation of the impact on population incidence, will be required to translate the "test-and-treat" hypothesis into significant gains at the population level. Notably, observational data on the impact of ART scale-up in communities heavily impacted by HIV-1 infection suggest that incidence decreases as ARV coverage in a population increases [546]. Reports from other populations with epidemics in such cities as Vancouver and San Francisco have described sustained declines in HIV incidence with increased testing, increased uptake of HIV treatment, and reduced

"community viral load" (an imputed surveillance measure of community infectiousness) [547, 548]. As heartening as these findings are, considerable effort and resources will need to be invested before early treatment translates into significant reductions in new HIV-1 infections worldwide [549].

9.1.4 Preexposure Prophylaxis (PrEP)

Early efforts at primary prevention in individuals prior to HIV exposure concentrated on vaginal microbicidal agents; however, hopes for success with two promising agents, nonoxynol-9 and cellulose sulfate, were deflated when clinical trials revealed not merely failure to achieve a beneficial effect but potentially increased risk of infection with their use. Lately, clinical trials have been more promising in their demonstration of benefit from various formulations of ARVs used as PrEP by high-risk HIV-uninfected persons. The use of a vaginal gel containing tenofovir applied during the time surrounding intercourse reduced the risk of HIV-1 acquisition in South African women by 39 % [550]. As noted above, daily cART given as treatment actually reduced transmission as well, although the benefit varied greatly by degree of adherence. However, other prevention trials in those at high risk of HIV-1 infection showed encouraging but mixed results with either oral PrEP [551–555] or vaginally applied tenofovir gel [555]. Taken together, these reports have generated cautious optimism that use of daily ARVs as PrEP is beneficial. However, these regimens may only work in selected populations.

Another encouraging development has been the demonstration in a randomized controlled trial among IDUs in Thailand that tenofovir prophylaxis could halve the frequency of new infections in all subjects and reduce infection in an even greater proportion of those with measurable blood levels of tenofovir. On the basis of those findings and additional data suggesting that the combination of tenofovir and emtricitabine is equally safe and optimal for prevention of sexual transmission for which IDUs are also at risk, CDC issued a formal recommendation for combination PrEP among IDUs at very high risk due to both parenteral and sexual transmission [205, 556]. Moreover, adherence to optimal regimens has been irregular, and still other barriers may limit their effectiveness [557].

Finally, other strategies for PrEP, e.g., use of long-acting injectable agents and administration of broadly neutralizing antibodies, are at early stages evaluation.

9.1.5 Government and Civil Society Commitments

As the devastating tragedy of the AIDS pandemic unfolded in the poorest regions of the world, it mobilized UNAIDS, the governments of individual nations in higher resource settings, as well as the civil society and the private sector. Innumerable local, regional, and international organizations now address the broad range of issues and needs. From repeated credits and citations throughout the chapter, the central role of WHO and its operational arm UNAIDS has been apparent. Space does not allow justice to be done to many others; discussion here focuses on two with enormous international presence and the key organization for domestic strategic policy making.

The Global Fund to Fight AIDS, Tuberculosis, and Malaria

Many of the initiatives to deliver drugs and other key resources to low- and middle-income countries have been coordinated by UNAIDS and other organizations. These initiatives have been supported by The Global Fund, which now focuses on generating the resources needed to accomplish its highly ambitious target goals, summarized for 2015 in Table 43.5. Between 2001 and 2013, paid pledges to the Global Fund totaled nearly $24 billion [44], and that does not include the numerous other public and private investments in treatment and prevention programs. On the other hand, resource deficiencies due to Global Fund donor failures to honor pledges in 2011 have highlighted the vulnerability of the global effort even after 10 years of collaboration. In the face of these shortfalls in governmental support, the Global Fund has nevertheless attracted contributions from numerous other private agencies (e.g., the Bill & Melinda Gates Foundation) as well as government entities (e.g., US President's Emergency Plan for AIDS Relief).

President's Emergency Plan for AIDS Relief (PEPFAR)

Launched in 2003, PEPFAR represents the commitment by the US government to funding the global fight against the HIV/AIDS pandemic. By 2012, through bilateral and regional partnerships in over 70 countries, PEPFAR had directly supplied 15 million people with care and support, including provision of ARVs to 4.5 million HIV-1-infected persons worldwide. In 2012, PEPFAR made antiretroviral prophylaxis for PMTCT available to more than 750,000 pregnant women who tested positive for HIV, which averted an estimated 230,000 HIV infections in children. The MMIS program for injection safety mentioned earlier is another initiative supported by PEPFAR.

National HIV/AIDS Strategy

In 2010 the US government developed and publicized the first domestically focused National HIV/AIDS Strategy (Table 43.5). Major goals included (1) reducing HIV incidence, (2) increasing access to care and optimizing health outcomes for people living with HIV, (3) reducing HIV-related health disparities and health inequities, and (4) achieving a more coordinated national response to the HIV epidemic. The plan includes clear and measurable target objectives in these areas to reach by 2015 [558].

Table 43.5 Specific targets set by UNAIDS for 2015

Public health targets	Reduce sexual transmission by 50 %
	Reduce transmission among IDUs by 50 %
	Eliminate new infections among children; substantially reduce maternal AIDS deaths
	Reduce deaths from TB among HIV + persons by 50 %
Investment targets	Reach global investment of $22–24B in low-/middle-income countries to close global AIDS resource gap
Structural and systems targets	Eliminate gender inequalities and gender-based abuse; increase capacity of women and girls to protect themselves from HIV
	Eliminate stigma and discrimination against people living with HIV by promoting laws/policies that ensure full realization of rights and fundamental freedoms
	Eliminate restrictions on entry, stay, and residence for those living with HIV
	Eliminate parallel systems for HIV-related services to strengthen the integration of the AIDS response in global health

9.2 Vaccines

With the announcement of the discovery of HIV in 1984, the Secretary of the US Department of Health and Human Services, naively, declared that an effective vaccine for HIV-1 would be produced in the next two years [559]. Far from realizing that infamous early promise, vaccinologists worldwide have not come close to accomplishing that goal in the three decades since the virus was discovered [560]. This has not been for a lack of effort; a relatively large number of investigators and organizations have accelerated work on an HIV vaccine in recent years [561, 562]. Because many highly efficacious vaccines appear to work by inducing antibody responses [563–568], the field focused on this goal early in the development phase. Antibodies that are able to neutralize virus in vitro (so-called neutralizing antibodies) are particularly desirable since such a response is theoretically able to eliminate pathogens or at least render them noninfectious. Encouraging early preclinical data demonstrated that when serum was transferred from a vaccinated chimpanzee to another chimpanzee in a passive transfer experiment, the recipient chimpanzee would be protected against HIV-1 infection following challenge [569, 570]. Antibody was clearly responsible for this protection because serum contains only proteins and no cellular components from the donor chimpanzee. This finding was initially greeted with much optimism in light of the recent success at development an effective hepatitis B vaccine using a similar approach. However, hepatitis B, a DNA virus with relatively high sequence conservation, posed a far less formidable challenge than HIV-1, an RNA virus with enormous sequence diversity [571, 572]. The realization of this critical distinction was a stark reminder that antibody responses are generally type-specific and would only be expected to protect against a few strains of virus. In fact, when the passive transfer studies were repeated using a challenge virus that was heterologous (in relation to the vaccine strain), the vaccine no longer protected the chimpanzee [573].

Nevertheless, because it was still conceivable that these preclinical studies did not accurately simulate natural HIV-1 infection, a protein-based vaccine was developed using the outer surface protein of HIV-1 termed gp120 [574]. Such a vaccine could induce broader antibody responses but generally not potent cytotoxic T-lymphocyte (CTL) responses. Bivalent HIV-1 gp120 vaccines (made from two viral strains) were tested in two separate trials. The first trial involved mostly MSM at high risk of HIV-1 infection in North America and the Netherlands; they received either vaccine or placebo in a 2:1 ratio, respectively, in a randomized double-blinded control trial [575]. Several years into the trial, the number of HIV-1 infections did not differ between vaccinees and placebo recipients. A comparable trial in a high-risk cohort of IDUs in Thailand yielded similar findings [576]. This approach presumably failed to induce antibodies that could efficiently neutralize heterologous viruses [577–580]. Furthermore, these protein-based gp120 vaccines appeared to neutralize mainly laboratory-adapted viruses rather than strains derived directly from a patient (primary viral strains). Thus, it seemed unlikely that antibody responses targeting a single or at most a few viruses could protect against the large and diverse array of viruses present in any given population.

These disappointing attempts to make a vaccine that would neutralize primary isolates partially redirected the field toward vaccines able to induce CTL responses [581]. CTLs can identify and kill virally infected cells, and they can recognize a broader range of viral strains including primary isolates. CTLs are more difficult to induce than antibodies and usually require recombinant vector technology that encodes HIV-1 proteins allowing cellular presentation of the desired antigen [582]. The best-known recombinant vector involved a recombinant adenovirus serotype 5 (Ad-5) vector developed by Merck that was genetically modified to be replication deficient but encode the gag, pol, and nef proteins of HIV-1 [583]. Preclinical studies using an SIV-1 counterpart in a nonhuman primate model did not protect against infection; however, it did appear to retard disease progression in

that the vaccinated monkeys rapidly controlled viral replication and did not develop AIDS [584]. This other similar findings renewed optimism that although a vaccine might not protect against infection, if it held viral load at lower levels and protected against AIDS, it would still be highly advantageous. This development was even more promising in light of the recent epidemiologic association of decreased transmission risk with lower viral loads [367, 368]. These encouraging developments led to an efficacy trial known as the Step Study in a high-risk MSM and female population mainly in the Americas. Surprisingly, the vaccine not only did protect against infection, it actually seemed to enhance infection risk in the vaccinated MSM who were uncircumcised and/or had preexisting immunity to adenovirus, serotype 5 [585]. Furthermore, the vaccine did not decrease viral load or protect against CD4 T-cell count loss in those who did become infected despite vaccination. As a result, the Phambil study of the same vaccine that was just beginning in South Africa at the time the Step Study findings were released was stopped prematurely [586]. While the mechanisms underlying these findings remain unknown, development of recombinant adenoviruses serotype 5 vectors for use as a commercially viable HIV-1 vaccine has essentially ceased.

More recently, another study evaluating a recombinant Ad-5 vector was undertaken using a series of three DNA primes followed by a single recombinant Ad-5 boost. Unlike the Step vaccine regimen, this vaccine also encoded Env with the hopes of inducing effective antibody responses. Although this vaccine did not protect against infection, at least there was no evidence for enhanced infection in the vaccine group [587].

Concurrent with the Step Study, another efficacy trial in Thailand was testing a vaccine regimen designed to induce T-cell and antibody responses [588, 589]. A recombinant canarypox vector encoding HIV-1 gag, protease, and gp120 (ALVAC) was given in four doses, the last two injections being coadministered with the bivalent gp120 vaccine that by itself failed to confer protection in an earlier Thai trial. About 16,000 Thai individuals at low, moderate, and high risk of HIV-1 infection received either an active vaccine or a placebo. This vaccine regimen conferred about a 31 % overall protection against HIV-1 infection [590]. As with prior vaccines, no change in viral load or CD4 counts was seen in vaccinees who became infected. The modest efficacy rates and the nonsignificant protective effect, mainly in those at low to moderate risk, raised doubts about the validity of this trial. However, subsequent immunologic studies have demonstrated a correlation between protection and vaccine-induced antibody responses to a specific region of gp120 [591]. Although many questions remain, these findings generated enough optimism to plan confirmatory efficacy studies of a similar vaccine regimen and have provided ample scientific rationale for improving upon it [562].

9.3 Antiretroviral Therapy

For virtually no other viral infection has there been either the intensity of scientific investment or the number of commercial successes in treatment or prevention as for HIV-1. Since the first antiretroviral medicine, zidovudine (originally, azidothymidine), became available for the management of HIV-1, enormous progress has been made in the areas of therapy and prophylaxis. Antiretroviral medicines are now able to target multiple parts of the HIV-1 replication cycle (Fig. 43.19).

By 2014, FDA had licensed more than two dozen different antiretroviral medications for clinical use. At the global level, therapy depends on three classes of drugs given singly or in combination: nucleoside reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, and protease inhibitors. However, there is rather broad agreement among the responsible US and European health organizations and WHO on the general recommendations for which HIV-positive patients should receive antiretroviral therapy. This includes recommendations about when to begin treatment in the presence of pregnancy, a history of AIDS-defining illness, tuberculosis, HBV or HCV infection, and HIV-associated nephropathy. Likewise, experts agree that therapy should be administered or strongly considered for prevention of transmission by the perinatal, heterosexual and other high-risk routes [592].

The most up-to-date recommendations and guidance for the many alternative regimens for use in adults and adolescents, children, pregnant women and several other special patient groups in the US are conveniently assembled at the website [593]. However, not all experts and advisory groups agree on an identical strategy for starting treatment with these drugs. At the time this chapter was in press, the US Department of Health and Human Services had taken a more aggressive approach by recommending initiation of therapy in all HIV-positive patients regardless of clinical status, whereas the WHO and the European AIDS Clinical Society were more cautious about treatment of asymptomatic patients who are relatively immunocompetent.

There is also on FDA-licensed agent in at least three other classes of promising drugs—an integrase inhibitor, a CCR5 receptor antagonist, and a fusion inhibitor. Because these agents are rather new and expensive, widely integrated into it is not clear whether and how they may be incorporated into regimens for use at the population level.

Treatment of HIV-1-infected adults with cART has resulted in significant reductions in AIDS-related mortality [492, 494, 594]. With optimal response to cART (a rise in CD4 T-cell counts above designated levels), patients can even safely discontinue taking medications for the primary and secondary prevention of opportunistic infections [595]. Reductions in AIDS-associated morbidity and mortality achieved by cART have been dramatic, but even the most

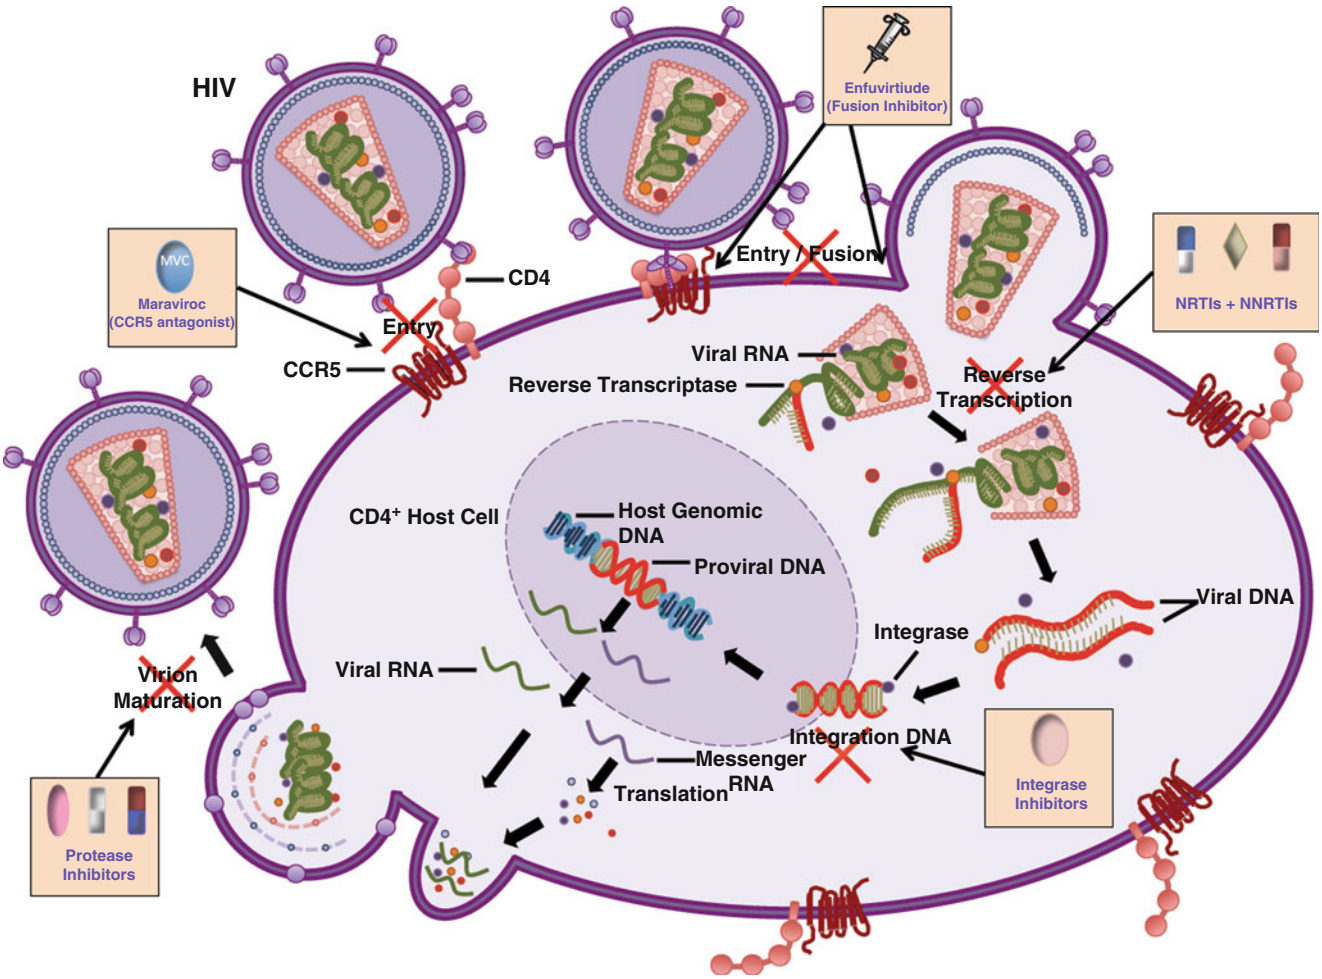

Fig. 43.19 HIV-1 replication cycle demonstrating mode of action of clinically available antiretroviral medications (Diagram is courtesy of Nilesh Amatya)

effective regimens do not completely abolish the chronic persistent immune activation that characterizes HIV-1 infection [510, 596–598], nor are these regimens entirely devoid of side effects of varying severity. Moreover, although it is premature to draw any definitive conclusions, there are indications that this chronically hyperactive immune state could be leading to side effects as described below. Furthermore, now that patients are living much longer without progression of their HIV-1 infection, coinfections such as hepatitis C virus are complicating the management of their disease (see Sect. 5) [599].

A variety of adverse responses to chemotherapeutic agents have occurred in distinctive patterns in populations. Three types of those responses illustrate the breadth of that variability. At one extreme is the case of the nucleoside analog reverse transcriptase inhibitor, abacavir, causing a severe inflammatory reaction. This complication was recognized as due to a striking, epidemiologically documented host genetic predisposition [600], which was promptly replicated in additional population studies and more recently corroborated with experimental work suggesting that drug-induced alterations of the HLA-peptide binding machinery and resulting T-cell response may be the mechanism [601]. A second response to cART is known by the name immune reconstitution inflammatory syndrome (IRIS) and by others. Its characteristic manifestation is a disproportionate immune reactivation including T-cell rebound in the presence of exposure to antigens of a variety of microbial agents and clinically significant opportunistic infections such as tuberculosis [602].

Another more insidious set of complications began to be observed soon after the introduction of the new, highly active protease inhibitors. Alone or in combination with other agents, they appeared to be associated with various patterns of fat redistribution and loss, dyslipidemia, and other metabolic derangements along with significant cardiovascular complications, that had not been previously observed in HIV-1-infected patients treated with other classes of antiretroviral agents [603, 604]. Despite intense study, the pathophysiology of these adverse consequences

of the combination of aging and treatment remains obscure. Although considerable attention has been paid to the adverse responses to agents in the cART repertoire, details about their distribution and determinants are beyond the scope of this chapter.

9.4 HIV-2

Treatment of HIV-2 infection has not been as well studied as HIV-1, but progress has been made in this area as well. While no strict guidelines have been established for HIV-2, it has been recommended that therapy starts when the CD4 cell count drops below 500/mm^3. One noteworthy distinction between the two viruses when using cART is that HIV-2 is inherently resistant to nonnucleoside reverse transcriptase inhibitors (NNRTIs) [605]. On the other hand, nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, and integrase inhibitors all show varying degrees of activity against HIV-2 depending on the specific ART [605–610]. On the basis of both a limited number of cART trials performed on HIV-2-infected patients and in vitro suppression data, it is recommended that patients be given an initial regimen of a boosted protease inhibitor (lopinavir or darunavir boosted with ritonavir) along with two NRTIs (tenofovir plus either emtricitabine or lamivudine or zidovudine plus lamivudine). Whether or when definitive research is likely to be conducted on the efficacy of ART in preventing transmission of HIV-2 will likely depend more on the availability of resources than on the sense of urgency felt in the countries where the epidemic is most intense.

10 Unresolved Problems

After 30 years of an unprecedented worldwide mobilization of human and physical resources to understand and combat the HIV/AIDS pandemic, there are still countless conceptual uncertainties about many aspects of the virus and the disease, and there are numerous obstacles to developing and implementing control measures that hold the greatest promise. The following are a few of those that loom prominently and seem likely to be difficult to solve.

At the most fundamental level, it is not clear how the virus maintains latency and whether it can be safely dislodged from its reservoir through some combination of antiretroviral and immunobiological action short of stem cell transplantation. Despite intense investigation of both nonhuman primate and human models of viral control, it is still unknown which components of the immune system permit the host to withstand high-level viral replication, in the case of the sooty mangabey, or suppress it to undetectable levels, in elite controllers, with little or no significant clinicopathologic consequences.

The licensure of new classes of antiretroviral agents and development of increasingly effective combinations of drugs, in some cases with significantly lower costs, have raised expectations for further reversal not only of the global trends in morbidity and mortality but also of the incidence of new infections. However, the best of these regimens is not equally successful in all patients. The potential for induction of antiviral resistance in some number of treated patients will continue to challenge even countries with adequate resources, let alone those in financial and social hardship. In an additional proportion of patients without detectably resistant virus, either replication may only be partially suppressed and eventually escape from control, or control of viremia is not accompanied by a corresponding improvement in immune function. Management of these patients can be particularly difficult. For others who experience the reconstitution syndrome, even in those instances when its origins are recognized, the adjunctive therapies needed are imperfect. The dyslipidemia and the fat redistribution syndromes complicating the course of infection can also be difficult to manage. Their pathophysiology in the context of both progressive immunodeficiency and aging is still poorly understood, as is the role of ART in their appearance.

In the past few years, the evidence for the effectiveness of very important new prevention modalities has accumulated. First, clinical trials have demonstrated that male circumcision as performed in several populations can approximately halve the rate of female-to-male transmission. Second, a more recent trial has provided a remarkable proof of concept that early treatment of infected individuals can suppress viremia to the point of drastically reducing transmission to an uninfected sexual partner. These breakthrough studies have raised high expectations that, coupled with more widely instituted testing and counseling programs, the promising new approaches will be capable of preventing a large proportion of new infections. However, aggressive efforts to adopt these strategies will still have to overcome the cultural resistance to circumcision, the financial obstacles to providing treatment to ever larger numbers, and the theoretically greater potential for induction of resistance to antiretroviral agents.

The success of treatment-for-prevention programs will further depend on a solution to another major unresolved problem. Even the most advance countries, including the USA, have failed to reach as many as quarter or more of infected individuals through HIV testing programs broadly enough to ensure detection of HIV infection at an early stage. Approaches more aggressive than the current ones will likely be needed.

Persistence of replicating virus and inevitable progression to immunodeficiency in virtually every infected human who remains untreated implies that complete and lasting natural

immunity rarely occurs. The hope, as yet unrealized, is to formulate a combination of antigenic and immunobiological substances with or without adjuvants that will stimulate the cellular and humoral arms of the immune system enough to achieve long-lasting immunity. Despite years of the most intense scientific inquiry, the continuing inability to definitively establish the elusive correlates of protective immunity, the holy grail of any quest for an effective vaccine, is perhaps the most troubling of all the unresolved issues.

Human Papillomaviruses: Cervical Cancer and Warts

44

Georgios Deftereos and Nancy B. Kiviat

1 Overview

Papillomaviruses (PV) are extremely widespread, small, non-enveloped, icosahedral, species-specific [1], double-stranded DNA epitheliotropic viruses [2, 3], which include human papillomaviruses (HPVs), known to infect humans. In humans, these viruses establish chronic epithelial infections, with each HPV type being associated with infection of specific anatomic sites and distinct natural histories [4]. The clinical manifestations of HPV infection include genital and cutaneous warts as well as genital tract lesions referred to as "intraepithelial neoplasia." Of greatest importance is that fact that a subset of HPVs (referred to as "high-risk" types of HPV) plays a central role in the development of most lower genital tract neoplasias as well as some head and neck carcinomas [5–10].

Classification of individual genotypes is based on sequence homology of the L1 region of the HPV genome [11]. More than 120 types have been identified, with additional new types being continuously cloned and characterized [11]. HPV types are classified as low-risk (LR) or high-risk (HR) types, depending on their association with cervical cancer. Currently 15 HPV types (16/18/31/33/35/39/45/51/52/56/58/59/68/73/82) are defined as HR HPV types, and 12 (6/11/40/42/43/44/54/61/70/72/81/CP6108) are defined as LR HPV types [12]. Over 40 types of HPV infect the anogenital tract, making HPVs the most common sexually transmitted viruses in both men and women.

Given its central importance in development of lower genital tract cancers, especially cervical cancers, detection of high-risk types of HPV now plays an important role in cervical cancer control, both for triage of women with equivocal cytological findings and for the follow-up of women treated for high-grade cervical lesions [13], and more recently as a primary screening test for cervical cancer [14]. Detection of HPV infection is also essential for epidemiologic studies to understand the natural history of HPV infection and the pathogenesis of cervical cancer [12].

While most genital HPV infections, including those with high-risk (HR) HPV types, are self-limited and without consequence, in some women infections persist and facilitate progression to cancer. Case–control studies among those with and without cervical cancer, as well as cohort studies examining risk of developing cervical intraepithelial neoplasia 3 (CIN 3) (the presumed immediate precursor of invasive cervical squamous cell cancer), have clearly shown that HR HPVs are central to the pathogenesis of cervical neoplasia including invasive cervical cancer (ICC) [15], with HR HPV DNA detected in 90–98 % of cervical cancers in different geographic populations. The mechanism by which HR HPV infection facilitates development of ICC is related to proteins produced by the HR HPV E6 and E7 genes. The interaction of E6 and E7 proteins with multiple cellular targets, such as the ones described later in this chapter, results in the deregulation of both the cell cycle and DNA repair [16]. Upon subsequent exposure to carcinogens and accumulation of mutations, malignant transformation occurs and ultimately leads to cervical cancer.

The direct implication of HPV in cervical carcinogenesis has led to the production of prophylactic vaccines to prevent infection with those types of HPV implicated in the pathogenesis of the majority of cervical cancers.

2 Historical Background

Descriptions of genital and cutaneous warts date from antiquity with a recognition of the viral nature of such manifestations dating from the early 1900s with the first human

DOI 10.1007/978-1-4899-7448-8_44,

experimental model using cell-free infiltrate to cause warts dating back to 1907 [17] and preceded by animal models.

In the 1930s, Shope conducted studies on cottontail rabbits that established the contagious nature of cutaneous papillomas and led to the characterization of the Shope papillomavirus, now known as cottontail rabbit papillomavirus (CRPV). This was the first animal papillomavirus to be identified. Shope's studies, followed by those of others like Rous, represented the first studies in DNA tumor virology [18–20].

2.1 Early Studies of Human Papillomaviruses

Ancient Greek and Roman literature [21] contain descriptions of genital warts. In the 1890s transmission of human nongenital cutaneous warts from person to person was experimentally confirmed, with transmission by cell-free filtrate demonstrated in 1907 [17]. Observational studies have long recognized and generally described person-to-person infectivity of genital HPV infections, with Barrett et al. [22] in the 1950s being the first to document the development of genital warts in the wives of World War II soldiers who, before returning home, reported having had a new sexual partner and new penile warts.

Although the relationship between cervical carcinoma and sexual behavior has been suspected for over a century, it was only in the 1960s when specific variables such as "lifetime number of different sexual partners" were shown by epidemiologists to be the major sexual risk factor, in contrast to "lifetime number of sexual acts," strongly suggesting an infectious rather than traumatic etiology [23, 24].

The fact that HPV infections produce morphological changes in squamous cells (seen on both cytological and histological specimens) was observed early on, but the presence of such changes is both insensitive and non specific for HPV infection. These changes were termed *koilocytotic atypia* by Koss and Durfee (*Koilos* from the Greek κοίλος for *hollow*) [25]. Twenty years later, Meisels and Fortin [26] and Purola and Savia [27] proposed that flat cervical lesions demonstrating koilocytotic atypia were cervical equivalents of condyloma acuminatum (genital warts).

Cervical neoplasia is currently termed invasive cervical cancer (ICC) if the neoplastic (i.e., cancer) cells have extended through the basement membrane into the underlying tissue or as an intraepithelial lesion if the neoplastic cells remain limited to areas normally populated by epithelial cells and are not found below the basement membrane. ICC precursor lesions include cervical intraepithelial neoplasia (CIN) grades 1, 2, and 3, and carcinoma in situ. Our current approach to cervical cancer control is based on the concept that ICC arises from intraepithelial precursor lesions termed cervical intraepithelial lesions grade 3 (CIN 3) and/or carcinoma in situ (CIS) and that treatment of these precursor lesions prevents progression to invasive cancer. The CIN classification system, which is still in wide use, was proposed over 45 years ago, prior to any understanding of the epidemiology and natural history of HPV infections and their central role in the pathogenesis of ICC [28]. At that time it was believed that cervical intraepithelial neoplasia (CIN) grades 1, 2, and 3 represented a morphological and biological continuum of progressive, consecutive stages in the development of invasive cancer. Most women with CIN 1 were expected to progress to CIN 3 and, if untreated, to ICC [29]. We now know that most CIN 1 lesions simply represent a morphological manifestation of infection with HPV and regress within 1–2 years [30–32]. Few data are actually available on the risk progression from CIS to ICC. Data from a small series of women with CIS who inadvertently were not treated, from studies carried out before ablative treatment became the accepted standard of care, and from women repeatedly undergoing biopsies rather than definitive treatment [33, 34] suggest that, if left untreated, only a minority of cases (12 % to at most 40 %) would develop invasive disease within the span of a normal lifetime [32, 35, 36]. Furthermore, in recent studies looking at the relationship between acquisition of HPV infection and development of various grades of CIN, morphological changes that are classified as CIN 2 and CIN 3 are found early after infection with "oncogenic" types of HPV [37, 38]. Pathologists do not routinely attempt to differentiate between CIN 3 and CIS, as such morphological differentiation is known to be difficult and non-reproducible [39] and the clinical management of these lesions is similar. Unfortunately, using morphology (microscopy), we are unable to differentiate those cases of CIN 3/CIS which, if untreated, would progress from those that carry little or no risk of progression, and therefore all such lesions are treated. It is likely that in the future ICC precursor lesions will be defined by the presence of specific cancer-associated molecular changes.

2.2 Early Molecular Studies of Human Papillomaviruses

The early molecular biological studies of HPV established the plurality of HPV types, identified previously uncharacterized types, and established the association between types and lesions occurring in different tissues as well as with different degrees of neoplasia [4, 32, 40]. HPV DNA was detected in the majority of cervical neoplastic lesions, ranging from CIN 1 to invasive carcinoma and in cell lines derived from cervical carcinomas, most notably HeLa cells, one of the first established and most widely used cell lines [40].

Along with the advances in HPV DNA detection techniques, notable progress was made in the modality of noninvasive

specimen-obtaining methods. By the early 1990s more advanced and standardized DNA testing was available. This permitted more accurate detection of an increasing number of HPV types from anogenital and oral cytology specimens and permitted the characterization of new HPV types in numbers that have constantly increased from around 70 in the late 1990s [24] to more than 120 known to date [41]. Furthermore, the complete sequencing of the entire genome of many human and animal papillomaviruses has opened that way for the understanding of HPV infection pathogenesis and natural history of disease and has permitted advances in therapy and prevention. In 2006 the first FDA-approved HPV vaccine (Gardasil, Merck, Rahway, NJ) was introduced, covering types 6, 11, 16, and 18, representing the first vaccine specifically used for cancer prevention.

3 Human Papillomavirus Biology

Papillomaviruses are small (52–55 nm in diameter), nonenveloped, icosahedral viruses that have a tropism for squamous epithelial cells. They each carry an 8,000 base pair, single molecule of double-stranded DNA. Their genome guanosine–cytosine content is on average 42 %. Papillomaviruses have a capsid composed of 72 monomers (capsomers) [42]. The papillomavirus capsid is composed of two structural proteins: L1, which represents approximately 80 % of the capsid and has a molecular weight of 55kd, and L2, which has a molecular weight of 70 kd that represents the remaining percentage. Both proteins are encoded by the viral genome, and while both are normally incorporated in the capsid, only L1 is required for the capsid formation. In fact viral particles can be produced only by expressing the L1 protein and are virtually indistinguishable from those containing both proteins [43, 44].

3.1 Genome Structure and Molecular Biology

The various human and animal papillomaviruses sequenced have made possible to demonstrate that all have similar genomic structure and organization. Of the two DNA strands, only one is the coding strand and is characterized by a number of open reading frames (ORFs), classified as early (E) or late (L), based on their location on the genome.

The most upstream region of the genome, known as upstream regulatory region (UPR), is a noncoding region, representing approximately 12 % of the viral genome, and contains the origin of replication for the viral genome. The early region contains regulatory genes as well as genes necessary for the initiation of replication, while the late region is expressed (and L1 and L2 proteins are found) only in actively infected cells [45–47]. The position and organization of the various ORFs are found to be similar in the various papillomaviruses.

3.2 Viral Replication Cycle

The papillomavirus replication cycle is initiated by infecting the basal layer cells of the squamous epithelium. Viral replication goes hand in hand with the epithelial cell differentiation in that early phase proteins are the only ones detected in the basal and parabasal layers, and it is only in more differentiated squamous cells that late-stage proteins are expressed, with the production of new viral particles occurring in the highest layers [48–50].

3.2.1 Early Stages

The papillomaviruses have to infect directly the basal layers of the epithelium. In order to do so, it is believed that presence of cuts or abrasions leading to exposure of the basal and parabasal layers is necessary. Various cell membrane molecules, such as integrins and glycosaminoglycans, are possible receptors for the viral particles [51, 52]. The result of this interaction is clathrin-mediated endocytosis [51]. This mechanism of entry is mediated by L1 protein, while L2 appears to play a role in virion disassembly, genome escape into the cytoplasm, and transportation of the genome into the nucleus [51, 53–55].

3.2.2 Transcription

Papillomavirus transcription mechanisms are an expanding field, due to the presence of multiple promoter regions described to date and to the variable splice patters and mRNA end products in different cells. The majority of the mRNAs described and certainly the only ones found in warts share a common polyadenylation site (Ae) located at nucleotide 4,180, downstream of the early (E) genes, while mRNAs found in transformed cells show a polyadenylation site (Al) located at nucleotide 7,156, located downstream of the L1 and L2 ORF. The presence of this polyadenylation site can only be found in terminally differentiated keratinocytes [21].

Differences have been also described between transcription mechanisms in high-risk and low-risk HPVs. The E6 and E7 mRNAs in the high-risk HPVs share a common promoter (P97 for HPV-16 and HPV-31 and P105 for HPV-18), whereas in low-risk HPVs the E6 and E7 genes have different promoters. When E6 and E7 are transcribed with a common primer, the E6 mRNA can be intact or with splices within the E6 gene. If the E6 is transcribed intact, the E6, but not E7, is translated as there is not sufficient spacing for the E7 translation. If the E6 gene is spliced, there is enough space for the E7 ORF, so the translation of E7 can proceed normally [49, 56].

3.2.3 Transcription Regulation in Papillomaviruses

The upstream regulatory region (URR) contains a series of enhancing sequences that respond differently in various epithelial layers and have been found to contain binding sites for transcription factors as well as for cell nuclear proteins. The different layers of the squamous epithelia that are infected by papillomaviruses show different transcription patterns [57–59], and the level of keratinocyte differentiation appears to play a role in the way the viral genome is transcribed and spliced.

3.2.4 E2 Regulatory Proteins

Many of the regulatory functions in papillomavirus transcription have been found to be executed by the various E2 proteins [21, 60]. E2 has been described playing a role in transcription and DNA replication, among other regulatory functions. The first evidence of the E2 regulatory function came with the characterization of multiple response elements throughout the viral genome [61].

The E2 protein is found to be well conserved between the various viral types, being composed by two domains: one DNA-binding, sequence-specific domain, located near the C-terminal of the protein that has also dimerization function, and another one in the N-terminal that has a transactivating function. The two domains are separated by a variable hinge region. The C-terminal domain recognizes ACCN6GGT consensus sequences in promoters containing E2 binding sites. This signal is the main signal found in HPVs with some exceptions, like HPV-41 [61–63].

The E2 protein has been found to function in both activation and repression of transcription and has been well studied in anogenital HPVs. E2 can suppress the transcription of E6 and E7 leading to inhibition of growth in HPV-infected cervical cancer cell lines. This inhibition is due to the reactivation of the Rb and p53 pathways that are inhibited by E6 and E7, as evidenced by study models using bovine papillomavirus (BPV) E2 proteins [21, 64, 65]. The target elements of E2 have been widely studied, and several have been described in detail (Table 44.1) [21, 66].

Finally, E2 has an important role in maintenance of episomal viral genomes within infected replicating cells [76–78]. The TA domain is necessary for the maintenance of the viral genome in dividing cells, and specific mutations of this domain have been shown to disrupt the papillomavirus genome association to mitotic chromosomes. This interaction has been demonstrated to occur either with mitotic chromosome chromatin or even directly with the mitotic spindle [79–82].

Table 44.1 Cellular targets and functions of the papillomavirus E2 oncoproteins

Associated cellular proteins	Functional consequences	Ref.
Bromodomain protein 4	Tethers E2 and DNA to mitotic chromosomes	[67]
	Mediates transcriptional activation function	[68]
TATA binding protein (TBP)		[69]
AMF-1/Gps2	Enhances transcriptional activation	[70]
	Enhances E2 interaction with p300	[71]
YY1 transcription factor		[72]
Nucleosome assembly protein 1	Ternary complex with p300	[73]
p53	Apoptosis (high-risk HPV types)	[74]
CREB-binding protein (CBP)	Transcription activation	[65]
Papillomavirus E1 protein	Viral DNA replication	[75]

3.2.5 Late Phase Transcription

The late stages of the viral cycle occur exclusively in differentiated keratinocytes, located within the middle and higher strata of the squamous epithelium. In accordance to that the transcription of the late phase proteins (L1 and L2) is initiated only in these layers. The common L1 and L2 transcription promoter (Pl) is also shared by a series of other nonstructural genes that are similarly expressed only in more mature keratinocytes, including the E4 [83, 84]. Polyadenylation of the L1 and L2 mRNAs in HPVs has been described to start from a site (Pl) found 3′ to the L1 ORF, which is similar to the polyadenylation site described in BPV. This site has been found to be inactive in transformed cells [45]. Cis-regulatory elements for the late phase mRNA transcription have also been described in the 3′ UTR of several HPVs (HPV-16, HPV-1), and many of them have been described to be conserved among HPVs [85, 86].

3.2.6 Viral DNA Replication

HPV DNA replication is found to be dependent in great degree upon the level of differentiation of the host keratinocytes as after infection of the basal cells there is a replication of the viral genome up to a total of 50–100 copies which is maintained as a stable plasmid. In the upper layers of the stratified epithelium, the expression of viral genes required for viral genome replication is markedly accelerated, while in the terminally differentiated keratinocytes, the vegetative viral replication and packaging result in complete virion production [87, 88]. The initiation of replication necessitates the presence of the origin of replication element in cis and E1 and E2 in trans. The origin of replication is described to have a T-rich region and binding sites for E1 and E2. E1 is the central molecule in this process, and initial studies demonstrated that even in the absence of E2, the replication can be still initiated, and E2 has the function to stabilize the E1 to

the site of origin [89]. However, subsequent study models showed viral DNA replication in the absence of both the proteins [88].

The E1 protein interacts with α-primase, a DNA polymerase, and initiates the host cell initiation complex. Interactions of E1 with other molecules including histones have been described, but the significance of these interactions remains to be determined. Studies are available showing that interaction of E1 with cyclin-dependent kinases is necessary for active viral replication [90].

The E2 molecule interacts with E1 and becomes a precursor to a larger E1 multimeric complex that initiates replication and enhances E1 ability to initiate replication. E1 forms a hexameric form and demonstrates intrinsic ATPase and DNA helicase function that is essential to its function in DNA replication–initiation [91, 92].

3.3 Immortalization and Transformation of Human Papillomaviruses

Some of the papillomaviruses have been proven to be able to induce cellular transformation in vitro, and the first papillomavirus to be extensively studied was bovine papillomavirus 1 (BPV-1), using various established animal cell lines [93–95]. It was shown that in the BPV-1 DNA was maintained as a multicopy plasmid in rodent cells. The integration of the viral DNA into the cellular DNA was shown not to be a prerequisite for transformation of the cells that however kept their transformed state while expressing the viral genes [21]. In fact, previously transformed cells treated with interferon and returning to their untransformed state do not express the papillomavirus any longer [96].

HPVs have been subsequently studied in depth with regard to their role and mechanisms in cell immortalization and transformation. Studies with animal cell lines as well as human keratinocytes and fibroblasts showed the capacity of high-risk HPVs such as HPV-16 and HPV-18 to produce immortalized cells in contrast to low-risk HPVs (HPV-6 and HPV-11) that lack such capacity [97, 98]. While E7 ORF has been shown to be the most widely expressed in transformed cells, it is important to note that infection with these high-risk HPVs alone did not achieve cell transformation and that the E7 gene can act upon activated *ras* protein forms to induce transformation [99–101].

3.3.1 Human Papillomavirus E5 Gene

The E5 gene encodes for short hydrophobic peptides that are seen expressed in a variety of epithelial papillomas caused by HPVs and other papillomaviruses, and cell models have demonstrated how the E5 expression is necessary for optimal viral growth [102, 103]. Furthermore, E5 has been shown to have some transforming activity in rodent cell lines, and it has been hypothesized that it acts through modification of the EGFR as well as of other signaling pathways [104, 105]. Finally, E5 is found to be lost during viral integration, and it has been suggested that lack of E5 signifies a switch from benign lesions to establishment of malignancy and could represent a target for noninvasive (CIN2 and 3) lesions [104].

3.3.2 Human Papillomavirus E6 Gene

The E6 gene codes for a 150-amino acid protein that appears to be of similar structure in both high-risk and low-risk HPVs. The various E6 proteins seem to share similar activation elements as well as two common zinc fingerlike domains, each containing two Cys-X-X-Cys sequences. The transforming capacity present in E6 proteins of high-risk HPVs is identified in the ability to bind and complex to the p53 protein and expressed by a highly conserved C-terminus domain, able to bind to PDZ domain proteins; this capacity is not seen in the E6 of low-risk HPVs [106]. This interaction leaves p53 unable to activate its dependent promoters but also ultimately leads to the degradation of the p53 protein itself. In HPV-16 this degradation has been shown to be mediated by an E6/E6AP (an ubiquitin-protein ligase) that results in ubiquitination and degradation of p53 [107]. In fact the observed levels of the p53 detected in HPV-related neoplasms are low [108]. It has been shown that the proapoptotic function of p53 is diminished in the face of oncogene-mediated cell death signals that normally would lead to apoptosis, thus leading to immortalization of the affected cells [109–111].

The overall result is a significant decrease of the p53 levels in transformed cells. Similar results are found in vivo in HPV-positive cancer cells [108, 112]. In models that employed the use of cytotoxic agents to induce cell death, a peak of p53 expression was seen in native cells, whereas in HPV-immortalized cells expressing E6, this was not seen, as DNA damage-mediated apoptosis mechanism is deficient due to the lack of p53 [111, 112].

The E6/p53 pathway is not the only one implicated in HPV cell immortalization. Cell models using a version of E6 with a mutated p53-binding domain resulted in DNA genetic instability similar to the one seen in the loss of E6-mediated p53 loss, thus suggesting alternate pathways affected by the E6 protein [113]. One proposed mechanism activation of the catalytic domain (hTERT) of human telomerases. Lengthening of the telomeres seen in immortalized cells has been described as possible through transcriptional activation of the hTERT or through activation of the alternative lengthening of telomeres (ALT) pathway [114, 115]. This activation of hTERT can be mediated by E6AP or independent of E6AP, through Myc-binding sites within the hTERT promoter [116–119].

The p53 pathway can be inhibited by E6 in other ways as some studies proposed the interaction with p300/CREB-binding protein, a p53 coactivator, thus providing an additional

mechanism of p53 inactivation [120]. Other interactions have been described, but their clinical significance in most cases is still to be determined.

3.3.3 Human Papillomavirus E7 Protein

The E7 protein is a small, 100-amino acid protein that demonstrates two conserved regions, CR1 and CR2 and a C-terminal zinc-binding region. The conserved regions are very similar among the high-risk HPVs, as well as with other tumorigenic viruses, such as SV40. These regions are important for the transforming activity of the E7, through inhibition of retinoblastoma oncosuppressor protein (pRB), and its related pocket proteins p107 and p130 [121–123]. The E7 appears to bind preferentially to the hypophosphorylated form of pRB (inactive form) resulting in its inhibition, which results in promoting cell cycling and replication. High-risk HPV E7 proteins show different properties in inhibiting the pRB family of proteins than low-risk counterparts that appear to lack this capacity [121]. The CR1 domain has been described as the one with the capacity to bind the pRB pocket-related proteins, and CR2 contributes to their degradation [16, 100, 124].

Other targets for HPV E7 have been described including inhibition of the cyclin-dependent kinase inhibitor p27kip1. p27kip1 participates in the TGF-β-mediated growth inhibition mechanism seen in keratinocytes. With the inhibition of the p27, this mechanism is overridden resulting in growth promotion [125]. More recent studies have suggested that the inhibition of the p27 function is not a result of degradation but that of accumulation of p27 in the cytoplasm, with no effect in cell cycle arrest and contact inhibition [125]. Finally, E7 has been shown to have the capacity to inhibit the p21cip1 with loss of its inhibitory effect on DNA replication and may be essential to the replication of HPV DNA in differentiated keratinocytes, where normally the p21 pathway inhibits DNA replication [109, 124, 126–128]. Finally, E7 (along with E6) is believed to be necessary for the stable maintenance of viral episomal DNA. As shown by model forms, E6 and E7 mutant genomes may be unable to properly segregate on cell division and can be, as a result, lost from the cell [129].

4 Taxonomy and Classification

The papillomaviruses constitute the family of *Papillomaviridae*, divided in the genera of *papillomavirus*. Until recently 16 groups of papillomaviruses or individual papillomaviruses had fulfilled the criterion of genera. These genera are included in the International Committee on Taxonomy of Viruses classification and are indicated by Greek letters alpha to pi (ICTV: 2009 release). HPVs are members of five genera (Alpha-, Beta-, Gamma-, Mu-, and Nu-PVs). Each of the two genera (Eta- and Theta- PVs) contains a single bird papillomavirus, while the remaining nine genera contain one or several papillomaviruses isolated from various mammals. Research over the last decade confirmed the notion that phylogenetic congruence of virus lineages with those of the host species is an important although not the only mechanism of papillomavirus evolution. Consequently, search for papillomaviruses in previously understudied and remotely related hosts led to the identification of papillomaviruses, whose distant relationship with one another and with all previously published papillomaviruses fulfilled the criterion to establish 13 additional genera. These include the first two papillomaviruses found in reptiles (marine turtles) [41, 130]. All the animal papillomaviruses are indicated by abbreviations indicating their host organisms [130].

Since the more recently described genera exhaust the Greek alphabet, one of the proposed classifications uses the Greek alphabet a second time, employing the prefix "dyo" ("δύο," Greek for "two"), but omits the designations Dyoalpha, Dyobeta, and Dyogamma, since the Alpha-, Beta-, and Gamma-PV genera include the most common and medically important HPVs. The genera are listed in the order they were described with no necessary connection between adjacent genera. The same authors created a phylogenetic tree using the L1 nucleotide sequences of 189 papillomaviruses, which was generated using a Bayesian algorithm (Fig. 44.1) that is continuously changing with the addition of newly described species.

Within the species, HPV types are defined based on proportion of DNA sequence homology. In the 1970s and 1980s, HPV types were determined by liquid hybridization, reassociation kinetics assays [131]. Viruses with less than 50 % cross-hybridization to previously typed HPVs were called new types (and numbered sequentially in order of acceptance by the Papillomavirus Nomenclature Committee centered at the German Cancer Research Center in Heidelberg). Of note, 50 % cross-hybridization represents much more than 50 % nucleotide sequence homology. A subtype (assigned letters) was defined as a papillomavirus that cross-hybridized under stringent conditions with a given HPV prototype but had a restriction endonuclease pattern distinct from the prototype pattern. A variant was defined as differing from the prototype by an undefined but limited number of nucleotide sequences [1, 132].

The taxonomy of the HPVs, as shown in the phylogenetic tree (Fig. 44.2), agrees closely with the epidemiologic data associating specific types of HPV with different tissues and grades of disease. Specifically, the HPV types that tend to infect skin appear as a phylogenetically related group in the trees. The rare cutaneous types found mainly in patients with the immunodeficiency disease epidermodysplasia verruciformis are also shown in the tree to be closely related viruses [133].

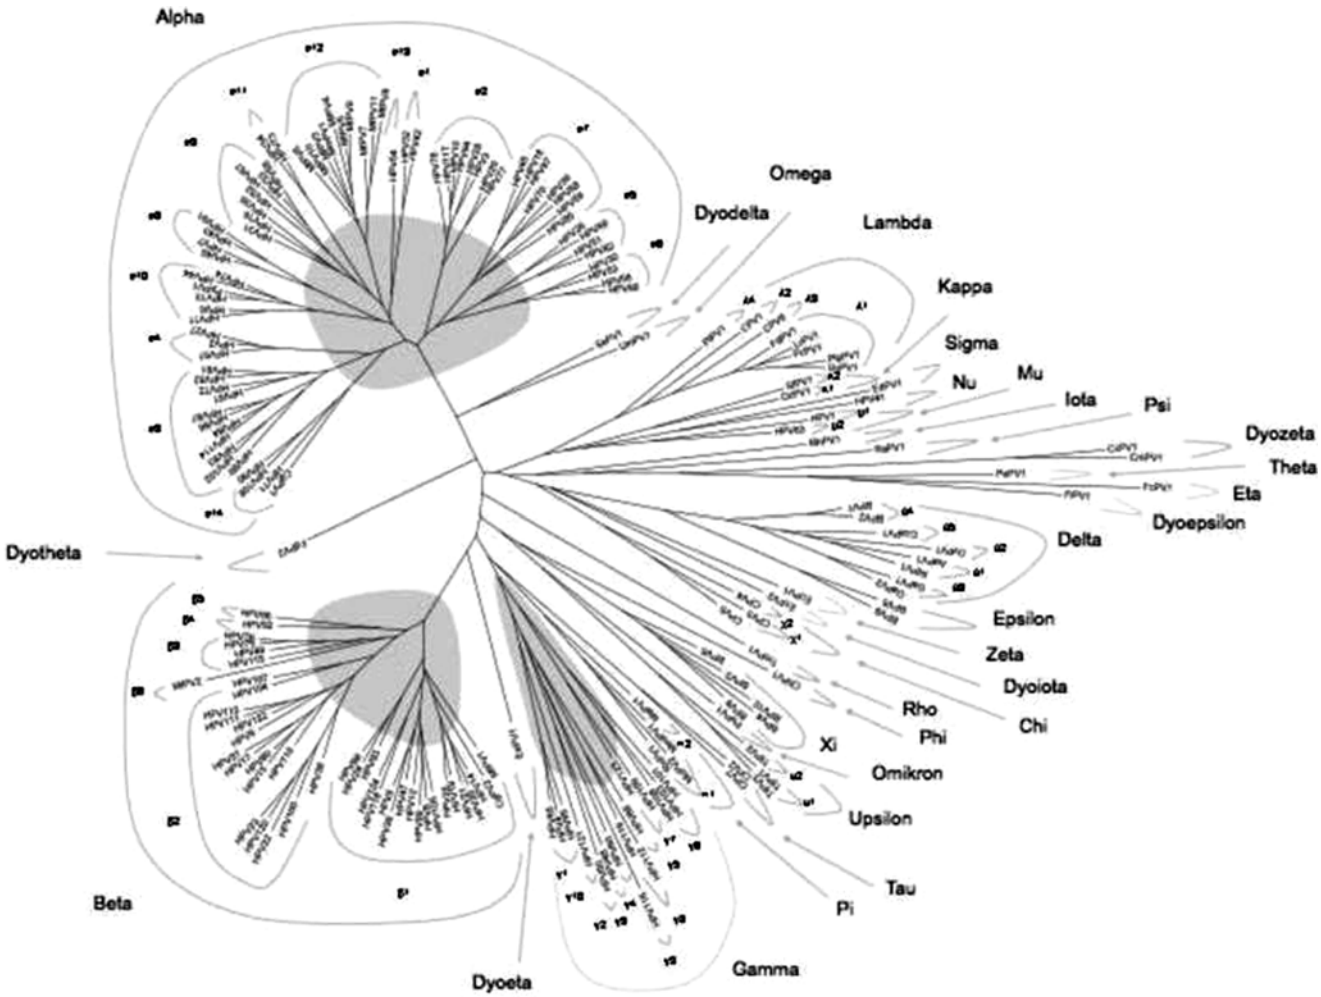

Fig. 44.1 Phylogenetic tree inferred from the L1 nucleotide sequences of 189 papillomaviruses (From Bernard et al. [130], with permission)

Among the mucosal HPV types, low-risk types found mainly in benign warty lesions cluster as a distinct group, separate from the high-risk types associated with invasive carcinomas. This concordance is evident in a comparison of the phylogenetic tree in Fig. 44.2 to epidemiologic data from large cross-sectional studies demonstrating the association between HPV type and grade of cervical neoplasia [134, 135].

In 1991, it was agreed by the Papillomavirus Nomenclature Committee that for a novel HPV isolate to be recognized as a new type, its entire genome must be cloned, and the nucleotide sequence of the three regions (URR, E6, and L1) should demonstrate less than 90 % nucleotide sequence identity with established papillomavirus types [24].

Previously described species HPV-46, HPV-55, HPV-64, and HPV-79 were proven not to meet the criteria as a unique HPV type; they were omitted and their numbers remain unassigned [41]. Among the more recently classified HPVs, HPV-101, HPV-103, and HPV-108 diverge convincingly from all other HPV types in that they lack an E6 ORF [136, 137]. In spite of this distinction, these three types are included in the genus Gamma-PV based on the present rules of sequence similarities in the L1 ORF and the resulting topology of the phylogenetic tree.

The definition and properties of PV subtypes and variants as DNA isolates with less than 10 % sequence diversity in the L1 gene have been discussed [41, 130]. While the ICTV does not implement taxonomic systems below the species level, nomenclature of variants of papillomavirus type based on complete genome sequences has been proposed in order to take into account the genomic heterogeneity, mainly within certain epidemiologically important HPV types (e.g., HPV-16, HPV-9). The proposed nomenclature systems have the intent to facilitate the comparison of variants across epidemiologic studies. Sequence diversity and phylogenies of these clinically important groups of HPVs provide the basis for further studies of discrete viral evolution, epidemiology (including geographic distribution), pathogenesis, and preventive and therapeutic interventions [138].

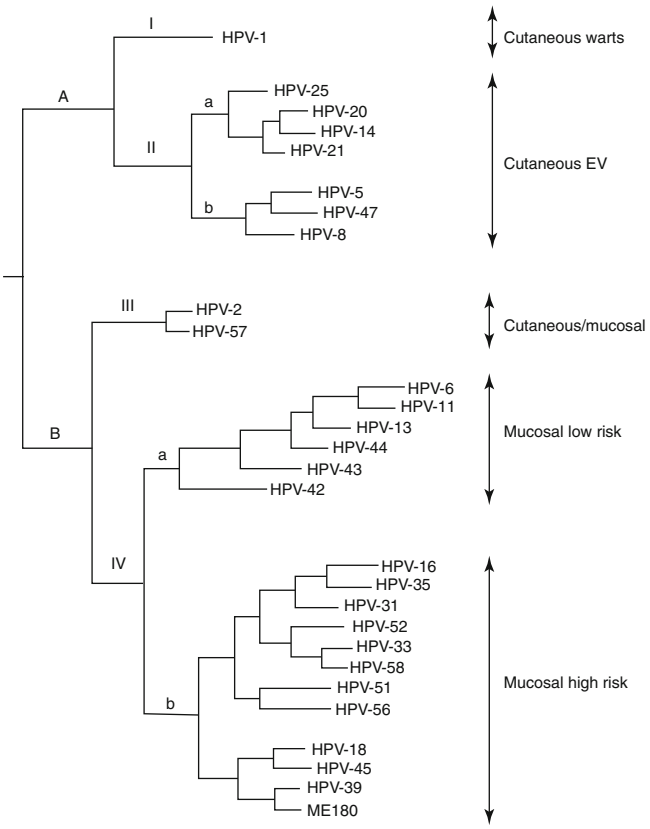

Fig. 44.2 Phylogenetic tree constructed from the alignment of 384 nucleotides in the E6 genes of 28 HPVs using maximum parsimony analysis (PAUP 3.0). To root the phylogenetic tree, bovine papillomavirus type 1 was used as an out-group (not shown). The labels on the right indicate the corresponding clinical category associated with each HPV type (From Van Ranst et al. [132], with permission)

5 Methodology Involved in Epidemiologic Analysis

Traditional virology methods, such as in vitro culture and serological assays, are not suited for detection of HPV. Replication of HPV is tightly linked to squamous epithelial cell differentiation, with capsids produced only in terminally differentiated squamous cells, making in vitro culturing of HPV difficult. Further, due to their strict species specificity, HPVs cannot be propagated in normal laboratory animals. The detection of serum antibodies to HPV is of little interest for the recognition of acute infection, due to the long time needed for the development of anti-HPV antibodies. Clinical and colposcopic examination, as well as microscopic examination of exfoliated cell samples (Pap smears) and tissue biopsies for koilocytes (cells whose nuclei demonstrate perinuclear clearing, with an increase in the density of the surrounding rim of cytoplasm), has been used for identification of HPV infections [139]. However, these morphological methods are both insensitive and nonspecific.

5.1 DNA-Based Detection of HPV Infection

HPV detection has relied on molecular assays that detect HPV DNA or RNA. Three categories of molecular assays are available for detection of genital HPV infection in tissue and exfoliated cell samples, all of which are based on the detection of HPV DNA. These include (1) non-amplified hybridization assays such as Southern transfer hybridization (STH), dot blot hybridization (DB), and in situ hybridization (ISH); (2) signal-amplified hybridization assays, such as Hybrid Capture assays; and (3) target amplification assays, such as polymerase chain reaction (PCR) and in situ PCR. Southern blot hybridization was initially used and considered the gold standard for HPV detection. However, it has serious shortcomings for routine clinical use. It requires large amounts of DNA and is extremely laborious. In addition, because interpretation of blot results is difficult and subjective, it lacks interlaboratory reproducibility. The presence of multiple or aberrant HPV types, incomplete DNA digestion by the restriction enzymes, and aberrant DNA migration and weak signals can all affect blot results. ISH has the advantage of preserving the topology of the tested tissue, thus allowing visualization of the location and physical state of HPV DNA. However, it also lacks sensitivity and specificity, as its limit of detection is approximately 5–10 HPV genomes per cell. Signal or target amplification assays are currently used in clinical and epidemiologic studies for the detection of genital HPV types. Both have a similar clinical sensitivity and specificity to detect the majority of genital HPV types.

5.1.1 Sample Collection and Preparation

HPV testing can be performed on a variety of samples, including biopsies; exfoliated cells from the female or male genital tract, urine, and blood; and paraffin-embedded materials. Exfoliated cervical epithelial cells can be collected using various devices that are available to collect cervical scrape samples for cytological examination. It is important that both the ecto- and endocervix are sampled to collect enough cells for HPV detection. Simple cotton-tipped applicators are well suited for this purpose because they do not sequester collected cells. Very little is known about the optimal devices for collecting exfoliated cells from men. In general, the collection medium of choice should be able to inactivate infectious agents and be free of PCR inhibitors. The most frequently used media include STM (Digene), 95 % ethanol, or ThinPrep PreservCyt solution. Formalin-fixed, paraffin-embedded, archived biopsy samples can also be used in PCR-based HPV tests. Several studies suggest that exfoliated cervical samples can be collected and stored as dry swabs for an extended time (up to a month) at room temperature without noticeable degradation of HPV DNA [140]. The samples are rehydrated and processed for genomic DNA isolation.

5.1.2 Signal Amplification Method

The Hybrid Capture II (HCII) assay approved by the US Food and Drug Administration (FDA) uses the sandwich enzyme-linked immunosorbent assay (ELISA) platform and a proprietary antibody against DNA–RNA hybrids. HPV DNA is released from clinical samples by denaturing in alkaline buffer and then hybridizing to a cocktail of HPV-specific RNA probes. The DNA–RNA hybrids generated are then captured by an immobilized antibody against the DNA–RNA hybrids. A second DNA–RNA hybrid antibody conjugated with peroxidase is used to recognize the DNA–RNA hybrids, and the hybrids are detected with a chemiluminescent substrate. The light emitted is measured as relative light units (RLUs) on a luminometer. The signal amplification is achieved through multivalent binding of antibody to the DNA–RNA hybrids and subsequent enzymatic reaction. Two sets of probes exist for detecting either low-risk HPV types (6/11/42/43/44) or high-risk HPV types (16/18/31/33/35/39/45/51/52/56/58/59/68), and they can be used either separately or in combination. For each assay run, the cutoff (CO) value is defined as the RLU of an appropriate calibrator sample at the concentration of 1.0 pg/ml in STM. The calibrator sample for the low-risk HPV test is cloned HPV-11 DNA, while the calibrator sample for the high-risk HPV test is cloned HPV-16 DNA. The result is reported as the ratio of RLU to CO. A sample is considered HPV positive if the RLU/CO is equal to or greater than 1 and negative if the RLU/CO value is less than 1. Samples with a RLU/CO ratio between 1.0 and 2.5 should be repeated to increase reproducibility. The assay is semiquantitative; although the RLU generated is proportional to the amount of HPV DNA present in the sample, there is no internal control for the input of cells in clinical samples.

5.1.3 Target Amplification by PCR

In PCR-based assays for HPV detection, the viral DNA is amplified in vitro by a DNA polymerase to generate an adequate amount of target, which is then directly visualized on gels, detected by hybridization using specific probes, or sequenced. The sensitivity of the PCR-based method is about 10–100 HPV viral genomes in a biopsy or smear containing 5×10^4 cells. Currently, there is no commercially available PCR-based assay for HPV testing in the United States nor are there standardized protocols for PCR-based methods. The analytical sensitivity and specificity of PCR-based assays depend on sample preparation, PCR reaction conditions (primers and polymerase used), and product detection methods. Furthermore, sensitivity varies as a function of the uneven distribution of multiple HPV-type infections in clinical samples. Type-specific PCR assays can detect only a single HPV type or a few very closely related ones. Since there are many different HPV types in any given population, this type of assay has limited utility on clinical specimens. However, being more sensitive than consensus PCR assays, the type-specific HPV PCR assays are useful in certain situations, such as in studies of persistent HPV infection. Several well-characterized consensus PCR-based assays are available for the detection of the majority of genital HPV types. The primers of these assays are designed that target the conserved regions in the HPV genome, such as the L1 region. Either non-degenerate consensus primers are used under low stringent amplification conditions, such as the GP5/6 and GP5+/6+ system, or degenerate consensus primers are used under stringent amplification conditions, such as the MY09/11 system. More recently, mixed primers have been developed to increase the sensitivity and reproducibility of degenerate primers, such as the PGMY09/11 and SPF systems [12].

The GP5/6 system has been extensively used in Europe. The primers are non-degenerate consensus primers that target the L1 region. By using a low annealing temperature during PCR, these primers are able to detect up to 27 different HPV genotypes, including types 43 and 44, which are less efficiently detected by the MY09/MY11 primer set. However, the low stringency conditions produce weak PCR signals and a relatively high background of co-amplified cellular DNA, which requires dot blot hybridization with a generic probe for unambiguous results. Using the GP–PCR consensus probe (consisting of 2 oligonucleotide probes cocktails identifying high- and low-risk HPV types), which was originally designed for GP5/6 primers, 1 fg to 10 pg of HPV DNA can be detected. An automated enzyme-linked immunosorbent format has been developed in conjunction with these primers. Biotinylated primers are used in the PCR reaction. The PCR products are captured on streptavidin-coated microtiter plates, denatured and hybridized to a mixture of digoxigenin (DIG)-labeled HPV consensus oligo probes. The DIG-labeled hybrids are then detected using an enzyme immunoassay (EIA). The sensitivity of the assay was found to be between 10 and 100 HPV-16 and HPV-18 viral genomes in a background of 100 ng of cellular DNA [141–143].

MY09/11 degenerate primers are based on conserved sequences of HPV types 6, 11, 16, 18, and 33 and target a 450-bp region of the L1 ORF of the genital HPV types [144, 145]. These primers have been widely used by researchers in North America, South America, and Asia. The amplified product contains both a conserved region and a highly differentiated region facilitating the design of both the generic and type-specific probes, respectively. HMB01 was added to increase the sensitivity for detection of HPV-51. Despite the presence of degenerate base sites, amplification across some HPV genotypes is uneven due to mismatches or low viral loads of specific HPV types. Because the random insertion of bases at degenerate positions is not a controlled process, and no analytical method is available to determine the proportion of each sequence in

each primer sample, the analytical sensitivity of the assay varies from primer batch to primer batch. For MY09/11, the generic probe was synthesized from the L1 PCR fragment of HPV-16, HPV-18, and HPV-31 using nested type-specific primers. Together, these fragments were found to detect a broad spectrum of HPV types. The presence of HPV is determined by dot blot hybridization with generic HPV probes. PGMY09/11 primers are an improved version of MY09/11 primers. They contain a pool of 18 primers (5 forward and 13 reverse), which amplify a 450-bp fragment at an annealing temperature of 55 °C. Importantly, each oligonucleotide is synthesized independently so that the pool contains a fixed proportion of each primer. Compared to the original MY09/MY11/HMB01 primers, the PGMY primers provide improved sensitivity, specificity, and reproducibility in detection of those HPV types that were not efficiently primed (especially when present at low levels) by the original MY09/11 primers [146, 147].

Another introduced system is the SPF1/SPF2 short PCR HPV consensus fragment system that originally consisted of a mixture of 6 primers (4 forward primers and 2 reverse primers used in equimolar quantities) which amplified a 65-bp fragment at an annealing temperature of 52 °C. Subsequently introduced, the SPF10 primer system improved on the original SPF1/SPF2 primers by adding four additional primers, for a total of 10 primers to increase the assay sensitivity [148]. The PCR product generated is hybridized to the generic probe in a microplate EIA assay to detect HPV-positive samples. Because the amplicon size is small, the SPF10 method is well suited for the analysis of paraffin-embedded materials or other specimens with degraded DNA.

More recently, Roche has developed a PCR-based HPV detection assay in a 96-well microplate format, the Amplicor HPV test, which was launched for clinical use in Europe. The kit uses a pool of 12 biotin-labeled primers to amplify a fragment of 165 bp in the L1 region. The HPV PCR fragment generated is then captured by immobilized probes that detect 13 high-risk HPV types. The biotin-labeled PCR product is then hybridized to horseradish peroxidase-conjugated streptavidin and detected using the chromogenic substrate. Sample adequacy is measured by including an additional primer pair for β-globin in the PCR reaction and detected with a separate microplate coated with the β-globin probe. The reaction mixture is read at 450 nm. An absorbance of greater than 0.2 is considered positive for the presence of HPV and β-globin.

Finally, PapType™ HPV test (Genera Biosystems, Australia) is a polymerase chain reaction (PCR)-based qualitative in vitro diagnostic test for the simultaneous detection and genotyping of 14 high-risk and 2 low-risk HPV genotypes with analytical sensitivity of 500 copies per reaction (PapType™ package insert).

5.1.4 Quantitative PCR

Although the HCII assay is quantitative, it does not normalize input cellular DNA. Current methods of HPV DNA quantitation rely on type-specific real-time quantitative PCR reactions using TaqMan probes (Applied Biosystems, Fall City, CA). Cellular DNA input is normalized by quantitating a housekeeping gene, such as β-actin. Since these assays are type specific, HPV genotyping of the sample is required beforehand. Multiplexing allows the detection up to 10 HPV types simultaneously. Similarly, HPV viral gene (E6, E7) expression can be quantitated using quantitative reverse transcription PCR on RNA samples. In general, the level of viral gene expressions is highly correlated with the viral DNA load. Quantitation of HPV DNA and RNA is of potential interest for several reasons. Since only 5–10 % of HPV-infected patients eventually develop cervical cancer, it is hypothesized that the level of HPV virus present (perhaps over time) might be associated with persistent infection and subsequent development of cervical neoplasia. Several studies showed that the viral load of HPV-16, HPV-18, and other high-risk HPVs increases with the severity of the lesion. Further, the viral load is associated with progression to cervical cancer and patient survival. More recently, it has been shown that HPV-18 E6/E7 transcript is associated with progression of cervical lesion [149–151]. However, due to the low prevalence of these other HPV types, larger studies are required to confirm this association for each individual HR HPV type.

5.2 Methods for HPV Genotyping

Currently, the well-established methods for HPV genotyping are various reverse line blot assays. These assays are based on solid phase hybridization of amplified HPV sequences to a slot blot membrane. The Liquid Bead Microarray (LBMA) assays are liquid-based hybridization assays and represent an alternative method, suited for high throughput and automation, being comparable to reverse line blot assays for HPV genotyping in clinical samples.

5.2.1 Roche Linear Array

The Roche Linear Array is a commercially available reverse line blot assay based on the PGMY09/11 PCR system and detects 37 HPV types (6/11/16/18/26/31/33/35/39/40/42/45/51/52/53/54/55/56/58/59/61/62/64/66/67/68/69/70/71/72/73/81/82/83/83/IS39/CP6108) (Roche Diagnostics, Pleasanton, CA). Specifically, HPV PCR products are generated using biotin-labeled primers, hybridized to a strip that contains type-specific HPV probes, and detected using the streptavidin-conjugated horseradish peroxidase and a chromogenic substrate. The sufficiency of the sample is monitored by the detection of β-globin gene.

5.2.2 Inno-LiPA

The Inno-LiPA HPV Genotyping (v2) assay is based on the SPF PCR system (Microgen Bioproducts, UK). The sequence variation in the inter-primer region has permitted the development of genotype-specific probes for 25 HPV genotypes (6/11/16/18/31/33/35/39/40/42/43/44/45/51/52/53/54/56/58/59/66/68/70/73/74). A recent study showed that the SPF10-INNO LiPA assay and Roche Linear Array assay are highly comparable and reproducible [152].

5.2.3 Liquid Bead Microarray

The LBMA assay is based on the Luminex-based technology (Luminex, Austin, TX), where HPV DNA is amplified using biotin-labeled consensus primers, then hybridized to a set of types of beads [153]. Each type of bead is attached with a probe specific to one HPV type. The beads with HPV DNA hybridized to them are then labeled with phycoerythrin-conjugated streptavidin and analyzed in the Luminex 100 instrument. Because of the unique fluorescent dye carried by each type of beads, HPV genotyping can be unambiguously determined. A recently developed and validated LBMA assay is available for genotyping 37 HPV types (6/11/16/18/26/31/33/35/39/40/42/45/51/52/53/54/55/56/58/59/61/62/64/66/67/68/69/70/71/72/73/81/82/83/83/IS39/CP6108) that can be useful for future clinical and epidemiologic research [153].

5.2.4 Other Novel Genotyping Methods

Several novel detection methods have been developed for HPV genotyping using DNA microarray, pyrosequencing, or mass spectrometry technologies. Based on DNA microarray technology, various HPV genotyping biochip assays have been developed, using different PCR consensus primers and detection method [154–157]. For example, Biomedlab in South Korea has developed HPV chips for genotyping of 15 high-risk (16/18/31/33/35/39/45/51/52/56/58/59/66/68/69) and 7 low-risk (6/11/34/40/42/43/44) HPV types [157]. In this assay, HPV is amplified using consensus primers in the presence of fluorescent-labeled nucleotides (Cy5-dUTP) and then hybridized to a DNA chip. The hybridized HPV DNA is visualized using a DNA chip scanner. Xu et al. developed an HPV biochip using spin valve sensor array and magnetic nanoparticle labels for genotyping four HPV types (16/18/33/45) [156]. The PapilloCheck test is a commercial DNA chip developed by Greiner Bio-One (Frickenhausen, Germany), which uses consensus primers targeting the E1 HPV gene and detects 15 high-risk HPVs (16/18/31/33/35/39/45/51/52/56/58/59/68/73/82), 2 probable high-risk HPVs (53/66), and 7 low-risk HPVs (6/11/40/42/43/44/70) [154]. More recently, a polymer-based HPV biochip has been developed using new consensus primers targeting the HPV L1-region and detecting 12 HPV types (6/11/16/18/31/33/35/43/52/56/58/73) [155]. The accuracy of these HPV biochip assays is determined by the sensitivities of the consensus primers to amplify all HPV types and the specificities of the probes to discriminate each HPV type. Early application of DNA pyrosequencing technology on HPV genotyping suggests that pyrosequencing is not only suitable for large-scale clinical application, but also able to identify novel HPV types and HPV variants. More recently, type-specific multiple sequencing primers are implemented to improve the ability of pyrosequencing assays to detect multiple HPV infections in clinical samples [158, 159]. Matrix-assisted laser desorption/ionization time-of-flight (MALDI–TOF) mass spectrometry (MS)-based assays have been also developed for HPV genotyping. Hong et al. described a method for HPV genotyping based on the restriction fragment mass polymorphism (RFMP) assay [160], while Soderlund-Strand et al. developed an HPV genotyping assay based on Sequenom MassARRAY platform [161]. These new technologies hold great promise in the future of clinical diagnosis. However, the successful implementation of these HPV genotyping assays requires the performance of studies to cross-compare different assays on a large number of clinical samples and the standardization of HPV genotyping assay protocols [162].

5.3 Recommendations and Limitations of Available Methods

In the United States, HCII is the only FDA-approved assay for detection of HPV. Furthermore, since there is no target amplification involved, the chance of sample contamination is low. This simple assay format is well suited for clinical settings because it does not require sophisticated equipment. Although the analytical sensitivity of the assay is lower than PCR-based assays, the HCII assay demonstrates a similar clinical sensitivity to target amplification methods. Therefore, HCII is the recommended assay for HPV testing in clinical settings. On the other hand, PCR-based HPV detection methods are recommended for epidemiologic studies where high analytical sensitivity and HPV genotype results are required. Currently, there is no commercially available PCR-based assay for HPV detection in the United States, although the Roche Amplicor HPV test has been launched in Europe. For clinical use, available PCR-based methods have shortcomings. Since there is no standardized protocol for sample preparation, PCR reaction conditions, and product detection, the analytical sensitivities and specificities of PCR-based assays vary from laboratory to laboratory. In addition, agreement between the HCII assay and various PCR-based assays for HPV detection in clinical samples is high.

It is important to recognize the limitations of both assays. For the HCII assay, cross-hybridization of the high-risk probe mix to low-risk HPV types, such as HPV-53 and HPV-66, can cause false-positive results. The assay also lacks

reproducibility for low viral load samples. In these circumstances, PCR-based methods might be used to corroborate the HCII result. Finally, the HCII assay cannot distinguish between single and multiple HPV infections since it does not provide viral genotype information; therefore, the assay is not suitable for detection of persistent HPV infection. Though PCR-based methods in general tend to have high analytical sensitivity, in comparison with the HCII assay, they have similar clinical sensitivity and lower specificity to detect cervical high-grade lesions and invasive cancer.

Several studies suggest that viral load, detection of persistent HPV infection, or detection of HPV integration into the host genome might be better markers for the risk of progression to cervical cancer. However, these assessments are not possible using currently available methods. Although the HCII assay is semiquantitative, it does not control for cell input. Even if cell input is controlled, it is still not possible to predict lesion size and percentage of abnormal cells in a clinical sample. It is impossible to determine whether the detection of a previously detected HPV type reflects persistent infection or a new infection because very little is known about the HPV life cycle and how fast the host immune system clears an HPV infection. Finally, because HPV integrates randomly into the genome, there is no molecular method that can be employed to assess the physical status of HPV (episomal or integrated) on large numbers of clinical samples [12].

5.4 Cytopathologic Diagnosis of Human Papillomavirus Infections

HPV infection can be diagnosed based on the histological or cytological recognition of characteristic cytopathic effects induced by the virus. In light microscopy, HPV can cause epithelial hyperplasia and a cytopathic effect in the skin or squamous epithelia that involves the superficial epithelial layers. This effect is related to the assembly of viral particles, followed by their release that occurs only in the superficial strata of the epithelium as described above. The cytopathologic changes are referred to as koilocytotic atypia [25]. Koilocytotic atypia, the hallmark of productive HPV infection, is characterized by nuclear hyperchromasia and wrinkling (described at times as "resinoid") associated with thick-walled perinuclear cavities that give the impression of "hallow" cytoplasm, hence the name as described previously. Virions in crystalline array are also visible by electron microscopy in the nuclei of degenerated cells. Hyperkeratosis (excess acellular keratin) or parakeratosis (nucleated keratinized cells) may be seen at the epithelial surface. The spiny or prickle layers may be particularly thickened (finding referred to acanthosis), particularly in exophytic, wart type lesions induced by certain types of HPV.

Recognition of exfoliated koilocytes, as part of cervical cancer screening, is considered characteristic for HPV infection. Analogous screening of other sites for HPV infection is also possible. For example, anal cytological screening can be performed in populations at high risk for anal carcinoma, such as homosexual men.

However, the low sensitivity and specificity levels of histological or cytological preparations for HPV-specific changes make the diagnosis of anogenital HPV infection impossible, relying solely on morphological diagnosis of HPV, because the findings are neither sufficiently accurate nor reliable. For example, based on conventional cervical cytological diagnostic practices, only about 10–20 % of HPV infections detectable by consensus primer PCR have concurrently abnormal cytological diagnoses of koilocytotic atypia. Cytological diagnosis of HPV is dependent on subjective interpretation of subtle morphological criteria, and the interpretation of the findings is hampered by wide interobserver variability [163, 164].

5.5 Clinical Diagnosis of Human Papillomavirus Infections

At the clinical level, some anogenital lesions can be diagnosed as possible HPV infections macroscopically. Skin warts have a characteristic raised appearance. Even when the lesions are flat and uncolored, on mucosal or skin surfaces, HPV-induced lesions may be diagnosed by application of 5 % acetic acid. HPV-induced lesions are usually "acetowhite," in that their color changes to white after local application of acetic acid. The mechanism behind this change in color is not known for sure, although several theories exist [165]. Acetowhitening is frequently used by clinicians examining the cervix, vagina, and vulva under magnification (colposcopy) following an abnormal cytological result, in order to identify and biopsy lesions. Cervicography is a clinical method of cervical cancer screening that also depends on acetowhitening to diagnose HPV in magnified photographic images of the cervix [166–168]. Because it represents a low-cost version of colposcopy, cervicography is adaptable to epidemiologic studies. However, acetowhitening is not specific for HPV infection as other types of epithelial conditions show similar tinctorial properties. Like colposcopy, anoscopy and peniscopy are possible in populations at risk of anal or penile carcinoma. Studies investigating the value of molecular testing of HPV from peniscopic and anoscopic samples are available [169–172].

The morphological diagnosis of HPV-related changes in anal lesions is the standard for defining the severity of anogenital HPV-related disease. However, the indications and modalities of histological and cytological specimen retrieval and diagnostic parameters related to these sites still remain to be fully defined [173].

5.6 Serological Assays

HPV types 16 and 18, the two most frequent cancer-associated types, as well as HPV-6 and HPV-11, the most common HPV types of genital warts, have been the HPV types most extensively studied, due to their higher epidemiologic impact. Associations have been described between HPV seropositivity and HPV-associated precancerous lesions like CIN [174] or carcinoma containing HPV-16 DNA [175–178].

While there is a relationship described between viral load and antibody response as well as persistent versus transient HPV infection and the capacity to produce HPV antibodies, epidemiologic studies have indicated that the proportion of women who develop these antibodies in the setting of a persistent infection varies and may be less than 60 % within 18 months of infection with HPV-16 and HPV-18 [179]. Although other studies have shown higher percentages [180–182], the response is not only patient dependent but also HPV-type dependent [179]. While HPV types differ in their immunogenicity, genetic and immunologic factors in individual patients regulate their capacity to produce antibodies against HPV, even in the setting of multiple HPV-type coinfections [179]. The chronologic relation between incident infection and antibody development varies; an interval of about 12 months following initial HPV DNA detection has been reported for HPV-16, HPV-18, and HPV-6 [179]. Furthermore, the antibody response tends to decline over time, despite the continued presence of detectable HPV DNA [179].

A variety of immunologic tests have been employed for the detection of antibodies produced, including enzyme-linked immunosorbent assays (ELISA), Western blot, and radioimmunoprecipitation assays (RIPA). Mainly, IgG and IgA antibodies have been assayed in serum, with a few studies of IgA in cervical secretions [174].

Among the HPV ORFs, E2, E6, E7, and L1 [183] are the ones most extensively studied, and for each ORF, several different epitopes have been tested. Researchers have attempted to define "HPV type-specific" epitopes as well as "type-shared" or "group-specific" epitopes reflecting exposure to any HPV [184]. The existence of apparently type-specific epitopes has been demonstrated by producing the same proteins (e.g., L1) from a series of HPV types and showing that antibody responses are restricted to a single HPV type or a few closely related types [179, 185].

Most antigens for seroepidemiologic studies of HPV have historically been produced as bacterial fusion proteins [185], chemically synthesized peptides [186], and in vitro-translated proteins [176, 178]. In the attempt to study the antigenicity of viral proteins in their native conformational state, viruslike particles (VLPs) have more recently been used for these immunoepidemiologic studies [179, 187, 188] and used instead of linear epitopes. Investigators have proposed that the neutralizing antibody response to HPV is directed predominantly against conformational antigens, created by the folding of the capsid (L1 and L2) proteins during virion assembly. As these antigens usually are not completely represented by linear epitopes, the use of VLPs has permitted a more accurate assessment of the immunologic response to the natural HPV antigenic epitopes. A number of investigators have successfully synthesized HPV VLPs for viral types 1, 6, 11, 16, 18, 31, 33, and 45 [48, 189, 190]. In the last years, specific antigenic peptides and their possible use as serological markers for HPV infection and HPV-associated malignancy have been studied [188, 191, 192], but the advancements in this field are far behind compared to DNA testing for HPV, mainly due to the extensive variability and the partial understanding of the immune response against these viruses and even more so its clinical significance. The major advancements in DNA testing for HPV detection and typing make HPV DNA testing the mainstay for epidemiologic and clinical methodology.

6 Descriptive Epidemiology

6.1 Prevalence and Incidence Data

HPV infections are extremely common in the general population. However, in the estimation of the exact burden of HPV, several factors should be taken in account: the type of tissue under study, the methods employed in the sample collection and analysis, and the geographic and other population characteristics. All the factors that are implicated in the natural history of disease caused by HPV infection complicate its epidemiologic study. Due to the clinical impact of cervical cancer, extensive studies and more reliable HPV prevalence estimates have been generated for the genital region, particularly the cervicovaginal epithelium, with increasing data available for other tissues.

6.1.1 Prevalence of Cervical Human Papillomavirus Infections

Studies looking into HPV cervical infection incidence and prevalence have shown highly disparate results, depending on the modality of collection of specimens, the analytical methods, and the age and sexual practices of the population. Individuals of younger and with higher levels of sexual activity appear to be at greatest risk; among the various populations studied, these groups appear to have the highest prevalences of HPV infection. This emphasizes the importance of accounting for these factors in reporting observed prevalence, rather than summarizing figures for whole populations [193–195].

Using the cytological diagnosis of koilocytotic atypia as the measure of HPV infection, the point prevalence varies

considerably among independent studies, and different populations with similar characteristics have shown different prevalences [196–198]. Conversely, studies employing more than one analytical technique have yielded different results when studying the same population [197]. Furthermore, the diagnostic criteria employed in the various studies are not uniform with regard to accepting the sole detectable HPV DNA in the population versus using clinical and cytological criteria for the definition of HPV infection. Early studies demonstrated significant percentages of detectable HPV in women with normal pap smears. Cervical HPV infection as defined by HPV DNA detection in cytologically normal women was higher in younger women with negative cytologies, while older women with negative cytologies showed lower percentages of HPV positivity. These findings were attributed to transient HPV infection with no clinical significance. Conversely, among women with cytological atypia, the percentages of HPV positivity did not change with age [199].

Table 44.2 presents data from large-scale HPV testing of cytologically normal women screened at Kaiser Permanente health clinics in Portland, Oregon [24]. Two different testing methods were used to study this population. The first group of women was tested for HPV using a consensus primer PCR, followed by typing of the amplification product by dot–blot hybridization. The second group was tested for 16 specific types of HPV by Hybrid Capture. Using either test method, HPV-16 was observed to be the most common individual type among cytologically normal women. Most HPV types individually accounted for only a small proportion (<10 %) of the total infections of this population. Unknown types at that time, cumulatively considered as a group, still accounted for a sizable fraction of infections among cytologically normal women tested by PCR.

The estimated prevalence values of HPV infection among women around the world range between 2 and 44 % [33]. The wide variation in estimates is largely explained by differences in the age range of the populations studied and the sensitivity of the DNA assay used for detection of HPV infection. Various methods used in these studies and the improvement of techniques over the course of the years also account for these different results. These DNA-based studies, when combined with measurements of type-specific antibodies against HPV capsid antigens, have shown that more than 50 % of sexually active women have been infected by one or more genital HPV types at some point in their lives. In a Planned Parenthood clinic population in the United States with mean age of 25 years, the prevalence of high-risk HPV infection was 27.4 % [200]. Similar prevalence estimates have been found among female university students in the United States and Canada [201, 202]. A recent study in Scotland showed the prevalence of PCR-detected HPV DNA in women with a mean age of 36.6 years attending routine cervical cancer screening to be approximately 20.5 % for all HPVs and 15.7 % for HR-HPVs [203], while a more recent study in Turkey showed a 17.9 % PCR-detected HPV DNA prevalence among women with normal cervical smears [204]. HPV-16, which is one of the more common types among cytologically normal women, is also the most common type among cervical cancer cases [36, 199, 201, 202, 205–208]. The prevalence of type-specific HPV infections among HPV-infected population-based controls from the International Agency for Research on Cancer (IARC) cervical cancer study and from a US Planned Parenthood population is shown in Table 44.3.

Table 44.2 Prevalence of individual HPV types among cytologically normal women, assayed by L1 consensus primer PCR or Hybrid Capture in cervical specimens from two random samples of Portland Kaiser gynecology patients (individual prevalence estimates expressed as percent of total positives)

	PCR ($n=453$)	Hybrid capture ($n=12{,}366$)
Total HPV positivity	17.6 %	4.6%[a]
HPV types (% of positives)		
6/11	9.7 %	9.0 %
16	14.6 %	16.8 %
18	1.2 %	7.9 %

[a]Hybrid Capture was performed for 16 specific types of HPV; thus, the total percentage of positivity cannot be compared to PCR without adjusting for which types were included in the respective tests

[b]*N/A* not assayed

[c]Types not characterized at the type of original PCR testing. Several of these types have since been assigned numbers, e.g., HPV-66 and HPV-68, or have been found to be subtypes or variants of known types

6.1.2 Incidence of Cervical Human Papillomavirus Infections

It is important in natural history studies to distinguish incident (newly acquired) cervical HPV infections from prevalent infections, because prevalence reflects the duration of

Table 44.3 Type-specific HPV DNA prevalence among HPV-infected women

HPV types	Percentage of all infected women (median age of 46 years) (IARC)[a]	Percentage of all infected women (median age of 25 years) (USA)[b]

infection as well as the incidence rate. However, this distinction has proven difficult to make for HPV. To distinguish HPV incidence from recurrence requires the knowledge at the outset that a woman has not been previously infected. With no marker of lifetime HPV exposure, the possibility of viral reactivation from a "latent" state below the level of current molecular detection must always be considered as an alternative interpretation of apparent incidence [24]. New acquisition of HPV is very common, and sexually active young females are the population group with the highest risk. The incidence of infection with high-risk HPV types appears to be higher than with low-risk types [201, 202, 205, 210]. In a prospective study in the United Kingdom, the cumulative incidence of HPV infection among women aged 15–19 was found to be 44 % over a 3-year period and increased to 60 % at the end of 5 years [36]. Similar studies in the United States have yielded similar results. Among two populations of college women in the United States, the 3-year cumulative incidence of HPV infection was 43 % in one study [201] and 42.8 % (95 % CI: 38.0, 47.9) in another [211]. In a cohort study of Brazilian women, the cumulative incidence of HPV infection was 23.6 % over 18 months [205], an estimate similar to the 18-month cumulative incidence figures in previous studies.

The differences in age-specific incidence rates for cervical HPV infection seem to parallel the differences in age-specific prevalence rates presented above. In particular, the apparent incidence of cervical HPV infection, as measured by new DNA detection or first cytological diagnosis under observation, is highest in sexually active young women, going hand in hand with the observations made on the prevalence rates of HPV in the various population groups [212, 213].

6.1.3 Prevalence and Incidence of Genital Warts

The clinical manifestation of a number of HPVs belonging in the low-risk category is an exophytic lesion known as *condyloma acuminatum* or simply genital warts. These are histologically characterized by arborescent, spiky papillae surrounding thick fibrovascular cores and showing normal maturation of the keratinocytes. These lesions show sharply demarcated base, with no evidence of invasion, and may present koilocytic changes. HPV types 6, 11, and related types [213] are the most commonly associated types with these lesions. However, the data available regarding the prevalence and incidence of genital warts are essentially based on clinical observation, as in common clinical practice these patients do not undergo DNA testing for HPV. Thus, the prevalence and incidence of clinically diagnosed genital warts, certainly a measure of infection with these HPV types, most likely represents an underestimation of the true infection rates.

A study by the California Family Planning Access Care and Treatment (Family PACT) program, looking at a little over 2 million people between 2007 and 2010, showed a prevalence of 0.7 % for females and 3.3 % for males in the general population [214] with the highest rates in the 20–25 years age range. Among a series of women in another clinical setting, genital warts are most commonly found in the following sites (in rough order of decreasing prevalence): the posterior part of introitus, labia minora and clitoris, labia majora, perineum, anus, vagina, urethra, and cervix. In men, the order of frequency is reported to be the frenum, corona and glans, prepuce (foreskin), meatus, shaft, anus, and scrotum [24, 215]. Finally, it has been noted that the clinical manifestation of genital warts usually involves more than one site in the genitourinary area, and very commonly these lesions are associated with concomitant HPV infection of the vagina and cervix, as documented by clinical and DNA testing [216–218].

6.1.4 Prevalence and Incidence of Nongenital Cutaneous Warts

Skin warts are so common and demonstrate so benign behavior that they raise very little epidemiologic interest. As a result of that, there are very few studies giving exact epidemiologic estimates available. Furthermore the lack of PCR assays used in these clinical settings makes the data less reliable.

One of the largest population surveys of the prevalence of skin diseases in the general population was conducted as part of the US Health and Nutrition Examination Survey (HANES) of 1971–1974 [219], studying over 20,000 subjects, and showed an estimated population prevalence of 850 per 100,000. More recently a study employing a PCR-based assay examining HPV types involved in cutaneous warts demonstrated that HPV types 1, 2, 27, and 57 were most commonly associated with cutaneous warts, being present in 89 % of cases [220].

6.1.5 Prevalence and Incidence of Other Human Papillomavirus Infections

The prevalence of vaginal HPV infection cannot be easily separated from cervical HPV infection, because vaginal cytological

specimen collection is characterized by admixture of exfoliated cervical cells. While the few small studies of HPV DNA prevalence in women with hysterectomies have found vaginal HPV infection to be common [221], the range of HPV types detected by cervicovaginal lavage is virtually identical to the types found in cervical swabs and scrapes [222] supporting the theory of concurrent infection of the urogenital tract by the various HPV types. HPV-related koilocytic cytopathic effect is well described, but, as cytological surveillance of vaginal lesions is not standardized as it is for cervical HPV infections, the assumption is that albeit the frequencies of infection by HPV for the vagina and cervix are similar, the malignant potential of the various HPV types is tissue specific.

In estimating the prevalence of HPV infection, the vulva must be considered as two separate subsites, the introital mucosa of the labia minora versus the cornified skin of the labia majora. The HPV types that cause exophytic genital warts (6, 11, 42, 44, and related types) commonly infect both subsites of the vulva, while the viruses associated with cervical carcinoma (16, 18, 26, 31, 33, 35, 39, 45, 51, 52, 54, 55, 56, 58, 59, 64, 68, and related types) infect the labia minora with higher prevalence, comparable to that of cervical infection [223], although high-grade intraepithelial and invasive vulvar neoplasias are relatively rare compared to cervical neoplasia. Other sites potentially infected include the urethra [224].

Similarly in the male, infection of the penis with cancer-associated types of virus appears to be very common. As with the vulvar skin, noninvasive sampling of the penile epithelium is difficult. Prevalence estimates of HPV infection (as measured by PCR-based assays of HPV DNA) in young men attending sexually transmitted disease clinics have given estimates as high as 84 % [225]. HPV-containing lesions of the penis have reportedly been found in a high percentage of men whose sexual partners have CIN [226, 227].

In a recent study conducted in the United States, Mexico, and Brazil with a combined study group of 1159 men, the incidence of a new genital HPV infection was 38.4 per 1,000 person-months, defined as newly diagnosed HPV infection by HPV DNA PCR detection. The presence of high-risk HPV infection was found to be significantly associated with a higher number of lifetime female sexual partners but also with a high number of male anal sexual partners. This study also looked into the median duration of infection and concluded that the clearance of high-risk HPV infection decreased in men with a high number of lifetime female partners. Age was seen to play a role in prognosis as clearance of high-risk HPV was more rapid in increasingly older patients [228].

HPV infection of the anus has been studied particularly in the context of human immunodeficiency virus (HIV)–HPV interactions in homosexual men [15, 173, 229]. HPV infection of the anal epithelium is very common in homosexual men, as diagnosed by HPV DNA detection or by morphological characteristics in cytological or histological specimens, independent of HIV status. Studies in HIV-negative homosexual men have shown that the prevalence of anal HPV infection is around 75 %, while that of high-risk HPV types is more than 50 % [230]. Positivity for HPV in squamous carcinomas of the anus has been reported as high as 93 % [173]. In accordance to the findings of urogenital lesions, HPV-16 is the most prevalent, while the most common types are the ones observed in the genital areas. The prevalence of HPV infection of the anus in the general male population is unknown. A few studies of anal carcinoma in women have suggested correlations with cervical carcinoma in the same populations, implying a common etiology most likely to be anogenital HPV infection [231].

HPV types showing tropism for the anogenital mucosa as well as nongenital cutaneous types can infect the oral cavity and other regions of the upper aerodigestive tract [232]. HPV can be found in biopsies from a variety of lesions of the oral cavity and appears to be the etiologic agent for one type of benign lesion called focal epithelial hyperplasia [233]. Despite studies available where HPV infection is tested in patients with oral squamous cell carcinomas, a cause-and-effect role for HPV in these carcinomas has not been established [234]. Studies examining the prevalence of HPV DNA in the oral cavity in the general population show rather discrepant results [235].

Described presence of detectable HPV in various other human tissues, including the esophagus [236], lung [237], prostate [238], and bladder [239], remains to be defined with regard to a possible clinical significance.

6.2 Epidemic Behavior

HPV infections are most commonly transmitted by person-to-person contact. It has been suggested that minor epithelial tearing is a prerequisite to transmission, permitting the virus to reach the target basal cells that are the virus initial targets. Transmission through the sharing of fomites HPV could be possible, and few studies have shown presence of HPV DNA on underclothes and gynecologic equipment [240] suggesting a mechanism similar to the transmission of plantar warts among school children. Similarly, airborne transmission of viral particles appears plausible in very special settings, such as laser ablation of genital warts in a gynecologist's office, with resultant virus-containing laser plumes [241]. The viability of HPV outside of the human body under varying conditions and the deriving risk of transmission are still unknown. Vertical transmission has been recently evaluated and the possibility of transplacental HPV infection has been reported as high as 70 % in immunocompromised mothers [242]. Other studies examining vertical HPV transmission have detected HPV DNA in amniotic fluid, cord blood, and fetuses. HPV transmission have detected HPV DNA in amniotic fluid, cord blood, and fetuses. These studies demonstrated that the virus can infect children during the perinatal period [243–246], while other

studies showed the possibility of horizontal, nonsexual transmission between family members and particularly between parents and neonates [247].

The age-specific prevalences of different types of HPV infection support the view that most infections are passed from infected to uninfected individuals. Common cutaneous warts (HPV-2 and HPV-4 and other types) are most frequently seen in school-aged children and adolescents [248]. Plantar warts have a later modal age peak in adolescence and early adulthood [248]. Male and female genital HPV infections (as measured by DNA, cytological diagnosis, or presentation of overt genital warts) peak in early adulthood concurrent with the age of usual onset of sexual intercourse [193, 199]. These peaks in age-specific point prevalences appear to represent the combined effects of exposure and immunity [24].

6.3 Geographic Distribution

6.3.1 Cervical Cancer Geographic Distribution

The geographic distribution of HPV DNA detection has been studied mainly in correlation with cervical cancer incidence rates, and efforts have been made to determine whether variation in prevalences of HPV measured by DNA would be reflected in cancer rates. In earlier studies, geographic differences in HPV did not correlate consistently with geographic differences in cervical cancer incidence [249].

In 2008 cervical cancer was the third most common cancer in women in the world, and the seventh overall, with an estimated 530,000 new cases in 2008. More than 85 % of the global burden occurs in developing countries, where it accounts for 13 % of all female cancers. High-risk regions are Eastern and Western Africa with an age-standardized rate (ASR) greater than 30 per 100,000, Southern Africa (26.8 per 100,000), South-Central Asia (24.6 per 100,000), South America, and Middle Africa (ASRs 23.9 and 23.0 per 100,000, respectively). Rates are lowest in Western Asia, Northern America, and Australia/New Zealand (ASRs less than 6 per 100,000). Cervical cancer remains the most common cancer in women only in Eastern Africa, South-Central Asia, and Melanesia. Overall, the mortality–incidence ratio is 52 %, and cervical cancer is responsible for 275,000 deaths in 2008, about 88 % of which occur in developing countries: 53,000 in Africa, 31,700 in Latin America and the Caribbean, and 159,800 in Asia (World Health Organization – International Agency for Research on Cancer, GLOBOCAN 2008 data).

6.3.2 Cervical HPV Infection Geographic Distribution

Studies on the prevalence of HPV DNA in cervical specimens from women with negative cytological results have findings that vary considerably, due to the selection of study subjects and to the different tests used to detect HPV DNA. A recent multicenter, centrally coordinated international study conducted by the International Agency for Research on Cancer (IARC) has provided data from 15 areas in 4 continents regarding women aged from 15 to 74 years. The age-standardized prevalence ranged from less than 5 % in some Mediterranean and Southeast Asian countries to more than 15 % in several countries in Latin America and among a few African populations [250]. In a comprehensive review of studies that used standardized inclusion criteria and controlled for variables that may have challenged the comparability of the studies, prevalence estimates of HPV infection among women with negative cytological results ranged from 10 to 15 %.

Age-specific prevalence estimates showed HPV DNA to be more prevalent among very young women, with a decline in young adult women and a variable pattern afterwards. In some countries, notably in the Americas, the prevalence increased again in postmenopausal age groups. In Europe, a plateau in the middle-aged groups was maintained, whereas in other high-prevalence countries in Asia and Africa, the prevalence remained fairly constant across all age groups [251].

6.4 Temporal Distribution

6.4.1 Cervical Human Papillomavirus Infections

In order to examine trends of HPV infection over time, sequential datasets submitted by different cancer registries are being used. The vast majority of data available involves cervical cancer, and while some conclusions can be made for high-risk HPVs, there is relatively little data for low-risk HPV infections. Although there is substantial variation in terms of the age-standardized incidence rates observed among different countries, generally, in developed countries, the incidence is declining at a broadly similar rate in the more recent time period. While the absolute incidence rates will, to a certain degree, reflect the prevalence of high-risk HPV infection in the respective populations, the decline is thought to be predominantly a result of the introduction of effective screening procedures combined with a range of sociocultural and economic factors [252]. Unfortunately, most of the data available comes countries with higher socioeconomic status, and while they may suggest that there is an overall worldwide decline in incidence, this is not universally the case. In some populations, mainly from parts of East and Southeast Asia and Eastern Europe, where data is available and in the absence of effective screening, incidence has remained stable or increased in successive generations of women as a result of changing sexual behavior and increasing risk of persistent HPV infection [252].

The GLOBOCAN 2008 database gives the possibility to make projections of the expected burden of cervical cancer up to 2030. These projections are based entirely on predicted variations in the demographics of the various populations,

including expected growth variations and changes in age distribution. Based on these estimates from global burden for cervical cancer of 530,000 new cases in 2008, it is projected that the annual incidence rates will increase by approximately 2 % annually to an estimated 770,000 new yearly cases by 2030 (World Health Organization – International Agency for Research on Cancer, GLOBOCAN 2008 data). However, these estimates are an average of the various regional trends and that again are very different between developed and developing countries [252].

Even within the same population however, different subgroups present their own particular trends. In a study taken place in Finland, the Finnish Maternity cohort, comparing between the time periods 1983–1985 and 1992–1994, the incidence of HPV-16 among women age ≤22 was seen to drop from 25/1,000 person-years to 13/1,000 person-years before increasing again to 31/1,000 person-years in the period 1995–1997. In particular, for women between the ages of 23 and 31, the HPV-16 incidence increased steadily from 5/1,000 person-years to 13/1,000 between 1983–1985 and 1995–1997 [253]. For noncancerous HPV-related disease, far less global data is available. In the United States, the age- and gender-adjusted incidence of genital warts increased from 13/100,000 to 106/100,000 between 1950–1954 and 1975–1978 [254] and appears to be on the rise even more recently [252]. A renewed interest for the trends of incidence of genital warts has been developed as a result of the introduction of HPV-6 and HPV-11 vaccination.

6.4.2 Other Human Papillomavirus Infections

The incidence of genital warts appears to have increased substantially over the past few decades, according to data available from the United States and the United Kingdom [255–257]. The incidence of condylomata in the United States increased about five times between 1966 and 1981, with most of the increase occurring prior to 1976. A similar tendency was observed in the United Kingdom between 1972 and 1982. Data on other types of HPV infections are less reliable because they rely mainly on clinical observation, and specific HPV DNA testing is normally not performed for these conditions [24].

6.5 Age

6.5.1 Cervical Human Papillomavirus Infections

At the simplest level, it appears that cervical HPV infection rates measured by DNA detection or cytology decline sharply with age, from a peak at 16–25 years of age [199, 258, 259].

The prevalence of HPV infection is highest among young women and appears to decrease with increasing age. In a meta-analysis using data from multiple international studies, the median high-risk HPV prevalence among all women was found to be 15.1 %, while the median high-risk HPV prevalence among women age 30 and older was 9.2 % [260, 261]. Since the occurrence of HPV infections in most cases is closely connected to the initiation of sexual activity and most are transient, the over-age-30 group of women who are HPV positive includes those who are persistent carriers as well as those with new infections. While most studies indicate a decrease in HPV prevalence with age, some data from studies conducted in several different international regions attest to the pattern of a peak prevalence of HPV infection in women below age 25, a decrease among women aged 35–54 and a second peak after age 55 [262]. This difference is highlighted in Fig. 44.3. This observed increase in HPV prevalence in older age groups (age group 45–54 years old) could be attributed to a cohort effect or to reactivation of latent virus [209].

The prevalence of HPV infection in women under 16 years of age is difficult to assess, because this is generally the minimum age of obtainable informed consent for most epidemiologic studies. To further support the connection between initiation of sexual activity and onset of HPV infections, albeit through limited DNA test data collected before sexual debut, it appears that cervical HPV infection is extremely uncommon in both girls and adult women who are sexually naïve [194, 263].

In many study populations, the prevalence of HPV infection as measured by DNA or cytology decreases strongly with age, from a peak at 15–25 years [199]. The profound drop in cervical HPV prevalence in women over age 30, seen in many different studies, is thought to be due to immunologic clearance or suppression of existing infections. This implies a transience of most HPV infections, in combination with less exposure to new HPV types from fewer new sexual partners after that age. The "sexual acquisition/immunologic clearance" explanation of the HPV age trend is supported by prospective data suggesting rapid, sexual acquisition of HPV [212, 264] and by other prospective data indicating that most HPV infections are only transiently detectable [213, 264].

The majority of women infected with a specific HPV type will not show evidence of that same type 6–12 months after initial detection [201, 205, 212, 264, 265]. In a prospective study of female college students, approximately 70 % of women no longer showed detectable HPV DNA within 12 months of follow-up after the incident HPV infection, while after 18 months over 80 % of the subjects appeared to have cleared their infections [201]. These findings have been supported by several other cohort studies having a median duration of HPV detectability of approximately 1 year [36, 205, 212, 266]. Some studies compared high-risk and low-risk HPV duration of infection and showed similar average duration [202], while others showed longer durations of infection for high-risk than for low-risk HPV types [201, 205, 212]. It appears that HPV-16 has a particularly long time to clearance relative to other HPV types [202, 207].

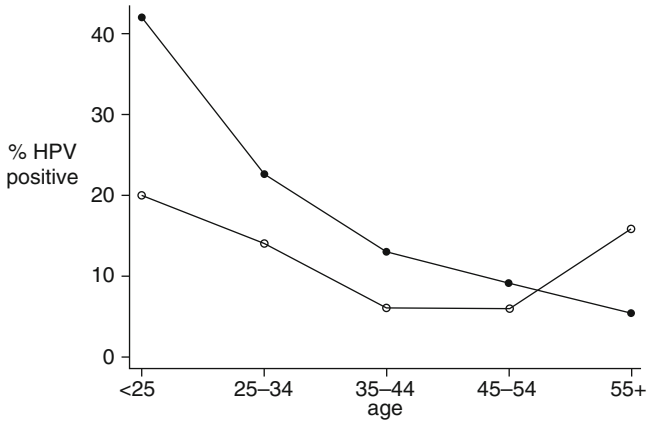

Fig. 44.3 Age-specific prevalence of HPV in a routine screening population in the UK, data source: Cuschieri et al. [203] (*solid circles*) and in rural Costa Rica, data source: Herrero et al. [262] (*open circles*) (Modified from Baseman and Koutsky [209], with permission)

When interpreting data on duration of HPV infection, it is important to keep in mind that there is no consensus regarding what constitutes a "persistent" HPV infection. The interval between follow-up visits varies among studies, and many aspects of the natural history of HPV remain unknown. Therefore, what constitutes an appropriate assessment interval, the significance of being positive at two points, and the distinction between "persistence" and "transience" of infection all still remain to be defined. Moreover, it is unclear whether undetectable HPV infections have been acquired and entirely cleared by the host or whether there is a period of viral latency in which HPV levels are maintained below the detectable threshold of current HPV DNA assays, a threshold which varies among these assays. If viral latency occurs, a woman who appears to have cleared her infection between follow-up visits would still be at risk for potential development of HPV-associated disease. In the same way, it is unclear whether HPV infections that are detectable over a certain interval of time result from persistent HPV infection or HPV clearance and reinfection. Reinfection with the same HPV type appears to be uncommon: three cohort studies of sexually active young women showed that the same HPV-16 variant was always detected in the same woman during follow-up examinations [267].

6.5.2 Other Human Papillomavirus Infections

Age trends in other genital HPV infections (e.g., condyloma acuminatum) tend to parallel the trends in cervical infections, with the peak rates occurring between ages 15 and 25 and connected to the usual onset of sexual intercourse. In accordance to that, genital warts in both men and women tend to peak at these ages [255, 257, 268], as does the prevalence of penile HPV DNA detection and the occurrence of flat HPV-containing lesions of the penis [225].

Age-specific prevalence rates of nongenital cutaneous HPV infections have been less well documented, and it is widely accepted that these lesions are extremely common. Historical reports include the HANES study of 1971–1974, and the prevalence of nongenital cutaneous warts was observed to peak in the 12–17-year age group and to decline thereafter [219]. The age peak in males (18–24 years) was later than in females (12–17 years). Plantar warts were not distinguished from common cutaneous warts; thus, these prevalence estimates are not site- or HPV-type specific, and also in these studies the diagnosis is clinical and corresponds to a cutaneous wart, without the confirmation of HPV infection. A more recent population-based British study of nongenital cutaneous warts was consistent with the HANES study, finding a prevalence of 3.9 % at age 11 and 4.9 % at age 16 [269]. Again, the sites and kinds of warts seen were not distinguished. From other school-based series, it appears that the peak age of plantar warts occurs a few years later than the peak age of common warts [270]. In the last few years, studies have been made available in multiple countries, and a recent Australian study in pediatric patients showed that the incidence of cutaneous warts among that population is that of 22 %, with common warts being 16 % alone, and that the prevalence changes with age as in the 2–4 years old group the prevalence was that of 12 %, only to double to 24 % in the 16–18 years old group [271].

6.6 Sex

6.6.1 Genital Human Papillomavirus Infections

Reliable prevalence estimates for genital HPV infections in males are more difficult to obtain than for females. It appears from the available data, which are sometimes conflicting, that genital HPV infections are about equally common in both sexes [255, 257, 272].

HPV-induced penile lesions can be found in the urethral meatus, on the glans and shaft of the penis, and on the scrotum [273], but, unlike with the localized, easily exfoliated mucosal surface of the cervix, the cornified epithelium of the penis and scrotum does not permit a reliable, standardized collection of relevant cells.

Since the advent of PCR-based HPV test methods, analysis of HPV infection in men is more feasible. A recent study tested male partners of women with genital HPV lesions and found that warts and high-grade intraepithelial neoplasia were diagnosed in 83 (78 %) and 23 (22 %) of cases, respectively. The prevalence of clinical HPV lesions in men ranged from 34 % in case of HG CIN to 80 % when the female partner suffered from genital warts. The authors concluded that peniscopy in males with female partners having an HPV-related lesion could be a feasible solution [274].

6.6.2 Nongenital Cutaneous Human Papillomavirus Infections

Data from the early HANES study (1971–1974) suggest that males have slightly higher prevalence of nongenital cutaneous warts (10.3 per 1,000) when compared to females (7.2 per 1,000) [219]. A strong male predilection was noticed only in the 18–24 age (21.5 per 1,000 for males compared to 4.0 per 1,000 for females). However, other surveys have not generally confirmed this disparity. In fact, a female excess for plantar warts among teenagers has been reported [275].

6.7 Race and Ethnicity

The correlation of HPV prevalence with race, controlling for known risk factors for infection, is not clear. To study the correlation of HPV with race demands random, strictly comparable sampling of different racial populations is necessary. Clinic-based studies are prone to confounding by correlates of race, such as differences in socioeconomic status and patterns of self-referral.

Epidemiologic studies in the United States have been able to compare different ethnic groups living in the same geographic areas, and the data produced show that African-American women have higher rates of cervical cancer and mortality rates compared to other races (US Cancer Statistics Working Group: United States Cancer Statistics: 1999–2009). Age-adjusted death rates show 4.3 per 100,000 for African-American women in comparison to 3.0 for Hispanic women and 2.2 for Caucasian women (US Census Bureau: 2000 Census). Paradoxically, data on Pap test use in 2008 show that African-American women have the highest screening rates nationally of all racial and ethnic groups at 80.1 % in contrast to 74.9 % for non-Hispanic white women and 75.4 % for Hispanic women (National Center for Health Statistics) [276]. This discrepancy between mortality and screening rate suggests a number of explanations including the continued existence of confounders that could distort certain comparisons between these groups. Potential confounders include socioeconomic, educational, and health system barriers impacting access and utilization of quality health care, as well as the failure of current interventions to account for the cultural diversity within this population and how it impacts their cervical cancer knowledge, attitudes, and practices [276].

The resulting increased rates of CIN and cervical carcinoma among African-Americans, Hispanics, and Native Americans (compared to non-Hispanic whites) are intertwined with socioeconomic differences in risk [277]. Another discrepant result was noticed from these studies: in contrast to cervical cancer rates, the frequency of genital warts [255, 257] and nongenital cutaneous warts [269, 278] has been reported to be higher in whites than in blacks.

6.8 Other Factors Influencing the Prevalence of Genital Human Papillomavirus Infections

6.8.1 Occupation

The only professions linked to HPV infection are those associated with an increased risk of exposure to the virus, and accordingly sex workers are at increased risk of clinical outcomes of genital HPV infection [23]. However, the prevalence of HPV DNA was not elevated in one survey of immunocompetent (HIV-uninfected) sex workers [279]; this finding may reflect their development of immunity. Meat and fish handlers are reported to be at increased risk of infection with HPV type 7 [280, 281], but the mode of transmission in this case remains obscure.

6.8.2 Socioeconomic Status

Cervical HPV prevalence appears to be increased in women of lower socioeconomic status [282], in accordance with their higher risk of cervical carcinoma [277]. One study of nongenital cutaneous warts also observed increasing prevalence in children of lower socioeconomic status [269].

6.8.3 Pregnancy

Current pregnancy, especially advanced pregnancy, has been found to increase the detection of cervical HPV DNA, although different studies show significant variability [283–285]. If confirmed, increasing susceptibility to HPV infection during pregnancy could suggest the possibility of viral reactivation.

6.8.4 Smoking

HPV infection has been associated with current smoker status [286] and past history of smoking [287]. However, only one study found that formerly smoking women had a significantly lower prevalence of HPV infection than women who had never smoked [282]. A more recent study investigated the relationship between smoking and oncogenic HPV infection and found no association between number of cigarettes smoked per day and presence of HPV DNA [288], and most other studies investigating the relationship between smoking and HPV infection have failed to detect an association [209, 289–292].

7 Mechanisms and Routes of Transmission

7.1 Evidence for Sexual Transmission of Genital Types of Human Papillomavirus

Sexual partners of women or men with HPV-related lesions are more likely themselves to have clinical, cellular, or DNA evidence of HPV infection [226, 273], and despite the fact

that clinically diagnosed lesions are often absent, studies have suggested that the majority of regular sexual partners of infected individuals show themselves detectable HPV infection [193, 194, 283].

The most consistent risk factor for HPV infection is believed to be an increased number of sex partners, and studies of women have demonstrated strong associations between lifetime number of sex partners and detectable genital HPV in both sexes [286, 289, 292–296]. Although HPV type-specific analyses have been limited by small sample sizes, the prevalences of both cancer-associated and noncancer-associated HPV types are associated with sexual history.

According to a few epidemiologic studies available, the epidemiologic variables "*lifetime* numbers of *different* sexual partners" or "*recent* numbers of *different* sexual partners" are superior predictors of risk of prevalent cervical HPV infection compared to "*lifetime* numbers of *regular* sexual partners," suggesting that long-term association with a partner is less likely to increase risk [283].

7.2 Nonsexual Transmission of Genital Human Papillomavirus

Although the sexual transmissibility of HPV has been extensively studied, the nonsexual person-to-person transmission and the possibility of indirect transmission are only partially understood.

In the study of nongenital HPV infections, documented transmission of HPV in laryngeal infections (often due to types 6 and 11) supports the notion that vertical transmission of genital HPV infections is possible [297]. The occurrence of laryngeal papillomas in children has been associated with genital warts in the mother, and cesarean section has been associated with some protection against laryngeal papillomas. Moreover, the types of HPV in laryngeal papillomas (types 6 and 11) are the same as in genital warts. However, the reported increase in the incidence of genital warts has not been followed by an appreciable increase in laryngeal papillomatosis.

Among 329 recently studied pregnant women, HPV genotypes present in the cervix of the mothers, their newborns, cord blood, and placenta samples were determined by molecular and immunologic techniques [298]. HPV DNA was detected in 17.9 % of oral samples from newborns and in 16.4 % of the cervical samples of the mothers. At delivery, mother–newborn pairs had similar HPV-genotype profiles, but this concordance disappeared in 2 months, while oral HPV carriage in newborns was most significantly associated with the detection of HPV in the placenta. The association between HPV in cord blood and oral HPV was also significant at delivery but disappeared within 1 month. Finally, the HPV antibodies detected in the infants were found to be of maternal origin. The study concluded that HPV is prevalent in oral samples from newborns and that the genotypic profile of newborns is more restricted than that of the maternal cervical samples. The close maternal–newborn concordance could indicate that an infected mother transmits HPV to her newborn via the placenta or cord blood.

7.3 Transmission of Nongenital Cutaneous Types of Human Papillomavirus

Direct skin-to-skin transmission is known to be the predominant mechanism of transmission of skin warts [248]. Activities associated with minor skin trauma promote person-to-person transmission and subsequent autoinoculation [275], which permit access for the HPV to the basal layer of the epidermis that the virus has a tropism for.

Although direct contact is the established route of transmission of most nongenital cutaneous HPV infections, the mode of transmission of the rare HPV types found in epidermodysplasia verruciformis is still a subject of study. Only a few hundred cases of the condition have been reported [133], and individual studies involve a very limited number of cases. The disease is believed to be an autosomal recessive genodermatosis with an increased susceptibility to specific HPV genotypes [299]. It has been associated with more than 20 known EV–HPV types, including 3, 5, 8, 9, 10, 12, 14, 15, 17, 19–25, 28, 29, 36, 46, 47, 49, and 50 [300].

8 Pathogenesis and Immunity

8.1 Pathogenesis

8.1.1 Definitions Related to Studies of Human Papillomavirus Pathogenesis

As knowledge surrounding HPV infections and diagnostic modalities evolved, the need to redefine the terms in which the HPV genesis of disease is described arose. These terms changed to better reflect the viral biology and the natural history of viral infection and eventual subsequent disease manifestations. This newer way to classify HPV pathogenesis, almost 20 years old now, had also the role to avoid the use imprecise terminology, in the face of lack of understanding of the various facets of HPV biology. The use of terms such as "latent" or "subclinical" infection is being abandoned, and, to facilitate the discussion of HPV pathogenesis, a classification system was proposed based on the diagnostic method that establishes the HPV infection [301].

According to the proposed system, the *molecular* evidence of HPV is established by the demonstration of viral particles, nucleic acids, or proteins, using methods such as electron microscopy, PCR, or other nucleic acid hybridization

techniques, but also Western blot and immunocytochemistry. *Cellular* (or microscopic) evidence of disease requires morphological evaluation for the presence of viral cytopathic effect in cytological and/or histological specimens. *Clinical* evidence of disease is based on the presence of symptoms or signs observed on physical examination with or without aids such as magnification and acetowhite staining. Finally, *immunologic* evidence can be added to this schema [24].

While these levels of detection may reflect the various phases of HPV infection, multiple diagnostic modalities are employed to characterize and confirm the presence of the virus in the host and to confirm its causality of the morphological and clinical findings associated with disease.

8.1.2 Pathogenesis of Genital Human Papillomavirus Infection at a Molecular Level

The mechanism of entry of the HPV into cells is still a subject of study. As mentioned in Section 3, the observation of early phase proteins along with the presence of episomal viral genome copies in the absence of late phase proteins and complete viral particles in the basal layers has suggested that the virus needs to infect proliferating cells found in the basal epithelial layers. In order to do so, the presence of microtraumatic tears of the overlying layers, with exposure of the basal layer for viral inoculation, is believed to be necessary. The evidence of HPV-related lesions in previously traumatized skin [302] and especially the microtrauma produced in the genital mucosa during sexual intercourse, as studied for other sexually transmitted agents such as human immunodeficiency virus (HIV), is thought to be the way of entry for the HPV viral particles. The completion of the full viral cycle is thus connected to the differentiation process [303].

Cervical HPVs are the most widely studied, and evidence suggests that in lesions that progress to high-grade dysplasia, a limited number of ORFs are preferentially expressed, and particular emphasis has been given to E6 and E7. E6 and E7 share a common primer site, and their differential expression is depended on alternate splicing patterns [304]. Progression to high-grade disease has been linked to higher levels of E7, and it has been suggested that a specific splicing pattern (named E6*I) is the one that promotes E7 production and is responsible for E7 production in high-risk HPVs. Ultimately, E6 and E7 regulate the expression of a series of genes and play a key role in the progression to high-grade dysplasia and cancer [305]. Integration of the HPV DNA into the cellular genome appears to be necessary in order to stabilize the HPV infection, thus permitting the progression of disease and finally the evolution to high-grade dysplastic manifestations. Studies trying to investigate HPV genome integration in different grade premalignant cervical lesions and cervical cancer showed that only a small percentage of grade 2 cervical intraepithelial neoplasias (CIN 2) have integrated HPV genetic material [306], with increasing proportions in CIN3 [18, 306].

Although the potential integration sites within the human genome are multiple, it has been observed that for any given cervical cancer, only a few contain integrated HPV genetic material. Frequently, these sites correspond to genomic fragile sites [307, 308]. Regulatory elements and the E6 and E7 ORFs are always preserved, with frequent disruption during integration of the E1 and E2 genes that normally inhibit E6 and E7 [309]. Thus, continuous production of E6 and E7 proteins appears to have a role in HPV carcinogenicity, and, in fact, the E6 and E7 regions of the HPV genome are transcriptionally active in HPV-associated cervical carcinomas and derived cell lines [4, 309]. It is also possible that the virus uses the genetic expression regulatory mechanisms, such as promoters, to increase viral gene expression. The necessity for viral genome integration in tumorigenic capacity appears to vary between HPV types. Viral integration occurs in almost all tumors and cell lines containing HPV-18. While the same holds true for most tumors and cell lines, a significant number exhibit episomal HPV-16 genomes [310].

The protein products of the E6 and E7 ORFs of HPV appear to be principally responsible for HPV neoplastic effects. The E6 and E7 proteins have been shown to be cooperative transforming proteins in vitro and appear to be necessary for the HPV-positive cell line viability and proliferation [97, 311, 312]. The E6 protein binds to and promotes the degradation of the p53 tumor suppressor protein by forming a complex requiring the cellular protein E6-AP [107, 313]. The E7 protein binds to and inactivates the retinoblastoma tumor suppressor protein [314]. The transforming proteins of cancer-associated HPV types such as types 16 and 18 have greater binding affinities for tumor suppressor proteins and greater in vitro transforming abilities than E6 and E7 proteins from low-risk HPV types like HPV-6 and HPV-11 [97]. Another biochemical demonstration of dysplasia is the expression of p16, which appears to be elevated in dysplastic cells, as a response to the pRB inactivation mediated by E7 [315–317]. p16 is thus used as an indirect marker of HPV-induced dysplasia by immunohistochemistry [38].

E6 and E7 are believed to be involved in the production of centrosome abnormalities and resulting aneuploidy which contributes to the dysplastic process. Abnormalities of the centrosomes can produce deregulatory effects in the mitotic sequence of events which may lead to aneuploidy. Studies have suggested aneuploidy, seen in many cervical lesions, has a high degree of association to the presence of integrated HVP genome in the cells [318].

As mentioned previously, telomerase activity is another factor that appears to be involved in cervical cancer pathogenesis [319, 320], and increase of this activity is mediated primarily by E6, with a p53-independent mechanism, but

also by E7 [321, 322]. Increased allelic imbalance in the locus 6q14-6q22 is found in CIN3 and invasive cervical carcinoma, suggesting the presence, on this chromosome 6 locus, of a gene that may antagonize HPV-induced telomerase activation [323].

Finally an association between increased E5 levels and elevated EGFR and its related protein ErbB4 has also been described, in both episomal and integrated HPV-16 DNA lesions, and it is possible that HPV-16 E5 plays a role in stimulating these factors, thus promoting cell transformation [101, 324].

It is not yet known how the interactions of HPV-transforming proteins with tumor suppressor genes and proteins translate in the spectrum of HPV growth-altering effects, starting from the production of benign warts and early intraepithelial neoplasia to the development of carcinoma. Many examples of human cancers result from the accumulation of genetic mutations and epigenetic alterations. In the molecular pathogenesis of cervical carcinoma, the persistent infection with an oncogenic HPV that expresses E6 and E7 can be viewed as the "first hit" event. Additional somatic genetic changes may then occur, including loss of heterozygosity. Loss of heterozygosity studies have suggested that tumor suppressors on chromosome regions 11q [325] and 3p [326, 327] may be involved in cervical cancer development.

8.1.3 Pathogenesis of Genital Human Papillomavirus Infection at a Chromosomal Level

Besides interaction of E6 and E7 proteins with cellular proto-oncogenes and oncosuppressor genes, other regulatory mechanisms are in play. Epigenetic deregulation of various genes, such as methylation [328], has been identified in cervical high-grade dysplasia and cancer, and its role is being defined [329–331] along with that of cytogenetic alterations. The genes affected by these cytogenetic alterations have not been identified in most cases. The c-Myc gene, frequently overexpressed in other tumors, can be upregulated in cervical cancer. About 10 % of cervical cancers present HPV DNA integration close to the c-Myc site with associated upregulation of this proto-oncogene [332].

A variable percentage of cervical cancers, between 25 and 50 %, present recurrent cytogenetic alterations, the most common of which is loss of heterozygosity (LOH) in the following regions: 3p14, 4p16, 6p21-22, 11p15, 11q23, 17p13.3, and 18q12-22. One of these loci, 3p14.2, has been described also in dysplastic areas, adjacent to the cervical cancer lesions examined [333]. This might imply that this particular LOH is an early event in the progression of HPV-related disease, and in fact the levels of the affected gene (FHIT), an oncosuppressor, have been described to be lower in cervical cancer [334, 335] and also to be inversely proportional to the degree of dysplasia demonstrated morphologically by the tissue [120, 336]. Gain of 3q24-28, per contrast (whose gene is part of the PI3 kinase/AKT signaling pathway), has been reported in cervical cancer, in very high percentages, whereas in high-grade dysplasia is rarely seen [337], suggesting it might represent a late event in carcinogenesis.

Loss of HLA class I antigens has finally been reported as well and has been tied to more advanced disease and poorer prognosis. In particular, HLA-B7/40 allelic loss is thought to be connected to metastatic disease, suggesting that this kind of alteration might be a way for the tumor cells to evade immune response [338–341]. Among the mechanisms possibly involved in this common loss of HLA antigens as described above [342] is the loss of region 6p21.3, where class I genes are located.

8.1.4 Pathogenesis of Genital Human Papillomavirus Infection at a Cellular Level

In cattle, experimental inoculation of BPV by scarification leads to microscopically evident epidermal papillomatosis in about 2–3 months [2, 3], and the pathogenesis of human skin warts may have a similar incubation period. As shown in Fig. 44.4, among cytologically normal women who are HPV DNA positive at enrollment using the Hybrid Capture assay, the absolute risk of incident abnormal smears rises to a very high level (approximately 25 % of smears taken) at 1–2 years following enrollment and declines thereafter, returning to baseline (1–2 % of smears taken) at about 4 years. This peak at 1–2 years may approximate the incubation period of cervical HPV infection [343].

The earliest and mildest cellular changes associated with cervical HPV infection are extremely subtle and nonspecific. It is moreover possible that many HPV DNA-positive women have lesions too small to be diagnosed. In this interpretation, the incidence of CIN following HPV infection shown in Fig. 44.4 could represent the growth of a focus of HPV-infected cells to cytologically detectable size. Alternatively, HPV DNA might be detectable before and after the briefer appearance of cytopathic changes. In other words, it is not clear whether molecularly diagnosed HPV infections, especially high levels of viral DNA, imply the existence of cellular abnormalities somewhere in the infected tissue. In cases that are confirmed positive by cytology however, HPV DNA is found in 90 % or more of cytologically diagnosed HPV infections, identified using the Bethesda system criteria [163].

A possible explanation to the pathomorphological changes that characterize dysplasia is that the expansion of the spiny layer of the epithelium in HPV lesions, particularly exophytic ones, results from a minor degree of cell differentiation and reduced squamous cell sloughing, rather than

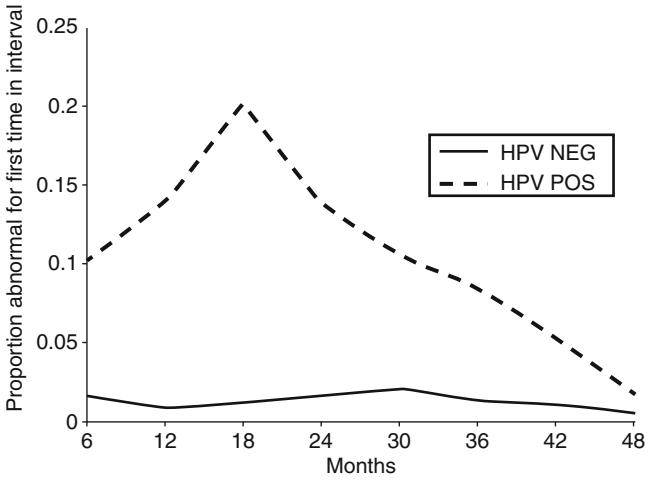

Fig. 44.4 Risk of new diagnosis of SIL by HPV DNA test result at enrollment. A cohort of 17,654 women with normal cytological diagnoses and no known past history of SIL were tested for 16 types of cervical HPV DNA using primarily Hybrid Capture. For each subsequent half-year time interval, the numbers of incident SIL diagnoses were calculated as a proportion of all women in the cohort obtaining smears during the interval. The relative and absolute risks of SIL were greatly increased in the 1,279 women testing positive at enrollment for HPV compared with the larger group testing HPV negative. The greatest risk of SIL following HPV DNA detection appeared in the second year of follow-up (From Schiffman et al. [24], with permission)

increased rate of cell turnover [344]. The result of this would be that the proliferative compartment (the number of cells dividing) is increased in HPV-infected epithelia, but the rate of cell division may not be [24].

Analysis of data from a large prospective study showed that the cumulative risk for a woman with negative cytology at enrollment of developing high-grade dysplasia or cervical cancer within 10 years of detection of HPV-16 or HPV-18 on HCII was 17.3 and 11.8 %, respectively. This was much higher than the 3 % cumulative risk for women with non-HPV-16 or HPV-18 high-risk types on HCII or the 0.8 % risk for women with negative HCII [343] (Fig. 44.5).

8.1.5 Pathogenesis of Genital Human Papillomavirus Infection at a Clinical Level

Most HPV-induced cellular abnormalities are transient and barely detectable at the clinical level. For example, flat HPV lesions of the penis are usually not recognizable, although they can be seen by peniscopy as acetowhite areas following the application of acetic acid [225]. Similarly, cervical intraepithelial neoplasia is asymptomatic and requires colposcopy to be seen.

The most commonly diagnosed clinical outcomes of HPV infection are nongenital cutaneous and genital warts. Warts tend to grow from an initially inapparent size to an appreciable but delimited lesion that then persists or regresses over the course of a few months to a few years. Clinically evident wart disease has been noted to worsen during pregnancy [345] and in response to immunosuppression, for example, secondary to renal transplantation [346, 347].

Compared to warts, the occurrence of HPV-related cervical carcinoma is a much rarer event, while infection with HPV explains a smaller fraction of the other HPV-related malignancies, whose etiologies may be more multifactorial than the etiology of cervical carcinoma.

8.2 Immunity

HPV infections, except as seen in carcinomas, are limited to mucosal and cutaneous epithelium above the basement membrane. Even after numerous studies conducted over many years, it is still unknown whether and how systemic or local immune factors affect HPV infections, nor are the mechanisms involved in the immune response to HPV or their efficacy yet fully understood. The fact that there is no known viremia and the impossibility of directly detecting in vitro antigens have meant that experimentation on HPV immunity relies greatly on constructs such as viruslike particles (VLPs), and to date there is no standardized test for the measurement of HPV antibodies [348]. Also unclear is whether infection with one type of HPV protects against infection with other types.

8.2.1 Immunity in Animal Papillomavirus Infections

Studies in animals, including experimental HPV infection models, have shed some light on the immunologic mechanisms of HPV infections. In the rabbit, development of a systemic immune reaction to papillomavirus infection is supported by the following observations: (1) All papillomas regress concurrently once regression begins; (2) suppression of the immune system inhibits regression, while vaccination with tumor preparations increases regression frequency; (3) regressing papillomas have a mononuclear infiltrate; and (4) rabbits with regressing papillomas are resistant to reinfection with CRPV DNA, while rabbits with persistent papillomas are not resistant to additional infection. In cattle, concurrent bovine fibropapillomas also regress simultaneously, accompanied by infiltrating mononuclear cells and by resistance to reinfection [2, 3].

8.2.2 Human Papillomavirus Infections in Immunodeficient Patients

Human immunodeficiency virus (HIV)-positive patients, posttransplant, and other immunodeficient patients are more prone to infections and tend to have more severe manifestations of disease. This has been observed in HPV infections of immunodeficient patients. For example, an excess in cutaneous and genital warts among subjects with iatrogenic

HPV status is defined hierarchically as positive for HPV-16 (*closed circles*), else positive for HPV-18 (*open circles*), else positive for the non-HPV-16/HPV-18 oncogenic types in Hybrid Capture 2 (*closed triangles*), and else oncogenic HPV negative (open triangles) (From Khan et al. [343], with permission)

immunosuppression following renal transplant has been demonstrated [346, 347, 349].

As mentioned above, patients with the rare syndrome epidermodysplasia verruciformis are subject to extensive HPV skin lesions containing characteristic types of HPV. Not only these types are typical to this clinical manifestation and rare in others, but the lesions are more prone to develop into squamous cell carcinoma. Although a specific immune dysfunction has been sought, the prevalence in HIV-positive patients, especially those that have acquired HIV through vertical transmission, is much higher [350].

HIV infection provides perhaps the most important example of the effect of immunosuppression on HPV infection. Individuals infected with HIV through sexual contacts are likely to be exposed to genital types of HPV as well, because both viruses are sexually transmissible and prevalent in sexually active populations. Furthermore, patients with one sexually transmitted disease are more prone to develop another sexually transmitted disease as well. Thus, an increase in HPV-related clinical outcomes would be expected in certain HIV-infected cohorts even if there were no causal connection. However, the diagnosis of HPV in HIV-infected individuals is definitely increased and associated with increasing immunosuppression, as measured in terms of progressively decreasing CD4 counts [9, 231, 351, 352] (Fig. 44.6). Concurrently, CIN is commonly diagnosed. Parallel situations are seen in studies of anal infection among homosexual men [231]. It is not known whether HIV immunosuppression permits reactivation of previously suppressed HPV infection, as opposed to allowing rapid infection or reinfection from environmental sources.

Although the association between HIV infection, HPV infection, and anogenital intraepithelial neoplasia is established, a causal role for immunosuppression in the risk of progression of intraepithelial lesions to invasive carcinoma is less clear. Anal carcinoma rates are increasing in the homosexual male population, probably related to HIV infection [171, 229], though progression from dysplasia to cancer occurs in much lower rates than in the cervix [353].

8.2.3 Serological Studies of Genital Human Papillomavirus Infections

Epidemiologists and immunologists are attempting to differentiate the serological responses conferring natural immunity to HPV infections from responses simply representing biomarkers of infection or disease progression. The available data from animal studies do not indicate a major role for antibody responses in wart regression [2, 3], while immunization of animals with papillomavirus capsid proteins blocks reinfection but does not appreciably affect existing warts.

No convincing evidence of a protective serological response in humans has been reported. Rather, several groups

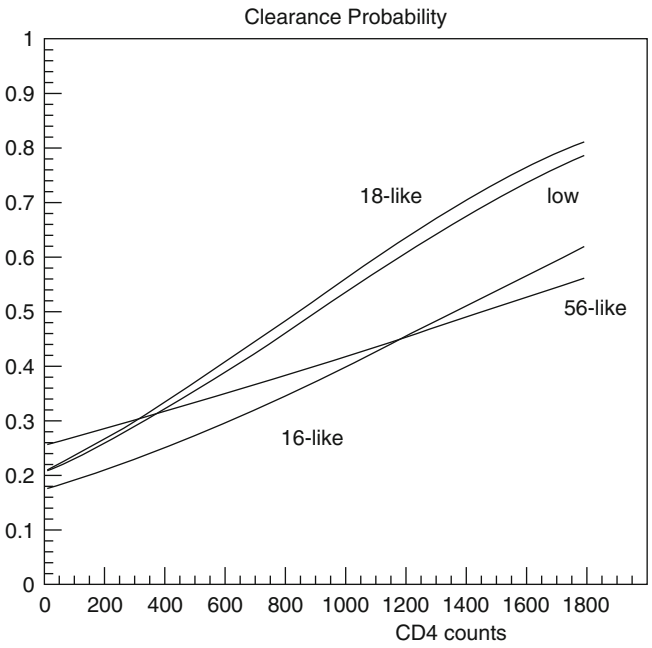

Fig. 44.6 The 3-month HPV type-specific probability of clearance depending on CD4 T lymphocytes in HIV-1-positive adolescent girls from the REACH cohort (From Kravchenko et al. [9], with permission)

have reported elevated HPV antibody levels in subjects with clinically evident HPV-associated disease compared with controls [183]. For example, elevated titers to HPV-16 E7 are observed in about half of HPV-16-associated cervical carcinoma patients [176, 178, 185, 354]. Measurement of HPV-16 and HPV-18 antibodies in women with positive DNA found prevalence rates of 63 and 57.5 %, respectively [355]. In the same study, women with positive cytology and/or high viral loads had higher antibody titers compared to women with negative cytology and/or low viral loads, but neither observation suggests that this might represent a systemic immune response to HPV.

As mentioned above, the majority of women with CIN or cancer, but also genital warts or nongenital cutaneous warts, have antibodies to the same HPV types found in their lesions. But in contrast to HPV DNA-positive women, with regard to HPV-16, women with very low probability of exposure, assessed by DNA testing and interview, have a very low HPV-16 seroprevalence, whereas individuals infected with other genital types of HPV have an intermediate seroprevalence [356] with the exception of those with in situ penile cancer [179]. The persistence of cervical HPV DNA positivity, even in the absence of cytological abnormalities, is highly predictive of seropositivity. Investigations so far have confirmed the associations of HPV infection with anal cancer [357] and other anal lesions [358].

8.2.4 Cellular Immune Responses to Human Papillomavirus Infections

Based on the animal experiments and the immunosuppression data, it is assumed that the key immune response involved in the clearance of HPV infections is cell mediated. Mouse models showed the evocation of a cellular immune response to HPV-6, HPV-11, HPV-16, and HPV-18 after DNA immunization [359, 360]. As in animals [2, 3], once multiple human warts of a single kind begin to regress, others regress concurrently [361], although warts of different kinds (e.g., plantar vs. common skin) may not regress concurrently. Histologically, regressing flat skin warts show infiltration with mononuclear leukocytes and other features suggestive of a cell-mediated immune response [268]. This is in accordance with the observation that while genetic defects affecting humoral immunity have little effect on the natural history of HPV infections, deficiencies of cell-mediated immunity profoundly elevate the prevalence of HPV infection assessed clinically, microscopically, or molecularly [361, 362].

The two classes of cells thought to be involved in the cellular immune response to HPV are antigen-presenting cells and lymphocytes. The usual antigen-presenting cells of the epithelium are the Langerhans cells. Langerhans cells are less numerous near HPV-induced epithelial lesions compared to normal epithelium; a possible mechanism is that HPV manages to downregulate proinflammatory cytokines, and in particular type I interferons, resulting in an attenuated cellular immune response, which includes these cells [302].

Finally the possible associations of specific HLA locus genotypes with the risk of invasive cervical carcinoma and the loss of HLA class I antigens as a possible HPV mechanism of cellular immune evasion point towards the primary role that cellular immunity has in response to HPV infections.

9 Patterns of Host Response

9.1 Warts

9.1.1 Nongenital Cutaneous Warts

Skin warts are a well-known and common response to infection with HPV cutaneous types, including 1, 2, 4, and related types. The most frequent skin wart is the common variety (verruca vulgaris), which occurs mainly on the back of the hands and fingers, but can occur anywhere on the skin [268]. Common warts are firm papules ranging in size from less than a millimeter to over a centimeter in diameter. They may occur singly or in groups. About two-thirds of common warts spontaneously regress within 2 years [363]. Malignant conversion is extremely rare [268].

Deep plantar warts (verruca plantaris) are most commonly associated with HPV type 1, which is phylogenetically and molecularly quite distinct from the viral types more commonly found in common skin warts [132]. Plantar warts are usually single but may be multiple. These lesions are sharply demarcated from the adjacent normal skin and possess a smooth hyperkeratotic collar. Regression is common but as variable as for common warts [268].

A less common kind of skin wart is the flat wart (verruca plana), which is smooth and flat or mildly elevated. Flat warts occur multiply, mainly on the face, back of the hands, and the shins. They may disappear suddenly after weeks or months or persist for years [268].

Multicentric nongenital cutaneous wart disease is very common, sometimes with mixed kinds of warts. Multicentric wart disease of the same kind is apparently related to autoinoculation by scratching, hand washing, and nail-biting [275].

9.1.2 Genital Warts

Almost all exophytic genital warts, also called condylomata acuminata, contain HPV types 6, 11, or related types [364]. Like warts of nongenital skin, they tend to regress spontaneously and only rarely are associated with malignant progression. However, genital warts can be multifocal, can become very large, at times gigantic (giant condyloma acuminatum of Buschke and Löwenstein). They may recur after treatment, creating significant discomfort and psychosexual morbidity in some patients.

9.1.3 Respiratory Papillomas

Respiratory (laryngeal) papillomatosis is a rare disease with a bimodal age occurrence [365]. Thirty to 50 % of cases become evident before the age of 5 years (juvenile onset), linked most probably to vertical transmission in children born to HPV-positive mothers, most often to HPV-6 or HPV-11 [297]. Another group of cases associated with the same HPV types occurs in adulthood (adult onset), with an unproven mode of infection. Adult-onset respiratory papillomas are more often solitary, recur less frequently, do not tend to spread, and exhibit a male predominance [365].

Respiratory papillomas most commonly affect the larynx, particularly the true vocal cords, and become clinically evident with hoarseness being the major symptom. The true vocal cords contain a junction (or transformation) zone, present between the stratified squamous epithelium and the columnar epithelium, very similar to that found on the cervix. The papillomas uncommonly undergo malignant transformation, although one report noted cases of malignancy following irradiation therapy [366]. Although considered benign, the papillomas may sometimes become life-threatening due to airway obstruction, particularly in young children. Laryngeal papillomas tend to recur in many cases despite repeated excision. This rare presentation of warts is among the most severe and debilitating [24].

9.2 Cervical Intraepithelial Neoplasia

The cervix, though a well-studied epithelial model, is a special histological case (as are the true vocal cords and anus), containing a transformation zone between the squamous epithelium and ectocervix that transitions in to the columnar epithelium of the endocervix. This transformation zone is particularly susceptible to neoplastic transformation following HPV infection. In vivid contrast, the neighboring mature vaginal epithelium of the ectocervix, though prone to HPV infection, very rarely develops carcinoma [367]. The reasons for the special susceptibility of the transformation zone are unknown.

9.2.1 Defining Cervical Intraepithelial Neoplasia

The morphological response of the cervical epithelium to HPV infection is usually not a raised wart but rather a flat lesion with warty colposcopic and cytopathic features. As a corollary, the flat lesions of the cervix contain mostly types of HPV not found in exophytic venereal warts (e.g., 16, 18, 26, 31, 33, 35, 39, 45, 51–56, 58, 59, 64, 66, and 68), although flat lesions may also contain the types associated with exophytic genital condylomata (e.g., 6, 11, 42).

The HPV-induced, flat intraepithelial lesions of the cervix form a gradient of risk of malignancy, first formalized by Richart and colleagues when they introduced the term cervical intraepithelial neoplasia (CIN) [368]. Usually, CIN is classified as CIN 1 (mild dysplasia), CIN 2 (moderate dysplasia), and CIN 3/CIS (encompassing severe dysplasia and carcinoma in situ). As illustrated on Fig. 44.7, the spectrum of CIN has no perfect "cut points" and is, therefore, a subjectively defined gradient that is difficult to categorize reproducibly, although relative recommendations are available.

In normal epithelium, proliferation is restricted to the basal layer. Epithelial cells differentiate on a fixed and orderly program that leads to their progressive differentiation moving towards the more superficial strata of the epithelium, their programmed death and sloughing. In low-grade lesions, squamous differentiation in the more superficial layers of the epithelium becomes abnormal, but the cells continue to differentiate, such that there is only a minimal effect on the expansion of the proliferative, basal layer. Histologically, in low-grade lesions, the proliferative layer remains less than one-third of the full thickness of the epithelium. Fundamentally, low-grade lesions can be thought of as viral infections that are common, minor, and usually transient.

For the most part, lesions designated as CIN 1 are virtually indistinguishable from koilocytotic atypia. The relatively recent combination of CIN 1 and koilocytotic atypia as LSIL, in the Bethesda classification of cytopathology, is supported by epidemiologic data demonstrating that the two subsumed diagnoses share the same broad HPV type spectrum, have similar demographic characteristics such as early age peaks, and share a transient and benign natural history [199].

A one-third to two-thirds replacement of the epithelium with proliferating cells is termed CIN 2. Virtual full-thickness replacement of the epithelium with proliferating cells, with loss of epithelial differentiation, is termed CIN 3, which includes carcinoma in situ. In CIN 2 and CIN 3, in addition to expansion of the proliferative compartment, there is also an increased appearance of progressively more serious

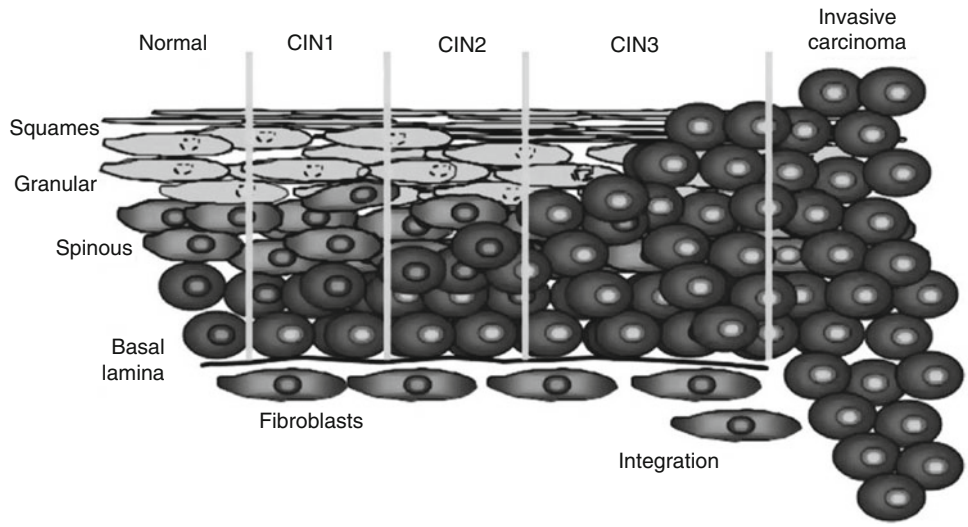

Fig. 44.7 Progression from a benign cervical lesion to invasive cervical cancer. In the diagram, HPV-positive cells are depicted by yellow nuclei. Infection by oncogenic HPV types, especially HPV-16, can cause formation of a benign wart, low- or high-grade dysplasia. CIN 1 and CIN 2 designations are reversible forms of precancerous lesions, and CIN 3 is irreversible. Carcinoma in situ occurs many years after an infection. This results from the effects of HPV genes, particularly those encoding E6 and E7, which are the two viral oncoproteins that are preferentially retained and expressed in cervical cancers by integration of the viral DNA into the host genome (From Angelletti et al. [369], with permission)

nuclear abnormalities. CIN 2 and CIN 3 are combined for cytology in the Bethesda system because (1) the categories are not reliably distinguished in practice and (2) both diagnoses lead to the same practical outcome, i.e., immediate colposcopic referral and biopsy, with ablative treatment if confirmed, through cold-knife conization or, more recently, loop electrosurgical excision procedure (LEEP) or other procedures.

9.2.2 Progression of Low-Grade to High-Grade CIN

A common conception in the beginning was that women who developed cervical cancer always progressed through distinct consecutive stages from low- to moderate- to high-grade intraepithelial lesions. Natural history studies however have raised doubt about the notion of a progressive continuum of cervical precancerous stages and led to the conclusion that low-grade and high-grade cervical lesions are distinct HPV infection processes. The cytological finding of low-grade squamous intraepithelial lesion (LSIL) appears to represent a transient manifestation in the course of viral infection, where the HPV-infected epithelium undergoes differentiation and maturation, exhibiting only minor cellular abnormalities. High-grade intraepithelial lesion (HSIL), the true cervical cancer precursor, instead occurs when HPV infection of replicating immature cells prevents squamous epithelial maturation and differentiation leading to continued replication of immature cells with consequent accumulation of genetic abnormalities that could ultimately lead to a clonal proliferation of cancer cells [209].

Although low-grade lesions caused by HPV are usually transient, statistically, women with low-grade cervical lesions are nonetheless at significantly increased risk of developing higher-grade CIN compared to the general population [31]. High-grade CIN usually emerges in women with low-grade CIN, but may sometimes arise in women with preceding, repeatedly normal cytology or only equivocal lesions [139, 370].

A diagnosis of low-grade CIN predicts an increased risk of a subsequent diagnosis of CIN 2–3, but it is not totally clear just how frequently women with low-grade lesions progress. While it is still not clear if, and in what measure, low-grade dysplasias will progress to high-grade dysplasias and cervical cancer, the type of HPV found in the cervix appears to predict the risk of the woman progressing to a diagnosis of CIN 2–3. This association has been verified in both cross-sectional [134, 135, 371] and prospective [372, 373] studies. While many HPV types are found in low-grade lesions, fewer types are found in CIN 2 and even fewer in CIN 3. Generally the types of HPV associated with CIN 3 are the same types found in invasive carcinomas. In lower-grade lesions, the cancer-associated HPV types increase steadily in relative prevalence with the severity of the diagnosis.

A recent prospective cohort analysis looked into recorded covariates as potential risk predictors of incident CIN 1, CIN 2, and CIN 3 using multinomial logistic regression models. In univariate analysis, the covariate profiles for incident CIN 1, CIN 2, and CIN 3 were unique. According to their finding, the only covariate significantly associated with all three CIN

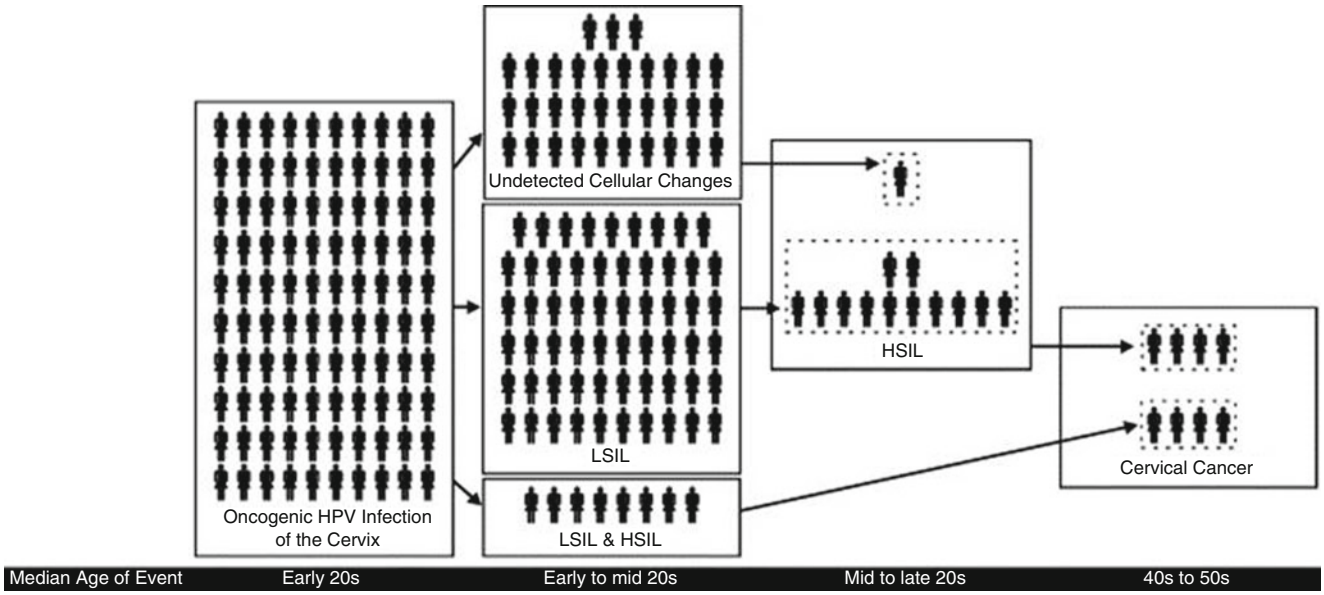

Fig. 44.8 Natural history of cervical HPV-associated disease (From Baseman and Koutsky [209], with permission)

end points was the baseline HR HPV status, which limits the use of HR HPV status as a predictor of CIN progression [374]. Moreover, in accordance to previous studies, the covariates associated with baseline CIN 1, CIN 2 and CIN 3, considered separately, are different [286]. As the data available suggests, cofactors associated with progression to CIN1 are different from those associated with incident CIN 2 or incident CIN 3, while there is no HPV cofactor significantly associated with all three outcomes [209].

Use of oral contraceptives has been suggested to be the only cofactor associated with two of these outcomes (incident CIN 2 and CIN 3). Factors such as current oral contraceptive use and Pap smear history were found to be individually confined to incident CIN1, whereas incident CIN2 was linked to the status of having ever been a smoker. Incident CIN3 was seen to be associated with different age groups and a baseline ASCUS (atypical squamous cells of undetermined significance) cytological diagnosis [209]. This diversity of HPV cofactors associated with progression to CIN1, CIN2, or CIN3 would seem to suggest that CIN1, CIN2, and CIN3 are three separate nosographic entities.

The cases that progressed to CIN2 and CIN3 were compared with those that progressed to CIN1 only, and incident CIN3 was compared with incident CIN2 in multinomial regression models. Also these results substantiate our concept that the three grades of CIN are, indeed, distinct entities with unique risk profiles, though specific clinical risk factors of progression seem to be identified. A schematic representation of the natural history of disease is provided in Fig. 44.8.

9.3 Invasive Cervical Carcinoma

Much attention has been given to the natural history of disease for cervical cancer. The mean age of women with invasive cervical cancer is around 50 years, while the mean age of women with HSIL is only approximately 28 years (Fig. 44.8), suggesting a long precancerous state. Epidemiologic studies have not been able to consistently identify risk factors for invasion, even though, as mentioned above, cofactors to HR HPV infection, such as smoking, long-term oral contraceptive use, infection with other sexually transmitted infections, and multiparity or integration of HPV into the host chromosome, have been hypothesized to play some role in this transition [8, 290, 375–379].

Historical literature suggested that between one- and two-thirds of women with HSIL will develop invasive cancer if left untreated [380, 381]. It is now known from histological evidence and a few early follow-up studies that invasive cervical carcinoma develops frequently from CIN 3. However, the absolute risk of untreated CIN 3 developing into invasive disease is still argued, with estimates averaging about 30 % but ranging from 10 to 90 %.

HPV-16 is consistently the most common cancer-associated type, and the epidemiologic definition of cancer-associated types correlates well with the relative transforming properties of the various viral types as defined in vitro and with "phylogenetic" studies grouping HPV types by genetic relatedness, suggesting HPV type itself to be a possible risk factor for progression [1, 132]. HPV-negative cervical carcinoma, on the other hand, appears to exist as a separate entity, with a worse prognosis [382] and possibly distinct molecular features [383].

9.4 Other Carcinomas Associated with Human Papillomavirus Infections

9.4.1 Other Genital Carcinomas

Genital HPV infection is associated with carcinomas and premalignant lesions of nearly all other parts of the female and male lower genital tracts, including vaginal, vulvar, penile, and anal neoplasia. Analogous to the concept of CIN for the cervix, pathologists recognize a spectrum of HPV-related intraepithelial pathologic changes called vulvar intraepithelial neoplasia (VIN), vaginal intraepithelial neoplasia (VaIN), penile intraepithelial neoplasia (PIN), and anal intraepithelial neoplasia (AIN). Multifocal intraepithelial genital lesions, associated with different HPV infections of cancer-associated types, are often diagnosed. As a result, some authors have coined the term of "lower genital neoplasia syndrome" for these pathological entities [216].

However, when investigating these premalignant lesions in these other genital carcinomas, the proportion attributable to HPV infection may be lower than for cervical carcinoma. It has been thus hypothesized that the other genital carcinomas may be more multifactorial than cervical carcinoma. In vulvar carcinoma, for instance, different histological subtypes of squamous cell vulvar carcinoma, with distinct epidemiologic profiles, are recognized [384, 385]. While typical squamous cell vulvar carcinoma in older women is not HPV associated, the basaloid and warty, two of the more rare subtypes, are found more often in younger women and are found to be HPV associated [385]. The role HPV in vulvar neoplasia is further supported by the fact that HPV-associated vulvar carcinomas are often found adjacent to intraepithelial lesions that may represent vulvar HPV infections.

Both vulvar and penile premalignant lesions are however less studied, and the amount of elevation in risk of subsequent carcinoma posed by these lesions on the vulva or penis is unclear. In the case of the penis, the term *bowenoid papulosis* is used to indicate multiple lesions that occur with a histological appearance resembling intraepithelial neoplasia [386]. Bowenoid papulosis occurs mainly in patients under 40 years of age and is thought to be benign, contrary to the fact that HPV-16 is the predominant HPV type [386].

Bowen's *disease*, in contrast, occurs at generally later ages and is synonymous with PIN 3 or VIN 3. Bowen's disease occurs most often as a solitary plaque shows a slowly progressive course [386]. Epidemiologic studies of intraepithelial HPV-associated lesions of the penis and vulva are limited so that prevalences and risks of progression are still not well defined. The role of HPV infection in the etiology of penile cancer is especially unclear [387]. In some regions, chronic inflammation appears to be a more important risk factor [388].

9.4.2 Nongenital Carcinomas Associated with Human Papillomavirus Infections

Benign HPV lesions of the oral cavity are quite common and are often asymptomatic. Genital HPVs, most commonly HPV types 6, 11, and 16, have been retrieved from the oral mucosa, in about 50 % of papillomatous oral lesions, with types 6 and 11 being responsible for most benign lesions. HPV types 13 and 32 are the most commonly found in focal epithelial hyperplasia (FEH). In any case, the remaining 50 % of lesions appear to be negative for HPV. Maternal transmission of genital HPV types to children with respiratory papillomatosis is better documented [389]. Furthermore, a variety of benign lesions of the oral cavity have been linked to HPV infection, including cases of focal epithelial hyperplasia, papillary hyperplasia, fibrous hyperplasia, lichen planus, and leukoplakia [390].

In head and neck pathology, HPV appears to play a role in at least some cancers [5–7, 10, 391] trailing well behind smoking and alcohol in order of importance. Out of the HPV-positive head and neck cancers, HPV-16 accounts for about 90 %. While most of these cases are squamous cell carcinomas, as is true for head and neck cancers, the HPV-related types have been described as showing a more basaloid pattern.

10 Control and Prevention

10.1 Primary Prevention of Human Papillomavirus Infections

The licensure and widespread adoption of HPV vaccines was an important scientific achievement and a monumental public health success. Work on the development of an HPV vaccine started in the 1980s, and ultimately, the vaccine was developed, in parallel, by multiple centers. In 2006, the US Food and Drug Administration (FDA) approved the first preventive HPV vaccine, Gardasil (Merck and Co., Whitehouse Station, NJ). In 2007, a second HPV vaccine, Cervarix (GlaxoSmithKline, London, UK), was approved in Australia and the European Union, while its approval in the United States came in 2009.

Both these HPV vaccines are based on hollow viruslike particles (VLPs) assembled from recombinant HPV coat proteins. Gardasil is a tetravalent recombinant vaccine (referred to also as HPV-4) that targets the two high-risk HPVs, types 16 and 18, which combined account for around 70 % of cervical cancers, along with HPV types 6 and 11, most commonly seen in genital warts. It contains inactive L1 proteins from these four different HPV types. Cervarix is a bivalent vaccine that targets HPV types 16 and 18 (referred to also as HPV-2).

Gardasil and Cervarix are designed to elicit virus-neutralizing antibody responses that prevent initial infection with the HPV types represented in the vaccine. The vaccines have been proven to be safe and to offer essentially 100 % protection against the development of cervical precancers and genital warts caused by the HPV types in the vaccine. The protective effects of the vaccine are expected to last a minimum of 4.5 years after the initial vaccination [392]. Between the years 2007 and 2009, HPV vaccines entered the recommended, and in some cases mandatory, vaccination schedules of most developed countries. The two vaccines are recommended for women who are 9–25 years old who have not been exposed to HPV. However, since it is unlikely that a woman will have already contracted all four viruses, and because HPV is primarily sexually transmitted, the US Centers for Disease Control and Prevention has recommended vaccination for women up to 26 years of age. HPV vaccines are approved for males in several countries, including Australia, South Korea, and the United Kingdom. The US Food and Drug Administration (FDA) has approved Gardasil for use in males age 9–26 for prevention of genital warts and anal cancer with advisory panel recommendations for male vaccination being available prior to that [393]. According to the current US Centers for Disease Control and Prevention vaccination schedule, a 3-dose series of HPV vaccine on a schedule of 0, 1–2, and 6 months is to be administered to all adolescents aged 11–12 years. Either HPV-4 or HPV-2 may be used for females, and only HPV-4 may be used for males. The vaccine series can be started beginning at age 9 years. The second dose is to be administered 1–2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose). For cases of catch-up vaccination, the vaccine series is to be administered to females (either HPV-2 or HPV-4) and males (HPV-4) at age 13 through 18 years if not previously vaccinated with the same recommended routine dosing intervals [394].

10.2 Treatment of Human Papillomavirus Infections

Standard treatment for HPV-associated, precancerous cervical lesions is either expectant management or treatment, aimed at the destruction of the lesion and the remaining cervical transformation zone by means of loop electrosurgical excision procedure (LEEP), cold-knife excision, cryosurgery, or laser [395]. Research for the use of therapeutic vaccines and targeted gene therapy is still in an early stage.

For genital wart disease, destruction of the lesions remains the major clinical modality, although the indications for therapy and the efficacy of current techniques can be questioned. Eradication of the virus is not an achievable goal through destructive means. Destructive methods include chemical applications, such as podophyllin or acids, and surgical means, including laser, cryosurgery, and electrosurgical loop excision. Trials of adjunctive interferon or antimetabolite administration have been conducted for severe recurrent genital warts, with variable success.

Nongenital cutaneous warts, when treated, can be destroyed by a wide variety of destructive methods including keratolytic agents, cytotoxic agents, chemotherapy, immunotherapy, cryosurgery, and various other surgical removal techniques [396].

10.3 Use of Human Papillomavirus DNA Testing in Cervical Cancer Screening

It has been demonstrated that HPV testing can be used in several ways to clarify and triage inconclusive or “atypical” Pap smear diagnoses [37, 164, 397, 398]. Even in the Bethesda system, which has attempted to sharpen the detection process and restrict the number of inconclusive diagnoses [399, 400], the triage and treatment of women with borderline smears consumes a disturbingly disproportionate amount of clinical resources. HPV testing is used to clarify inconclusive cytological diagnoses, providing quality control of the diagnosis of ASCUS in cytopathology laboratories and, most importantly, clarification and triage of the individual inconclusive cytological result. The current guidelines for the prevention and early detection of cervical cancer as per the American Cancer Society, the American Society for Colposcopy and Cervical Pathology, and the American Society for Clinical Pathology [401] are summarized in Table 44.4.

Table 44.4 American Cancer Society, American Society for Colposcopy and Cervical Pathology, and American Society for Clinical Pathology screening guidelines for the prevention and early detection of cervical cancer

Population	Recommended screening method[a]	Management of screen results	Comments
Aged <21 years	No screening		HPV testing should not be used for screening or management of ASC-US in this age group
Aged 21–29 years	Cytology alone every 3 years	HPV-positive ASC-US[b] or cytology of LSIL or more severe: refer to ASCCP guidelines [402] Cytology-negative or HPV-negative ASC-US[b]: rescreen with cytology in 3 years	HPV testing should not be used for screening in this age group
Aged 30–65 years	HPV and cytology "cotesting" every 5 years (preferred)	HPV-positive ASC-US or cytology of LSIL or more severe: refer to ASCCP guidelines [402] HPV positive, cytology negative: Option 1: 12-months follow-up with cotesting Option 2: test for HPV-16 or HPV-16/HPV-18 genotypes If HPV-16 or HPV-16/HPV-18 positive: refer to colposcopy If HPV-16 or HPV-16/HPV-18 negative: 12-months follow-up with cotesting Cotest-negative or HPV-negative ASC-US: rescreen with cotesting in 5 years	Screening by HPV testing alone is not recommended for most clinical settings
	Cytology alone every 3 years (acceptable)	HPV-positive ASC-US[b] or cytology of LSIL or more severe: refer to ASCCP guidelines [402] Cytology-negative or HPV-negative ASC-US[b]: rescreen with cytology in 3 years	
Aged >65 years	No screening following an adequate negative prior screening		Women with a history of CIN2 or a more severe diagnosis should continue routine screening for at least 20 years
After hysterectomy	No screening		Applies to women without a cervix and without a history of CIN2 or a more severe diagnosis in the past 20 years or cervical cancer ever
HPV vaccinated	Follow age-specific recommendations (same as unvaccinated women)		

Modified from Saslow et al. [401]. (Table 44.1), with permission
[a]Women should not be screened annually at any age by any method
[b]ASC-US cytology with secondary HPV testing for management decisions

Acknowledgments The authors of this chapter acknowledge and greatly appreciate the meticulous work of Drs. Mark Schiffman and Robert Burk, the authors of the HPV chapter in the previous edition; many excerpts from that chapter have been retained verbatim because of their enduring accuracy and relevance.

Human T-Cell Leukemia Viruses Types 1 and 2

45

Edward L. Murphy and Roberta L. Bruhn

1 Introduction

Human T-lymphotropic virus (HTLV) is a member of the RNA virus Retroviridae family, genus *Deltaretrovirus*, which causes chronic infection of humans, and is divided into four currently recognized genotypes and serotypes (HTLV-1 through HTLV-4). Discovered several years prior to human immunodeficiency virus, HTLV is actually an ancient virus of humans, having been transmitted from simian species thousands to tens of thousands of years in the past. It causes a chronic, latent infection with integration of proviral DNA into the host lymphocyte DNA and expansion of the infection predominantly by means of lymphocytic proliferation rather than cell-to-cell transmission of virus. Pathogenesis has been well-defined for HTLV-1 and HTLV-2. Most HTLV-1-infected humans are asymptomatic, but serious disease occurs in approximately 5 % of those infected. Unique among human viruses, HTLV-1 causes T-lymphocytic malignancy manifested as a peripheral T-cell lymphoma with or without leukemia in adults. A chronic inflammatory myelopathy characterized by lymphocytic infiltration and degeneration of the thoracic spinal cord, paraplegia, and bladder dysfunction occurs in both HTLV-1 and HTLV-2 infection. Finally, a variety of inflammatory syndromes including uveitis, pneumonitis, and dermatomyositis have been linked to HTLV infection.

However, knowledge of and research into the epidemiology and pathogenesis of HTLV has been overshadowed by that directed at HIV, another human retrovirus which has caused a global pandemic since its discovery using techniques originally used to isolate HTLV. HTLV is most prevalent in low- and middle-income countries and, because of its relatively modest pathogenesis in comparison to the more famous lentivirus, receives little resources for prevention and diagnosis. In the USA and Europe, HTLV may practically be considered an orphan infection due to its very low prevalence, unfamiliarity to most practicing physicians, and small portfolio of research funding and involved laboratories.

However, HTLV is important in several respects. First, research on HTLV-1 and adult T-cell leukemia/lymphoma (ATL) provides insights into the mechanisms of hematologic malignancy. Despite three decades of research, the mechanism of malignant transformation remains unclear. Alternative mechanisms include: the action of viral proteins including trans-acting viral regulatory protein Tax or the HTLV-1 basic leucine zipper protein HBZ; an imbalance between lymphocyte proliferation and host immunologic control; the accumulation of somatic mutations in lymphocytes proliferating due to HTLV; or, less likely, insertional mutagenesis due to insertion of HTLV-1 genes in sensitive regions of the host genome. Second, HTLV myelopathy provides an interesting model for other inflammatory neurologic conditions, including multiple sclerosis. In this case, a high HTLV proviral load has been clearly associated with increased risk. Specific human leukocyte antigen (HLA) genotypes in the host have also been linked to increased or reduced risk for myelopathy. Finally, HTLV provides both biological and epidemiologic parallels to HIV infection that may be useful in the control of the latter pandemic. For example, current research into the eradication of minimal, latent HIV infection may benefit from research into the predominantly latent infection of HTLV. In addition, the practice of interrupting HTLV mother-to-child transmission, by substituting bottle-feeding for breast-feeding by infected mothers, may be applicable to the HIV setting provided that safe infant formula is available.

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_45,

This chapter will give historical background on this human retroviral infection and then continue with a synopsis of current knowledge relevant to HTLV biology, epidemiology, and public health control. Wherever possible, we have attempted to include original references for key scientific contributions and to identify new work of relevance to the field. We shall cover in somewhat less detail the clinical diagnosis and management of HTLV-related diseases, as these have been reviewed recently in other textbooks [1, 2].

2 Historical Background

In 1970, Temin and Baltimore reported the discovery of a novel reverse transcriptase enzyme associated with retroviruses, for which they were jointly awarded the Nobel Prize in 1975 [3, 4]. This enzyme defined a class of viruses in which virally encoded reverse transcriptase reverses the normal flow of nucleotide transcription, allowing a DNA sequence to be copied from the viral RNA template and inserted into the host genome. Gallo et al. subsequently developed sensitive assays for the detection of reverse transcriptase, facilitating the search for retroviruses in human and animal specimens [5]. Cancer-causing retroviruses, first discovered in animals at the beginning of the twentieth century, had proven elusive to researchers seeking a viral etiology for human cancer and leukemia and most had abandoned this quest and focused instead on viral transforming genes that occur as oncogenes in human tumors. However, the new molecular assays for reverse transcriptase combined with astute translational investigation of lymphoma cases in the USA and Japan soon led to the successful end of this search [6].

The human T-cell lymphotropic virus type 1 (HTLV-1), the first recognized human retrovirus, was described in 1980 by Poiesz, Gallo, and coworkers [7, 8], who isolated retroviral particles with type C morphology budding from fresh cultured lymphocytes of a 28-year-old American man with a diagnosis of cutaneous T-cell lymphoma similar to cases seen in the Caribbean. Soon thereafter, Yoshida et al. similarly isolated a new retrovirus from cases of adult T-cell leukemia, which had been recognized as common in southwestern Japan, and the two isolates were subsequently found to be the same virus [9, 10]. The techniques used to isolate and characterize HTLV-1 provided the intellectual and technical basis for the discovery of the human immunodeficiency virus (HIV) in 1983 [11, 12], which was shown to be the cause of acquired immunodeficiency syndrome (AIDS) in 1984 [13]. In fact, the Gallo HIV isolate was originally named "HTLV-III" and renamed HIV when it was recognized to be a lentivirus, not an oncovirus. This, in part, led to the persistent misimpression that HTLV is associated with AIDS.

Consistent with the geographic distribution of ATL, it was soon demonstrated that HTLV-1 is endemic to the Caribbean and southwestern Japan. Cases of ATL were shown to represent a high proportion of T- lymphocytic lymphomas in both of these areas [14]. Then, in 1985, Gessain recognized that HTLV-1 antibodies were frequently demonstrated in patients with a myelopathy in Martinique then known as tropical spastic paraparesis or TSP [15]. Japanese investigators soon realized that a similar neurologic syndrome, which they called HTLV-1-associated myelopathy or HAM, was occurring among HTLV-1-infected patients in Japan [16]. It is now accepted that these two syndromes are the same disease, which is generally referred to as HAM or HAM/TSP.

The second HTLV type, now known as HTLV-2, was isolated 2 years after HTLV-1 from a patient with an unusual T-lymphocytic case of hairy cell leukemia [17, 18]. However, several years passed before it was recognized that HTLV-2 had become epidemic among injection drug users in the USA and Europe [19, 20], and it was several more years before HTLV-2 was known to be endemic among Amerindians and African Pygmies [21–23].

The most recent chapter in HTLV research has included the discovery of two new HTLV types: HTLV-3 (not to be confused with the former HTLV-III renamed HIV) and HTLV-4 in Central African Pygmies and bushmeat hunters [24, 25]. As with past HTLV discoveries, two separate teams of investigators published articles on these new HTLV types within a short window of time. As of this writing, these new viruses have been recognized in only a handful of humans and it is unclear whether they represent recent simian-to-human transmissions or the new establishment of retroviruses transmitted among humans [26–28].

3 Methods for Epidemiologic Analysis

3.1 Sources of Mortality Data

While HTLV-related mortality data are still sparse, there have been significant contributions to the literature within the last three decades. In 1984 the Miyazaki Cohort Study (MCS) was established to determine the natural history of HTLV-1 infection in the endemic population of Miyazaki Prefecture, Japan [29, 30]. This cohort probably has the largest number of HTLV-related deaths, and cohort investigators have published estimates of mortality related to adult T-cell leukemia as well as on the interaction between HTLV-1 and hepatitis C-related liver mortality [31–33]. The Retrovirus Epidemiology Donor Study (REDS) HTLV Cohort was established in 1990 and continued as the HTLV Outcomes Study (HOST), a prospective study of health outcomes including mortality in HTLV-1- and HTLV-2-infected former US blood donors as well as their sexual partners, with

follow-up from 1992 to 2008 [34]. This study found a non-significant increase in mortality among HTLV-1-infected persons, but a significant increase in both overall and cancer mortality among HTLV-2-infected persons [35]. The Nagasaki Cohort Study prospectively monitored subjects with HTLV-1 infection for cancer incidence and survival from 1993 to 2000 [36]. They found increased all-cause mortality but not increased cancer mortality (excluding ATL) in HTLV-1-infected patients. Finally, a case-control study suggested higher mortality in the mothers of HTLV-infected persons in Miyasaki, Japan [37].

3.2 Sources of Morbidity Data

In addition to the studies listed above, several new studies are providing information on morbidity related to HTLV-1 and HTLV-2. The Interdisciplinary HTLV-1/2 Research Group (GIPH) Cohort Study (1997–ongoing) is an open prevalence prospective cohort study conducted by the Hemominas Blood Center in Brazil to assess behavioral and environmental risk factors for seropositivity [38–40]. The UK HTLV National Register, established in 2003, is the first prospective study in Europe designed to capture progression and onset of disease, consisting of subjects recruited from UK blood service donors and recipients as well as patients from specialty HTLV clinics [41]. Another contribution to morbidity statistics came from a nationwide survey of neurologists regarding HAM/TSP incidence in Japan [42].

Because of the rarity of some HTLV outcomes, consortia of several studies are promising new approaches to quantifying HTLV-1 morbidity. The Study of Adult T-Cell Leukemia/Lymphoma Among Carriers of HTLV-1 is a collaborative study of the immunologic and genetic risk factors for ATL with participants drawn from eight studies of HTLV-1 carriers including the Jamaica Mother-Infant Cohort Study, Jamaica Family Study, Jamaica Food Handlers Study, Miyazaki Cohort Study in Japan, Nagasaki Cohort Study in Japan, Japan Public Health Center-based Prospective Study on Cancer and Cardiovascular Disease, the HOST cohort in the USA, and GIPH Cohort Study in Brazil [43]. A large consortium for the prospective study of ATL has also been formed in Japan [44]. The Comprehensive Oncology Measures for Peripheral T-cell Lymphoma Treatment Registry (COMPLETE) is a prospective, longitudinal, multinational, observational study that will collect data on how patients with peripheral T-cell lymphoma (PTCL) are treated in academic and community practices (www.clinicaltrials.gov). While not exclusive to HTLV-1 carriers, it is the first comprehensive assessment of PTCL treatment and outcomes.

Case-control studies have also proved an efficient approach for studying the etiology of ATL and HAM/TSP, albeit with the drawbacks of the retrospective design, including inability to access pre-diagnostic biological specimens. Examples include case-control studies of HTLV-1 proviral load and antibody titers as risk factors for ATL [45–47] and of mode of infection, HTLV-1 proviral load and HLA genotype as risk factors for HAM/TSP [48–50].

3.3 Prevalence Data

Seroprevalence surveys for HTLV have often utilized convenience samples in concert with other surveillance studies, most frequently HIV surveillance in high-risk populations, intravenous drug users (IDUs), and pregnant women. Analysis of blood samples from Japanese case series of ATL, HAM/TSP, or neurologic abnormalities of unknown etiology provided the first evidence linking HTLV seropositivity with adverse outcomes [51, 52]. Studies that took advantage of special sampling frames such as infant screening for metabolic diseases or food handling safety have contributed prevalence data from a broader population base [53, 54]. Blood donation screening allowed initial estimation of population prevalence, assembly of research cohorts, and initiation of larger population-based surveys in many countries [55–57]. However, truly population-based surveys remain rare [58].

3.4 Laboratory Diagnosis

Detection of antibody to HTLV-1/2 in serum or plasma is the primary method of establishing infection as nearly all anti-HTLV-positive individuals harbor virus, attributable to HTLV persistence via host genome integration. Several standard serologic techniques have been employed as anti-HTLV screening and diagnostic assays, including the enzyme immunoassay (EIA), the chemiluminescent immunoassay (ChLIA), the immunofluorescence assay (IFA), the radioimmunoprecipitation assay (RIPA), the particle agglutination assay (PAA), and the Western blot (WB). While high sensitivity and specificity have been demonstrated in clinical evaluation of most screening assays, false-positive results are common when these assays are used in low-prevalence populations. The most common algorithm for diagnosing seropositivity is to repeat the initially reactive screening assay in duplicate, and then test any repeatedly reactive (minimum two of three replicates) sample with a supplemental or confirmatory test. An alternative, potentially more economical, strategy is to insert a screening assay from a different manufacturer between repeatedly reactive and confirmatory testing steps [59, 60]. HTLV-1 and HTLV-2 antibodies often cross-react on screening serologic assays in common use. For discrimination, testing with an HTLV-1 and HTLV-2 antigen-specific EIA, ChLIA, IFA, Western blot, or RIPA or subsequent testing by polymerase chain reaction (PCR) is required.

The most common qualitative screening assays used in the USA are the EIA, which utilizes viral lysate and recombinant antigens in a colorimetric assay, and the ChLIA, which incorporates the same antigens in a light-emitting assay. Both assays perform well and comparably in terms of sensitivity and specificity when used for initial screening [61]. In Japan, a PAA, consisting of purified HTLV antigens coated on artificial gelatin particles, was developed and performs quite well, especially in their HTLV-endemic population [62]. IFA or RIPA may be used for confirmatory testing, but are not suited for high-volume screening as they are more labor and cost intensive than EIA or ChLIA. PCR may be useful as confirmatory testing in endemic areas with a high frequency of WB indeterminate results following a repeatedly reactive EIA. In Africa, the abundance of indeterminate WB results may be influenced by the high rate of coincidental *Plasmodium falciparum* infection [63].

Precursor proteins in provirus production have characteristic molecular weights and at least one *env* gene product and one *gag* gene product should be used as the immunologic targets in WB analysis. Modified WB assays use both group- and type-specific proteins to allow simultaneous confirmation and differentiation of HTLV-1 and HTLV-2 with high accuracy [64–68]. Antibody quantification may be done with serial serum dilutions testing with EIA, PAA, or IFA.

HTLV-1 and HTLV-2 proviral detection and quantification may be done with PCR, where proviral DNA is amplified in repeat enzymatic reactions and HTLV-specific nucleic acid sequences are detected with targeted probes. PCR is an excellent research tool and very sensitive in detection but is not recommended for clinical screening due to false-positive results in low-risk populations. Culturing of HTLV-1, HTLV-2, and other retroviruses may be done from PBMCs obtained from human and simian blood samples together with uninfected lymphocytes with or without cell growth factors [69]. However, the technique is cumbersome and is therefore used mainly for research. For the establishment of relatedness and presumed viral evolution between HTLV viruses, proviral DNA sequence variation may be determined by DNA sequence analysis and/or restriction fragment length polymorphism [70, 71]. However, these analyses are limited by the relatively low degree of sequence variation within the major HTLV-1 genotypes.

4 Biological Characteristics

4.1 Genomic Structure and Replication

The HTLV are diploid retroviruses, consisting of two molecules of single-stranded positive RNA (ssRNA) per virus particle. HTLV-1 and HTLV-2 are approximately 100 nm in diameter with a nearly spherical ribonucleoprotein inner core surrounded by a lipid envelope with glycoprotein projections. Structurally, the complete provirus genome of HTLV-1 contains 9,032 nucleotides and HTLV-2 comprises 8,932 nucleotides (Fig. 45.1). Their genomes are 65 % homologous, but their encoded amino acids are less so, especially between viral capsid and envelope proteins. In general, retroviral genes code for large overlapping polyproteins that are processed by viral protease into functional peptides.

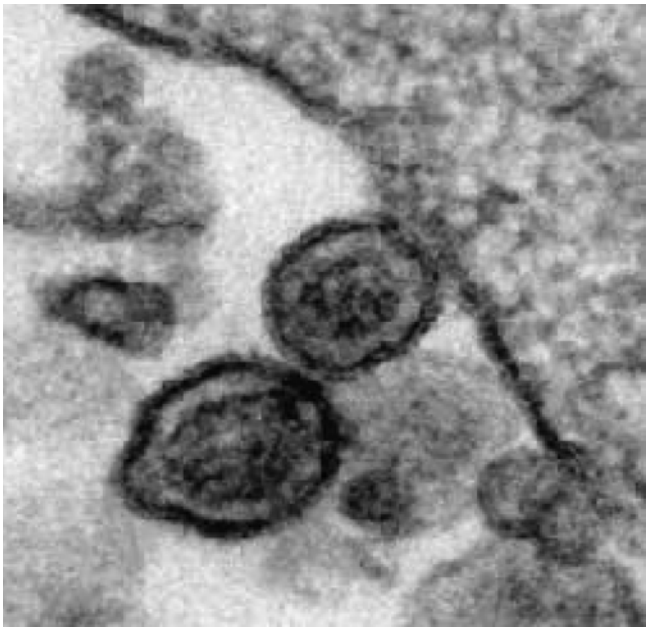

Fig. 45.1 HTLV-1, just after release from an infected T cell; electron micrograph from the National Institutes of Health

The replication strategy of HTLV is typical of members of the Retroviridae family, wherein the RNA genome undergoes reverse transcription into a DNA provirus that integrates into the host genome. Once in the cell, the virally encoded RNA-dependent DNA polymerase (reverse transcriptase) complexed to the genomic RNA of the virus transcribes viral RNA into double-stranded DNA. This double-stranded viral cDNA is transported to the nucleus where, through a complex process mediated by the viral integrase, it is inserted into the host genome. Subsequent virion production is via this integrated DNA under control of the viral regulatory genes. When the DNA provirus is expressed (transcribed by a cellular RNA polymerase), viral genomic mRNA and, subsequently, viral proteins are made by the cell. New genomic RNA is assembled at the cell membrane and packaged for release. During the budding process, the envelope incorporates some of the cell's lipid bilayer, producing an infectious virion of about 100 nm. The host-cell genomic integration of HTLV establishes a lifelong infection and is crucial to both the virus replication cycle and amplification of provirus.

The HTLV genome includes the coding regions of *gag* (group-specific antigen), *pol* (polymerase), and *env* (envelope)

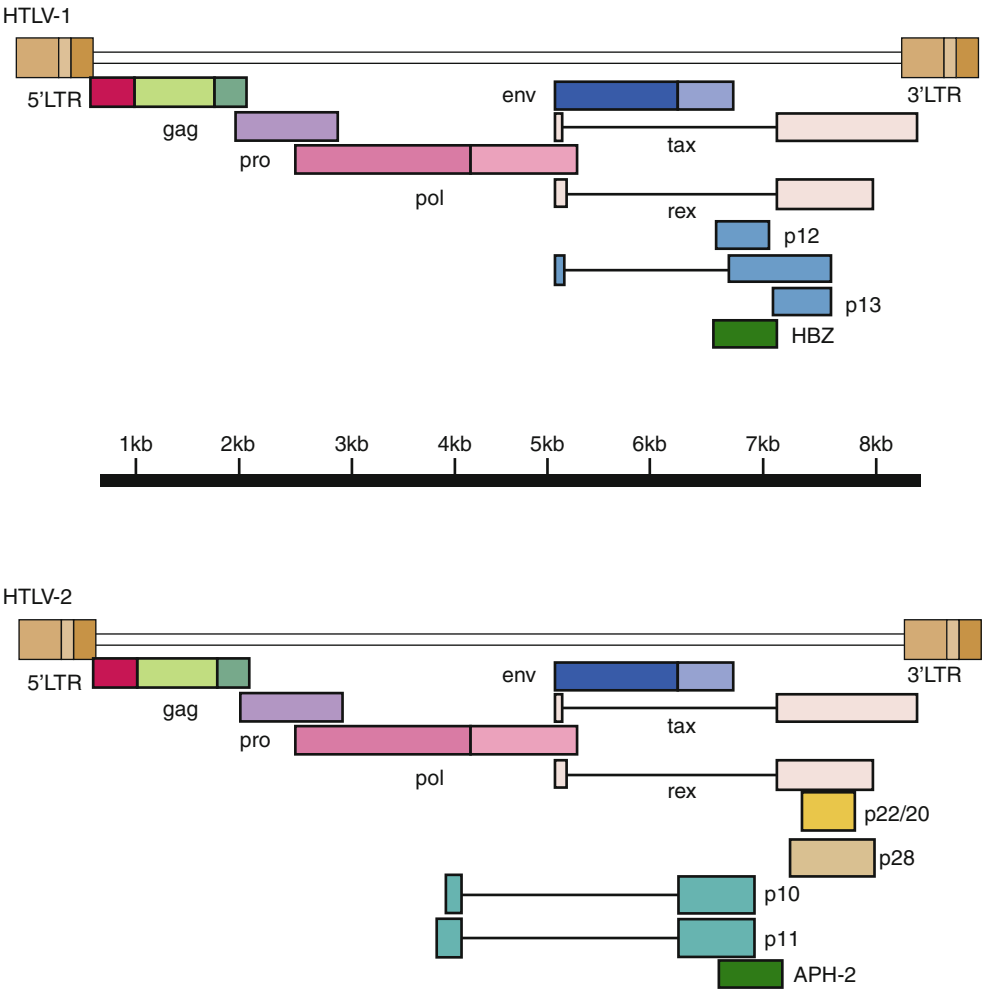

Fig. 45.2 Genomic organization of HTLV-1 and HTLV-2

common to other retroviruses, plus an additional coding region, *pX*, consisting of four open reading frames (ORFs): pX-I, pX-II, pX-III, and pX-IV. The long terminal repeat (LTR) with three distinct regions (U5, R, and U3) flanks the genome at the 5′ cap and 3′ poly-A tail, and these sequences have been shown to be identical between the HTLV-1 and HTLV-2 genomes (Fig. 45.2).

4.2 Molecular Biology

The *gag* gene encodes structural proteins of the nucleocapsid, capsid, and matrix. The *pol* gene encodes a protease that cleaves Gag and Gag/Pol polypeptides into proteins of the mature virion; a reverse transcriptase that generates double-stranded DNA from the RNA genome; and an integrase that incorporates viral DNA into the host-cell chromosomes. The *env* gene encodes the major components of the viral coat including a surface glycoprotein (gp46) and a transmembrane glycoprotein (gp21).

The *pX* ORFs I and II code for accessory and regulatory proteins with putative functions of cell-cycle regulation. The *pX* ORF I codes for the 12-kDa protein, $p12^{I}$, and *pX* ORF II results in the production of two nuclear proteins, $p13^{II}$ and $p30^{II}$. The protein of *pX* ORF I enhances T-cell activation and is essential for establishing persistent infection while proteins of both *pX* ORF I and II impact cell proliferation and modulate host immune responses to HTLV-1 infection.

The pX ORFs III and IV encode the trans-acting proteins Tax and Rex, which are the major regulators of HTLV replication. HTLV-1 Tax is a 40-kilodalton (kDa) protein (p40), and HTLV-2 Tax is a 37-kDa protein (p37). These proteins localize primarily to the nucleus of infected cells, although small amounts of Tax have been found in the cytoplasm. The Tax proteins are responsible for enhanced transcription of viral and cellular gene products. The Tax viral regulatory protein for HTLV-1 plays an important role in promoting viral replication and disease pathogenesis via trans-activation of cellular genes, such as those encoding interleukin-2 (IL-2) and the IL-2 receptor (IL-2R), which

promote cell proliferation; the proto-oncogenes c-fos and c-erg; the gene encoding granulocyte-macrophage colony-stimulating factor; the human lymphotoxin gene; the parathyroid hormone-related protein gene; and an array of early response genes [72]. The process is also modulated by simultaneous trans-repression of other genes, including the β-polymerase gene. The Tax protein interacts with both nuclear regulatory elements (the NF-κB pathway) and cytoplasmic elements through induced nuclear translocation of transcriptional activation factors [73, 74]. The *rex* gene of HTLV-1 and HTLV-2 encodes two proteins in each virus. In HTLV-1, a 27-kDa protein (p27) and a 21-kDa protein (p21) are formed, while in HTLV-2, a 26-kDa protein and a 24-kDa protein are formed. Previous studies have suggested that while the Tax proteins activate transcription, Rex proteins act only posttranscriptionally to regulate viral gene expression via cytoplasmic export of unspliced or incompletely spliced viral mRNAs encoding *gag/pol* and *env* and that nuclear export and expression of the doubly spliced tax/rex RNA is Rex independent. However, Tax expression dependent on the Rex-response element (RxRE) and the RNA binding property of Rex has recently been demonstrated as well [73]. The overall balance of tax and rex expression may influence the rate of viral replication and possibly disease progression [74].

Elements in the viral LTR are essential to integration and replication; they form the sites for covalent attachment of the provirus to cellular DNA and provide important regulatory components for transcription. The LTR U5 and R regions form the leader sequence encoded at the 5′ end of mRNA. An overlapping region of R and U3 constitutes the binding site for Rex (RxRE) and contains sequences that control transcription of provirus as well as termination and polyadenylation of mRNA. Specifically, the 5′ end of the U3 region encodes the carboxyl terminus of the Tax protein. Transcription initiated from the 3′ LTR (antisense transcription) of HTLV-1 produces the HBZ (HTLV-1 basic leucine zipper (bZIP) factor) protein, while antisense transcription in HTLV-2 and in the recently discovered HTLV-3 and HTLV-4 governs production of a protein with some similarity in structure and function to HBZ, the antisense protein of HTLVs (APH), denoted APH-2, APH-3, and APH-4 for each virus, respectively [75–78]. The HBZ protein is capable of inhibiting Tax-mediated activation of the HTLV-1 LTR, activating cellular transcription, and promoting T-lymphocyte proliferation [79]. The APH-2 and APH-4 proteins localize in the nucleus of transfected cells, as does HBZ, while APH-3 localizes in both the nucleus and cytoplasm. All APH proteins discovered thus far demonstrate the ability to repress Tax-mediated viral transcription [77, 78]. Recent research has also shown that while APH-2 is associated with higher proviral load, it neither promotes cell proliferation nor causes lymphocytosis [75, 76].

4.3 Cellular Biology

While recent work has identified three proteins expressed on human cells that are important for HTLV-1 entry (glucose transporter 1, heparin sulfate proteoglycans, and neuropilin-1), the precise interaction with the virion and/or each other remains uncertain [80–82]. Natural infection occurs in Old World primates, and numerous animal species can be infected experimentally (mice, rats, rabbits, New World and Old World primates as well). Although HTLV-1 can infect a number of different cell types in vitro, its growth and propagation in vivo are supported mainly by CD4+ cells and to a lesser extent CD8+ cells. In contrast, HTLV-2 preferentially infects CD8+ cells over CD4+ cells.

Based on epidemiologic data demonstrating that HTLV-1 transmission is strongly cell-associated and supported by in vitro cocultivation studies, transmission of HTLV is via live cells and not cell-free body fluids. For this reason, HTLV-1 is not easily transmitted and universal biohazard precautions are adequate for handling potentially infectious blood or bodily secretions. Because HTLV is highly cell associated, the mechanism of initial viral attachment is not well characterized but cell-surface adhesion proteins and cell-to-cell contact are important for facilitating transmission, and, similar to other retroviruses, fusion of the virion with the host-cell membrane results in uncoating of the diploid RNA genome of the virus [83].

Wattel, Wain-Hobson, and colleagues first demonstrated that expansion of HTLV-1 proviral load occurs mainly through expansion of infected lymphocytes rather than through viral replication and infection of new lymphocytes [84]. HTLV-1 carriers with high proviral load as well as patients with HAM/TSP often have oligoclonal expansion of a limited number of large clones [85]. Clonal expansion may also play a role in the pathogenesis of ATL via the accumulation of somatic mutations in host DNA flanking the HTLV-1 clonal integration site [86]. The relationship between the number of clones and the size of each clone may be determined by mode of transmission, with vertical transmission leading to large oligoclonal expansion and sexual transmission leading to polyclonal expansion [87, 88].

4.4 Immunology

Upon initial infection with HTLV, the first detectable antibodies are directed against the transmembrane Env glycoprotein and multiple distinct regions of the Gag polyprotein. Over a longer time-course (weeks to months), subsequent development of antibody to the surface Env glycoprotein occurs and around half of infected individuals will exhibit detectable levels of antibodies against the Tax protein as well. Antibody titers vary from patient to patient in both HTLV-1 and HTLV-2

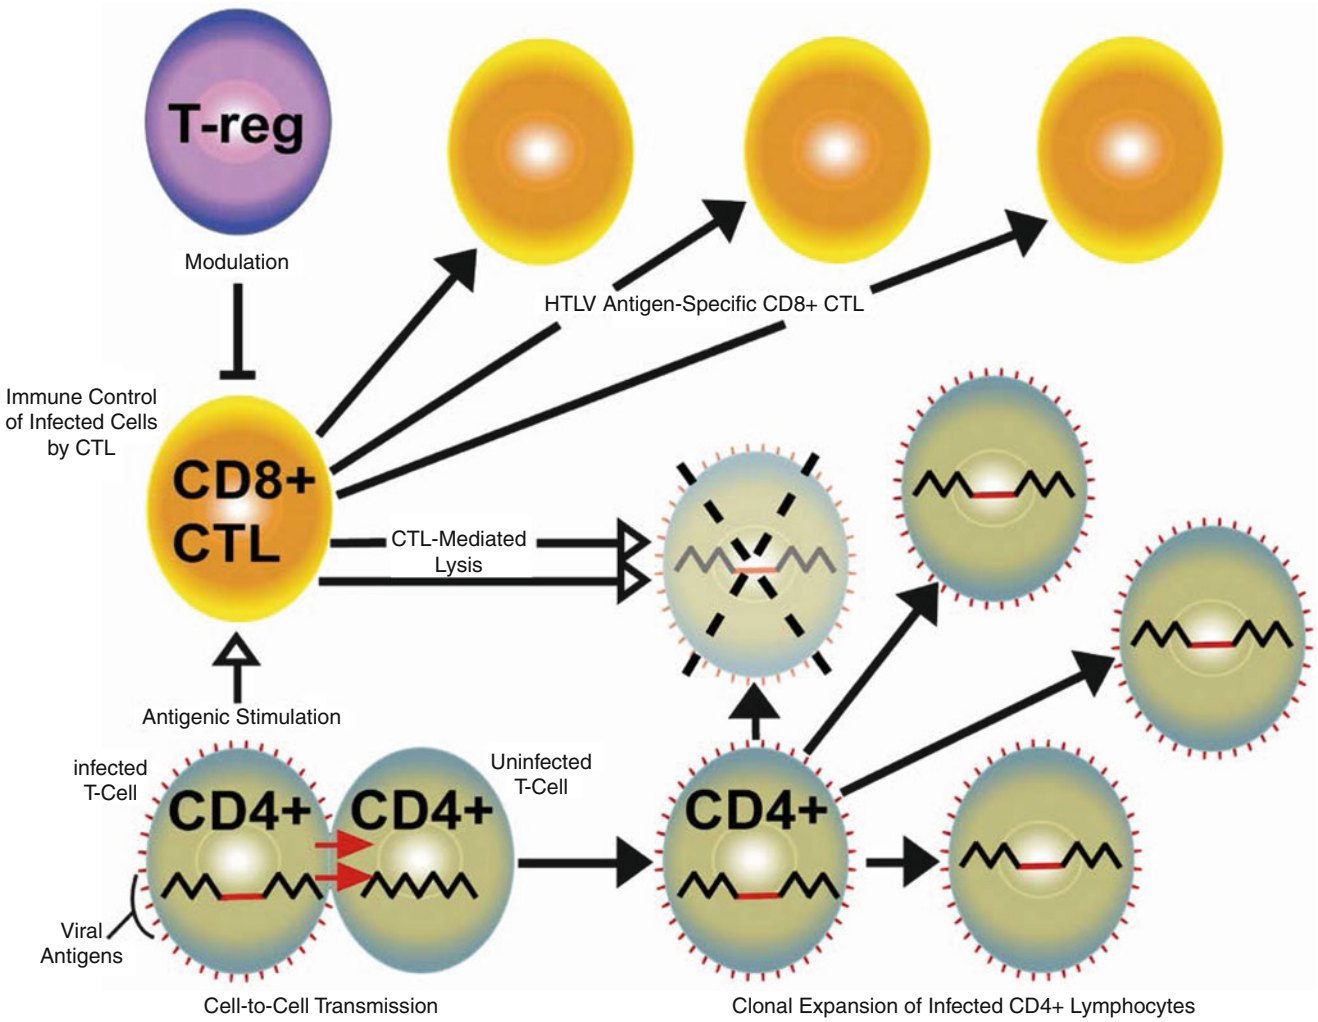

Fig. 45.3 Cell-to-cell transmission, clonal expansion of infected lymphocytes, and cell-mediated immune response to HTLV-1 infection

infection but in general correlate with proviral load, although a protective effect of antibody on HTLV proliferation or disease progression has not been seen in humans [89–91]. Instead, cytotoxic T lymphocytes (CTL) drive the cell-mediated immune response in primary HTLV infection (Fig. 45.3). CTLs in primed patients can recognize numerous epitopes of HTLV, including the Tax antigen. As viral replication results in expression of Tax and $CD4^+$ cell proliferation, the subsequent destruction of infected $CD4^+$ cells via CTLs releases HTLV proviral particles that are then free to infect additional $CD4^+$ cells. As Tax-mediated $CD4^+$ cell expansion escalates, so too does the CTL response, with corresponding $CD8^+$ cell expansion. In an attempt to keep the HTLV infection in check, this process repeats cyclically in infected individuals [92].

Thus, cell-mediated immune response to HTLV infection is inadequate to abrogate persistent viral infection. The effect of $CD4^+$ T-helper 1 (Th1) cell response in HTLV infection has not been extensively characterized, but recent work demonstrated that the HBZ protein, which is constitutively expressed in infected cells, directly suppressed production of Th1 cytokines in a murine model, diminishing the effect of cell-mediated immunity and resulting in higher rates of opportunistic infection when challenged [93]. Cell-mediated immune response to HTLV may also be responsible for the pathogenesis of HAM/TSP (see below).

5 Descriptive Epidemiology

5.1 Molecular Epidemiology and Simian Origins

HTLV and the related simian T-lymphotropic viruses (STLV) together are designated as the primate T-cell lymphotropic viruses (PTLV). It is generally accepted that HTLV resulted from cross-species STLV infections either through a nonhuman

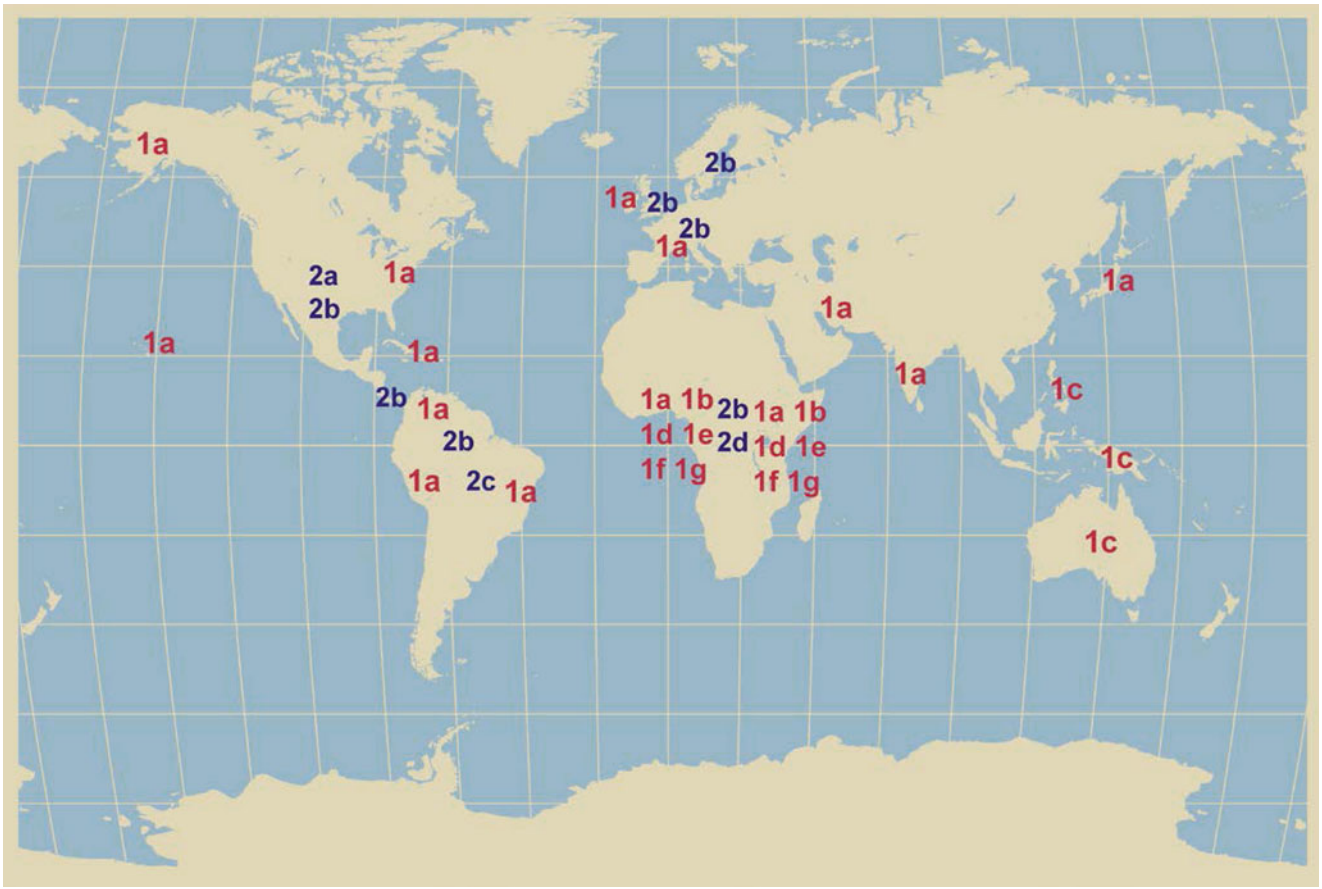

Fig. 45.4 Geographic distribution of HTLV-1 (indicated by "1") and HTLV-2 ("2"). Subtypes indicated by letters

primate bite or through the process of hunting and butchering a primate carcass. Africa is the only continent where all known PTLV have been identified, and this evidence, along with phylogenetic analyses, strongly suggests a common ancestor of Central African origin [26, 70, 94–97]. Currently, four types of HTLV are recognized: HTLV-1, HTLV-2, HTLV-3, and HTLV-4, but only three related STLV counterparts have been identified (STLV-1, STLV-2, and STLV-3). The first HTLV was isolated in 1979 and subsequently identified as HTLV-1 in 1980. Of the remaining types, HTLV-2 was identified in 1982, while HTLV-3 and HTLV-4 were both discovered in 2005 [6, 26]. All HTLV types exhibit a low level of genetic drift, reflected in high genetic consistency among isolates maintained in cell culture from the same geographic area or within a related strain. The broad geographic dispersion of HTLV-1 is thought to be linked primarily with the slave trade while HTLV-2 clusters are more closely aligned with geographically segregated indigenous peoples and IDUs (Fig. 45.4) [70, 95, 96]. Seven molecular subtypes of HTLV-1 have been identified, primarily distinguished by nucleotide sequence within the LTR region: the cosmopolitan subtype, 1a, has worldwide distribution and is further separated into subgroups (A–E); five African subtypes (1b and 1d-1 g); and a Melanesian/Australian subtype (1c) (Fig. 45.5) [98]. Some HTLV subtypes cluster by racial and ethnic group within a limited geographic region, but closely related isolates have also been found in widely disparate locations, including the Caribbean, Japan, Chile, Iran, and Kuwait [99]. Four subtypes of HTLV-2 (a–d) have been identified; although there is still controversy as to whether 2-c is a separate subtype, a *tax* gene of very different length supports a distinction (Fig. 45.6). Two subtypes of HTLV-3 (b and d) have been isolated [26, 94], but, as yet, no subtype or STLV counterpart has been identified for HTLV-4, and extensive genetic analysis has clearly demonstrated its monophyletic nature. HTLV-4 is also considered the oldest known strain of the PTLV lineage [26]. Fairly extensive data are available on the seroprevalence of HTLV-1 and HTLV-2, but there are only limited data on the extent of HTLV-3 or HTLV-4 infection, mostly from studies of Pygmies and those exposed to nonhuman primates in Central Africa [100, 101].

5.2 HTLV-1 Prevalence by Geography and Risk Group

Prevalence data are primarily collected via cross-sectional serologic surveys and convenience samples from targeted groups that may not be representative of the general

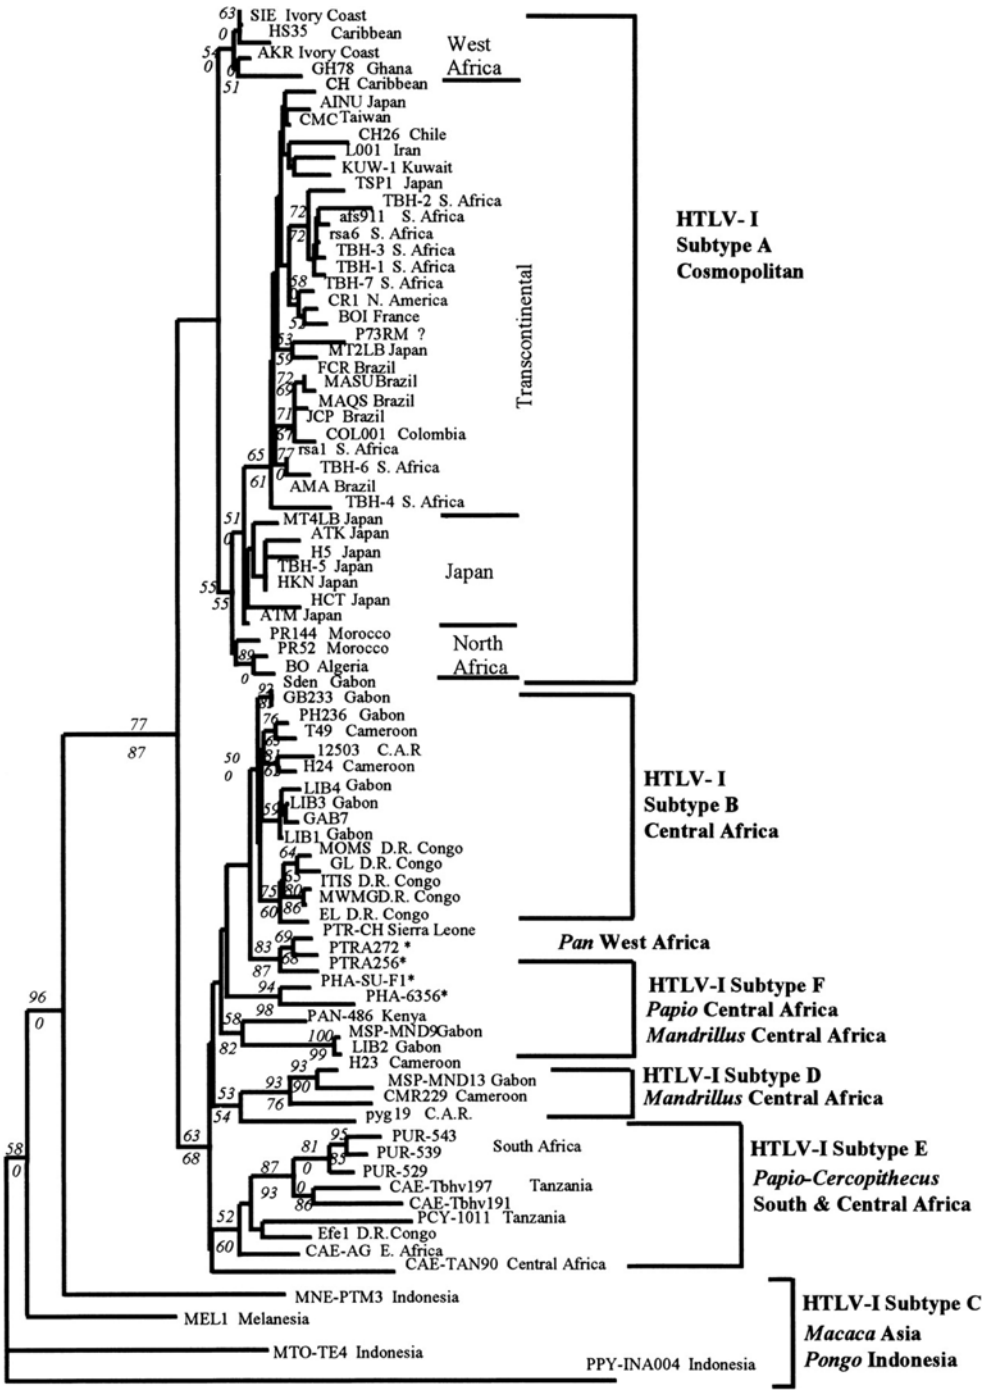

Fig. 45.5 Phylogenetic classification of HTLV-1 based upon the LTR region (per Slattery et al. [70])

population, such as low-risk blood donors or high-risk sex workers and IDUs. Prevalence estimates prior to the 1990s must be viewed with caution because many were based upon screening with early EIAs that suffered from reduced specificity, lacked confirmation by Western blot or other more specific tests, or did not discriminate between HTLV-1 and HTLV-2 cross-reactivity.

The seroprevalence of HTLV-1 is age and sex dependent in most populations, increasing with age and higher in females (Fig. 45.7). There is often localized geographic clustering or clustering within ethnic and social groups due to transmission primarily within families or among individuals with shared risk behaviors. Ongoing mother-to-child transmission and higher sexual transmission rates from males to females may account for the characteristic age and sex distribution. Birth-cohort effects are seen with HTLV-1 and HTLV-2 prevalence and may be due to higher prevalence in past versus current generations attributable to increased

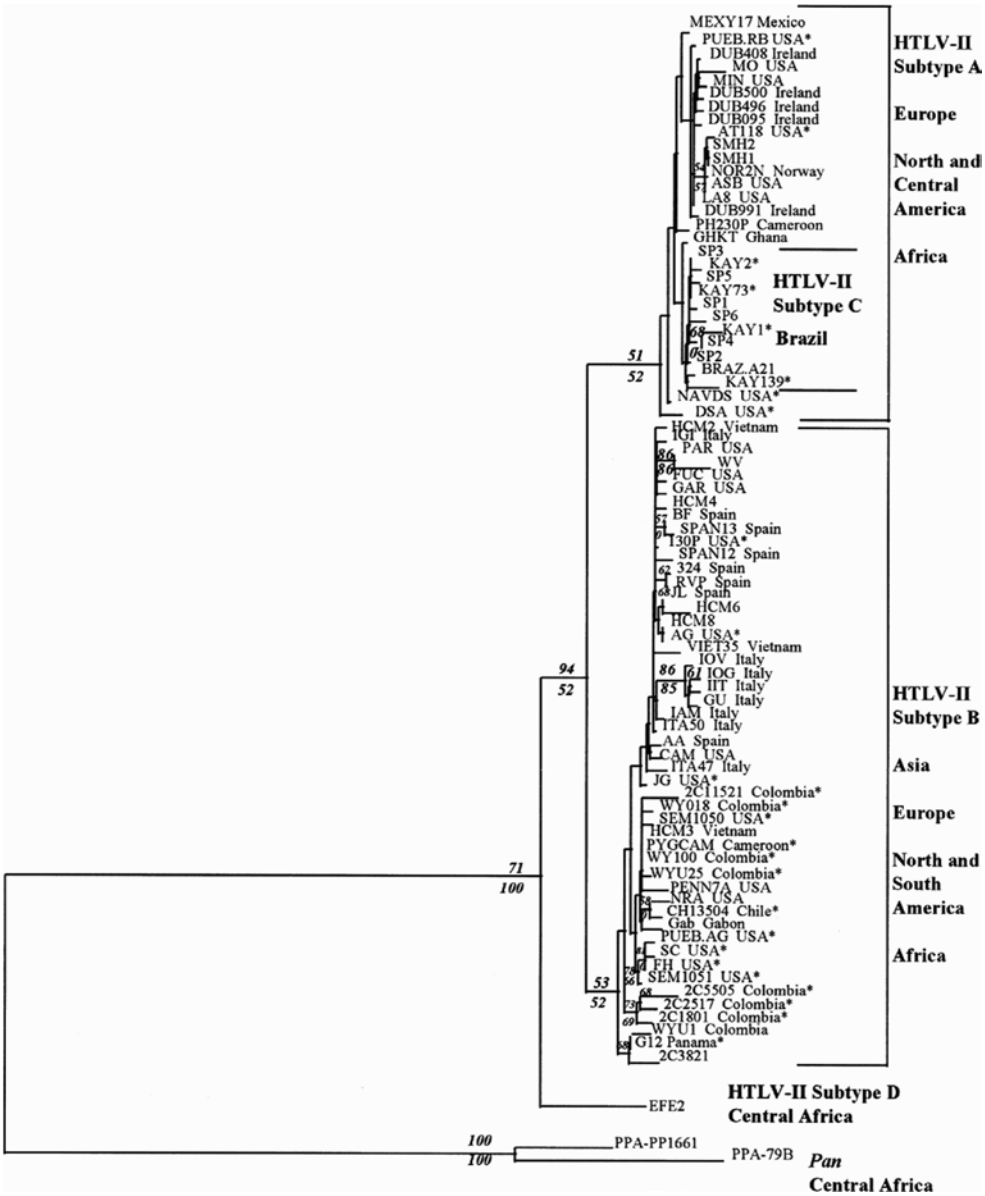

Fig. 45.6 Phylogenetic classification of HTLV-2 based upon the LTR region (per Slattery et al. [70])

condom use, reduced breast-feeding, or reduced injection drug use [56, 102].

Regions with the highest HTLV-1 seroprevalence rates are southwestern Japan, sub-Saharan Africa, islands of the Caribbean basin, and Central and South America [54, 56, 58, 95, 103, 104]. The most recent study (2006–2007) of HTLV-1 in Japan measured seropositivity first-time blood donors and extrapolated the data to fit the general population, resulting in nationwide prevalence estimates of 0.66 % in males and 1.02 % in females [105]. However, pockets of high endemic prevalence in the Japanese islands (up to 36 %) still remain [58]. Several studies in Africa report 1.9 %, 5 %, and 6.6–8.5 % prevalence in Cameroon, Guinea-Bissau, and Gabon, respectively [58, 98, 106]. The Caribbean islands are endemic with HTLV-1, mainly in populations of African slave descent. Prevalence in Jamaica was about 4 % according to a survey in the 1980s [54]. In South America, prevalence in blood donors ranged from 0.14 % in Brazil, 0.73 % in Chile, and 0.07 % in Argentina [58, 60]. In Peru and southern regions of South America, HTLV-1 infection is most prevalent in indigenous people [96]. HTLV-1c subtype is found in Aborigines of northern Australia at a rate of 14 % [58]. Population-based surveys were conducted in two separate villages of a newly endemic region in Mashhad, Iran. One study reported 2.42 and 1.31 % prevalence in men and women, respectively, and the other reported overall prevalence of 2.12 % with no difference between males and females [107, 108]. In both locations seropositivity was significantly associated with age and the subtype was exclusively HTLV-1a.

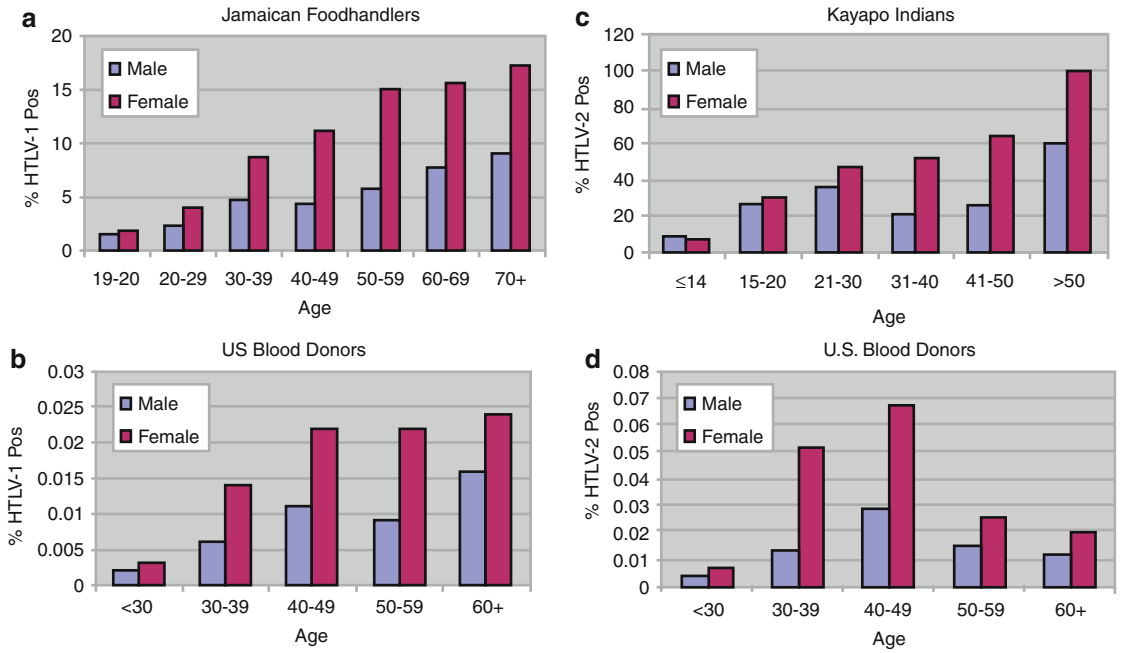

Fig. 45.7 Seroprevalence of HTLV-1 and HTLV-2, illustrating typical age and sex dependence of HTLV-1 among endemic Jamaicans (panel **a**, Murphy et al. [54]) and US blood donors (panel **b**, Murphy et al. [110]). For HTLV-2, a similar age and sex dependence is seen for endemic Kayapo Indians (panel **c**, Murphy *J Infect Dis* 1992) but a probable birth-cohort effect is seen among US blood donors (panel **d**, Murphy et al. [110])

In Europe and North America, the prevalence of HTLV-1 is quite low and is often associated with immigrant populations. The overall prevalence in foreign-born pregnant women in Spain was 0.2 % [109]. Prevalence in French blood donors was reported as 0.0039 % while surveillance data from US blood donors indicated seroprevalence of 0.01 % [110]. HTLV-1 is also found in Native Alaskans in the USA, supporting the association with human migratory patterns [96].

5.3 HTLV-2 Prevalence by Geography and Risk Group

For HTLV-2, there is an age-dependent rise in seroprevalence within endemic Amerindian populations; however, age-specific prevalence among US blood donors peaks between the ages of 40 and 50, consistent with a 1960s–1970s injection drug use-induced birth-cohort effect, plus secondary sexual transmission (Fig. 45.7). HTLV-2 is endemic in many Native American populations in North, Central, and South America as well as the Pygmy tribes (4 % prevalence) in Africa [111, 112]. In Brazil, seroprevalence is highest in the indigenous peoples of the Amazon basin (8–58 %) [111]. A small study of Brazilian blood donors showed a prevalence of 0.006 % [113]. Argentine IDU and urban populations are most frequently infected with subtype 2a, while subtype 2b is detected in Aborigines from Northern Argentina [114]. In Pueblo and Athapaskan Indians in New Mexico, USA, 8 (3.2 %) of 250 persons being treated for sexually transmitted diseases and 15 (3.4 %) of 446 clinic outpatients were seropositive for HTLV-II [115].

In the USA and Europe, HTLV-2 is found at highest prevalence among IDUs. Among 3217 IDUs in 29-drug-treatment centers in the USA, seroprevalence rates of HTLV-2 varied widely by city, ranging from 0.4 % in Atlanta to 17.6 % in Los Angeles [20]. Prevalence is associated with older age, black race, and duration of heroin injection [116]. In Spain and Italy, HTLV-2b subtype is most often detected in IDUs who are coinfected with HTLV-1. The same subtype is also found in Spain and Portugal, while HTLV-2a is most common in North America and Eastern Europe [117].

6 Mechanisms and Routes of Transmission

HTLV-1 and HTLV-2 have several shared routes of transmission: perinatal, primarily through breast milk; sexual; and parenteral, via injection drug use or transfusion of infected cellular blood products. The dominant route of transmission may vary by population. For example, maternal-child and sexual transmission are the norm in endemically infected groups such as Australian Aborigines and Native Amerindian populations while parenteral infection predominately occurs among IDUs [6, 95, 96, 111, 118, 119]. Transmission routes

for HTLV-3 and HTLV-4 have not been established, but in vitro studies of HTLV-3 demonstrate a high affinity for both CD4+ and CD8+ lymphocytes, as seen with HTLV-1 and HTLV-2 [26].

6.1 Maternal-Child Transmission

Transmission from mother to child through breast-feeding is a significant factor in sustaining HTLV-1 and HTLV-2 infection in endemic populations. Provirus from both HTLV-1 and HTLV-2 has been detected in breast milk [120–122]. The risk of vertical transmission is most closely associated with high provirus load in breast milk, the concordance of HLA class I type between mother and infant, and duration of breast-feeding [121, 123–129]. Both high proviral load and antibody titer of the infected mother have been significantly associated with vertical transmission, but only for HTLV-1 [128, 130]. Maternal antibodies readily cross the placenta and can be detected for a time in newborns, but protection from subsequent infection appears to be short-lived, most likely due to the cell-associated nature of HTLV. Ingestion of infected lymphocytes in breast milk is the hypothesized source of infection, and transcytosis of infectious HTLV-1 virions across a tight human epithelial layer, such as occurs in the digestive tract, has been demonstrated in vitro [131]. In addition, evidence of transplacental transmission for both HTLV-1 and HTLV-2 has been documented, but at rates much lower than transmission through breast-feeding [121, 122, 132]. Transplacental infection likely accounts for the small rate of residual mother-to-child infection in infants who are not breast-fed.

6.2 Sexual Transmission

Studies of HTLV-1- or HTLV-2-infected individuals have clearly demonstrated sexual behavior as a risk factor for transmission. While fewer HTLV-2 studies are available, several show evidence of sexual transmission in blood donors, patients at sexually transmitted disease clinics, and Native Amerindian tribes. Case-control and prospective studies of HTLV-discordant couples and seroconversion of negative sexual partners provided the strongest evidence of sexual transmission [71, 133, 134] for both HTLV-1 and HTLV-2. Some studies support higher male-to-female than female-to-male transmission [135, 136], although other studies of discordant partners show more bidirectional infection [134]. The risk of infection also increases with higher proviral load in the transmitter and longer duration of sexual relationship [136]. Cross-sectional studies showing prevalence in both males and females gradually increasing with age support sexual transmission as a predominant source of infection within a community [125, 137–139].

6.3 Blood Transfusion

Transfusion transmission of HTLV-1 and HTLV-2 has been well documented and may still occur in endemic areas where blood products are not routinely screened for HTLV antibody. The first transfusion-transmitted cases of HTLV-1 to be documented in the literature were in a retrospective study of blood donors from the endemic areas of the Japanese islands. Analysis showed that 60 % of recipients who received whole blood later determined to have been positive for HTLV-1 (via testing of routinely stored donor/donation samples) seroconverted within 4–8 weeks of transfusion [140]. Results from this study led to the recommendation that all blood donors be screened for antibody to HTLV. Other studies in Jamaica and another in the USA also confirmed transfusion transmission, albeit with somewhat lower transmission rates. Cold storage of blood and leukoreduction of blood products also lower transmission, presumably due to killing or removal of infected lymphocytes [141–143].

The prevalence of HTLV-1 and HTLV-2 infection in two large US blood bank networks was reported as 9.6 per 100,000 in 2001 and 21.9 per 100,000 in 2000–2009, with the latter showing a decreasing secular trend [144, 145]. Together these surveys covered nearly three-quarters of the US donor population. In the year 2000, the risk of transfusion-transmitted HTLV in the UK, where blood donors are routinely screened for antibody to HTLV-1 and HTLV-2, was reported to range from 0 to 1 per 5,939 recipients, while the most recent data from 2002 to 2006 estimate the risk of an HTLV-1 infectious donation entering the UK blood supply at a very low 0.11 per million donations [146, 147]. In Australia, 0.0003 % of donors were identified as HTLV-1 or HTLV-2 positive between 2000 and 2006 and the modeled residual HTLV transfusion-transmitted infection risk was calculated at substantially less than one per million transfused units [148, 149]. Nucleic acid testing (NAT) has been instituted for other transfusion-transmitted viruses including HIV, HBV, and HCV, but not HTLV, most likely because NAT is performed on plasma and HTLV is primarily lymphocyte associated.

6.4 Injection Drug Use

Both HTLV-1 and HTLV-2 can be transmitted by drug injection, but HTLV-2 has shown a predilection for transmission via this route, especially in the USA where infection in IDUs occurs nationwide and in Europe. Very high prevalence (2–17 %) clusters of either HTLV-1 (2–9 %)- or HTLV-2

(11–25 %)-infected IDUs in the USA can be located on the West and upper East coasts as well as in some Southeastern states [20, 116, 150].

6.5 Other Parenteral Transmission

Other routes of infection are rare, but documented transmission via organ donation and needle-stick injury has occurred. Three recipients of organs from a single HTLV-1-positive donor seroconverted after transplantation and a Japanese health-care worker seroconverted subsequent to a skin puncture with an HTLV-1 contaminated syringe [151]. One HTLV-2-infected blood donor in the USA had no risk factors except occupation as a dentist [143].

7 Pathogenesis and Immunity

7.1 HTLV-1

HTLV-1 exhibits the ability to infect a variety of cell types directly, including T lymphocytes, B lymphocytes, and macrophages, but preferentially targets CD4+ T lymphocytes. In addition, extracellular matrix-mediated transmission and dendritic cell-assisted infection has been described, but how large a role these mechanisms have in establishing persistent infection or in person-to-person transmission is not known [81, 152–154]. Beyond provirus replication at the initial site of infection, it is believed that infection of immune cells occurs within the regional lymphatic system and may result in dissemination of HTLV-1+ cells to reservoirs such as the skin, thymus, liver, spleen, mucosal, and perivascular lymphoid tissue. However, viral replication is not believed to be the primary modulator of persistent infection; instead, clonal proliferation of HTLV-1-infected cells has a significant role [85, 155, 156]. The HTLV Tax proteins have been implicated in the majority of processes leading to persistence and pathogenesis, including cellular activation, transformation, cytokine expression, and inactivation of host tumor-suppressor genes. At initial infection, the immune system mounts a response and most infected individuals develop antibodies within 1–2 months, but periods as long as 18 months prior to seroconversion have been seen in perinatal studies [157]. Antibody usually persists at stable levels throughout life and the majority of HTLV-1 carriers remain asymptomatic, but 2–5 % will develop clinical disease, either ATL or HAM/TSP or rarely both [158]. Why some infected individuals remain asymptomatic while others progress to clinical disease is not well understood and continues to be an area of active research. Recent work has focused on host factors, specifically genetic polymorphisms of HLA alleles and associated immune response. By analyzing HLA alleles in ATL and HAM/TSP familial clusters and the associated HLA allele immune response to HTLV-1, their differential susceptibility to clinical outcome was assessed. Sonoda and colleagues have hypothesized that genetic polymorphisms of HLA alleles determine HTLV-1 clinical outcome, with low immune responder HLA carriers exhibiting no positive immune response and being permissive to HTLV-1 and high immune responder HLA alleles being nonpermissive to HTLV-1 and exacerbating the host inflammatory response. The low responder HLA allele would predispose carriers to ATL and the high responder allele to HAM/TSP [97]. Further studies are needed to elucidate whether specific HLA alleles have predictive potential for exact clinical disease outcomes, analogous to studies that have elucidated the modest genetic contribution to control of HIV infection [159].

7.1.1 ATL Pathogenesis

Adult T-cell leukemia (ATL) develops after many years of chronic infection with HTLV-1 and then in 4 % or less of those infected [160]. The risk of developing ATL appears to be greatest in individuals who acquire HTLV-1 via mother-to-child transmission [161–164]. One hypothesis is that infection of thymocytes early in life leads to the later development of ATL. This theory is supported by in vitro experiments demonstrating that infection of both mature and immature thymocytes resulted in proliferation of HTLV-1-positive thymocytes expressing identical phenotypes [165]. Leukemogenesis is thought to be primarily driven by Tax protein mechanisms that have been well elucidated, including induction of genetic instability and repression of DNA repair mechanisms, transformation and proliferation of primary CD4+ T lymphocytes, and disregulated cytokine production [91, 166, 167]. After Tax has initiated clonal expansion, strong evidence exists that another HTLV-1 protein, HBZ, is critical in maintaining the transformed clonal phenotypes [80, 168–172]. The clones may have functional genomes with the potential for continued expansion or defective genomes that lead to cell senescence [166, 173, 174]. Subsequently a dominant or several dominant clones undergo uncontrolled cell cycling and expansion resulting in clinical manifestation of ATL. Depressed T-cell response and elevated proviral load is a hallmark of ATL. Observation of this pattern in a subpopulation of asymptomatic HTLV-1 carriers suggests that it may be an underlying risk factor [91]. Several studies have correlated antibody level and proviral load with clinical disease outcome as well [175, 176].

7.1.2 HAM/TSP Pathogenesis

HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP) is a chronic progressive inflammatory myelopathy localized predominantly to the thoracic spinal cord. The incidence of HAM/TSP in HTLV-1 carriers is estimated to

be less than 4 % [15, 177]. Epidemiologic evidence suggests that sexual rather than vertical transmission of HTLV-1 is associated with HAM/TSP. This contention is supported by the female predominance of HAM/TSP [178], by sexual activity at an earlier age and higher frequency in HAM/TSP patients compared to controls and by a lack of HTLV seropositivity in the mothers of HAM/TSP patients [48]. Additionally, a study examining fresh, uncultured peripheral blood mononuclear cells for the presence of HTLV-1 tax/rex mRNA by in situ hybridization in HAM/TSP patients and their spouses revealed higher numbers of HTLV-1 mRNA-positive cells in the female spouses of male HAM/TSP patients [179]. The onset of disease is usually gradual and symptoms generally develop when carriers are well into adulthood (40s to 50s), but occasional reports of children with HAM/TSP do occur.

Pathological abnormalities, specifically CD8+ lymphocyte infiltration of brain and spinal cord, have been observed in clinical cases, as has high frequency of cytotoxic T lymphocytes (CTL) with specificity directed against MHC class I-restricted epitopes derived from the Tax protein. Together this is highly suggestive that an immune mechanism involving activated lymphocytes is involved in the development of HAM/TSP. HTLV-1-specific T-cell responses elicit antitumor and antiviral effects in experimental models and are considered to be one of the most important determinants of the disease manifestation, since they are activated in HAM/TSP but not in ATL patients. HAM/TSP patients characteristically have HTLV-1 antibodies or antigens in the blood and cerebrospinal fluid and elevated levels of the lymphokines IL-6, tumor necrosis factor-α, and IL-2. The role of CD4+ T-helper 1 (Th1) cells in CTL response is not as well characterized; however, an association has been seen between HTLV-1 carriers with a specific HLA genotype, lower HTLV-1 proviral loads, and lower rate of progression to HAM/TSP, most likely because of their ability to mount a strong cell-mediated immune response. Control of HTLV-1 infection appears to be by both acquired and innate immunity, and conflict between the two systems may influence disease progression [91, 97, 160, 180–196].

As mentioned above, HLA genotype influences immune response to HTLV-1 infection and has been proposed as a major determinant of HAM/TSP pathogenesis. Bangham and colleagues have shown that the possession of HLA-A*02 and HLA-Cw*08 genotypes was associated with lower proviral load and was protective against HAM/TSP risk in HTLV-1 carriers and that HLA-B*5401 was associated with both a higher provirus load and increased susceptibility to HAM/TSP [197]. In contrast to the theory proposed by Sonoda, above, these authors hypothesized that a strong class I-restricted CTL response to HTLV-1 reduces the proviral load and hence the risk of disease.

7.2 HTLV-2

In contrast to HTLV-1, HTLV-2 clearly does not cause ATL. While HTLV-2 has been linked with HAM/TSP, evidence from cohort studies suggests the risk of acquiring clinical disease is lower than for HTLV-1. These differing pathophysiological outcomes have yet to be fully explained on a molecular, biological, or immunologic basis. Proviral load has been shown to be lower for HTLV-2 than for HTLV-1, different among individuals, but persistent at the same level for many years within the same individual [198]. The reasons for lower HTLV-2 proviral load are not fully understood but may be related to differences between Tax-2 and Tax-1 or between antisense proteins APH-2 and HBZ [74, 75]. In a rabbit model, HBZ and APH-2 may affect proviral load through the later modulation of clonal expansion of HTLV-1- and HTLV-2-infected cells rather than immediately following infection [199]. Finally, a strong CD8+ CTL response directed primarily against Tax-2 does exist in HTLV-2 infection and is inversely correlated with HTLV-2 proviral load, suggesting that differences in immune response could also explain lower pathology with HTLV-2 [200, 201].

8 Patterns of Host Response

8.1 ATL Clinical Manifestations and Treatment

Disease associations of HTLV-1 and HTLV-2 are shown in the Table 45.1. Adult T-cell leukemia/lymphoma (ATL) is a malignancy of peripheral T lymphocytes characterized by monoclonal integration of HTLV-1 provirus in tumor tissue. It may be classified into four forms: acute, chronic, smoldering, and lymphoma types [29]. The acute form of ATL comprises 55–75 % of all ATL [29, 202], with the chronic and the cutaneous forms together comprising the remaining 25 %. Distributions of these subtypes may differ by geographic area. In Japan, ATL typically presents among individuals aged 50–70, while in the Caribbean the typical patient presents at age 40–50.

ATL is almost invariably associated with peripheral and/or central lymphadenopathy. Hepatosplenomegaly is the next most common manifestation, described in approximately 50 % of patients. These findings may be preceded by or occur coincidentally with cutaneous manifestations. Skin lesions are generally described as indolent, nodular, and sometimes indurated. Occasionally patients are reported to present with a more diffuse rash with exfoliation and erythroderma. Pulmonary, CNS, and intestinal involvement are reported less frequently and other extranodal sites are unusual.

Significant anemia and thrombocytopenia are rare early in disease since bone marrow infiltration is unusual. White blood

Table 45.1 Diseases and conditions associated with HTLV-I and HTLV-II infection, with level of evidence for each association

Disease/condition	HTLV-1	HTLV-2
Adult T-cell leukemia/lymphoma	++++	No
HTLV-associated myelopathy	++++	+++
Overall mortality	+++	+++
Cancer mortality	No	++
Infective dermatitis	+++	No
Uveitis	+++	Unknown
Lymphadenopathy	++	++
Pneumonitis	++	++
Polymyositis	++	Unknown
Sjogren's syndrome	++	Unknown
Disseminated strongyloides	++	Unknown

Key: ++++ very strong evidence, +++ strong evidence, ++ possible association, + weak association, *No* evidence does not support association, *Unknown* no evidence in favor or against association

cell (WBC) counts are nearly always elevated and may range into the hundred thousands. Very high WBC counts and elevated serum LDH and calcium are markers of a poorer prognosis. Peripheral blood smears will generally reveal the atypical lymphoid cells with pleomorphic, multilobulated nuclei known as "flower cells." Compared to Sézary cells, nuclear convolutions are more marked in ATL cells. The surface phenotype of ATL cells is usually CD3+/CD4+/CD7−/CD8−/CD25+/CD30+ and terminal deoxynucleotidyl transferase (TdT) negative. Clonally integrated HTLV-1 provirus and clonally rearranged T-cell receptor V-β and V-γ can be detected by inverse PCR of flanking host DNA or southern hybridization [203]. Without treatment acute ATL is invariably rapidly fatal, with pulmonary complications, opportunistic infections, and sepsis emerging as the principal cause of death.

Uncontrolled hypercalcemia also contributes to fatality. Hypercalcemia is described in approximately 30–60 % of patients with ATL and is frequently associated with lytic bone lesions [29, 202]. The pathogenesis of the hypercalcemia may involve Tax-mediated overexpression of parathyroid hormone-related peptide in HTLV-1-infected T cells [204]. More recent evidence suggests that ATL cells overexpress the receptor activator of nuclear factor kappa-B (RANK) ligand gene [205]. Expression of this gene was shown to induce differentiation of human hematopoietic precursor cells into osteoclasts in vitro, in the presence of macrophage colony-stimulating factor (M-CSF).

The chronic and smoldering forms of ATL comprise more infrequent presentations. Monoclonal HTLV-1 integration appears to present in both forms, and thus many of these individuals will eventually transform to acute forms of ATL after many years. Chronic ATL presents with minor cutaneous involvement and persistent lymphocytosis, with fewer cells exhibiting the typical flower-cell morphology. Differentiation of chronic from smoldering forms of ATL seems to be mainly the extent of lymphocytosis and lymphoid cell morphology [5]. In the smoldering form, abnormal lymphocytes comprise <3 % the cells seen on peripheral smear.

The lymphomatous form of ATL may present in the absence of blood or bone marrow involvement in approximately 10–15 % of cases of ATL. T-cell lymphomas typically present with large, firm peripheral lymphadenopathy but may also present as primary CNS or body cavity lymphomas. Lymph node biopsy shows leukemic-type infiltration with medium-sized lobulated lymphoid cells and may closely resemble non-Hodgkin's lymphoma with cells resembling Reed-Sternberg cells [206]. However, the presence of T-cell markers and detection of HTLV-1 proviral sequences, along with HTLV-1 seropositivity, differentiates these tumors. Hypercalcemia is generally absent although eosinophilia has been reported.

The diagnosis of ATL is confirmed by the detection of monoclonally integrated HTLV-1 proviral sequences in leukemic blood or tumor biopsy specimens [207]. A presumptive diagnosis may be made in a patient with serum antibodies to HTLV-1 who has several classic features of ATL including: (1) onset in middle age, (2) presence of abnormal lymphoid cells expressing the T-cell phenotype, (3) peripheral and/or body cavity lymph node enlargement, (4) hypercalcemia with no other explanation, and (4) evidence of clonal T-cell receptor gene rearrangements. Chronic and smoldering forms of ATL may be more difficult to diagnose, but establishment of clonal T-cell receptor gene rearrangements in skin biopsies or blood and detection of HTLV-provirus strongly support the diagnosis.

Treatment for ATL patients is best done in a tertiary care center with expertise in the treatment of HTLV-1-associated malignancies. Median survival with standard lymphoma chemotherapy (e.g., cyclophosphamide, doxorubicin, vincristine, prednisone) is less than 2 years, so innovative treatments are being investigated. Oral zidovudine in combination with high daily doses of interferon alpha has shown promise despite the absence of active HTLV-1 replication in ATL [208]. Recent evidence suggests that arsenic trioxide may induce cell-cycle arrest and apoptosis of ATL cells in vitro and is in consideration as an adjuvant chemotherapeutic agent in combination with interferon alpha [209]. Reports from Japan suggest the use of allogeneic stem cell transplantation following cytoreductive chemotherapy [210, 211]. Waldman and colleagues have attempted immunotherapy using humanized monoclonal antibodies directed against the interleukin-2 and other receptors expressed on ATL cells, with limited success [212, 213].

8.2 HAM/TSP and Other Neurologic Manifestations

Shortly after the discovery of HTLV-1 and its link to ATL, Gessain and colleagues established an association between HTLV-1 and a chronic myelopathy known as tropical spastic

paraparesis or TSP in the Caribbean. This initial report was followed by the recognition of a similar HTLV-1-associated myelopathy, or HAM, in Japan and the acronym HAM/TSP was coined by international consensus [15, 16, 214]. The most prominent feature of HAM/TSP includes chronic inflammatory changes in the spinal cord, most notably a meningomyelitis of the lower thoracic cord, with inflammation localized around capillaries and venules. Hyalinosis of blood vessels, meningeal fibrosis, and glial scars become more prominent in chronic cases, suggesting that treatment to reverse inflammation ought to be implemented early in the course of disease [215]. The occasional cooccurrence in the same patient of ATL in HAM/TSP has been reported [216–219].

HTLV-1 has been causally implicated in HAM/TSP because (1) HTLV-1 has been isolated from the cerebrospinal fluid (CSF) of HAM/TSP patients [220], (2) intrathecal synthesis of HTLV-1 antibodies within the CSF can be detected in some patients [221], (3) viral genome can be detected within involved tissues by polymerase chain reaction (PCR) and by in situ hybridization [222, 223], and (4) HAM/TSP has been shown to develop following blood transfusion to an HTLV-1 seronegative recipient from an HTLV-1-infected donor [224].

HAM/TSP typically develops after years of infection with HTLV-1. Some of the youngest patients reported were still in their first decade of life [225]; however, the majority of individuals present in their fourth or fifth decade. HAM/TSP is gradual in onset and typically presents with leg weakness, spasticity, and low-back pain [226, 227]. Symptoms of urinary frequency or urgency, erectile dysfunction, and sensory neuropathy are common. Weakness and spasticity predominates in the lower versus upper limbs and with progression patients will frequently require a walker or wheelchair. In contrast to multiple sclerosis, cognitive function is spared. HIV vacuolar myelopathy needs to be excluded in cases of HIV and HTLV coinfection.

Although it does not cause ATL, HTLV-2 has been associated with HAM/TSP with a similar presentation, albeit milder in severity and progression, to HTLV-1 cases. As summarized in a recent critical review, there are currently about a dozen known cases of HTLV-2-associated myelopathy [228]. These include four cases from a well-defined prospective cohort of 405 HTLV-2-infected blood donors (cumulative prevalence 1.0 %, 95 % CI 0.3–2.5) followed over more than 10 years [177]. In this same study, six cases of HTLV-1-associated myelopathy were detected among 160 donors (cumulative prevalence 3.7 %, 95 % CI 1.4–8.0), suggesting that the risk of acquiring HAM may be lower in HTLV-2 carriers. Lehky et al. reported another four cases of HAM/TSP in patients with HTLV-2, including four African-American patients, of whom which three were also of Amerindian decent [229]. Magnetic resonance imaging from three of these patients showed white matter disease and HTLV-2 antibodies in the cerebrospinal fluid and serum. HTLV-2 RNA was also detected from a spinal cord biopsy in one patient [229]. These clinical findings along with other case reports of HAM/TSP support a neuropathogenic role for HTLV-2.

In addition to HAM/TSP, HTLV-2 may be associated with several other neurologic disorders, including an ataxic variant of HAM, peripheral neuropathy, and spinocerebellar syndrome. Ataxic HAM shares many of the same signs and symptoms of classic HAM, namely, paraparesis and spasticity, but is distinguished by prominent ataxia, neuropathy, and mental changes. Several cases of ataxic HAM have been reported [230–232]. Finally, some studies have reported an increased incidence of sensory neuropathy in persons infected with HTLV-2 or HIV/HTLV-2 coinfection [15, 42, 177, 233–240]. However, a well-controlled study showed no difference in monofilament sensation between HTLV-2 subjects and uninfected controls, suggesting that confounding by other causes of neuropathy may have been present in earlier reports [241].

Current management of HAM/TSP is suboptimal [242]. Corticosteroids and immunosuppressive agents such as azathioprine may ameliorate disease progression but are unsuitable for chronic use due to adverse effects [243]. Immunotherapy with interferon alpha has produced minimal to moderate results, depending on the degree of inflammation and tissue destruction within the involved tissue [244, 245]. Antiretroviral therapy with zidovudine and 3TC showed initial promise but was ineffective in a controlled trial [242, 246]. Symptomatic therapy for spasticity and bowel and bladder dysfunction is important.

8.3 Autoimmune and Infectious Diseases

A number of rheumatologic syndromes have been linked to HTLV-1 (and possibly HTLV-2) infection. However, with the exception of HTLV-1 uveitis, epidemiologic proof of association between HTLV-1 and autoimmune diseases is weak. In the example of HTLV-associated uveitis [247], HTLV viral sequences can be detected in vitreous fluid in conjunction with higher numbers of HTLV-1-infected T lymphocytes compared with the peripheral blood [248]. High levels of HTLV-1 proviral load have also been associated with Sjogren's syndrome and keratoconjunctivitis sicca [249, 250]. Concurrent autoimmune-mediated disorders, including polymyositis, Graves' disease, arthritis, and HAM/TSP, have been described in several case series.

Infectious diseases and opportunistic infections occur most frequently in the context of acute ATL. These include *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) infection, pulmonary aspergillosis, cytomegalovirus (CMV) pneumonitis, disseminated herpes zoster, infection

with *Cryptococcus neoformans*, *Mycobacterium avium-intracellulare* infection, and hyperinfection syndrome with *Strongyloides stercoralis*. Trimethoprim/sulfamethoxazole prophylaxis against *P. jiroveci* infection should be administered to patients with acute forms of ATL and possibly to patients with chronic ATL. Patients with prior tuberculin reactivity or residency in countries with high rates of tuberculosis should be considered for isoniazid (INH) prophylaxis.

Some HTLV-1- and HTLV-2-infected carriers without ATL also appear to have immune deficiency associated with an increased risk for certain infectious disease complications, including strongyloidiasis and *Pneumocystis* pneumonia. Other infections associated with HTLV-1/2 infection (single case reports) include Norwegian scabies, disseminated molluscum contagiosum, and extrapulmonary histoplasmosis. Finally, staphylococcal and streptococcal skin infections are common in the infectious dermatitis syndrome [251] described in Jamaica. Interestingly, infectious dermatitis occurs in Jamaica, Brazil, and South Africa but not in Japan, suggesting either socioeconomic or genetic cofactors [252–255].

HTLV-2 has been associated with an increased incidence of pneumonia, bronchitis, tuberculosis, bladder or kidney infection, and abscess. While several studies have found that respiratory disorders were significantly higher among persons infected with HTLV-2, particularly pneumonia and bronchitis [256–259], the pathological mechanism has yet to be determined. HTLV-2 has also been associated with increased incidence of tuberculosis (TB) in studies involving IDU [260] and blood donors [256, 261].

HTLV-2 subjects were similar to uninfected controls in both pulmonary function and production and function of antipneumococcal antibody in response to pneumococcal vaccination, although baseline levels of antipneumococcal antibody were increased [262, 263]. Murphy and colleagues hypothesized that increased incidence of pneumonia and acute bronchitis in HTLV-2 could be the result of transient pneumonitis or bronchiolitis with or without concomitant respiratory infections [258]. An inflammatory pneumonitis has been demonstrated in HTLV-1 patients, in which bronchoalveolar lavage fluid has been found to contain cytokines and other inflammatory markers. Recently, bronchiectasis has been associated with HTLV-1 infection among Australian Aborigines [264].

Skin and soft tissue infections are common among injection drug users, a population in which HTLV-2 is prevalent. The incidence of abscess and the risk factors associated with its occurrence among IDU has received limited investigation. A cross-sectional study found that HTLV-2-seropositive IDU were more vulnerable to skin and soft tissue abscess than were seronegative IDU [259]. However, the findings of this study may have been confounded by factors related to both abscess and HTLV-2 seropositivity, such as sex, race, and frequency of drug injection. Subsequent case-control studies with better control for possible confounding variables did not find a significant association between abscess and HTLV-2 infection [265, 266].

8.4 Other Cancers and Mortality

A prospective cohort study of 138 HTLV-1, 358 HTLV-2, and 759 seronegative former blood donors reported that HTLV-2 was associated with both increased cancer mortality and all-cause mortality [34]. No specific cancer diagnosis predominated. The same study found a nearly twofold increased HTLV-1 mortality that did not reach statistical significance, consistent with increased mortality seen with HTLV-1 and HIV-2 coinfection in West Africa [267]. Another large prospective study also found increased all-cause mortality, but not increased cancer mortality in HTLV-1 patients [36]. Ongoing follow-up of large cohorts will be needed to confirm these findings and determine which causes of death are linked with HTLV-1 and HTVL-2.

8.5 Clinical Laboratory Abnormalities

A number of abnormalities in clinical laboratory tests have been reported with HTLV infection. Abnormal lymphocytes, characterized by poly-lobulated and convoluted nuclei, may be observed in small number among healthy HTLV-1 seropositives but are also characteristic of the leukemia associated with ATL [268]. Lymphocyte and platelet counts are slightly increased among healthy HTLV-1 and HTLV-2 carriers, and red blood cell mean corpuscular volume may be slightly increased in HTLV-2 carriers [269–271].

8.6 HTLV-2 and HIV Coinfection

Since HTLV-2 is prevalent among IDUs in the USA and Europe, coinfection with HIV-1 is common and therefore research on HIV-1/HTLV-2 coinfection is particularly relevant. Recently, investigation has focused on HTLV-2 as a potential modifier of HIV disease progression [272]. Earlier studies on HIV-1/HTLV coinfection did not differentiate between HTLV-1 and HTLV-2. More recent findings have been contradictory; some studies suggest that HTLV-2 coinfection accelerates HIV disease progression and other studies demonstrate no significant effect. Many of the studies had limitations however, including cross-sectional design and small numbers of coinfected patients. Addressing many of the limitations of prior studies, the best analysis on HIV-1/HTLV-2 coinfection included pooled longitudinal data on 370 HIV-infected IDUs from four cohort studies [273]. Dates

of HIV seroconversion for each subject were clearly defined, thereby allowing for the prospective monitoring of clinical AIDS development or AIDS-related mortality in IDUs with and without HTLV-2 coinfection. The rates of decline in CD4 cell percent were similar in singly HIV-1-infected and HIV-1/HTLV-2-coinfected IDUs, and the study concluded that overall, HTLV-2 coinfection did not independently affect HIV disease progression.

Conversely, data concerning the effect of HIV-1 coinfection on HTLV-2 viral load have been limited. One study found no significant difference in viral load between HTLV-2-infected and HIV-1/HTLV-2-coinfected individuals, and similarly, no correlation was seen between HTLV-2 viral load and CD4+ or CD8+ counts in HIV-1-coinfected individuals [274]. Another focus of current research has been on the effects of highly active antiretroviral therapy (HAART) on HIV-1/HTLV-2 coinfection. Preliminary data suggests that HAART may have a paradoxical affect of raising HTLV-2 proviral load. Two separate case series found a similar and marked increase in HTLV-2 proviral load after initiating treatment, which was then followed by a decrease in viral load over time; however, the degree of decline in HTLV-2 proviral load differed between the two studies [262, 275].

8.7 Unconfirmed Disease Associations

HTLV-2 infection has also been diagnosed in certain rare hematologic malignancies, including atypical hairy cell leukemia [17, 276], B-lymphocytic chronic lymphocytic leukemia [277], large granular lymphocytic leukemia [278], and mycosis fungoides [279]. Systematic surveys have not identified any association of these lymphoid malignancies with HTLV-2, suggesting that these patients are coincidentally infected [280]. Finally, an initial report of an HTLV-2 association with chronic fatigue syndrome was not confirmed by a more definitive study [281, 282].

9 Control and Prevention

9.1 Preventing Mother-to-Child Transmission

The efficacy of substituting infant formula for breast-feeding in the prevention of mother-to-child transmission from an HTLV-1-infected mother has been well demonstrated. In late 2010, Japan initiated a nationwide public health intervention to prevent vertical HTLV-1 transmission by HTLV-1 testing of pregnant women and substitution of infant formula for breast-feeding [129]. This followed a successful demonstration program in Nagasaki Prefecture beginning in 1987, which revealed a marked reduction of HTLV-1 transmission from 20.3 to 2.5 % [283]. The same study also demonstrated that breast-feeding for less than 6 months still carried a 7 % risk of transmission, so is not to be recommended. An interventional study has also demonstrated the efficacy of bottle-feeding for prevention of mother-to-child HTLV-1 infection in Brazil [284]. This program was careful to provide infant formula and training in its hygienic use to the mothers. However, experience with bottle-feeding as part of HIV prevention programs lends a note of caution to this approach in low-income countries due to the risk of gastrointestinal infection in infants where adequate hygiene for the preparation of bottle-feeding is not available [130]. This suggests that the risks and benefits of bottle-feeding interventions need to be evaluated on a country-by-country basis before implementation. In addition, human breast milk donated for consumption by other infants should be tested for HTLV, as pasteurization would likely also eliminate the risk of transmitting HTLV infection [285].

9.2 Preventing Sexual Transmission

Although formal clinical trials have not been accomplished and would be ethically questionable, observational data support the efficacy of routine condom use in the prevention of sexual transmission of HTLV-1 and HTLV-2 in serodiscordant couples [134, 136, 286]. The use of latex condoms should also be recommended to HTLV-1 and HTLV-2-infected persons with multiple sexual partners and those engaged in sex work, as these precautions will also prevent HIV and other sexually transmitted diseases in addition to HTLV. The more widespread use of condoms in programs designed to prevent HIV transmission may have had the secondary effect of preventing sexual transmission of HTLV-1 in countries where both are prevalent.

Testing for HTLV-1 has also been integrated into programs for assisted reproduction, with legal requirements in many US jurisdictions [287]. The appropriate counseling of persons found to be HTLV-1 seropositive in this setting should include the performance of confirmatory testing as detailed above. Advances in reproductive technology may also allow the safe use of sperm from HTLV-1-infected men [288].

9.3 Preventing Transmission by Blood Transfusion and Parenteral Exposures

Screening for HTLV-1 and HTLV-2 infection in blood donors is mandated in many countries throughout the world. The efficacy of this approach is clear in countries with high prevalence and routine HTLV antibody screening of all blood donations has likely prevented thousands of HTLV infections. The "residual risk" of HTLV infection, namely, the risk of transmission from an HTLV infection not detected by serologic screening,

has been shown to be less than one infection per million transfused blood units in the USA and Australia and slightly higher (5 per million units) in Brazil [60, 149, 289]. Most of this risk is due to recent infections during the "window period" before antibodies have developed, although some are due to false-negative screening tests. Routine screening of blood donors also provides useful data on prevalence and secular trends of HTLV infection in endemic countries [105]. However, the cost-benefit ratio is less favorable in countries with very low HTLV prevalence, where false-positive screening tests also pose the risk of false notification of donors regarding HTLV infection [55, 61]. In some settings with very low HTLV incidence, testing blood donors only at their first blood donation may be a viable strategy; a similar approach has recently been adopted for *T. cruzi* testing in the US blood donors.

Although specific studies have not been undertaken, universal precautions for the prevention of parenterally transmitted viruses should be effective in the prevention of HTLV-1 and HTLV-2 infection. Similarly, the efficacy of needle exchange programs in prevention of HTLV infection among IDUs has not been explicitly demonstrated, but it is likely that such programs would be effective since HTLV is considered to be less transmissible by small parenteral exposures than HIV or hepatitis C virus.

9.4 Vaccine Development

The development of a vaccine for HTLV-1 has received relatively little research attention and even less commercial interest, especially compared to vaccine development for HIV-1. An effective HTLV-1 vaccine should elicit both humoral response and cell-mediated immunity. As summarized in a recent review [290], approaches to HTLV-1 vaccine development have included: heat-inactivated HTLV-1, Env glycoproteins produced in *Escherichia coli,* DNA vaccines encoding *tax* or *env* genes (in combination with RVV-env or RVV-env+gag), synthetic peptide derived from *env* gp46 and Tax, complex chimeric synthetic multivalent peptide vaccines, and recombinant vaccinia viruses expressing Gag and/or Env proteins. Despite limited success in eliciting protective responses in animal models, none of these vaccines achieved final development, mainly due to partial or short-lived response, safety concerns, and perhaps also a lack of interest from an industrial partner.

9.5 Clinical Management of HTLV-1 and HTLV-2 Seropositives

Evaluation and treatment of asymptomatic HTLV-1 and HTLV-2 carriers are the most frequently encountered clinical situations and generally follow HTLV diagnostic screening of asymptomatic blood, tissue, sperm, or oocyte donors. The first step is to confirm HTLV infection, either by review of positive screening EIA and confirmatory tests performed by a reputable testing laboratory or by submission of another specimen. False-positive results are common using EIA alone in low-risk patients, and they may be relieved of a burdensome diagnosis by the simple performance of a confirmatory assay. Typing of the infection as HTLV-1 or HTLV-2 is important because of the different disease outcomes associated with the two viral types. This can be done either by type-specific Western blot or immunoblot, differential antibody titration on IFA, or PCR. A clinical history regarding risk factors for HTLV infection is important in establishing the pretest probability of infection and can be helpful in typing the infection. Familial or sexual contact with people from HTLV-1 endemic areas favors that infection, while a history of injection drug use or sex with an IDU is more consistent with HTLV-2 infection. Patients with "indeterminate" WB results are also unlikely to be infected if they have no risk factors for HTLV infection [291]. Population-based screening for HTLV infection (except for blood donors) is generally not indicated because of the low penetrance of disease and lack of effective therapies.

According to CDC guidelines, persons with confirmed HTLV-1 or HTLV-2 infection should be informed that they are infected with HTLV [292]. They should be told that HTLV is not the AIDS virus, that it does not cause AIDS, and that AIDS is caused by a different virus called HIV. They should be told that HTLV-1 and HTLV-2 are lifelong infections. They should be given information regarding modes and efficiency of transmission, disease associations, and the probability of developing disease. In particular, persons infected with HTLV-1 or HTLV-2 should be advised to: (1) share the information with their physician; (2) refrain from donating blood, semen, body organs, or other tissues; (3) refrain from sharing needles or syringes with anyone; (4) refrain from breast-feeding infants; and (5) consider the use of latex condoms to prevent sexual transmission.

If the HTLV-positive person is in a mutually monogamous sexual relationship, testing of the sex partner should be recommended to help formulate specific counseling advice. If the sex partner is also positive, no further recommendations are indicated. If the sex partner is negative, the couple should be advised that the use of latex condoms can help prevent transmission of HTLV-1 or HTLV-2 to the negative partner, male or female. Male-infected and female-noninfected couples desiring pregnancy should be made aware of the finite risk of sexual transmission of HTLV-1 or HTLV-2 during attempts at pregnancy and of the small risk for vertical transmission from mother to infant unrelated to breast-feeding. Such couples might be advised to use latex condoms at all times except during the fertile period while they are attempting pregnancy. The use of latex condoms is

strongly recommended for HTLV-1-positive persons with multiple sex partners or otherwise engaging in non-mutually monogamous sexual relationships. These persons should be reminded of the risk of acquiring other sexually transmitted infections, including HIV.

Asymptomatic seropositive patients should be followed up by their primary care or infectious disease physician, with annual to biennial return visits. Medical history should elicit symptoms of leukemia, lymphoma, or neurologic disease. Physical examination is directed at the lymph nodes, neurologic system, and skin in order to detect manifestations of ATL, HAM/TSP, or HTLV dermatitis. Laboratory evaluation may be limited to a complete blood count. Whereas small increases in the absolute lymphocyte and platelet counts and alteration in red blood cell mean corpuscular volume have been described in prospective studies of HTLV-1 and HTLV-2 carriers, there is no indication that these findings have clinical significance [271, 293]. More important is to rule out subclinical leukemia by a normal lymphocyte count and absence of "flower-cell" morphology. In general, asymptomatic carriers or those with nonspecific symptoms should be reassured by reminding them of the low penetrance of hematologic and neurologic disease.

There is also substantial psychological and social morbidity associated with chronic HTLV infection [294–296]. While some authors have suggested a causal role for HTLV in major depression [297], others concluded that physical symptoms related to HTLV infection were more likely mediators of self-reported anxiety and depression [298]. The treating physician needs to screen for psychological effects of chronic HTLV infection and consider referral for counseling and/or psychiatric evaluation should these symptoms be severe.

10 Unresolved Problems

10.1 Epidemiologic Puzzles

Despite almost 30 years of epidemiologic research, several puzzles remain regarding the geographic dispersion of HTLV-1. Its origins in Africa appear to be well founded, with multiple isolates having been identified, differing in molecular sequence according to geography but closely resembling isolates from simian species in the same regions. Similar evidence supports the Melanesian origin of the HTLV-1c variant. Beyond that, the picture is more complicated. While it seems clear that HTLV-1 was transported with human populations during the slave trade to the Caribbean and the Americas, defining specific linkages between regional variants in the New World and their source populations in Africa has been challenging. The search has been made more difficult by the relative lack of variation within the so-called cosmopolitan HTLV-1 subtype. Recently, scientists have identified foci of HTLV-1 in isolated South American populations that appear to map closely with African strains [299]. The high HTLV-1 prevalence in Kyushu and Shikoku in southwestern Japan, in contrast to absent or very low prevalence in neighboring China and Korea [300, 301], remains a puzzle. Initial hints of substantial HTLV-1 prevalence in Mongolia have not been borne out by further research [302]. The hypothesis that HTLV-1 was introduced into southern Japan by Portuguese traders, who also traded with Africa and included Africans among the crew, was initially dismissed but might bear further scrutiny. Finally, the presence of isolated pockets of HTLV-1 such as those among populations in Mashhad, Iran, suggests historical infections and/or human migrations still to be explained [108].

A similarly complicated picture applies to the geographic dispersion of HTLV-2, although the details differ. There is internal consistency with the finding of HTLV-2b among African Pygmies who live in proximity with simian species who harbor closely related STLV-2 viruses. Recent data from Central African Bakola Pygmies confirms high HTLV-2b prevalence (2.5 %; 27/105) [112]. Similarly, HTLV-2b is found in native Amerindians, although New World monkeys have not been found to be infected with STLV. What is puzzling is the extreme molecular homology between HTLV-2b viruses from isolated South American Indians and Bakola Pygmies from Central Africa. These findings are difficult to reconcile with contemporary models of human migrations whereby Amerindians migrated from Asia more than 40,000 years before the present. Thus, there remains an apparent paradox in HTLV-2 evolution: an ancient African origin of HTLV-2a, 2b, and 2d and migration to the New World with human peoples or, less likely, a more modern introduction into both Pygmies and Amerindians.

A second, more modern pandemic of HTLV-2 can be found among IDUs in North America and Europe. Among North American IDUs, HTLV-2a predominates, and it is likely that the virus was introduced from Amerindian populations within the last hundred years and amplified by the parenteral transmission route, which is more efficient than sexual or mother-to-child transmission. Adding an additional twist, IDUs in Europe are more likely to harbor HTLV-2b than HTLV-2a. Whereas one would assume that European IDUs received HTLV-2 from their North American IDU counterparts, the real story may be more complicated, with several Amerindian-to-IDU transmissions and separate amplifications in concert with more modern geographic dispersion among IDUs [303]. Such a picture is supported by the mix of HTLV-2a and HTLV-2b among blood donors in North America, most of whom were infected via IDU or secondary sexual transmission. However, the precise Amerindian population of origin and the timing of this introduction remain unknown and would require much larger studies including both IDUs and Amerindians from a broad geographic area in North America.

Finally, the recent discovery of HTLV-3 and HTLV-4 among Pygmies in Central Africa opens new ground for epidemiologic research. As of now, there are several identified HTLV-3 isolates but only a single HTLV-4 isolate. Given the close proximity to simian species and predominance of hunting and bushmeat consumption, it is likely that these viruses represent relatively recent simian-to-human transmissions. A detailed study of a large extended family failed to reveal evidence of human-to-human transmission of HTLV-3 [100]. Thus, until a greater number of infected humans are identified, it remains speculative that either of these viruses has established a true human reservoir of infection. Likewise, demonstrating any disease outcomes associated with HTLV-3 and HTLV-4 will require larger epidemiologic studies. In this context, the study of blood donor populations in Cameroon and the Democratic Republic of Congo may be revealing.

10.2 Etiologies of ATL and HAM/TSP

Despite more than three decades of research, the etiologies of ATL and HAM/TSP remain poorly defined. It is clear that the virus, by stimulating lymphocytic proliferation, favors the emergence of potentially malignant genome mutations in lymphoid tissue. While the majority of past research has focused upon the *tax* gene because of its ability to transactivate both HTLV and human genes proximal to the integration site, the past several years have seen a new focus on the HBZ gene pathway. Most research on HTLV-1 malignant transformation has focused on in vitro models but has included some animal work, such as the generation of mice transgenic for the *tax* gene. A major obstacle for translational and epidemiologic studies has been the relatively low incidence of malignancy among chronically infected humans together with the long latency between retroviral infection and the occurrence of ATL. Thus, prospective cohort studies have been able to capture only a relatively small number of incident ATL cases among well-defined study populations. The recent study by Birmann, Hisada et al. overcame this limitation by assembling cases of incident ATL and matched HTLV-1-infected controls from across multiple prospective cohorts [304]. Another large multicenter study from Japan showed that HTLV-1 proviral load and a family history of ATL were significant risk factors for development of ATL among 1218 previously healthy HTLV-1 carriers [44]. During follow-up, 14 participants (proviral load 4.17–28.58 copies/100 PBMCs) progressed to ATL, but no cases occurred among those with a baseline proviral load lower than approximately 4 copies/100 PBMCs. Other promising approaches could involve case-control designs and genomic analyses of biological samples from ATL cases and HTLV-1-infected healthy carriers. The HTLV-1 and ATL model may also be seen as a promising one for future studies of the genomics of cancer.

Similarly, HAM/TSP occurs in only a small percentage of those infected with HTLV-1 and HTLV-2 and has an insidious onset. Encouragingly, virological and immunologic studies have yielded several adverse prognostic markers including high proviral load and both deleterious and protective HLA haplotypes. However, future research into the etiology of this immunologic-based neuropathic disease will require the prospective study of large, well-characterized cohorts of HTLV-infected subjects. For both ATL and HAM/TSP, the potential impact of transmission route on disease occurrence requires further study. The preferential occurrence of ATL following mother-to-child transmission, and HAM/TSP following sexual or parenteral transmission, may yield clues to the different pathophysiological pathways of these two disease outcomes.

Finally, effective treatments for both ATL and HAM/TSP are sorely lacking and suffer from their status as orphan diseases occurring predominately in low- and middle-income countries. The recent establishment of a clinical trials network for the ATL is an encouraging sign [305], and a similar working group for the treatment of HAM/TSP has recently been established under the auspices of the International Retrovirology Association [43]. These working groups are attempting to select drug targets that are effective, practical, and affordable in the low- and middle-income country setting. They will then design simple clinical trials and attempt to fund and implement these trials in endemic countries.

10.3 Directions for Future Epidemiology Research

Future epidemiologic research in HTLV-1 and HTLV-2 should focus upon monitoring the prevalence and incidence of infection in endemic populations and the adaptation from the HIV field of population-based prevention strategies that may be effective for HTLV. Secular trends of HTLV-1 and HTLV-2 prevalence in well-defined populations such as blood donors should be monitored as sentinels for infection in broader populations. Such studies have already demonstrated declining prevalence due to birth-cohort effects in both the USA and Japan but have yet to be tied to the effectiveness of a specific intervention. The blood donor population presents the advantage of routine screening of a segment of the general population, albeit of relatively low risk, and allows the collation of data over time. Specific puzzles in HTLV epidemiology may be addressed by larger-scale, geographically based prevalence studies with sequencing of both HTLV isolates and human population genomic markers in order to determine past transmission and human migrations.

While it is clear that condom use and interruption of breast-feeding are effective in preventing sexual and mother-to-child HTLV transmission, respectively,

additional epidemiologic studies of these prevention strategies are warranted. Specifically, it will be important to determine in several endemic countries whether the relatively low burden of HTLV-associated disease prevented is worth the potential risk of infant mortality due to the substitution of infant formula for breast-feeding. Modeling and simulation studies may be useful to understand the potential impact of various intervention strategies in endemic countries. For example, concurrent implementation of HIV prevention may be expected to have a significant effect upon HTLV-1 prevalence in dually endemic countries such as Brazil. Changes in ATL and HAM/TSP incident should also be monitored in response to prevention interventions aimed at HTLV-1 and HTLV-2.

Polyomaviruses: Progressive Multifocal Leukoencephalopathy and Other Diseases

46

Raphael P. Viscidi, Loubna Tazi, and Keerti V. Shah

1 Introduction

Polyomaviruses are small, nonenveloped, double-stranded DNA viruses, which are widely distributed in nature. Viruses of this family infect many species including humans, monkeys, cattle, rabbits, rodents, and birds. The viruses are species specific and they do not naturally infect any species other than their natural hosts. Primary infections with human polyomaviruses generally occur in childhood and are not associated with serious illness, but the viruses persist in the infected host. Most of the diseases associated with human polyomaviruses occur later in life in immunosuppressed groups, probably as a result of recrudescence of active infection brought about by the immune deficiency of the host. Human illnesses associated with these viruses include progressive multifocal leukoencephalopathy (PML) which is caused by JC polyomavirus (JCPyV) and is a frequent complication in individuals with HIV/AIDS, nephropathy in renal transplant recipients, and hemorrhagic cystitis in bone marrow transplant recipients, both caused by BK polyomavirus (BKPyV) and Merkel cell carcinoma, which is associated with the recently recognized Merkel cell polyomavirus (MCPyV).

2 Historical Background

The first polyomaviruses were isolated in the 1950s from rodents. The mouse polyomavirus (MPyV) was so named because of its ability to produce many (Greek poly) types of tumors (Greek oma) in experimentally inoculated mice. The first primate polyomavirus to be identified was simian virus 40 (SV40) in 1960 from primary kidney cultures of the rhesus macaque [1]. SV40 was oncogenic for experimentally inoculated hamsters [2, 3]. MPyV and SV40 have been extensively used in laboratory studies of virus-induced cancer, and these studies have led to a detailed understanding of cellular transformation, integration of the viral genome in the cellular chromosomes, cell cycle regulation, and oncogenes and tumor suppressor genes. In vitro studies of replication of SV40 origin-containing DNA have helped understand eukaryotic chromosomal DNA replication. The genomes of MPyV and SV40 were among the first to be physically mapped and also among the first that were completely sequenced. Daniel Nathans was a corecipient of the Nobel Prize in 1978 for the study of the structure of the SV40 DNA by restriction endonuclease enzymes.

The first recognized contact of humans with polyomaviruses was with SV40, which was a contaminant of the inactivated commercially available polio vaccines and of the experimental live polio vaccines [4]. The virus pools for these vaccines were grown in rhesus kidney cultures, many of which were contaminated with the indigenous SV40. The presence of SV40 in the rhesus kidney cultures was not recognized because the virus was not cytopathic for these cultures and was identified only after these cultures were inoculated into African green monkey kidney cultures where SV40 produced a cytopathic effect. It is estimated that almost 100 million people in the USA, about 62 % of the population, had received the inactivated polio vaccine during the time (1956–1960) when some of the vaccine lots were contaminated with SV40 [4]. But the proportion of the vaccine lots that was contaminated, or the amount of live SV40 in the contaminated lots, is not known. The formalin that was used to inactivate polioviruses

DOI 10.1007/978-1-4899-7448-8_46, © Springer Science+Business Media New York 2014

also inactivated SV40, but to a lesser extent. It has been established that a proportion of the inactivated polio vaccine lots contained live SV40, in small amounts, when they were administered to people by the subcutaneous route. Individuals who received contaminated oral live polio vaccines in the early trials received a larger amount of SV40 by the oral route. Inactivated adenovirus vaccines, which were administered to military personnel, were also contaminated with SV40. Whether this exposure of humans to live SV40 has led to the establishment of SV40 as a human infection or to any SV40-induced illnesses and cancers is a matter of debate. These data are summarized in Sect. 8 of this chapter.

The identification of the first human polyomaviruses was reported in 1971. JCPyV was recovered in primary human fetal glial cell cultures after inoculation of brain extracts from a patient with PML [5], and BKPyV was isolated after inoculation of urine from a renal transplant recipient into Vero cell, a continuous cell line derived from African green monkey [6]. No additional human polyomaviruses were recovered until 2007 when the genomes of two new polyomaviruses, KIPyV and WUPyV, were independently detected in respiratory tract secretions of children by use of molecular techniques [7, 8]. In 2008, Merkel cell polyomavirus (MCPyV) was identified by employing mass sequencing of a messenger RNA library of Merkel tumor cells and bioinformatic analysis to identify nonhuman sequences which have homology to the genomes of known infectious agents [9]. MCPyV is commonly found on healthy skin. Three additional human polyomaviruses, HPyV 6 and HPyV 7 in 2010 and HPyV 10 in 2012, were identified from skin swabs by using the rolling circle amplification (RCA) technique to isolate circular DNA viral genomes [10, 11]. Another new polyomavirus, trichodysplasia spinulosa virus (TSPyV), was recovered, also using the RCA technique, from the facial tissue of a heart transplant patient who was suffering from a rare skin disorder, trichodysplasia spinulosa, which only occurs in immunosuppressed individuals [12]. In 2011, a new polyomavirus, HPyV 9, was recovered from the urine and blood of a renal transplant recipient using generic PCR [13]. HPyV 9 is closely related to the African green monkey-derived lymphotropic polyomavirus (recently renamed the B-lymphotropic polyomavirus (LPyV), which was isolated in 1979 [14]. A new polyomavirus, Malawi polyomavirus (MWPyV), was identified by pyrosequencing purified virus-like particles recovered from the stool of a child in Malawi [15]. This virus is genetically highly related to HPyV10 and is likely the same viral species. Additional polyomaviruses have recently been detected in stool samples from children and adults with diarrhea [16–18]. The rapid increase in the number of human polyomaviruses beginning in 2007 is undoubtedly related to the use of molecular methods to identify viral genomes in place of cell culture techniques previously used to identify infectious agents.

The evolutionary relationships between human polyomaviruses based on a maximum-likelihood analysis of VP1 amino acid sequences are shown in Fig. 46.1, which also include select polyomaviruses of nonhuman origin [19]. A recent taxonomic revision of the species has divided them into three genera [20]. The *Avipolyomaviruses* comprise the species that infect birds. They form a distinct lineage not closely related to human polyomaviruses. The biology of the *Avipolyomaviruses* is markedly different from that of the mammalian polyomaviruses. Compared to asymptomatic infection, which is characteristic of mammalian polyomaviruses in immunocompetent hosts, the *Avipolyomaviruses* are frequently associated with acute fatal disease. A second genus, the *Wukipolyomaviruses*, includes only human polyomaviruses. They form a distinct lineage very distantly related to the other human polyomaviruses, and the genus at present contains no known polyomaviruses from other host species. The viruses in this genus are not known to cause disease and knowledge of their natural history is limited. All the remaining known human and animal polyomaviruses are currently grouped in the genus *Orthopolyomavirus*, which comprises many distinct lineages. Many lineages of the polyomavirus family contain viruses from humans as well as from nonhuman primates. For example, JCPyV and BKPyV are closely related to one another and to simian viruses SV40 and SA12; MCPyV is most closely related to a chimpanzee polyomavirus and TSPyV to an orangutan polyomavirus. The closest relative of HPyV 9 is the lymphotropic polyomavirus (LPyV) of African green monkeys. This phylogeny argues against a strict co-divergence of polyomaviruses, with their respective hosts, as previously believed [21, 22], and favors cross-species transmission events in the evolution of human polyomaviruses [23, 24].

The human polyomaviruses, illnesses associated with them, and the body sites from which they are recovered most frequently are listed in Table 46.1. In the following sections, JCPyV, BKPyV, and MCPyV are described in detail. Information on the other human polyomaviruses is summarized in Sect. 8.

3 Methodology Involved in Epidemiologic Analyses

3.1 Mortality Data

Polyomavirus infections are not associated with mortality except in immunosuppressed populations. BKPyV-associated nephropathy was first identified in 1995 and is not currently a reportable disease. Mortality data for PML in the USA between 1979 and 2005 are available from the National Center for Health Statistics, Centers for Disease Control and Prevention [25]. During this time period, the

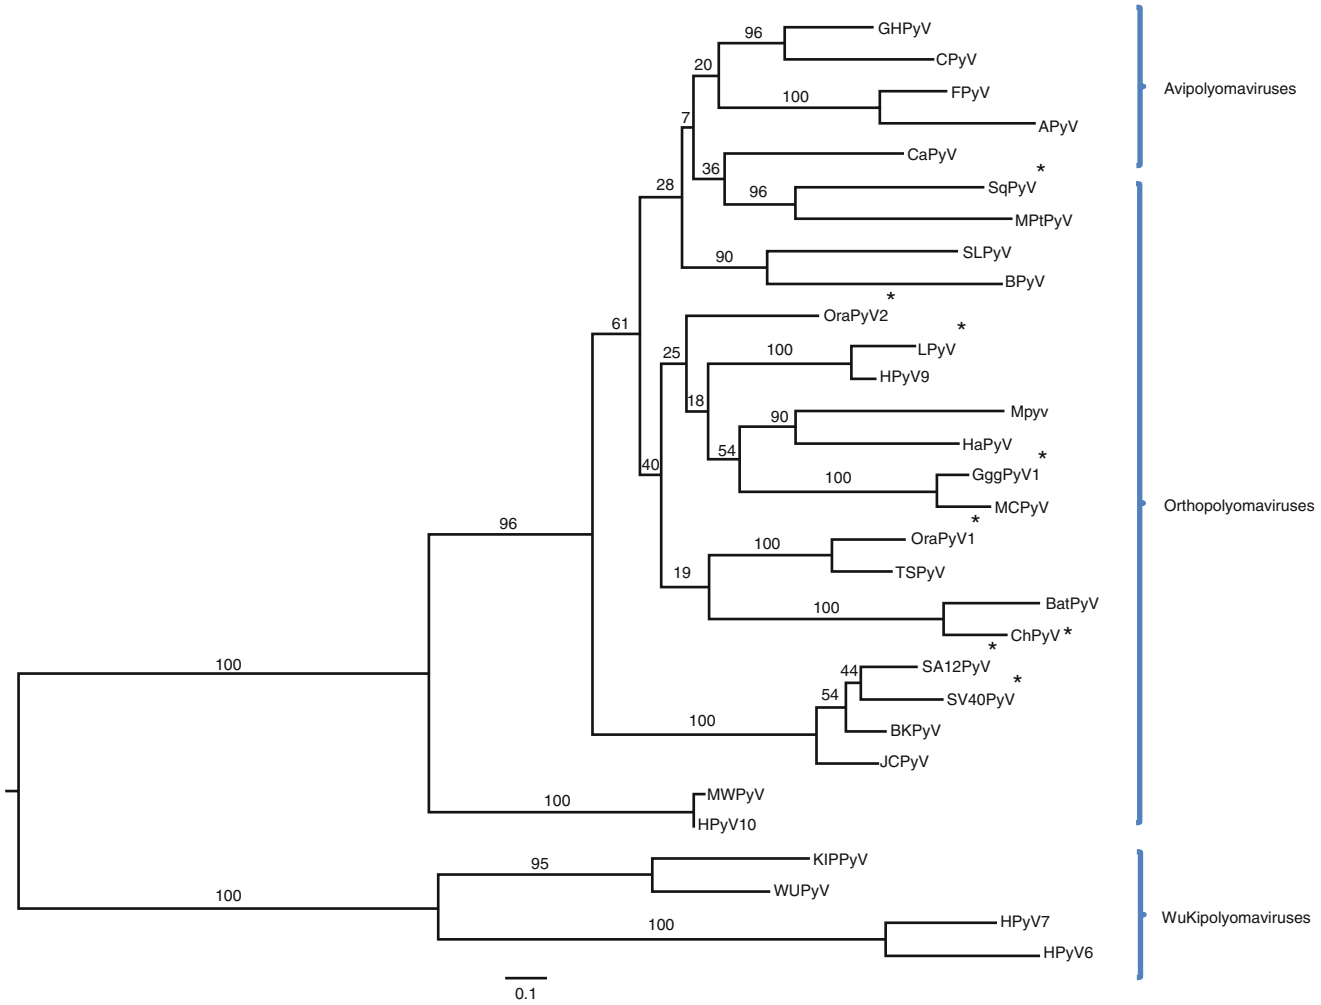

Fig. 46.1 Phylogeny of polyomaviruses. Midpoint-rooted phylogenetic tree of VP1 sequences of polyomaviruses. Phylogenetic analysis was performed using a maximum-likelihood method implemented in PhyML [16]. Bootstrap values are indicated in the branches, as percentage of 100 pseudo-replicates. The VP1 sequences used in this analysis are *BKPyV* (NC_001538), *JCPyV* (NC_001699), *WUPyV* (NC_009539), *MCPyV* (NC_010277), *HPyV6* (NC_014406), *HPyV7* (NC_014407), *TSPyV* (NC_014361), *HPyV9* (NC_015150), *HPyV10* (JX262162), *MWPyV* (JQ898291), *KIPyV* (NC_009238), *SV10PyV* (NC_001669), *OraPyV1* (NC_013439), *OraPyV2* (FN356901), *ChPyV* (NC_014743), *GggPyV* (HQ385752), *SA12PyV* (NC_007611), *LPyV* (NC_004763), *SqPyV* (NC_009951), *BatPyV* (JQ958886), *BPyV* (NC_001442), *SLPyV* (NC_013796), *HaPyV* (AJ006015), *MPyV* (NC_001515), *MPtPyV* (NC_001505), *APyV* (NC_004764), *CaPyV* (GU345044), *CPyV* (NC_007922), *FPyV* (NC_007923), and *GHPyV* (NC_004800). The human polyomaviruses are underlined and in bold font. The nonhuman primate polyomaviruses are marked with an asterisk. Viruses within the *Avipolyomaviruses*, *Orthopolyomaviruses*, and *Wukipolyomaviruses* genera are indicated by brackets

Table 46.1 Human polyomaviruses

Virus	Year of report	Common site of recovery	Associated illness	Reference
JCPyV	1971	Urine and PML[a] brain	PML	[5]
BKPyV	1971	Urine	Nephropathy and hemorrhagic cystitis	[6]
KIPyV	2007	Upper respiratory tract	Not known	[7]
WUPyV	2007	Upper respiratory tract	Not known	[8]
MCPyV	2008	Merkel cell carcinoma, skin	Merkel cell carcinoma	[9]
TSPyV	2010	Skin	Trichodysplasia spinulosa	[12]
HPyV6	2010	Skin	Not known	[10]
HPyV7	2010	Skin	Not known	[10]
HPyV9	2011	Urine and blood	Not known	[11]
HPyV10	2012	Skin	Not known	[13]
MWPyV	2012	Stool	Not known	[15]

[a]*PML* progressive multifocal leukoencephalopathy

average annual age-adjusted PML death rate was 1.07 per 1 million persons. The rate was much higher in males compared to females (1.81 vs 0.35) and among Blacks compared to Whites (2.03 vs 0.97). The rates varied by age group with the highest rate observed among persons 35–49 years of age at death (2.72). The PML rates were low in the earliest years and steadily increased to peak in the mid-1990s. The rise in the PML death rate is largely attributable to the increasing incidence of HIV after 1984, and over time, the demographic characteristics of persons dying from PML have closely mirrored the changing demographics profile of the AIDS epidemic. PML death rates decreased dramatically between 1992–1995 and 2002–2005 from 2.76 to 0.66. This was mostly attributable to a decrease among males, among Whites, and among persons 20–34 years of age and 35–49 years of age. The proportion of HIV-associated deaths with a PML diagnosis on the death certificate decreased after 1996, from a high of 1.5 % in 1996 to a low of 0.9 % in 2003 and 1.02 % in 2005. The most likely explanation for this decline in the PML death rate is the introduction of highly active antiretroviral therapy (HAART) in 1996. Similar declines in incidence of PML in HIV-positive patients were reported in the only available national, population-based study, which was conducted in Denmark [26]. In the large EuroSIDA cohort, the incidence of PML among HIV-positive patients decreased from 10 to 1 case per 1,000 person-years between 1995 and 2001 [27].

Although no mortality data for MCPyV-associated Merkel cell carcinoma (MCC) are available, the virus has been detected in at least 80 % of Merkel cell cancers in several case series and, as detection methods improve, the proportion of virus-associated cases is likely to rise. Population-based statistics have been reported for MCC in the period 1978–2006 using the Danish Cancer Registry [28]. From 1978 to 1984, only a few incident cases (<20) were reported. MCC incidence increased progressively between 1985 and 1994. Between 1994 and 2006, MCC incidence was stable at 2.2 cases per million person-years. MCC incidence was very low among those younger than 60 years (on average 0.19 cases per million persons-years) and increased to 11.5, 19.5, and 50.3 cases per million persons-years among individuals who were 70–79 years old, 80–90 years old, and 90 years or older, respectively. Five years after MCC diagnosis, 55 % of patients with localized disease, as compared to 84 % of the patients with nonlocalized disease, had died.

3.2 Morbidity Data

Primary polyomavirus infections may cause mild nondescript illnesses which are not well characterized.

3.3 Serological Surveys

Serological surveys of human polyomaviruses have shown that, in general, initial exposure to these viruses occurs in early childhood and continues to a greater or lesser extent throughout life, with a very high proportion of individuals eventually showing serological evidence of infection. However, the age-seroprevalence profiles for individual viruses also differ in some respects and suggest that there may be virus-specific differences in the route and efficiency of transmission or in environmental exposure. An age-seroprevalence study undertaken in England in 1991 using hemagglutination inhibition (HI) assays for BKPyV and JCPyV showed very different patterns for the two viruses [29]. Overall, 81 % of sera tested positive for BKPyV, and the seroprevalence varied significantly by age. Sixty-four percent of children in the youngest age group (1–4 years) were positive, and the figure rose to 91 % at 5–9 years. After 40 years of age, the prevalence of detectable antibody slowly declined to 68 % at 60–69 years of age. By contrast, the overall seroprevalence to JCPyV was only 35 %, but it also varied significantly with age. Only 11 % of children <5 years of age and 14 % 5–9 years of age were JCPyV seropositive, but the seroprevalence thereafter rose throughout life to reach a peak prevalence of 50 % at 60–69 years of age. In the same study, age-seroprevalence to SV40 was measured by neutralization assay. The antibody prevalence to SV40 remained at 1.3–5 % throughout all age groups and titers were low. There was a significant positive association between the presence of antibody to SV40 and antibody to both BKPyV and JCPyV, and also to the titer of BKPyV antibody, suggesting possible cross-reactivity between SV40 and the human polyomaviruses. In fact, competitive inhibition assays using viruslike particle (VLP) ELISA have shown that nearly all the SV40 reactivity in human serum can be explained by cross-reacting BKPyV or, less commonly, JCPyV antibodies [30–32].

A serological survey of Italians attending outpatient clinics between 2005 and 2008 using VLP ELISA assays showed a similar age-seroprevalence profile but a higher overall seroprevalence compared to that measured by HI assays, consistent with the greater sensitivity of the former assay method (Fig. 46.2) [33]. For JCPyV, seroprevalence increased steadily with age, from 0.5 % for children <10 years of age, to 50 % for young adults 10–19 years of age, to a peak seroprevalence of 80 % in adults >70 years of age. BKPyV seroprevalence was already 62 % for children <10 years of age, peaked at 79 % for those in the second decade of life, remained stable through the third and fourth decades of life, and began to gradually decline starting with adults 40–49 years of age (64 %), finally reaching its nadir of 55 % in adults >70 years of age.

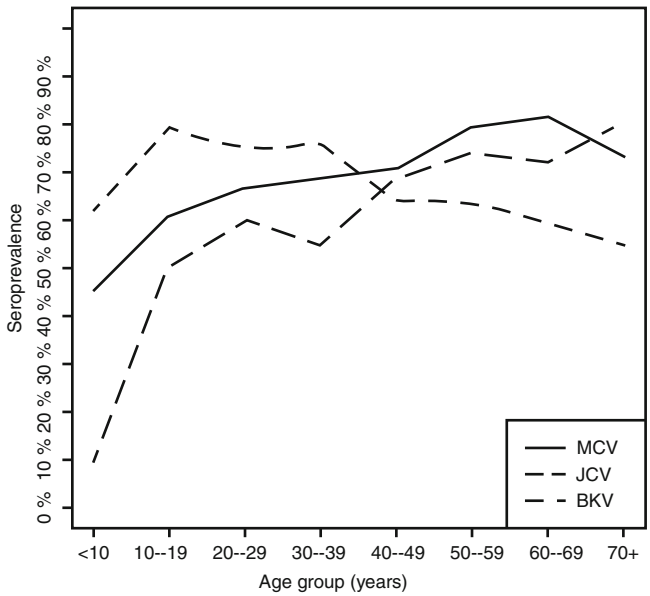

Fig. 46.2 Age-specific seroprevalence of Merkel cell polyomavirus, *BK virus*, and *JC virus* among 945 individuals recruited from hospital-based general and subspecialty outpatient clinics. Serum samples were tested at a 1:200 dilution in viruslike particle (VLP)-based ELISAs. The distribution of reactivities of serum samples from children less than 10 years of age was used to set cutoff points for seropositivity, and results are displayed as the percent positive in 10-year age groups (Copyright © American Society for Microbiology, Viscidi et al. [33])

Substantially similar age-seroprevalence profiles for BKPyV and JCPyV have been reported by others using VLP ELISA assays [34, 35]. In the study using Italian serum samples, MCPyV age-seroprevalence was also measured. In children <10 years of age, 45 % were MCPyV seropositive. Seroprevalence rose to 60 % by 10–19 years of age and peaked at 81 % in adults 60–69 years of age. There was a slight fall off in adults >70 years of age (73 %). MCPyV titers were positively associated with age, while BKPyV titers declined with age, and there was a null association of JCPyV titers with age. The reasons for these changes in the level of virus-specific antibody with age are unknown but may be due to differences in endogenous or exogenous sources of antigenic stimulation.

An age-seroprevalence survey for KIPyV and WUPyV revealed profiles that share many of the features of the profiles for the other human polyomaviruses, namely, evidence that primary infection occurs commonly in children and seroprevalence remains high or rises in adult life [36]. Among children 1–5 years of age, the seroprevalence to both WUPyV and KIPyV was 45 %. For KIPyV, a peak seroprevalence of 61 % was recorded in children 1–15 years of age and gradually declined to 50 % in adults >70 years of age. For WUPyV, seroprevalence rose slowly throughout adulthood, peaking at 71 % in 50–60-year-olds and remaining at this level in adults >70 years of age.

3.4 Laboratory Methods

3.4.1 Virological Methods

Virus isolation has not been routinely used for laboratory diagnosis of polyomavirus infections. As discussed below, two forms of the viral genomes of BKPyV and JCPyV exist, which are designated archetype and rearranged based on the DNA sequence of the regulatory regions. The archetype form of each virus is thought to be the transmissible form that is capable of establishing a persistent infection in the host, while the rearranged form is characteristic of disease-associated virus. The archetype form cannot be isolated in cell culture. Rearranged variants of BKPyV and JCPyV are able to grow in cell cultures of renal proximal tubule epithelial (RPTE) cells and human fetal glial cells, respectively [37, 38], but the availability of simple and highly sensitive methods for viral protein and DNA detection make cell culture an unattractive and rarely used method for polyomavirus diagnosis. None of the newly discovered human polyomaviruses have been successfully cultivated. Viral proteins can be detected in disease tissue by immunohistochemical methods. Because these techniques are highly specialized and labor intensive, they are used mostly for research purposes. Additionally, well-characterized reagents are not commercially widely available.

The standard and most commonly used method for virus detection is based on polymerase chain reaction (PCR). PCR, developed in 1983, is a method to amplify a few copies of a target DNA sequence by several orders of magnitude. The method relies on thermal cycling, consisting of repeated cycles of heating and cooling for melting and enzymatic replication of DNA. The reaction relies on short DNA fragments called primers, complementary to a target DNA sequence, to initiate the enzymatic activity of a heat-stable DNA polymerase, most commonly a bacterial *Thermus aquaticus* (Taq) polymerase. DNA generated in the reaction is itself a template for replication allowing for a chain reaction and exponential amplification of target DNA, and thus the name polymerase chain reaction. When the technique was first developed, DNA products of the reaction were measured by gel electrophoresis. A significant advance in the technology has been the development of quantitative real-time PCR. The key feature of this method is that the amplified DNA is detected as the reaction progresses in real time. In addition to providing quantization of the number of target DNA copies in the starting sample, the method provides much greater precision than the older method of measuring the end products of PCR. Another technical advance has been the introduction of fluorophore-containing probes, such as TaqMan, to measure the amount of amplified product in real time. TaqMan probes consist of a fluorophore attached to the 5′-end of a probe and a quencher at the 3′-end. As long as the fluorophore and the quencher are in proximity, quenching

inhibits any fluorescence signals. TaqMan probes are designed such that they anneal within a DNA region amplified by a specific set of primers. As the Taq polymerase extends the primer and synthesizes a nascent DNA strand, the 5′–3′ exonuclease activity of the polymerase degrades the probe. Degradation of the probe releases the fluorophore, thus relieving the quenching effect and allowing fluorescence of the fluorophore. Fluorescence detected in the real-time PCR reaction is directly proportional to the fluorophore released and the amount of DNA template present in the PCR. TaqMan PCR assays have become the preferred method for detection of polyomavirus DNA in clinical specimens, and several laboratories have developed assays for BKPyV, JCPyV, and MCPyV, as well as the other recently discovered human polyomaviruses [39–44].

No polyomavirus PCR assays are FDA approved. However, the clinical need for the diagnosis of BKPyV-associated nephropathy has spurred the development and clinical validation of several TaqMan assays for BKPyV. Consistent with the expected performance of TaqMan assays, the published assays have shown linear ranges of several $\log_{10}$ orders of magnitude, detection limits of 100–1,000 copies per ml or less, and very good intra- and inter-assay precision. A quantitative real-time PCR assay for a target in the VP2 gene of BKPyV, the Simplexa BKPyV assay (Focus Diagnostics), has been developed and shown to quantify DNA linearly over a range of 2.7–10.4 Log_{10} copies/ml, with a limit of detection of about 3000 copies/ml in plasma and urine [45]. Intra-assay precision yielded coefficients of variation (CV) ranging from 0.3 to 3.9 % and inter-assay precision yielded CVs of 1.1–7.8 %. By comparison to a reference laboratory real-time PCR, the Simplexa BKPyV assay had a sensitivity of 100 % and a specificity of 85 %. The assay showed no cross-reactions in samples containing JCPyV, HSV1, HSV2, enterovirus, adenovirus, HBV, HPV, EBV, and CMV. An evaluation of the Artus BK Virus RG PCR test (QIAGEN), which targets a conserved region of the VP2 and VP3 genes, showed a linear range of quantification from 2.28 to 8.29 $\log_{10}$ DNA copies/mL and a limit of detection of 2.00 $\log_{10}$ copies/mL [46]. The precision of the assay was highly reproducible among runs with coefficients of variance (CV) ranging from 0.2 to 7.0 %. Too few samples were tested to determine accurately the sensitivity of the assay. No biological false positives were found with other pathogens potentially found in human urine and plasma. Genotyping analysis using large T antigen sequences demonstrated that 90 % of the positive samples were BKPyV subtype I. In the absence of standardization, comparisons among assays are difficult and many factors can contribute to differences, including sample type, DNA extraction and purification method, preparation used to generate standard curves, amount of input template, choice of primers and probe, and PCR amplification conditions. In a comparison of seven TaqMan real-time PCR assays for BKPyV, the most significant source of error among individual specimens was primer or probe mismatch due to subtype-associated polymorphisms, primarily among subtype III and IV isolates [47]. The importance of genetic variation in circulating BKPyV genotypes as a source of error in the performance of BKPyV TaqMan PCR assays has also been described by other investigators [40, 48]. The greatest limitation to the clinical application of BKPyV PCR assays is the lack of a robust definition of clinical relevance since the inherently high sensitivity of PCR assays can lead to positive results that may not inform clinical practice. The use of PCR in management of BKPyV nephropathy is discussed in Sect. 8. TaqMan PCR assays for JCPyV, MCPyV, KIPyV, and WUPyV have been published, but none of the assays have been standardized and no commercially produced reagents are available.

3.4.2 Serological Methods

Antibodies to JCPyV and BKPyV capsid protein can be measured by hemagglutination inhibition (HI) assays, but ELISA techniques have largely replaced them. Because JCPyV and BKPyV are difficult to cultivate and MCPyV and the other recently identified human polyomaviruses have not been cultivated, recombinant proteins are used as antigens. For some viruses, it has been possible to produce viruslike particles by the expression of the major capsid protein VP1 in eukaryotic expression systems [32]. Viruslike particles are formed by the spontaneous self-assembly of the VP1 protein into a capsid that morphologically resembles a virion and displays conformationally correct epitopes on its surface. Alternatively, the VP1 protein can be expressed in *E. coli* as a glutathione-S-transferase (GST) fusion protein [49]. For ELISA, the antigens are immobilized on plastic microtiter plates, allowed to react with serum, and bound antibodies are detected with enzyme-labeled antihuman immunoglobulin following the addition of an appropriate substrate. An alternative method involves immobilization of GST-VP1 fusion proteins to polystyrene beads containing fluorescent dye (Luminex technology). After incubation of the beads with serum, bound antibody is reacted with an antihuman immunoglobulin labeled with a different fluorophore from that in the bead. The reaction mixture is measured in a flow cytometry device that allows simultaneous detection of the antigen-loaded bead and antigen-antibody complexes bound to the bead. Since over 100 beads with different fluorescent intensities are available, up to 100 antigens can be employed in a single reaction, allowing for high-throughput detection of multiple antibody specificities in a single test. No direct comparisons of the performance of VP1 fusion proteins versus viruslike particles as serological reagents have been done, but the fact that VLPs more closely resemble authentic capsids suggests that they may be superior in displaying native conformational epitopes.

The high titers of antibody elicited by polyomavirus infections suggest that ELISA assays should be very sensitive, but because primary infections are asymptomatic and rarely diagnosed, it has not been possible to establish the true sensitivity of serological measures of exposure. The specificity of serological assays for BKPyV and JCPyV antibodies has been demonstrated by competitive inhibition assays which have shown that reactivity can be completely inhibited by preincubation of sera with the homologous antigen and the reactivity is not inhibited by heterologous antigen [31] Competitive inhibition assays have also demonstrated that cross-reacting antibodies elicited primarily by infection with BKPyV explain the low level of human seroreactivity to the macaque polyomavirus, SV40 [50]. Since the other human polyomaviruses are genetically more distantly related to each other than BKPyV is to JCPyV, it is likely that seroreactivity to these viruses is also highly species specific. An interesting but unexplained biological response to JCPyV and BKPyV infection is the negative correlation in the level of antibodies to the viruses. Thus, individuals who react strongly to JCPyV tend to react more weakly to BKPyV and vice versa.

The only commercially available serological assay for a human polyomavirus is the Focus Diagnostics JCPyV serology assay. The assay is performed in two steps, a screening standard microtiter plate VLP-based ELISA followed by a confirmatory step in which the serum is preincubated with JCPyV VLPs and retested in the ELISA assay. Serum samples that are positive in the ELISA and inhibited by >40 % in the confirmatory step are scored as JCPyV antibody positive. Using serum samples from natalizumab-treated multiple sclerosis patients, the JCPyV seropositivity rate was 53.6 % [51]. The sensitivity of the assay to identify those infected with JCPyV was estimated to be 97.5 % based on the percentage of serum samples from urinary JCPyV DNA-positive patients that tested positive for anti-JCPyV antibodies. Diagnostic specificity (false-positive rate) could not be established because most JCPyV infections are asymptomatic. The intra-assay precision for low and high positive controls and negative controls was 5.7, 2.9, and 3.7 %, respectively, and inter-assay precision for the respective controls was 9.7, 8.7, and 7.0 %. Robustness, as measured by performance across different laboratories, showed a concordance among laboratories of 95–98 %. The use of the assay for clinical management of multiple sclerosis patients eligible to received natalizumab is discussed in Sect. 9.1.

3.4.3 Cytological Methods

Polyomavirus-associated nephropathy and hemorrhagic cystitis are frequently accompanied by the presence of cytologically abnormal cells, referred to as decoy cells, in the urine that can be visualized by Papanicolaou stain (Fig. 46.3). They are virally infected renal tubular or uroepithelial cells characterized by an irregular shape and enlarged nuclei with basophilic inclusions [52]. Quantitative urine cytology is one modality for screening for BKPyV reactivation and diagnosis of BKPyV-associated nephropathy in renal transplant recipients. While the method has very high negative predictive value, the positive predictive value is low because urinary shedding of polyomaviruses is common in healthy persons, it cannot distinguish different types of polyomaviruses, and urinary shedding of cytomegalovirus is also associated with decoy cells. Additionally, special skill is required to interpret urinary cytology.

4 Biological Characteristics of Polyomaviruses

4.1 Physical Properties, Genomic Organization, and Function of Viral Proteins

Polyomavirus particles measure about 44 nm in diameter and have a buoyant density in CsCl of 1.34 g/cm^3. The virion is a nonenveloped, icosahedral capsid composed of three virus-encoded proteins, VP1, VP2, and VP3. The major capsid protein, VP1, accounts for more than 70 % of the virion mass and has a molecular weight of 39–44 kDa. The capsid encloses a single molecule of circular double-stranded DNA that is in complex with cellular histone proteins. The viral DNA genome is ~5,000 bp and is organized into three functional regions, the early and late coding regions and a regulatory region (Fig. 46.4).

The early region encodes two viral regulatory proteins, the large T and small t antigens (T-Ag and t-Ag). T-Ag possesses multiple enzymatic activities and has the ability to bind DNA and a number of cellular proteins. T-Ag regulates the production of early mRNA, initiates viral DNA replication, and activates late gene transcription. Among the cellular proteins that interact with T-Ag are two proteins important for regulation of cell growth, the tumor suppressor proteins, retinoblastoma susceptibility protein (Rb) and p53. The interaction of T-Ag with these two proteins plays a central role in the ability of polyomaviruses to transform and immortalize cells in vitro and to induce tumors in animals. The t-Ag protein may serve an ancillary role to T-Ag activity in cell transformation. The t-Ag is known to inactivate protein phosphatase 2A leading to increased cyclins D1 and A, and downregulation of p27. The cyclins and p27 are involved in control of cell cycle progression. The role of the t-Ag in the viral life cycle is not fully defined, but it is known to be dispensable for the lytic cycle of polyomaviruses in cultured cells. Alternately spliced T-Ag transcript have been described for JCPyV and BKPyV, and further research may reveal similar transcripts in other human polyomaviruses. The functions

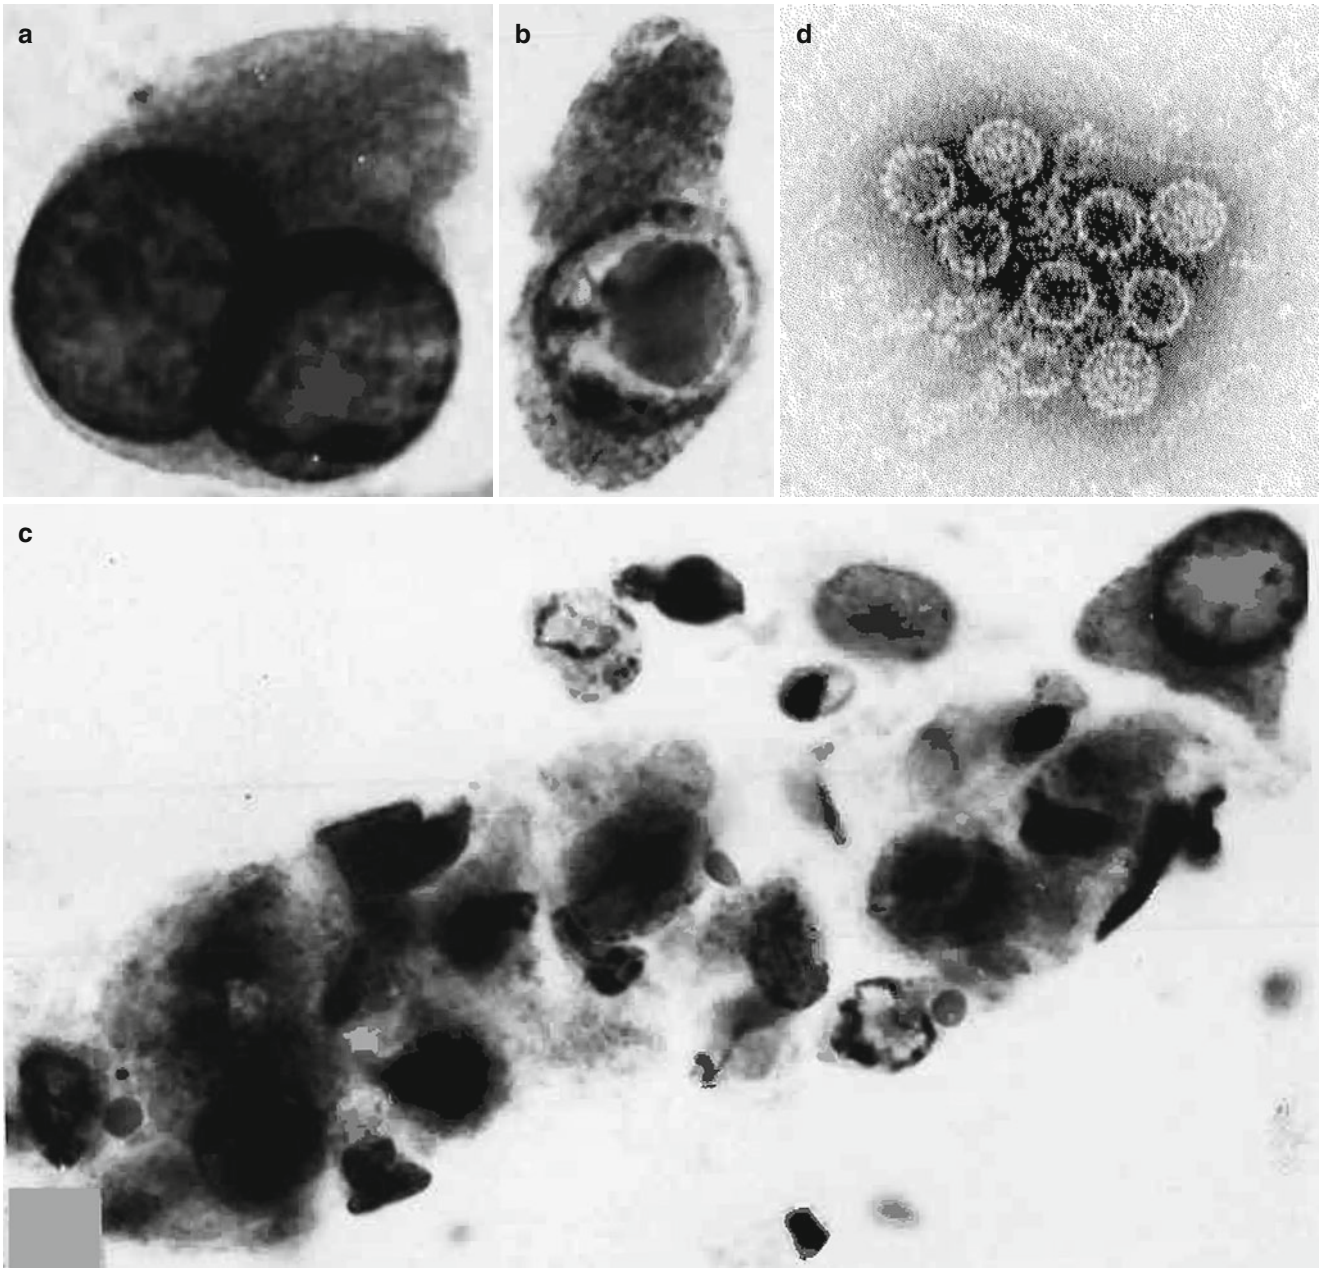

Fig. 46.3 BKPyV urinary cytopathology and viruria. Urinary epithelial cells in a renal transplant recipient; (**a**, **b**) cells with enlarged nuclei, (**c**) cast formation of virus-infected epithelial cells. (**d**) Electron micrograph of virions of BKPyV in urine; virus particles are aggregated with an antiserum (From Ref. [49] with permission)

of the proteins encoded by these alternately spliced transcripts have not been well defined. The effect of polyomavirus infection, and particularly the early region proteins, on the cell transcriptome has been investigated using global gene expression techniques. Studies of primary kidney epithelial cells infected with BKPyV [53] and of primary human fetal glial cells infected with JCPyV [54] have shown upregulation of numerous genes involved in cell cycle and proliferation, including genes involved in apoptosis, signal transduction, transcriptional regulation, DNA damage repair, protein ubiquitination and folding, RNA processing, and cellular trafficking and structure.

The late coding region contains the genetic information for the major structural protein, VP1, and the two minor structural proteins VP2 and VP3. The sequence of VP3 is contained entirely within that of VP2. Based on the crystal structure of SV40 [55], the human polyomavirus capsids are predicted to contain 360 molecules of VP1 arranged in 72 pentameric subunits. Each pentamer associates with a single VP2 or VP3 molecule to form the individual capsomeres.

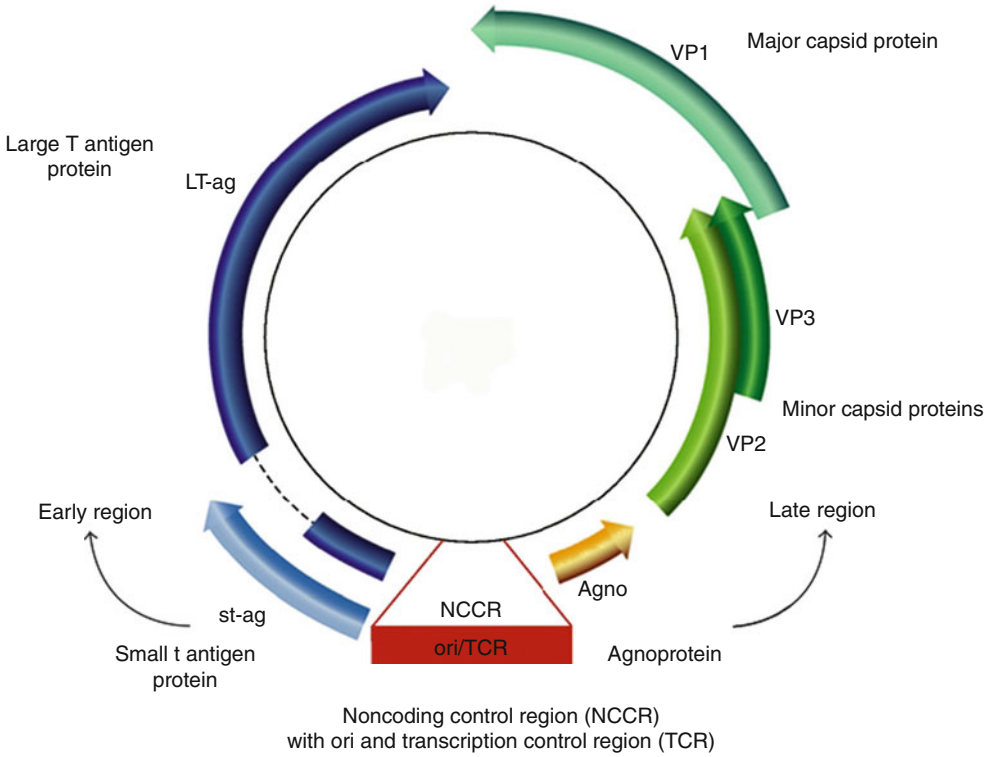

Fig. 46.4 Simplified representative human polyomavirus genome. Polyomavirus genomes are circular double-stranded DNA ~5,000 bp in length. The noncoding control region (*NCCR*) is ~300–400 bp in length and contains the origin of replication (*ori*) and promoter and enhancer elements. Genes are transcribed in opposite directions from opposite strand of DNA. The early region transcribes the large T antigen and small t antigen. The late region transcribes three viral structural proteins, the *VP1* major capsid protein and the *VP2* and *VP3* minor capsid proteins. BKPyV and JCPyV, but not the other human polyomaviruses, also transcribe an accessory protein, agnoprotein

The late region of BKPyV and JCPyV, but not of the other known human polyomaviruses, encodes an agnoprotein. The JCPyV agnoprotein appears to play a role in viral DNA replication and transcription and perhaps also in the dysregulation of cell cycle control and DNA repair [56]. JCPyV agnoprotein may also play a role in nuclear and cellular release of the virus [57, 58]. BKPyV agnoprotein has been shown to interact with α-SNAP, a molecule involved in disassembly of vesicles during secretion; however, the functional relevance of the interaction is unclear [59].

The viral noncoding regulatory region (NCRR) spans 300–500 bp and is located between the early and late coding regions. The NCRR contains the DNA replication origin, the TATA box, T-Ag binding sites, cellular transcription factor binding sites, and the promoters and enhancers for transcription of early and late genes. Hypervariability of the regulatory region is a typical feature found in polyomaviruses, particularly for BKPyV and JCPyV. Classification schemes for regulatory region variants of JCPyV and BKPyV divide them into archetypal variants, which are characteristic of viruses found in urine, and rearranged or tandem repeat variants, which are associated with disease [60–63]. The archetypal regulatory region is divided into defined blocks of sequence that are duplicated or deleted in the rearranged variants. In BKPyV, the archetype virus NCCR is divided into five blocks of sequence designated O, for the origin of replication, P, Q, R, and S. The JCPyV archetype regulatory region is similarly divided into blocks of sequence designated a, b, c, d, e, and f, with the origin of replication located between block a and the early genes. The regulatory region of archetypal variants is organized into a linear series of promoter and enhancer sequences. Rearranged variants contain partial or complete duplications and deletions of the various sequence elements. The sequence variability in the NCRR among BKPyV and JCPyV variants is believed to confer selective growth advantages to these viruses in their hosts [61, 64].

4.2 Infectious Life Cycle of Polyomaviruses

The life cycle of polyomaviruses is initiated by the adsorption of virions to the cell surface. This process requires interaction with cell surface sialic acids. For BKPyV, an N-linked glycoprotein with α(2,3)-linked sialic acid serves as the receptor [65], and for JCPyV, an N-linked glycoprotein containing terminal α(2,6)-linked sialic acid is used [66]. The proteinaceous component of the cellular receptor for BKPyV is unknown; however, the serotonin receptor $5HT_{2A}$ was identified as the putative receptor for JCPyV [67]. Polyomaviruses enter the cytoplasm by endocytosis. BKPyV enters by caveolae-mediated endocytosis [68] and JCPyV by clathrin-dependent endocytosis [69]. Polyomaviruses are next transported to the endoplasmic reticulum (ER). Within the ER, the capsid is destabilized by the disruption of disulfide bonds, allowing

virions to be translocated across the ER membrane into the cytoplasm. Capsid stability is further disrupted by the low calcium concentration in the cytosol, exposing nuclear localization signals. The partially disassembled virions enter the nucleus through nuclear pores. Within the nucleus, virions are fully uncoated and associate with nuclear domain 10 (ND10) bodies. Most likely ND10 bodies are used as a scaffold for viral DNA replication and assembly of new progeny virions. The viral minichromosome is replicated and transcribed in the nucleus. DNA replication is initiated by the large T antigen through interactions with host proteins. Replication proceeds bidirectionally. In addition to its direct role in viral DNA replication, the large T antigen also binds to cellular proteins to induce signals to drive quiescent cells toward S phase. Dividing host cells are enriched for the host molecular machinery necessary for efficient viral DNA replication. In the nucleus, the viral genome serves as a template for the host RNA polymerase II transcriptional machinery. The restriction of viral tropism at the cellular level is believed to be governed in part at the transcriptional level. Regulation of transcription is dependent on sequences in the NCRR and the availability of host transcription factors. Unlike other human DNA viruses, such as herpesviruses, polyomaviruses do not encode for transcriptional activating proteins. The transcription factors, NF-κB, Tst-1, and NF-1 have been demonstrated to contribute to the neurotropism of JCPyV [70, 71]. Interestingly, the NCRR of BKPyV contains an estrogen response element, which mediates an increase in viral promoter activity upon hormone stimulation [72]. Thus, the elevated estrogen levels during pregnancy might contribute to viral reactivation and explain the increase in BKPyV shedding observed in pregnant women. Following viral transcription, there is a switch to DNA replication. While early transcription is believed to be a determinant of viral cell tropism, DNA replication is a determinant of species specificity. Polyomavirus T-Ag interacts with host cell DNA polymerases in a species-specific manner [73]. Once the viral genome has been replicated, T-Ag mediates repression of early gene transcription and stimulates transcription of late genes. Expression and subsequent nuclear localization of the viral structural proteins VP1, VP2, and VP3 leads to assembly of virion capsids. Assembly occurs predominantly in the nucleus. Newly packaged virions are thought to be released by either lytic rupture of the host cell or secretion from the plasma membrane.

5 Descriptive Epidemiology

5.1 Incidence and Prevalence

The incidence rates of primary polyomavirus infections in humans are unknown because the infections are asymptomatic and rarely diagnosed. Estimates of the prevalence of polyomavirus infection are based on serological surveys and good estimates are only available for JCPyV, BKPyV, and MCPyV, as described in Sect. 3.3.

5.2 Geographic Distribution

Polyomaviruses are widespread in human populations. However, geographic and ethnic differences exist in the distribution of genetic subtypes of BKPyV and JCPyV. BKPyV is divided into four major subtypes, I, II, III, and IV. Subtype I is the most prevalent, followed by subtype IV, with subtypes II and III occurring less frequently. Subtype I has been subdivided further into the three subgroups Ia, Ib, and Ic [74]. A regional distribution of these subgroups is also apparent: subgroup Ic is prevalent in Japan, Ib is widespread in European countries [75, 76], and Ia is prevalent in Africa [77]. Subtype Ib has recently been further subdivided into Ib-1 and Ib-2 [77]. With the exception of Japan, BKPyV subtype IV was found to be widely prevalent in East Asia [78]; however, prevalence of this subtype has likely been underestimated in other regions [77]. Six subgroups of subtype IV have also been identified, each showing a close relationship to population geography [79]. All JCPyV strains belong to a single serotype. Based on genetic variations, three JCPyV "superclusters" (A, B, and C) are distinguishable [80]. Type A is distributed throughout Europe, type B throughout Asia and Africa with a minor subtype found in Europe, and type C in West Africa [81]. Types A and B have each been split further into a number of "subordinated lineages" and "sublineages" [81, 82].

5.3 Occurrence in Special Epidemiologic Setting

Almost all of the illnesses associated with JCPyV and BKPyV infections occur in conditions associated with immunodeficiency of the host, but the two viruses have different tropisms and react differently to the immunosuppressing event or regimen. In healthy individuals previously infected with JCPyV, virus recrudescence as evidenced by viruria occurs in about 20–30 % of the people and increases in older age [83]. Infection with HIV does not affect this rate of JCPyV viruria [84]. In contrast, BKPyV recrudescence and viruria are markedly elevated by HIV infection, for instance, from 5 to 22 % in one study [84]. JCPyV is a neurotropic virus causing PML, whereas BKPyV is largely a urinary tract virus responsible for pathological lesions in the kidney, urinary bladder, and ureter. HIV infection has resulted in a tenfold increase in the incidence of PML, whereas increase in BKPyV-induced pathology is largely determined by the nature of drugs and the intensity of the

immunosuppressive regimens in transplant recipients. Despite these generalizations, there are some instances where JCPyV is responsible for cases of nephropathy [85, 86] and BKPyV for isolated cases of encephalitis in normal [87], or HIV-infected [88] individuals and in a bone marrow transplant recipient [89]. The pathology related to MCPyV, Merkel cell cancer, occurs in older (>50 years of age), fair-skinned individuals with a history of sun or ultraviolet light exposure and in persons with T cell immune suppression, such as HIV-infected patients and organ transplant recipients [90, 91]. Merkel cell cancer incidence is increased in individuals with a prior diagnosis of other skin cancers or chronic lymphocytic leukemia or lymphoma [28, 92].

6 Mechanisms and Routes of Transmission

The best-studied human polyomaviruses are BKPyV and JCPyV. Infection occurs at an early age in human populations, although the steadily increasing seroprevalence of JCPyV throughout life suggests exposure may also occur at a later age in some individuals. The absence of clinical symptoms during primary polyomavirus infection has made the identification of the site of entry difficult. The most likely site is either the respiratory tract or the gastrointestinal tract. In support of an oral route of transmission, BKPyV has been detected in saliva and has been shown to replicate in salivary gland cells [93]. JCPyV has been identified in human tonsil stromal cells and in B lymphocytes contained in tonsils and has been shown to productively infect tonsillar stromal cells in culture [94]. However, JCPyV has not been detected in saliva or oropharyngeal secretions [95, 96]. BKPyV, JCPyV, and other human polyomaviruses have been detected in urban sewage, which also supports the possibility of oral-fecal transmission [97, 98]. Human polyomaviruses have been shown to be stable at pH 5 and for prolonged periods of time in sewage at room temperature [99]. These findings support the possibility of transmission through diverse environmental exposures. Although mouse polyomavirus can be acquired vertically through transplacental transmission, there is little virological or serological evidence to support in utero transmission of human polyomaviruses [100, 101]. In addition to in utero passage across the placenta, vertical or perinatal transmission of viruses can occur during the birthing process or soon after birth. Using a postnatal rise in the IgG level or the transient appearance of an IgM or IgA response in newborns as evidence of infection, one small study reported BKPyV and JCPyV infection of newborns in 21 and 16 % of pregnancies, respectively [102]. Transmission within families has been shown to be the principal mode of spread of JCPyV [103, 104]. In fact, intrafamilial transmission is so common that genetic variation of the JCPyV genome has been used as a marker for the migration of human populations [80, 105]. Molecular evolutionary analysis of JCPyV genetic variants has demonstrated two distinct viral lineages, both arising from the ancestral African type, in support of the model of human dispersal out of Africa [106]. These analyses have also identified a split of the Asian lineage of JCPyV into two main branches, one diffusing in Japan and Americas, the other in Southeast Asia. Although intrafamilial spread of BKPyV is also common, analysis of BKPyV genotypes in Japanese-Americans living in southern California supports substantial transmission outside the family as well [107].

7 Pathogenesis and Immunity

7.1 Pathogenesis

After initial replication at the site of entry, polyomaviruses spread hematogenously to other organs. This stage of infection is clinically silent and presumably the host immune response rapidly controls viral replication before any tissue damage can occur. There is no evidence that polyomaviruses establish a latent state of infection. They most likely persist as infectious virus in cells where a low virion output is minimally injurious to the host and the infection is contained by still not fully understood immunological mechanisms. The principal site of persistence of BKPyV and JCPyV is the kidney, as demonstrated by periodic amplification of low-level infection and urinary shedding of virus. Immunostaining has shown that the sites of viral replication are the epithelial cells of the kidney, ureter, and bladder. In a study of healthy blood donors, asymptomatic urinary shedding of BKPyV and JCPyV was observed in 7 and 19 %, respectively, of 400 subjects [34]. The shedding of JCPyV was more commonly observed among individuals who were seropositive only for JCPyV, compared with individuals who were seropositive for both BKPyV and JCPyV, suggesting limited cross-protection from BKPyV immunity. Because of the lack of longitudinal studies, it is unknown if urinary shedding is persistent or intermittent. Additionally, it is unknown whether a subset of infected individuals shed virus for long time periods or the majority of infected persons will shed virus at some point in time. Viremia is rare in healthy persons. Among the 400 blood donors, neither JCPyV nor BKPyV were detected in plasma [34]. However, another report described detection of JCPyV viremia in approximately 2 % of normal individuals [108]. Whether JCPyV or BKPyV establish persistence in tissues other than kidney is controversial. JCPyV has been detected by PCR in B lymphocytes from tonsillar tissue and bone marrow; however, in vitro studies have failed to show that the virus infects and replicates in B cells, but rather the virus remains cell

surface associated. JCPyV has also been detected in stromal tonsillar cells and has been shown to infect these cells in culture [109]. In addition to its presence in kidney, BKPyV has been detected by PCR in peripheral blood, but the cell type harboring the virus has not been determined. Once JCPyV reaches the central nervous system, it replicates vigorously in oligodendrocytes, leading to PML. Two models have been proposed for brain infection with JCPyV. One model proposes that primary infection occurs in tonsillar tissue with subsequent trafficking of virus to bone marrow and kidney. Upon immunosuppression, the virus is amplified and mobilized from the bone marrow and crosses the blood-brain barrier. An alternative model proposes that the brain may serve as a site of low-level persistence, and with immunosuppression, the virus present in the brain is amplified. This model is based on studies which have shown detection of JCPyV DNA in brain of healthy persons [110–112]. The pathogenesis of MCPyV bears many similarities to that of JCPyV and BKPyV, but a significant difference is evidence for infection of cutaneous tissue, which is not observed for the latter two viruses. MCPyV DNA has been detected in skin samples from 40 to 95 % of healthy persons [10, 113, 114]. The virus has also been detected in respiratory tract secretions [115, 116]. Additionally, MCPyV has been detected in a high proportion of swab samples of environmental surfaces [117]. The mode of transmission of MCPyV is unknown but cutaneous, fecal-oral, or respiratory routes are all possibilities. Primary infection appears to be asymptomatic.

7.2 Immunity

Polyomaviruses induce robust humoral immune responses to viral capsids, with high levels of immunoglobulin G detectable in serum of many individuals by ELISA assays. When viral recrudescence occurs in association with disease, antibody levels generally rise as the viral load increases [118, 119]. There is no evidence for antibody-mediated protection against disease. Once a persistent viral infection is established, the principal mechanism of immune-mediated control of viral replication is believed to be cellular immunity. This paradigm likely applies to polyomaviruses because recrudescence of viral replication and virus-associated disease occurs in immunosuppressed individuals. There is circumstantial evidence to support a protective role of cellular immunity in polyomavirus-associated disease. Several studies have shown that BKPyV-specific T cell responses are associated with recovery from BKPyV infection in renal transplant recipients, while low or undetectable responses correlate with viral persistence [120–124]. Similarly, JCPyV-specific T cell responses are associated with clinically quiescent PML, while patients without detectable responses fail to control their neurological disease [125, 126]. The presence of MCPyV-specific CD8+ T cells in Merkel cell tumors is associated with improved survival [127].

8 Patterns of Host Response

8.1 Clinical Manifestations

8.1.1 Progressive Multifocal Leukoencephalopathy (PML)

PML is a fatal subacute demyelinating disease of the central nervous system that occurs as a complication of a wide variety of conditions of T cell deficiency. These T cell deficiencies include lymphoproliferative disorders such as Hodgkin's disease, chronic lymphocytic leukemia, and lymphosarcoma; chronic diseases such as sarcoidosis and tuberculosis; primary immunodeficiency diseases; prolonged immunosuppressive therapy as, for example, in organ transplant recipients and in patients with rheumatoid arthritis, systemic lupus erythematosus, and myositis. Pathologically, the PML is characterized by foci of demyelination in the white matter of the central nervous system. Oligodendrocytes, which are the myelin-producing cells in the brain, have enlarged nuclei containing inclusion bodies, and they surround the areas of demyelination (Fig. 46.5). Astrocytes, sometimes of greatly increased size and with bizarre nuclear changes, are found in the area of demyelination. The disease was described under many names until 1958 when it was recognized as a single entity [128]. In 1961 Richardson, noting the nuclear changes in oligodendrocytes, the lack of inflammatory response in many cases, and the relationship to immunodeficiency, suggested that the disease may be a result of lytic infection of

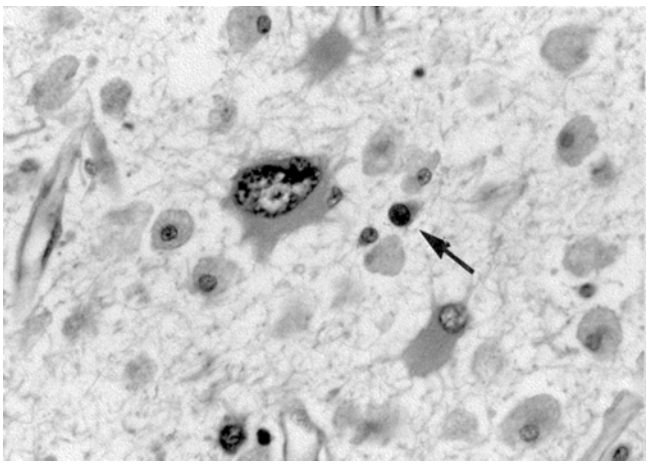

Fig. 46.5 Progressive multifocal leukoencephalopathy: cytopathology of PML. Bizarre giant astrocytes and oligodendrocytes with enlarged nuclei (*arrow*) (Courtesy of Dr G Zu Rhein, Madison, Wisconsin, from Ref. [49] with permission)

oligodendrocytes with an opportunistic virus [129]. Polyomavirus particles were visualized in the nuclei of the affected oligodendrocytes in 1965 [130, 131], and the causative virus, JCPyV, was isolated in 1971, after inoculation of extracts of a PML brain in primary human fetal glial cell cultures [5].

The advent of AIDS in the 1980s markedly changed the incidence and the age distribution of PML cases [132–134]. Deaths due to PML increased fourfold between 1979 and 1987. PML was recognized as an AIDS-defining illness in 1987 and is reported in as many as 5 % of AIDS cases with neurological abnormalities [135] and in 0.72 % of all AIDS cases reported to the CDC between 1981 and 1990 [134]. A marked increase in the number of PML cases from 0.2 per million persons in 1984 to 3.3 per million persons in 1994 is ascribed to AIDS [136]. It has been estimated that 55–85 % of current cases occur in HIV-positive individuals with AIDS [137]. Previously, PML was a disease occurring in the fifth and sixth decades of life. As most cases of AIDS occur in the 20–49-year age group, the age distribution of PML cases has shifted to younger ages. PML in patients with primary immunodeficiency diseases and in renal transplant recipients is a disease of young children and young and middle-aged adults. Cases of PML in the older patients are most likely the result of recrudescence of a persistent low-level JCPyV infection. In the younger patient, it is possible that unchecked primary JCPyV infection may lead to PML.

In early 2005, the administration of monoclonal antibodies was recognized as a new risk factor for PML when two patients with multiple sclerosis and one patient with Crohn's disease developed PML in association with the administration of natalizumab, a monoclonal antibody to α4 integrin that prevents entry of inflammatory cells into brain and other tissues [138–140]. The estimated incidence of PML was roughly one in 1,000 for all patients enrolled in trials of natalizumab and one in 300 for patients undergoing treatment with the drug for 2 or more years. More recently, PML has also been documented in patients taking efalizumab for psoriasis, and rituximab for a variety of disorders [141]. The incidence and pathogenesis of PML following immunomodulatory drugs have been discussed [142–144]. Bloomgren and colleagues [144] collected data from many sources to identify risk factors for PML in patients with multiple sclerosis who were treated with natalizumab. There were 212 confirmed cases of PML among 99,571 natalizumab-treated multiple sclerosis patients worldwide. Using different subsets of data, they estimated that the lowest risk was among those who were negative for JCPyV antibodies before the treatment (0.09 per thousand) and the highest risk (11.1 per thousand) for those who were JCPyV antibody positive before treatment, had received immunosuppression prior to natalizumab treatment, and had also a long period (25–48 months) of natalizumab therapy. In contrast to the high mortality rate of PML in AIDS patients, only 52 of 242 reported cases of PML caused by natalizumab died (https://medinfo.biogenidec.com). However, survivors have varying levels of disability ranging from severe to mild.

Clinical and Pathological Features

Clinically, PML has an insidious onset and may occur at any time in the course of the underlying illness. The signs and symptoms point to a multifocal involvement of the brain. Impaired speech and vision and mental deterioration are common early features of the disease. The patient remains afebrile and headache is uncommon. Interestingly, careful monitoring of natalizumab-treated patients with magnetic resonance imaging (MRI) has led to the report of 3 patients with "asymptomatic PML" [145–147].

As a rule, the disease is progressive, resulting in death within 3–6 months after onset [148]. Paralysis of limbs, cortical blindness, and sensory abnormalities occur in later stages. A few patients may survive for years with stabilization of the condition and even apparent remission. A longer survival time is thought to be associated with a more marked inflammatory response in the brain. Patients who have JCPyV-specific CD8+ cytotoxic T lymphocytes appear to survive longer than patients without such cells [149]. The introduction of highly active antiretroviral therapy (HAART) for HIV/AIDS has had only a modest effect on the incidence of PML, which may be related to the fact that it can present at relatively higher CD4 counts than some other opportunistic infections [150, 151]. HAART has, however, led to an improvement in the prognosis of PML in HIV/AIDS patients [152].

The diagnosis of PML can be conclusively established by pathological examination of a biopsy or at postmortem. Macroscopically, the brain shows foci of demyelination that may vary widely in size and may become confluent and necrotic in the advanced stages of disease. The lesions are most frequent in the subcortical white matter. The cerebrum is almost always affected. Microscopically, the presence of enlarged oligodendrocyte nuclei around the foci of demyelination is diagnostic. These altered nuclei contain abundant amounts of JCPyV particles, antigen, and DNA. JCPyV particles or antigen are not found in normal brains or in non-diseased areas of PML brains. Noninvasive techniques, particularly nuclear magnetic resonance imaging (MRI) of the brain, provide an effective means for the diagnosis of PML. MRI scans of the head are nearly always abnormal in association with PML. The typical MRI abnormalities are localized to the subcortical white matter with increased T2 signal and little contrast enhancement after gadolinium administration [153]. Cerebrospinal fluid (CSF) analysis typically shows minimal pleocytosis, less than 20 cells per microliter, and only modestly elevated protein, usually amounts less than 100 mg per deciliter. PCR analysis of CSF for JCPyV DNA is the best

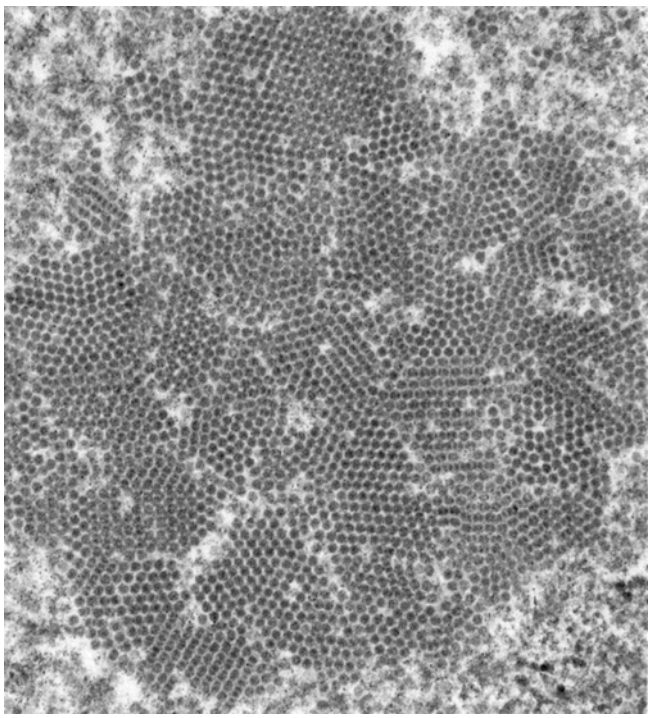

Fig. 46.6 Virions in the nucleus. Crystalloid arrangement of JCPyV virus particles in an infected oligodendrocyte nucleus (from patient JC) (Courtesy of Dr G, Zu Rhein, Madison, Wisconsin, from Ref. [49] with permission)

noninvasive test for the confirmation of PML. Its sensitivity is ~80 %, and it is highly specific [154].

Virological Aspects

The nuclei of the altered oligodendrocytes in the affected area contain abundant amounts of JCPyV particles that are often found in dense crystalline arrays (Fig. 46.6). Old "burnt-out" lesions of PML may be devoid of oligodendrocytes and viral particles. In situ hybridization or immunoperoxidase staining readily detects the virus in affected tissue. The virus is also found in cerebrospinal fluid [155] and in small amounts at extraneural sites [156]. JCPyV DNAs from PML cases show specific changes in their regulatory regions. JCPyV DNA from urines of normal individuals display an "archetypal" regulatory region [157]. PML isolates as a rule show a duplication of domain A and a deletion of domain B of the regulatory region [158]. Such rearrangements are not seen in JCPyV DNAs from healthy individuals, and it is very likely that they occur in the course of a prolonged JCPyV multiplication in the brain and that they increase the ability of JCPyV to grow in the central nervous system.

Pathogenesis of PML

The key pathogenetic event in PML is the cytocidal infection of oligodendrocytes with JCPyV. The destruction of oligodendrocytes results in demyelination, because these cells are responsible for the formation and maintenance of myelin. Neurons are not affected in PML. The widespread and multifocal distribution of discrete foci of demyelination is suggestive of a hematogenous spread of the virus to the brain. The JCPyV genome is present in B lymphocytes following infection with JCPyV, and it has been suggested that in the immunocompromised host, infected B lymphocytes transport the virus to the brain and initiate PML [159]. An alternative explanation is that the virus is already seeded in the brain at the time of primary infection and that a low-level persistent infection is amplified during immunosuppression to initiate PML [160]. PML occurs on the background of severely depressed cellular immunity, and lymphocytes of patients with PML have a decreased ability to respond to JCPyV antigen [161]. This may allow higher JCPyV multiplication and facilitate virus entry into the brain.

Why natalizumab, a monoclonal antibody to alpha4 integrin that prevents entry of inflammatory cells into the brain, would uniquely predispose persons to the development of PML remains unknown. The drug could increase the risk of PML by mobilizing persistently infected B lymphocytes from the bone marrow and spleen. Alternatively, the drug may impair the cellular immune response to JCPyV by preventing the entry of virus-specific cytotoxic T lymphocytes into the brain or sites of viral persistence.

Treatment of PML

There is no specific antiviral drug against JCPyV with proven efficacy in the treatment of PML. Although cidofovir has in vitro antiviral activity for nonhuman polyomaviruses and has been used to treat PML, a recent analysis of pooled raw data from multiple studies, including 370 HIV-associated PML patients, showed that cidofovir did not influence PML-related mortality or residual disability [162]. The best treatment is the restoration of the immune system, although this carries the risk of immune reconstitution syndrome (IRIS). IRIS is a term used to describe a group of clinical syndromes associated with immune reconstitution following HAART therapy for HIV patients. The manifestations are diverse, including fever and worsening of the clinical manifestations of an underlying opportunistic infection. The diagnosis requires distinguishing between progression of the initial opportunistic infection, development of a new opportunistic infection, unrelated organ dysfunction, and drug toxicity. The influence of IRIS on patient survival is variable and can be favorable or unfavorable [163, 164]. Treatment of PML caused by natalizumab involves discontinuation of the drug and in some cases its removal from the bloodstream by plasmapheresis/immunoadsorption. IRIS can occur in patients with natalizumab-associated PML, particularly after removal of the drug [165].

8.1.2 JCPyV Granule Cell Neuronopathy

Neurons are not productively infected in PML, but productive infection of neurons with JCPyV is seen in this rare disease, which may occur alongside PML [166] or without concurrent PML [167].

8.1.3 Nephropathy and Hemorrhagic Cystitis

BK Virus-Associated Nephropathy (BKVAN)

Although BKPyV was recognized as a virus infection of the urinary tract from the time of its isolation in 1971, its harmful effect on the kidney, BKVAN, was not evident until the 1990s. BKVAN is an important cause of progressive graft dysfunction and graft loss in patients with renal allografts [168]. The expanding use of tacrolimus and mycophenolate mofetil in immunosuppressive regiments to control graft versus host disease may have increased the incidence of BKVAN. The intensity of immunosuppression appears to be a more important factor in disease than the specific agent. BKVAN is the most common virus-induced pathology affecting renal allografts with an incidence of ~8 % and resulting in graft loss in the range of 10 % to greater than 80 % of the individuals who have nephropathy [169]. Histological features of BKVAN include epithelial cells containing intranuclear inclusion bodies characteristic of BKPyV replication, necrosis of cells of the tubules and collecting ducts, and varying degrees of interstitial inflammation. The majority of cases occur in the first year posttransplantation. Depending on the extent of virus-induced renal injury, patients present with varying degrees of allograft dysfunction. Serum creatinine can vary from normal in early-stage disease to a marked increase in late-stage disease with extensive renal damage. Systemic signs of infection such as fatigue and fever are absent. Host factors, such as age greater than 50 years, male gender, white ethnicity, and diabetes mellitus, and allograft factors, such as number of human leukocyte antigen (HLA) mismatches between donor and recipient, tubular injury due to drug toxicity and proinflammatory state of the graft brought on by surgical injury, warm ischemia, and reperfusion during implantation, can also increase the risk of BKVAN [170]. The nephropathy almost always occurs in the transplanted kidney. A less than optimal BKPyV-specific T cell response may underlie BKVAN [171]. JCPyV infection is a rare cause of nephropathy [86].

The definitive diagnosis of BKVAN requires a renal biopsy showing polyomavirus-induced cytopathic changes in tubular or glomerular epithelial cells. However, because BKVAN can be focal in distribution, a negative biopsy result does not rule out BKVAN with certainty. A consensus conference has proposed a histological staging scheme for BKVAN [172]. Stage A, early disease, is characterized by small numbers of tubular epithelial cells showing signs of viral replication with intranuclear inclusion bodies. In stage B, florid disease, the above findings are accompanied by signs of tubular injury and interstitial inflammation. Stage C, the late sclerosing stage, is characterized by tubular atrophy and diffuse interstitial fibrosis.

Noninvasive diagnostic techniques can be used to screen for BKPyV replication and to make an early diagnosis of BKVAN. Polyomavirus inclusion bearing "decoy cells" are easily detected in urine with a Papanicolaou-stained cytology preparation. The positive predictive value of the detection of decoy cells for BKVAN is low, but cytological monitoring of the renal transplant patients would identify those at risk of BKVAN. Similarly, the finding of high copy numbers of BKPyV DNA by PCR is of some clinical value for the diagnosis of BKVAN. In contrast, testing for BKPyV DNA in plasma appears to be more promising as a noninvasive diagnostic test for BKVAN. In one study, PCR assays for BKPyV DNA in plasma had a sensitivity of 100 % and a specificity of 88 % for detecting biopsy confirmed BKVAN [169]. A high level of BKPyV viremia was closely associated with concurrent BKVAN, probably because the viremia was the result of a high level of virus multiplication in the kidney.

Hemorrhagic Cystitis

Bone marrow transplant recipients undergo heavy immunosuppressive treatment in preparation of transplant from a donor. A transient hemorrhagic cystitis that occurs in the first few days after transplantation is thought to be a result of toxicity of the immunosuppressive drugs. A late-onset hemorrhagic cystitis (2–12 weeks post transplant) which occurs in some recipients is of a longer duration (longer than 7 days). BKPyV viruria is strongly associated with the late-onset disease. In one study where BKPyV viruria, as estimated by an ELISA assay, was related to 16 of 18 well-characterized cases, BKPyV was detected in 55 % of the urines collected during the cystitis episodes and 8–11 % of specimens collected in cystitis-free periods [173]. The onset and termination of BKPyV viruria often coincided with the onset and termination of the disease. BKPyV viruria levels in patients with hemorrhagic cystitis are much higher than those in the viruria in asymptomatic BMT patients [174]. BKPyV viruria in BMT recipients may also be associated with gross or microscopic hematuria without evidence of clinical cystitis [175]. In a study of hemorrhagic cystitis in 26 children receiving stem cell transplantation, BKPyV viruria was found in 21 children, adenovirus viruria in 4 children, and JCPyV viruria in a single child [176]. The intensity of the conditioning regimen and allogeneic transplant are additional risk factors for BKPyV-associated hemorrhagic cystitis [177]. The disease may also occur in HIV-infected individuals who have not received a transplant [178] or in individuals who have received transplants other than bone marrow.

8.1.4 Relation of JCPyV and BKPyV to Human Cancer

Polyomaviruses are oncogenic for experimental animals and many can transform human cells. Therefore, a variety of human tumors have been investigated for possible polyomavirus etiology. Tumor tissues or tumor-derived cells have been

examined for viral particles, viral T antigens, viral genomes, and viral transcripts. For most of the positive studies, the copy number per cell, when estimated, has been much less than one, and supporting evidence for the presence of virus (e. g., detection of virus in tumor cell by in situ hybridization, presence of viral transcripts) has been lacking. Other studies of the same tumor types have been negative. Therefore, it has been difficult to decide if the positive studies represent virus involvement in tumor formation, or detection of a persistent infection in rare cells present in tumor tissue, or laboratory artifacts. In addition to the studies of viral sequences, sera from cancer cases and controls have been screened for antibodies to viral capsid and T antigens. The International Agency for Research on Cancer (IARC) has reviewed extensively the data on the carcinogenicity for humans of JCPyV, BKPyV, and MCPyV (IARC vol104). The Agency examines both the evidence in experimental animals and in humans. In analyses of the human evidence, it puts more emphasis on prospective and case-control studies than on case reports and case series. The evidence IARC has reviewed and its conclusions are summarized below.

JCPyV

It has been suggested that brain tumors that coexist with PML may have a JCPyV etiology [179, 180]. In patients without PML, JCPyV DNA and T antigen have been reported in an oligoastrocytoma [181], and JCPyV DNA has been amplified with nested PCR from a xanthoastrocytoma [182]. Several investigators have reported JCPyV sequences from brain tumors [183–185], but other studies of similar brain tumors have been negative [186–188]. JCPyV sequences have also been reported from leukemia and lymphoma [189] and from colon tumors [190].

The IARC (vol 104) classified JCPyV as possibly carcinogenic to humans (group 2B) [191].

BKPyV

BKPyV sequences have been reported from a wide variety of human tumors which include pancreatic B-islet adenomas [192], brain tumors of several histological types [193], osteosarcoma [194], Kaposi sarcoma [195], kidney carcinoma [196], childhood neuroblastomas [197], and prostate carcinoma [198]. Other studies of brain tumors have been negative [186–188].

In a patient with both a kidney and pancreas transplantation, the recipient developed BKPyV-produced interstitial nephritis as well as a carcinoma of the bladder with widespread metastases. High levels of BKPyV T antigen were detected in the primary tumor as well as in the metastatic carcinoma [199]. This patient may represent the carcinogenic potential of BKPyV in a severely immunosuppressed individual. But BKPyV is not a common cause of bladder carcinomas. In another study, BKPyV sequences were not detected in tissues of transitional cell carcinoma of the bladder [200].

The IARC (vol 104) classified BKPyV as possibly carcinogenic for humans (group 2B) [191].

8.1.5 Merkel Cell Carcinoma

Merkel cell cancer (MCC) is an aggressive neuroendocrine cancer of the skin. The presence of electron dense neurosecretory granules in the tumor cells allowed for classification as a neuroendocrine tumor, and since Merkel cells are the only cutaneous cells which form such granules, it was postulated that these carcinomas derive from Merkel cells. However, alternative hypotheses suggesting a role for skin stem cells of epidermal lineage or immature B lymphocytes have also been proposed [201, 202]. The incidence of MCC is about 1,500 cases per year in the USA, and has been increasing in the USA, with an estimated annual percentage change of 8 % during the period from 1986 to 2001 [203]. Whether the increase is due to a true rise in the incidence of MCC or improved diagnosis is unknown. The cancer presents as a rapidly growing, painless, firm, non-tender, dome-shaped red skin nodule, most commonly involving the head and neck, less commonly the extremities, and rarely the trunk. At presentation the disease is usually localized but it can spread to regional lymph nodes and metastasize widely. In one series, the median survival was 40 months for patients with localized disease and 13 months in those with distant metastases [204]. Exposure to sunlight and ultraviolet (UV) light are recognized risk factors for MCC, based on its anatomic predilection, geographic distribution, association with white fair-skinned individuals, and association with other UV light-related skin cancers. Immunosuppression is an additional risk factor since the disease has an unusually high prevalence in organ transplant recipients, HIV-infected patients, and those with B cell malignancies [90, 205–208]. However, the vast majority (>90 %) of MCC patients have no clinically apparent immune dysfunction [92]. The primary treatment modality for localized disease is surgical excision. MCC is a radiosensitive malignancy and adjuvant radiotherapy has been advocated for local and regional disease control [209]. Because involvement of regional lymph nodes is common in MCC at presentation, prophylactic lymph node dissection is sometimes employed in treatment of localized disease [210, 211]. The prognosis for patients with distant metastases is very poor. Various chemotherapeutic regimens have been tried with limited success [212, 213].

In 2008 a novel polyomavirus was detected in Merkel cell cancer tissue using next-generation high-throughput sequencing of cDNA and analysis of the sequence data for nonhuman sequences with homology to known viral sequences in public databases [9]. Two transcripts were identified with partial homology to lymphotropic polyomavirus (LPyV). A complete polyomavirus genome was sequenced from tissue DNA and shown to differ from previously known human polyomaviruses and given the name Merkel cell polyomavirus (MCPyV).

The virus was detected by Southern blot in 8 (80 %) of 10 cases and, in 6 tumors, the restriction digestion pattern was consistent with monoclonal integration into the host genome. Subsequent studies have generally supported the estimate for the proportion of Merkel cell cancers containing MCPyV DNA [214–217]. Determination of viral load in MCC tissue by quantitative PCR has shown copy numbers ranging from 0.05 to 173 copies per cell [218, 219]. Of note, although MCPyV DNA has also been detected in normal skin and other non-MCC tissues, the viral copy number per cell equivalent of DNA in these samples is several orders of magnitude lower than that in MCC tissues which have high copy numbers. In nearly all tumor-derived MCPyV genomes sequenced, missense mutations or deletions in the early region result in the expression of truncated large T antigen proteins [218, 220]. The large T antigen proteins retain domains capable of binding pRB, but lose their helicase domains and p53 binding domains. Although clearly lacking all the functions of an intact large T antigen, the truncated form of the protein has been shown to be essential for the survival of MCPyV-positive tumor cells in vitro and for their sustained proliferation [221, 222]. None of the reported mutations affect expression of an intact small t antigen oncoprotein. Seroprevalence studies show that MCPyV, like other human polyomaviruses, is highly prevalent in human populations and that exposure occurs during childhood. Precisely when MCPyV infects Merkel cells and what events need to occur for development of MCPyV-associated tumors are unknown.

Human Carcinogenicity of MCPyV

The paradigm of small DNA tumor virus-induced carcinogenesis envisions a necessary role for viral oncoproteins in activation of transduction pathways and interference in tumor suppressor pathways in order to induce cells to enter the cell cycle and proliferate. These functions are essential for the viral life cycle, which depends on an actively dividing cell to provide the host machinery for viral replication. However, in a cell which is not permissive for a lytic viral infection, the induction of cell division can cause oncogenic transformation of the cell and lead to a cancer. Transformation caused by MPyV, SV40, JCPyV, and BKPyV has been extensively studied and reviewed in the literature [223–227]. Transformation requires functions of the large T antigen, small t antigen, and in some cases proteins encoded by alternately spliced early region transcripts. Although the precise mechanism of transformation differs among the polyomaviruses, the ability of large T antigen to bind p53, the retinoblastoma protein (pRb), and heat shock protein 70 and that of small t antigen to bind protein phosphatase 2A (PP2A) appears to be essential.

The mechanism of MCPyV-induced cell transformation is still poorly understood. In most MCPyV-positive MCC tumor tissues, the virus is integrated into the host chromosome [9, 228], a signature feature of virus-induced tumors since it allows maintenance of the viral genome in dividing cancer cells. Integration sites within the host genome are unique for each patient and the break points within the viral genome are also unique, but they occur mainly in the second exon of the large T antigen [9, 228]. There is no evidence that integration occurs in cellular genes implicated in carcinogenesis. A requirement for oncogenic viral proteins for maintenance of MCC cells was demonstrated by growth arrest and cell death of MCPyV-positive cell lines in vitro when all early region transcripts were inhibited by siRNA knockdown [221]. Selective knockdown of MCPyV small t antigen alone has also been shown to retard growth of virus-positive cell in vitro [229]. MCPyV small t antigen, unlike that of SV40 and MPyV, is sufficient to cause transformation in rodent cell assays and is not dependent on interactions with PP2A [229]. Perhaps uniquely, MCPyV small t antigen perturbs the PI3K-Akt-mTOR pathway, which is important for cap-dependent translation, by maintaining hyperphosphorylation of the eIF4E binding protein via an unknown mechanism [229]. MCPyV large T antigen and small t antigen expression have been detected by immunohistochemistry in the majority of MVPyV-positive MCC tumors [218, 229]. Serum antibody directed against a shared portion of early region proteins can be detected in up to 40 % of MCC cases, while these antibodies are present in <1 % of virus-positive healthy controls [230]. Humoral immune responses to viral oncoproteins are also seen in patients with papillomavirus-associated cervical cancer and head and neck cancers and are tumor-specific markers [231, 232].

The IARC (vol 104) on the basis of the strong mechanistic evidence for its carcinogenicity classified MCPyV as "probably carcinogenic for humans" (Group 2A) [191].

8.1.6 Other Human Polyomaviruses

In addition to JCPyV, BKPyV, and MCPyV, described above, eight other polyomaviruses have been recovered from humans.

KIPyV and WUPyV Polyomaviruses

The genomes of these two viruses were recovered and identified from respiratory secretions of individuals with mild respiratory illness [7, 8]. They are closely related, sharing 65–70 % amino acid identity with each other as compared to only 15–50 % identity with JCPyV and BKPyV. The antibody prevalence to these viruses in the general population is high, 55–90 % for KIPyV and 69–98 % for WUPyV virus [36, 233, 234]. Although these viruses were detected in respiratory secretions, subsequent studies have failed to identify a role for KIPyV or WUPyV in respiratory tract disease in healthy children or immunocompromised children [235, 236]. At present the viruses are not associated with any specific illness.

Human Polyomavirus 6 (HPyV 6), 7(HPyV 7), and 10 (HPyV 10)

HPyV 6, HPyV 7, and HPyV 10 were detected in human skin swabs using the rolling circle amplification technique [10, 11]. At present there is no illness associated with these viruses. Due to the lack of serological reagents, the prevalence of infection in human populations is unknown. Likewise, the natural history of infection with these cutaneous human polyomaviruses is also unknown, although they are suspected to share many features of the natural history of MCPyV.

Trichodysplasia Spinulosa-Associated Virus (TSV)

Trichodysplasia spinulosa (TS) is a rare disease of the skin which occurs in recipients of solid organs on immunosuppressive therapy and in patients with lymphocytic leukemia [237–239]. The patient develops follicular papules and keratin spines (spicules) on the face, often accompanied by alopecia of the eyebrows and of the eyelashes. Pathologically, the hair follicles are markedly distended and show abnormal maturation. The inner root sheath cells of the follicles are highly proliferative and contain polyomavirus-like particles, as seen by electron microscopy [237].

TSV genome was isolated from plucked spicules of a TS patient [12] and has also been detected in lesions of other TS patients [240]. Phylogenetically, TSV is tightly linked to Bornean orangutan polyomavirus, and among human polyomaviruses, it is closest to MCPyV [240] . It is a common human infection, with antibody prevalence of 80 % in adults and 89 % in renal transplant recipients [240, 241]. The presence of TSV in high copy numbers in the pathological lesions of TS suggests that the virus may be etiologically related to TS.

Human Polyomavirus 9 (HPyV 9)

Scuda et al. [13] identified a human polyomavirus, HPyV 9, from blood and urine of renal transplant recipients, which is closely related to a virus reported in the 1970s from African Green monkey, now named B-lymphotropic polyomavirus (LPyV) [14, 242]. A virus nearly identical to HPyV 9 has also been recovered from the skin surface of a patient with Merkel cell carcinoma [243]. The virus was shed for >20 months from this patient and was also found on the skin of his spouse. Using a capsomere L1 ELISA, an HPyV 9 seroprevalence of 47 % was determined in healthy adults and adolescents and 20 % in a group of children [244]. In another study using a viruslike particle-based ELISA, the seroprevalence of HPyV 9 among adults was approximately 33 % and that among children 1–7 years of age was 10 % [245]. These studies suggest that exposure to this virus is less common than that to the other human polyomaviruses and that infections occur at all ages. Both studies demonstrated cross-reactivity between LPyV and HPyV 9, and thus substantiated the hypothesis put forth in 1981 that human seroreactivity to LPyV, which was discovered in African green monkey cells, might signify the existence of a human virus closely related to LPyV [242].

Malawi Polyomavirus (MWPyV) and HPyV10

A novel polyomavirus was discovered in the stool of a healthy child from Malawi using shotgun pyrosequencing of purified viruslike particles recovered in feces, and the virus was named Malawi polyomavirus (MWPyV) [15]. The virus was also detected in stool samples from the United States suggesting it has a wide geographic distribution. At present it is unknown whether the virus causes infection in humans or is an environmental contaminant present in stool. There is no known illness associated with the virus. It shares 99 % homology with HPyV10, a virus detected in skin specimens from a patient with a rare genetic disorder known as warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome, and may be the same viral species [11].

8.1.7 SV40 and Human Disease

The possibility that millions of people in the USA may have been exposed to live SV40 between 1956 and 1960 because SV40 was a contaminant of the polio vaccines and the adenovirus vaccines, combined with the demonstration that SV40 was oncogenic in laboratory animals, sparked many investigations to determine if the virus caused any harm in humans. The review of the circumstances of the human exposure to SV40 and of the early studies concluded that while there were no immediate dire consequences following SV40 exposure, continued surveillance was necessary to detect neurological disease and cancers which may occur at a low frequency and after a long interval [4].

Beginning in 1992 several laboratories, employing PCR technology, reported the detection of SV40 sequences in pediatric brain tumors [246], mesothelioma [247], osteosarcoma [248], non-Hodgkin lymphoma [249, 250], and other tumors. The proportion of tumors reported to be positive for SV40 was high (20–60 %), but the SV40 copy number per cell in the virus-positive tumors, when estimated, was quite small, much lower than one copy per cell. The authors of these studies suggested that SV40 was circulating in the human population and it may have contributed to the development of these tumors. Other studies of the same tumors for SV40 sequences were essentially negative for mesothelioma [251], brain tumors [187, 252], and non-Hodgkin lymphoma [253, 254]. In a blinded study, the SV40 PCR assays were evaluated in nine participating laboratories; SV40 sequences were found at about the same low frequency in mesothelioma, normal lung, and negative controls [255]. In a careful study, Lopez-Rios et al. [256] definitively identified contamination with common laboratory plasmids that contain SV40 sequences as the reason for false-positive data in SV40 PCR in their own laboratory and also identified a previously published study from another laboratory [257] where plasmid

contamination may have led to false-positive data. Despite more than 50 reports of SV40 genomic sequences in tumors, firm evidence of SV40 genomes or of SV40 transcripts in tumors is lacking.

It has been known since the 1960s that a small proportion of human sera have low antibody titers to SV40 [258]. After the discovery of human polyomaviruses JCPyV and BKPyV in 1971, this reactivity to SV40 has been shown to be a result of cross-reactivity with antibodies to JCPyV and BKPyV [30, 32]. In case-control studies of mesothelioma, brain tumors, and lymphomas SV40, seroreactivity in cases was similar to that in controls [251, 259–261].

The risks of mesothelioma, brain tumor, and non-Hodgkin lymphoma have also been compared in epidemiologic studies where populations exposed to potentially contaminated polio or adenovirus vaccines were compared to those not exposed to these vaccines [262–264]. These studies revealed no evidence that the risk of these cancers was greater in groups more likely to have received contaminated vaccine.

A working group at the International Agency for Research on Cancer concluded that "in view of the strongly negative human data on infection and carcinogenesis, SV40 is "not classifiable as to its carcinogenicity to humans" (Group 3) [191].

8.2 Diagnosis

All of the recognized illnesses associated with JCPyV and BKPyV infections are caused by infection and lysis of specific cells by the viruses. As described in previous sections, characteristic cytological and pathological features and demonstration of the viruses from affected tissues by PCR allow diagnosis of the diseases. For MCPyV-associated Merkel cell carcinoma, the diagnosis can be made by histology showing cells with the characteristic monoclonal antibody staining pattern of Merkel cells, the presence of electron dense neurosecretory granules and the detection of MCPyV by PCR [265, 266].

9 Control and Prevention Based on Epidemiologic Data

9.1 PML

A large majority of cases of PML occur in HIV-infected individuals. Preventing HIV by a vaccine or by drugs or by change in behavior would have a major impact on the incidence of PML. Treatment of HIV-infected individuals who also have PML by highly active antiretroviral treatment (HAART) has been reported to be beneficial for PML patients [152, 267]. With the continued improvement in antiretroviral therapy, the progression of HIV infection to AIDS is less rapid and less frequent, and many more infected individuals now lead a near-normal life. They are less likely to develop PML.

Because years may elapse between infection with HIV and the onset of PML, it would be useful to find predictors of PML in HIV-infected patients. In a study of 28 HIV-infected PML patients for whom specimens were available up to 12 years (median 6.4 years) before the diagnosis of PML, JCPyV viruria, viremia, and antibody status were examined for their predictive value [268]. The frequency of viruria in HIV-infected individuals who developed PML was similar to that in individuals who did not develop PML, but persistent viruria was more common in cases than controls. No cases had detectable viremia prior to diagnosis. In a study of prediagnostic serum viral markers among 83 HIV-infected PML cases with samples collected every 6 months up to 2.5 years before diagnosis, an increase in JCPyV IgG levels was observed in cases compared to controls in the 6-month window preceding diagnosis [119]. There was no statistically significant difference in plasma JCPyV viremia between cases (17 %) and controls (12 %). The viremia was low titered in both cases and controls.

9.2 BKVAN

In contrast to PML in HIV-infected individuals where no predictors of PML were identified, BKVAN can be predicted in renal transplant recipients. Screening of recipients by urinary cytology and BKPyV viruria will identify patients who are at risk for BKVAN, and presence and level of BKPyV viremia implies impending or concurrent BKVAN. This allows the clinician to change or reduce the immunosuppressive regimen and may lead to patient recovery.

It has been suggested that BKVAN in the transplanted kidney is a result of deficient BKPyV-specific T cell immunity, which allows the recrudescent virus to infect and destroy the transplant [171]. It may be possible to bolster BKPyV-specific immunity for all transplant patients by appropriate immunization.

9.3 Merkel Cell Carcinoma

MCPyV infects many individuals early in life, and it is not known why in a few instances the infection leads to carcinoma. The risk factors for Merkel cell carcinoma are not known well enough to identify protective measures.

9.4 Vaccines

Almost all the pathogenic effects of human polyomaviruses are related to recrudescence of the virus which remains persistent at a very low level after primary infection. It may be

possible to prevent the primary infections by prophylactic vaccines. However, the vaccines would have to be administered in early childhood and may need to be repeated in subsequent years. At present, there are no candidate prophylactic vaccines against any of the human polyomaviruses. It may be possible to boost immunity in patients who have been previously infected and are at risk for disease, such as prospective recipients of renal transplants. Whether a vaccine should target humoral or cellular immune responses is unknown. In general, cellular immunity is required to clear an established infection. Some hope has been raised by the success achieved at preventing herpes zoster (shingles), a disease caused by the reactivation of varicella zoster virus, with a vaccine that elicits antiviral cellular immunity. However, the genetic mismatch between the recipient and kidney donor may limit the development of a similar approach for BKVAN. Development of therapeutic vaccines for the treatment of cancer is an active area of experimental and clinical research. Intratumoral MCPyV-specific CD4+ and CD8+ T cells have been detected in Merkel tumors, and the presence of intratumoral CD8+ lymphocytes is associated with improved survival [127, 269]. Experimental DNA vaccines that elicit cellular immune responses to MCPyV large T antigen have shown efficacy in animal models with MCPyV large T antigen expressing tumors [270, 271].

10 Unresolved Problems

10.1 Pathogenesis of PML

It is not clear if PML is caused by recrudescence of a persistent low-level JCPyV infection which is already seeded in the brain during primary infection or if the virus in the urinary tract or other sites of persistence is amplified and crosses the blood-brain barrier to infect the brain. JCPyV recovered from PML brains shows specific changes in the regulatory region of the genome, which presumably enable the virus to multiply in the brain. It is not known if these changes occur in the virus prior to the establishment of a lytic infection in the central nervous system or if the changes occur in the course of prolonged multiplication of the virus in the brain.

10.2 Is MCPyV Infection Etiologically Linked to Merkel Cell Carcinoma?

A minority of Merkel cell carcinomas is virus negative. Does that represent a disease etiologically distinct from virus-positive Merkel cell carcinoma and with different risk factors? If they are the same disease, what is the role of MCPyV in the formation of the tumor? The virus-tumor association should be evaluated for its strength, consistency, specificity, plausibility, and temporality [272].

10.3 Pathogenesis of MCPyV-Associated Cancer

In nearly all MCPyV-positive MCC tumors, the early region open reading frame contains mutations leading to a predicted truncated form of the large T antigen protein, which eliminates the p53 binding region [228, 273, 274]. Since mutations in the p53 gene are uncommon in MCC [275], how the virus causes cancer without affecting p53 function remains unclear.

Part IV

Other Transmissible Agents

Prion Diseases

47

Ermias D. Belay and Jason C. Bartz

1 Introduction

Prion diseases, also known as transmissible spongiform encephalopathies, are a group of invariably fatal neurodegenerative diseases that affect both humans and animals. They are caused by an unconventional agent termed a prion. Strong evidence indicates that their etiology and pathogenesis involve modification of a host-encoded normal cellular protein known as the prion protein (PrP^C) [1, 2]. Unusual characteristics of prion diseases include their occurrence sporadically without any apparent environmental source of infection in some species, genetically in association with specific prion protein gene mutations in humans, and their transmissibility either within or across different species [2]. In most prion diseases, characteristic neuropathologic features include widespread neuronal loss, spongiform lesions, and astrogliosis, corresponding with accumulation of the agent in different parts of the brain. The presence of the abnormal prions can be demonstrated in the brain and often in other tissues of humans and animals affected by prion diseases [3–6]. Several laboratory tests such as immunohistochemistry and biochemical tests are used to determine the presence of infecting prions in tissue specimens [4, 6, 7]. Acquired forms of prion diseases have very long incubation periods often lasting for years and sometimes even decades [8–10].

Prion diseases of humans include kuru, Creutzfeldt-Jakob disease (CJD), variant CJD, Gerstmann-Sträussler-Scheinker syndrome (GSS), and fatal familial insomnia (FFI) (Table 47.1) [2, 11].

Kuru was first described in the 1950s as a fatal ataxic neurologic disease among the Fore tribe of the highlands of Papua New Guinea [9, 12–15]. In 1959, Hadlow made the crucial observation that the neuropathology of kuru was similar to scrapie, raising the possibility that, similar to scrapie, kuru might also be transmissible [16, 17]. However, transmissibility was not confirmed until the 1960s when Gajdusek and colleagues successfully transmitted kuru by intracerebral inoculation of brain tissue from deceased patients into chimpanzees [18–23]. This was the first instance of human prion disease to be successfully transmitted to experimental animals.

Kuru is the first epidemic human prion disease to be thoroughly investigated. Since the 1950s, over 2,700 kuru cases have been documented [9, 24]. Strong epidemiologic evidence suggests that the disease spread among the Fore people by ritualistic cannibalism. In ancient Fore culture, giving respect for the dead involved a mourning ritual with plastering of brain tissue all over the body, including mucous membranes and consumption of the decedent's body parts. Relatives who died of kuru were honored with this practice exposing surviving family members to infectious brain tissue which might have amplified the kuru epidemic [25, 26]. After the ritualistic practice ended in the late 1950s, the number of new cases dramatically declined and no persons born after 1959 developed the disease. Likely incubation periods of the most recent seven male cases reported by Collinge et al. ranged from 39 to 56 years, although the longest incubation period may have been up to 7 years longer [9].

Prion diseases of animals include scrapie in sheep, goats, and mouflon; bovine spongiform encephalopathy (BSE) in cattle; feline spongiform encephalopathy in domestic and zoo cats; ungulate spongiform encephalopathy in exotic zoo ruminants; chronic wasting disease (CWD) in deer, elk, and

Table 47.1 Animal and human prion diseases

Type of prion disease	Affected host	Year first described or identified	Mode of disease transmission/occurrence
Animal prion diseases			
Scrapie	Sheep and goats	1730s	Contaminated environment, possibly direct contact, oral
Bovine spongiform encephalopathy	Cattle	1986	Contaminated feed, oral
Chronic wasting disease	Deer, elk, and moose	1967	Contaminated environment, direct animal contact, oral
Transmissible mink encephalopathy[a]	Mink	1947	Contaminated feed, oral
Feline spongiform encephalopathy[b]	Domestic and wild cats	1990	BSE-contaminated feed, oral
Ungulate spongiform encepahlopathy[b]	Exotic ruminants (e.g. kudu, nyala)	1986	BSE-contaminated feed, oral
Human prion diseases			
Kuru		1950s	Ritualistic cannibalism involving brain tissue ingestion, oral
Sporadic CJD		1920s	Unknown
Iatrogenic CJD		1974[c]	Via pituitary hormones, dura and cornea grafts, neurosurgical equipment
Variant CJD		1996	Consumption of BSE-contaminated cattle products, human blood products
Familial CJD		1924	Prion protein gene germline mutations, inherited
Gerstmann-Sträussler-Scheinker syndrome		1936	Prion protein gene germline mutations, inherited
Fatal familial insomnia		1986	Prion protein gene germline mutations, inherited

CJD Creutzfeldt-Jakob disease
[a]The last known outbreak of transmissible mink encephalopathy occurred in 1981 in Wisconsin
[b]The known feline and ungulate spongiform encephalopathies are believed to have resulted from BSE transmission
[c]The first report of iatrogenic CJD was in 1974 in a recipient of cornea obtained from a CJD decedent; human pituitary growth hormone-associated CJD was first reported in 1985 and dura mater graft-associated CJD in 1987

moose; and transmissible mink encephalopathy (TME) in farmed mink (Table 47.1) [27].

Epidemiologic evidence indicates that feline and ungulate spongiform encephalopathies were caused by transmission of the BSE agent via consumption of BSE-contaminated feed [28]. Although strong evidence is lacking, speculations persist that scrapie in sheep was the original source of prion diseases in other animals, such as BSE and CWD.

TME occurred in outbreaks among farmed mink primarily in the United States but also in Canada, Finland, Germany, and Russia [28]. TME outbreak investigations suggested that the disease was causally linked with consumption of scrapie-contaminated meat [28]. The last known outbreak of TME occurred in 1985 in Wisconsin. An investigation of this outbreak indicated that the mink on that particular farm were fed only downer cattle, igniting much speculation about the existence of a spontaneous prion disease in cattle even before BSE was identified in the United Kingdom. Non-epizootic cases of TME have not been reported.

2 Etiologic Agent of Prion Diseases

Before the 1980s, prion diseases were widely believed to be caused by "slow viruses" despite the fact that no viral particles or disease-specific nucleic acids were identified in association with scrapie transmission in laboratory animals [29, 30]. The scrapie agent, which was most widely studied at the time, could not be grown in cell culture. Its successful transmission to laboratory mice in 1961 greatly facilitated research efforts to understand the nature of the agent [1]. Because of the long incubation period associated with scrapie, transmission to wild-type mice was tedious and in many instances required a year to complete. Development of transgenic mice greatly facilitated prion disease research by allowing closer modeling of the diseases and reducing the incubation period in the experimental models [31, 32].

Two distinctive properties of the scrapie agent led to the suspicion that the agent was devoid of nucleic acids and, thus, may not be a virus but primarily composed of a protein. These properties included: (1) resistance of the scrapie agent to procedures, such as treatment with ultraviolet light and ionizing radiation, that normally inactivate other microorganisms, including viruses, and (2) the reduction of scrapie infectivity by procedures that denature or degrade proteins [1]. The concept that the scrapie agent might replicate in the absence of nucleic acids or might just be a protein was postulated as early as the 1960s by Alper and colleagues, Pattison and Jones, and Griffith [30, 33, 34]. In 1982, Prusiner and colleagues described the successful enrichment of a hydrophobic protein, the presence of which was required for scrapie transmission in laboratory animals [1, 35, 36]. Prusiner

introduced the term "prion" to describe this protein by borrowing and mixing the first few letters from the descriptive phrase "*pro*teinaceous *in*fectious" particle [1]. Since then, additional evidence has accumulated indicating that prions may be acting alone in causing prion diseases. However, the critical steps in the production, propagation, and pathogenesis of this infectious protein remain unclear. As a result, the study of prions has become an important, relatively new area of biomedical research. Some critics of the prion hypothesis still believe that nucleic acids undetected by current methods may play a crucial role in the pathogenesis of prion diseases [37–40]. Prions seem to be almost entirely composed of proteins with a glucose moiety attached to them. Creation of prion infectivity by modifying the conformation of synthetic or recombinant polypeptides has led credence to the view that prions may entirely consist of proteins with no nucleic acid genome [41, 42]. How a protein-only agent would confer strain specificity to prions causing different diseases in different species has been a topic of debate for many years. Studies have suggested that strain specificity may be enciphered in the different physical properties of prions and their varying protein conformations.

2.1 Cellular Prion Protein

Soon after the nature of infecting prions was described, researchers discovered the similarity of the abnormal prions with that of a normal protein found as a structural component of cell membranes [43–45]. This discovery marked a turning point in our understanding of prion diseases and partially explained the absence of inflammatory infiltrates in pathologic specimens of infected tissues and the lack of humoral response in several prion diseases. PrP^{C} is usually found as a monomeric GPI-linked glycoprotein on the cell membrane and is soluble in mild detergents. In humans, PrP^{C} is encoded by the prion protein gene located on the short arm of chromosome 20 [43, 44]. Similar to other proteins, PrP^{C} is produced in the endoplasmic reticulum and transits through the Golgi apparatus to the cell surface.

PrP^{C} is expressed in large quantities in neurons, but it is also expressed in lymphoid tissues and other organs and tissues in relatively smaller quantities. Several possible functions have been proposed for PrP^{C} [46]. Its location in parts of the cell membrane specializing in signaling was believed to indicate that it may be involved in signal transduction. Other studies have hypothesized that PrP^{C} interacts with other membrane proteins to provide neuroprotective functions, although more direct evidence is lacking. Another perhaps more widely studied proposed function of PrP^{C} is binding copper and involvement in its metabolism [46]. PrP^{C} readily binds copper in physiologic concentrations, and its overexpression has been shown to promote cellular uptake of copper, indicating that it may play a significant role in copper homeostasis [46].

Prions appear to be composed largely or entirely of the abnormal protein designated as PrP^{Sc}. The underlying pathophysiologic mechanism in the occurrence of prion diseases involves the biochemical conversion of PrP^{C} into the pathogenic PrP^{Sc}. This conversion occurs by a poorly defined post-translational autocatalytic process, possibly requiring the aid of cofactors such as proteins or nucleic acids. It appears that PrP^{Sc} reproduces itself by recruiting PrP^{C} and stimulating its conversion into the disease-causing isoform [47–51]. This conformational change confers protease-resistant properties to PrP^{C} and a three-dimensional structure distinguishable from the infecting prions [49, 52]. The initial instigating PrP^{Sc} molecule may originate from exogenous sources or within the brain from somatic or germ line prion protein gene mutations. Knockout mice devoid of the prion protein gene are resistant to scrapie infection, indicating that the production of PrP^{C} is required for the generation and propagation of PrP^{Sc} [53]. During its conversion, PrP^{Sc} acquires more beta-sheet structure that renders it resistant to proteolytic enzymes, conventional disinfectants, and standard sterilization methods. A higher proportion of the tertiary structure of PrP^{C}, on the other hand, is composed of alpha helices which make it more sensitive to denaturation by proteinase-K treatment [54, 55]. Removal of the neuroprotective functions of PrP^{C} as more of it becomes converted to the pathogenic PrP^{Sc} and accumulation of PrP^{Sc} in neurons have been suggested as major contributory factors in the underlying pathogenesis of prion diseases and widespread neuronal death.

3 Creutzfeldt-Jakob Disease

CJD is the most common form of prion disease in humans and has been reported in all continents of the world. It was first recognized in Europe in the early 1920s and bears the name of two German neurologists, Hans Gerhard Creutzfeldt and Alfons Maria Jakob, who separately reported patients with rapidly progressive neurodegenerative diseases [56]. At least two of the patients initially reported by Jakob had the typical neuropathologic features that have since been recognized as the hallmark of CJD.

The clinical manifestation of CJD is usually characterized by the onset of dementia, ataxia, or behavioral abnormalities. As the disease progresses, patients commonly develop dysarthria, movement disorders such as gait abnormalities, myoclonus, and tremors. These neurologic deficits are rapidly progressive and patients often develop akinetic mutism towards the terminal stages of the illness, usually over a period of weeks to several months [57–62]. CJD is invariably fatal with median illness duration of about 4 months. Over 50 % of patients die within 6 months and about 80 % within 1 year of disease onset [57]. The presence of a characteristic electroencephalogram (EEG) finding of triphasic, periodic sharp wave complexes can be demonstrated with multiple

testing in approximately 75 % of patients [63–65]. Elevated levels of 14-3-3 proteins in the cerebrospinal fluid (CSF) can also be found in most CJD patients [66–71]. Elevated CSF 14-3-3 is a marker for rapid neuronal death and, in the appropriate clinical context, can often help in making a premortem diagnosis of CJD. This test is nonspecific, however, and may be elevated in other neurologic conditions that result in rapid neuronal death. A similar CSF test that detects tau proteins can also aid in the premortem diagnosis of CJD. Elevated tau protein levels in combination with a positive 14-3-3 test may increase the sensitivity and specificity of a CJD diagnosis [71]. Magnetic resonance imaging (MRI) findings showing high intensity in the basal ganglia and cortical regions of the brain have been correlated with a CJD diagnosis [64, 72–79]. The characteristic EEG and MRI findings and elevated levels of 14-3-3 in the appropriate clinical context are used as diagnostic criteria for CJD [78].

In the United States, the median age of CJD patients at the time of death is 68 years with approximately 70 % of cases occurring between 55 and 75 years of age (Fig. 47.1) [80–82]. Overall, CJD has been reported in many countries with an annual incidence ranging from one to two cases per million populations, including in the United States (Fig. 47.2). However, the incidence increases with age and approaches five cases per million populations for those ≥65 years of age. A decline in CJD incidence in persons ≥80 years of age has been consistently reported in many developed countries which may be due to ascertainment bias in this older age group. In the United States, epidemiologic studies have consistently shown that the incidence of CJD is at least 2.5 times lower in blacks than whites [81–83]. The precise reason for this wide discrepancy is not well understood, but under diagnosis among black populations is unlikely to entirely explain the striking difference in CJD incidence. The age-adjusted incidence for males in the United States is slightly higher than that for females, particularly among those ≥60 years of age [83, 84]. CJD has been shown to occur in three different forms: sporadic, iatrogenic, and familial forms.

A definitive diagnosis of CJD can only be made by histopathologic or immunodiagnostic testing of brain tissue obtained at autopsy or biopsy. Histopathologic examination of brain tissue demonstrates the hallmark triad of spongiform lesions, neuronal loss, and astrogliosis. Since more specific diagnostic tests have been developed, histopathology alone is rarely used to confirm the diagnosis of CJD. Immunodiagnostic assays, such as immunohistochemistry and Western blot testing that show the presence of PrP^{Sc}, are widely used to confirm the CJD diagnosis. Recently, a new test termed real-time quaking-induced conversion (RTQuIC) was developed to detect prions in peripheral tissues or fluids such as the CSF, blood, or urine [85]. The detection method used in this test is based on that used in protein misfolding cyclic amplification. RTQuIC can detect minute amounts of prions and has been shown to be 80% sensitive and over 90% specific in confirming a CJD diagnosis from CSF specimens. In addition, the presence of infecting prions has been demonstrated in the olfactory epithelium of CJD patients [86]. Because these tissues are accessible from the nasal cavity, specimen collection by deep nasal swab and subsequent testing by RTQuIC has shown promising results as a non-invasive, rapid, antemortem, diagnostic assay for CJD.

Currently, no effective treatment exists for CJD or any other prion disease. Clinical management of patients is primarily supportive to ameliorate some of the aggravating symptoms of the disease [87]. Many compounds and drugs (e.g., pentosan polysulfate, quinacrine, and doxycycline) have been investigated as possible therapeutic modalities in CJD patients and in animal models [88–97]. Although some compounds have been shown to be effective antiprion agents in in vitro experiments, they were only successful in prolonging the incubation period and survival times in animal models. Prolongation of survival or no effect has been reported in human patients treated with some of the drugs that have already been licensed for indications other than CJD treatment. Limited randomized trials are underway to evaluate the usefulness of some of these drugs. Development of disease-specific treatment regimens is complicated by the fact that widespread neuronal damage has already occurred by the time signs and symptoms appear. Therefore, the ideal antiprion treatment should not only inhibit the propagation of infecting prions but also reverse neuronal damage or degeneration that may have already resulted in cognitive impairment and physical disability. Such a drug or a compound should also be able to readily pass the blood-brain barrier. Lack of a reliable antemortem test poses a challenge in diagnosing patients as early as possible so that they could be enrolled in clinical trials to initiate investigational treatment in time to alter the course of the disease.

3.1 Sporadic CJD

Sporadic CJD accounts for approximately 85 % of cases and occurs in the absence of outbreaks with no known environmental source of infection. Decades of research has not identified a specific source of infection for sporadic CJD patients. Spontaneous generation of the pathogenic prions was hypothesized as a cause for sporadic CJD, possibly resulting from age-related random somatic mutations or errors during prion protein gene expression. The surprisingly stable and uniform incidence of sporadic CJD in time and space and the absence of recognizable transmission patterns to account for a substantial number of the cases were the strongest arguments favoring the spontaneous occurrence of sporadic CJD. Not all researchers are convinced about the spontaneous occurrence of sporadic CJD, and many studies have been

Deaths obtained from the multiple cause-of-death data for 1979–1998 are based on ICD-9 codes, and those beginning in 1999 are based on ICD-10 codes with available computerized literal death certificate data. Death information was also obtained from other surveillance mechanisms; includes familial prion disease. Rates are adjusted to the US standard 2000 projected population

Table 47.2 Characteristics of subtypes of sporadic Creutzfeldt-Jakob disease (CJD) and sporadic fatal insomnia (sFI)

Subtype	Number of patients ($n=609$)	Percent	Clinicopathologic features
MM1/MV1	352	57.8	Typical CJD clinical and neuropathologic manifestations, typical EEG, rapidly progressive disease.
VV2	90	14.8	Commonly ataxia at onset and late dementia, typical EEG rare, short duration, subcortical pathology, plaque-like deposits
MV2	83	13.6	Similar to VV2 but long duration and presence of kuru-type amyloid plaques in cerebellum
MM2	52	8.5	Progressive dementia, typical EEG rare, long duration, cortical pathology, coarse spongiosis
VV1	25	4.1	Usually young age at onset, typical EEG rare, severe pathology in cerebral cortex with relative sparing of cerebellum, faint synaptic prion staining
MM2 (sFI)	7	1.1	Similar to FFI but without prion protein gene mutations

Data used in the table were obtained from the National Prion Disease Pathology Surveillance Center, Cleveland, OH
M Methionine, *V* Valine

conducted to search for possible sources of infection and risk factors for the disease [98–102].

Possible environmental sources of infection for sporadic CJD have been explored using multiple case-control studies [100–109]. Consumption of animal products, including the brain and other organs; receipt of blood and blood products; occupational exposures; and exposures via surgical procedures were evaluated in these studies. Because of the long incubation period of CJD, obtaining a reliable history of such exposures many years in the past may not be easy. In addition, exposure histories are usually obtained from next-of-kin who may not be familiar with the timing and extent of the exposures. Types of controls used (community or hospitalized) and the timing of selection and interview of the controls could also bias findings of case-control studies [109]. In a study that combined data from Denmark and Sweden, researchers attempted to minimize these biases specifically for evaluating surgical exposures by obtaining information about surgical procedures for both cases and controls from existing hospital records [102]. The study indicated that any major surgery conducted ≥20 years before CJD onset was significantly more common in cases than both matched and unmatched controls. A much larger European study using community controls showed a similar association of history of surgery with the risk of sporadic CJD, albeit using different data collection methodologies [101]. A similar study in Australia also showed that surgical procedures were significantly associated with the development of sporadic CJD [110]. No significant difference in the frequency of surgical procedures was identified among sporadic CJD cases compared with controls in a study performed in Japan [111]. These studies raised the possibility that a certain proportion of sporadic CJD cases may result from exposure to prion-contaminated surgical instruments. Because of the rarity of CJD, confirming or refuting such an association in a small proportion of patients is extremely difficult.

A possible risk of occupational transmission of CJD to health professionals has been raised repeatedly. This risk has recently been reviewed in a study published in Eurosurveillance [112]. The authors used various data sources, including published case reports, case-control studies, and surveillance data from 21 countries contributing to the EuroCJD program. A wide variety of health professionals had been reported with CJD, but the study findings did not suggest increased risk of CJD among health professionals [112].

Sporadic CJD is a heterogeneous disorder which can be further subdivided into five different subtypes based on the Western blot characteristics of protease-resistant fragment of PrP^{Sc} and the polymorphism at codon 129 of the host prion protein gene. These different subtypes, first proposed by Parchi et al., correspond with characteristic clinical and neuropathologic phenotypes (Table 47.2) [113–118]. The most common subtype is associated with a 21 kDa PrP^{Sc} fragment, designated type 1, and the presence of methionine at the polymorphic codon 129 of the prion protein gene. The phenotypic expression does not necessarily neatly fit into these various categories in some patients. In fact, both type 1 and type 2 prion fragments have been reported to coexist in up to 25 % of sporadic CJD patients [113, 119].

A cluster of sporadic prion disease cases termed variably protease-sensitive prionopathy (VPSPr) with a phenotype distinct from other known subtypes of sporadic CJD was recently reported in the United States [120]. The major distinguishing characteristics of VPSPr include sensitivity of the agent to proteinase-K digestion and clinicopathologic manifestations different from sporadic CJD patients. On Western blot analysis, the electrophoretic profile of proteinase-K-resistant fragments from VPSPr patients shows a ladder-like pattern with five major bands corresponding to fragments with different molecular weights. This pattern is clearly different from that seen in sporadic CJD patients but shares some similarities with that observed in some GSS patients. However, no prion protein gene mutations have been identified in association with VPSPr [120]. All the three codon 129 polymorphisms have been identified in patients with VPSPr with slightly variable clinical and histopathologic phenotypes, indicating that the polymorphism at codon 129 modifies the phenotype as it has been shown to do in sporadic CJD patients and several genetic prion diseases.

3.2 Iatrogenic CJD

Iatrogenic CJD, which accounts for <1 % of CJD cases, is associated with transmission of the CJD agent via medical interventions such as administration of contaminated human pituitary hormones and the use of contaminated dura mater and corneal grafts and neurosurgical equipment [121]. Iatrogenic transmission of CJD was first identified by Duffy et al. in 1974 in a patient who, 18 months before CJD onset, received a corneal graft obtained from a donor who died of confirmed CJD [122]. Since then, 10 cornea-associated CJD cases have been reported worldwide, but definitive evidence of CJD in the donors was available for only two of the cases [121, 123, 124]. In the remainder, information on the donors was unavailable or they died of conditions other than a prion disease [124]. Sporadic CJD unrelated to transplanted corneas is expected to occur among elderly patients with a history of cornea transplantations because of a large number of such patients alive in the United States (over 30,000 corneal transplantations are performed annually). Using statistical analysis, Maddox et al. have suggested that one coincidental sporadic CJD case among patients with a history of cornea transplantation is expected to occur every 1.5 years in the United States [124].

In 1977, CJD transmission was reported in two unusually young patients who underwent EEG procedures with implantation of depth electrodes 16–20 months before CJD onset; several months earlier, the electrodes were implanted in a patient who subsequently died of confirmed CJD [125]. Experimental implantation of the EEG electrodes into a chimpanzee 18 months after their original use transmitted CJD, demonstrating that the electrodes were indeed contaminated with the CJD agent [126].

Almost a decade after iatrogenic transmission of CJD was first reported in the corneal recipient and via EEG electrodes, other modes of CJD transmissions were identified, including the use of contaminated cadaveric human growth hormone in 1985 and dura mater grafts in 1987 [59, 127–132]. Reports of these initial iatrogenic CJD cases in the United States were followed by identification of similar cases in other countries [121, 128, 133–151]. Human growth hormone-associated CJD cases were primarily reported in France, the United Kingdom, and the United States. In these countries, large cohorts of young individuals were given human growth hormone (hGH) injections as a treatment for stunted growth resulting from growth hormone deficiency. Extraction of hGH by batch processing of pituitaries from multiple cadaver donors may have led to contamination of an entire batch if one of the donors was in the preclinical phase of disease or had died of CJD. In the United States, after identification of the first three hGH-associated CJD cases, a cohort of >6,000 recipients of hGH sponsored by the National Hormone and Pituitary Program were enrolled in a follow-up study. Among this cohort, as of April 2012, a total of 29 hGH recipients have developed CJD [121, 152]. All of these patients began their treatment prior to the introduction of a size exclusion chromatography purifying step in 1977. To date, no patient who began treatment with hGH purified using this method has developed CJD. A recent analysis of the US data indicated that the absence of cases among patients treated after 1977 may represent a real difference in risk between hGH produced before and after that year [152]. Worldwide, a total of 226 hGH-associated CJD patients have been identified, including the 29 US cases, 119 cases from France, and 65 cases from the United Kingdom [121]. The attack rate ranged from 0.4 % in the United States to 6.3 % in France. Incubation periods ranged from 5 to 42 years with a mean of 17 years [121].

Beginning in the mid-1980s, a parallel iatrogenic CJD outbreak was occurring among patients who received dura mater grafts. The initial case was identified by an astute physician in the United States in a patient who received Lyodura, a brand of dura mater graft processed by a German company [131, 133]. Subsequent to this report, several cases of dura mater graft-associated CJD cases were identified, including 142 from Japan, 14 from Spain, 13 from France, 10 from Germany, 9 from Italy, 8 from the United Kingdom, 5 each from Australia and the Netherlands, 4 each from Canada and the United States, and a smattering of cases from other countries [121]. Over 60 % of the worldwide 228 dura mater graft-associated CJD cases were reported from Japan, where Lyodura was used in much higher quantities than elsewhere [121, 153, 154]. In addition, isolated cases of CJD associated with Tutoplast, another brand of dura mater graft produced by a different German company, have been reported, including in the United States and Japan [137, 153, 154]. The higher number of iatrogenic CJD transmissions associated with Lyodura is believed to be due to the sourcing and processing practices prevalent at the company in the 1980s before revisions were made in response to the occurrence of the initial few Lyodura-associated CJD cases. Almost all Lyodura-associated CJD cases received products processed before these revisions were made. The mean incubation period for the cases identified worldwide was 12 years with a range of 1.3–30 years [121].

4 Bovine Spongiform Encephalopathy and Variant Creutzfeldt-Jakob Disease

4.1 Bovine Spongiform Encephalopathy

Prion diseases attracted unprecedented scientific and public attention after a large outbreak of BSE in cattle emerged in the United Kingdom in the mid-1980s and spread to other countries [155–157]. This attention increased dramatically when strong scientific evidence indicated in 1996 that the

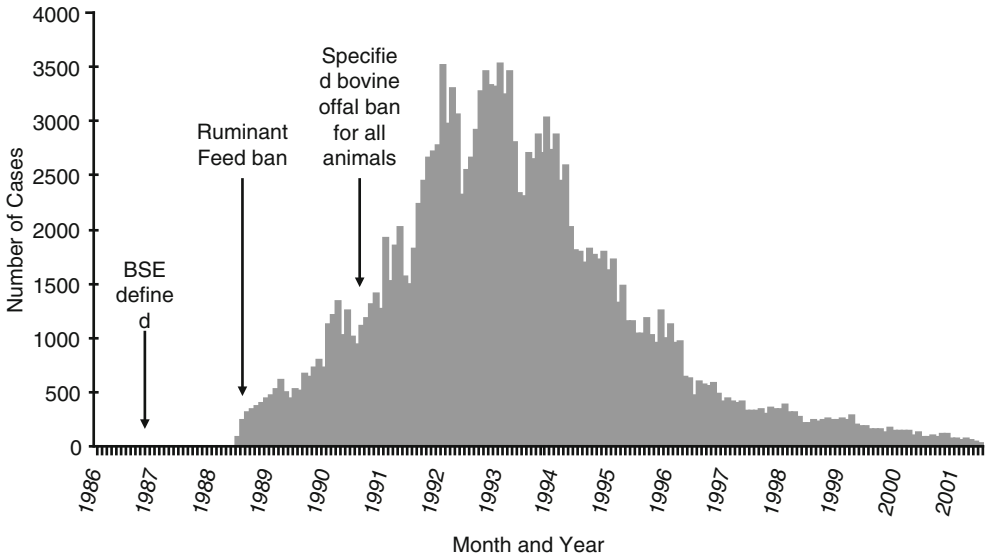

Fig. 47.3 Epidemic curve of bovine spongiform encephalopathy outbreak, the United Kingdom

BSE agent has been transmitted to humans causing a new form of CJD, later termed variant CJD [158]. The implication that prion diseases could be transmitted via contaminated food or bovine-derived products potentially exposing a large number of consumers sent shockwaves through the cattle industry and international beef trade. By far the largest number of BSE cases was reported from the United Kingdom, followed by several other European countries, including Ireland and Portugal [27, 133].

Although BSE was first recognized in the United Kingdom in 1986, undetected cases probably occurred since the early 1980s [159]. The number of UK BSE cases increased rapidly in the second half of the 1980s and early 1990s, peaked in 1992 with 37,280 confirmed cases, and has markedly declined since then (Fig. 47.3). As more stringent control measures were implemented to prevent cattle exposure to meat and bone meal, the number of confirmed UK BSE cases continued its dramatic decline throughout the late 1990s and 2000s consistent with the hypothesis that BSE was orally transmitted via contaminated meat and bone meal [27, 157, 160].

Clinically, the signs of BSE include neurologic dysfunction, including altered behavior, unsteady gait with falling, and abnormal responses to touch and sound [161]. In some animals, the onset of BSE can be insidious and subtle and may be difficult to recognize. During the early phase of the UK BSE outbreak, the public media introduced the popular term "mad cow" disease to describe the strange disease causing fearful and aggressive behavior in some of the cattle infected with BSE.

Although the original source of the BSE outbreak is unknown, the two most accepted hypotheses are cross-species transmission of scrapie from sheep to cattle and the transmission of a spontaneously occurring BSE within the cattle population [157, 160, 162, 163]. The latter hypothesis is predicated on the occurrence of spontaneous BSE, and more convincing data about its occurrence may become available with increased detection and monitoring of rates of atypical as well as classic cases of BSE [164, 165]. Strong epidemiologic evidence indicates that the practice of feeding cattle protein derived from rendered animal carcasses presumably contaminated with the scrapie or spontaneous BSE agent may have triggered the cattle epidemic [157]. In the past, cattle feed rendering in the United Kingdom involved several treatment steps, including exposure of the feed to prolonged heating in the presence of a hydrocarbon solvent. Some researchers have suggested that omission of these steps in the late 1970s and early 1980s in the United Kingdom contributed to the emergence of BSE by allowing scrapie or spontaneous BSE infectivity to survive the rendering process [157, 162, 166, 167]. Regardless of the origin of BSE, the epidemiologic evidence indicates that feeding cattle rendered BSE-infected carcasses greatly amplified the BSE outbreak. Several other factors may have contributed to the emergence of BSE in the United Kingdom, including a relatively high rate of endemic scrapie, a high population ratio of sheep to cattle, and the inclusion of rendered meat and bone meal at high rates in cattle feed.

Since the BSE outbreak was first detected, an estimated >2 million cattle have been infected with BSE in the United Kingdom [133, 167]. Approximately half of these BSE-infected cattle would have been slaughtered for human consumption, potentially exposing millions of UK residents [133, 168, 169]. Beginning in 1988, UK animal and public health authorities implemented several protective measures to prevent further exposure of animals and humans to BSE-infected cattle products. The implementation of these measures, particularly animal feed bans, led to a dramatic decline in the UK BSE outbreak (Fig. 47.3).

Because cattle carcasses were included in the production of animal feed, potential transmission of BSE to other animals was considered during the early phase of the BSE outbreak in the United Kingdom. BSE-like dis-

eases were identified in zoo animals (ungulate spongiform encephalopathy) beginning in the late 1980s and in domestic cats (feline spongiform encephalopathy) beginning in 1990, indicating the potential for the BSE agent to cross the species barrier and infect other animals [28, 170]. This development increased the concern about the possible transmission of BSE to humans and led to the establishment of enhanced CJD surveillance in the United Kingdom.

BSE was reported for the first time outside the United Kingdom in Ireland in 1989 and in Portugal and Switzerland in 1990. By August 2006, the number of countries that reported one or more BSE cases in native cattle increased to 25, including 21 countries in Europe. The four countries outside Europe that reported BSE cases are Canada, Israel, Japan, and the United States. The BSE outbreak appears to be declining in most European countries, although small numbers of cases continue to occur.

In North America, BSE was first detected in 1993 in a cow that had been imported into Canada from the United Kingdom. Rendered remains of imported cohorts of this cow may have been responsible for the BSE cases subsequently identified during 2003–2011 among cattle born in Canada. One of these cases was identified in Washington State but was later traced to a farm in Canada [171]. As of May 2012, a total of 19 BSE cases have been identified in Canada, and at least 13 of these cases were born after the 1997 ruminant feed ban which was implemented to prevent BSE transmission among cattle [172]. Because of the continued occurrence of new BSE infections after the 1997 ruminant feed ban, US and Canadian authorities tightened the specified risk material ban in 2007 by excluding potentially infectious nervous tissues from all animal feed. In 2005 and 2006, respectively, nonclassic forms of BSE termed atypical BSE were confirmed in an approximately 12-year-old cow born and raised in Texas and a 10-year-old cow from Alabama [173, 174]. The source of BSE infection for these two cows remains unknown. In 2012, as part of USDA's ongoing surveillance, a third BSE case was identified in a dairy cow aged over 10 years in California. Similar to the previous 2 BSE cases reported in the United States, the third case was reported to have atypical BSE. The initial two cases were reported with H–type and the third case with L-type BSE. The occurrence of these cases renewed speculations that atypical BSE may in fact constitute a prion disease that arises spontaneously among older potentially predisposed cattle.

4.2 Variant Creutzfeldt-Jakob Disease

In 1996, the identification of a cluster of young patients (median age, 28 years) with a prion disease was reported in the United Kingdom as part of the CJD surveillance system that was established in response to concerns about the potential spread of BSE to humans [158]. Because of the patients' unusually young age and the distinct clinical and neuropathologic findings, which were different from patients with the classic form of CJD, the occurrence of the cluster was believed to signify the transmission of BSE to humans. Since 1996, variant CJD cases increased in number and geographic distribution, and strong scientific evidence supported initial suspicions that variant CJD was indeed BSE in humans [175, 176]. As of June 2014, a total of 229 variant CJD patients were reported worldwide, including 177 patients from the United Kingdom; 27 from France; 5 from Spain; 4 from the United States; 3 from the Netherlands; 2 each from Canada, Italy, and Portugal; and 1 each from Japan, Saudi Arabia, and Taiwan [177]. Seven of the non-UK variant CJD patients (2 each from the United States and Ireland and 1 each from Canada, France, and Japan) were believed to have acquired variant CJD during their past residence or visit in the United Kingdom. The third US and second Canadian vCJD patients were believed to have acquired the disease during their residence in Saudi Arabia.

Variant CJD can be distinguished from the more common classic CJD by the clinical and laboratory findings (Table 47.3) [133, 175, 178]. The median age at death of variant CJD patients is 40 years younger than that of sporadic CJD patients (28 and 68 years, respectively); the median illness duration for vCJD is longer (14 months) than that of sporadic CJD (<6 months). The distinguishing clinical features of variant CJD include a predominantly psychiatric manifestation at onset with delayed appearance of frank neurologic signs and the appearance of sensory abnormalities with dysesthesia and paresthesia [175]. On the MRI, a typical "pulvinar sign" is often demonstrated in a majority of vCJD patients consisting of a hockey-stick-like, symmetrical hyperintensity in the pulvinar region relative to the intensity in other structures [179]. The diagnostic EEG finding that is common in classic CJD patients is very rare in patients with variant CJD. All variant CJD patients tested to date had methionine homozygosity at the polymorphic codon 129 of the prion protein gene [177, 180]. This homozygosity is present in approximately 35–40 % of the general UK population. A definitive diagnosis of variant CJD requires laboratory testing of brain tissues. In addition to the spongiform lesion, neuronal loss, and astrogliosis typical of most prion diseases, the neuropathology in variant CJD is characterized by the presence of numerous "florid plaques," consisting of amyloid deposits surrounded by a halo of spongiform lesions [177, 181] (See Fig. 47.4).

Studies in the United Kingdom have indicated the probable secondary person-to-person transmission of the variant CJD agent in three patients by blood (non-leukodepleted red blood cells) collected 17–40 months before variant CJD onset in the donors [177, 182–187]. The incubation period in

Table 47.3 Clinical and pathologic characteristics distinguishing variant Creutzfeldt-Jakob disease (variant CJD) from classic CJD

Characteristic	Variant CJD	Classic CJD
Median age (range) at death (years)	28 (14–74)	68 (23–97)[a]
Median duration of illness (months)	13–14	4–5
Clinical presentation	Prominent psychiatric/behavioral symptoms, painful sensory symptoms, delayed neurologic signs	Dementia, early neurologic signs
Periodic sharp waves on electroencephalogram	Almost always absent	Often present
"Pulvinar sign" on magnetic resonance imaging[b]	Present in >75 % of cases	Very rare or absent
Presence of "florid plaques" on neuropathologic sample	Present in great numbers	Rare or absent
Immunohistochemical analysis of brain tissue	Marked accumulation of PrP-res[c]	Variable accumulation
Presence of agent in lymphoid tissue	Readily detected	Not readily detected
Increased glycoform ratio on Western blot analysis of PrP-res	Present	Not present
Genotype at codon 129 of prion protein	Methionine/methionine[d]	Polymorphic

[a]U.S. CJD surveillance data 1979–2001
[b]Symmetrical high signal in the posterior thalamus relative to that of other deep and cortical gray matter
[c]Protease-resistant prion protein
[d]A patient with preclinical vCJD related to bloodborne transmission was heterozygous for methionine and valine

these patients ranged from 6.5 to 8.5 years, and all three had methionine homozygosity at the polymorphic codon 129 of the prion protein gene. A fourth patient who was heterozygous at codon 129 had laboratory evidence of vCJD but died of a non-neurologic condition >5 years after receipt of red blood cells from a donor diagnosed with vCJD 18 months after donation [182]. Because a large proportion of the UK population has potentially been exposed to the BSE agent, concerns still exist about additional secondary spread of the agent via blood products and possibly via contaminated surgical instruments. Testing of retrospectively collected appendectomy samples from 12,674 UK residents identified three positive samples, indicating an estimated prevalence of 237 vCJD infections per million populations [188]. Two of the three positive samples with prion protein gene analysis were homozygous for valine at codon 129.

4.3 Atypical Bovine Spongiform Encephalopathy

Since 2003, BSE cases with histopathologic features and Western blot characteristics of the infecting prions distinct from that of the classic form of BSE were increasingly identified from several European countries, Canada, Japan, and the United States [173, 189–193]. Based primarily on the molecular weight of the unglycosylated, proteinase-K-resistant fragment of the PrP^{Sc}, atypical BSE cases were classified into two groups. The fragment with a higher molecular weight than the classic type (C-type) was designated the H-type, and the fragment with a lower molecular weight than the C-type was designated the L-type [194, 195]. It is widely believed that these different properties of the infecting prions may represent different strains of the BSE agent. Initially, the L-type BSE was called bovine amyloid spongiform encephalopathy or BASE because of the presence of amyloid plaques in histopathologic preparations of brain tissues from infected cattle [189]. Because the H- and L-types of BSE seem to be rare and because they tend to occur in older cattle, some researchers have suggested that these atypical BSE cases arise spontaneously as a result of sporadic, random mutations of the prion protein gene [195]. However, the possibility that they may also be strain variations of the large C-type BSE outbreak should not be excluded. Regardless of the origin of atypical BSE, its continued occurrence could still pose a risk of contamination of the animal feed and human food supplies. Spontaneous occurrence of BSE may actually be an ominous sign because feed control measures may not completely eliminate its occurrence and herald the need for continuing surveillance and maintaining effective feed bans even after the C-type BSE outbreak is under control.

Whether or not atypical BSE can be transmitted to humans and the possible phenotype it may represent remain unknown. The possible transmission of L- and

H-type BSE to humans has been assessed using transgenic mouse models expressing the human prion protein homozygous for methionine at codon 129. L-type BSE transmitted to the transgenic mice with no apparent barrier, whereas C-type BSE had a substantial transmission barrier; no transmission of the H-type was reported [196, 197]. Transmission of L-type BSE to lemurs has also been reported via intracerebral and oral challenges and to cynomolgus macaques by intracerebral inoculation [191, 198]. A comparison between the pathogenesis of classic and atypical BSE is currently an area of active research because this could have potential implications for possible exposure to humans and animals [199–201].

5 Chronic Wasting Disease and Interspecies Transmission

CWD was first identified in the late 1960s as a fatal wasting syndrome of captive mule deer in research facilities in Colorado and subsequently in a similar facility in Wyoming. It was not recognized as a spongiform encephalopathy until 1977 [202, 203]. CWD was recognized as a disease of free-ranging animals in the early 1980s, and by the mid-1990s, its endemic occurrence was reported in deer and elk in a contiguous area in northeastern Colorado and southeastern Wyoming. Mule deer, white-tailed deer, and Rocky Mountain elk are the major known natural hosts for CWD [204]. In 2005, a hunter-killed moose was confirmed with CWD in Colorado, suggesting that this member of the deer family is also a natural host. As of December 2013, CWD has been identified in free-ranging cervids in 18 US states (Fig. 47.5) and 2 Canadian provinces and in greater than 100 captive herds in 15 states and provinces in North America.

The occurrence of CWD in free-ranging animals is spreading to wider geographic areas, and prevalence is increasing in many CWD endemic locations. Parts of Wyoming now have CWD prevalence rates approaching 50 % in mule deer, and prevalence in areas of Colorado and Wisconsin is less than 15 % in deer. The prevalence of CWD in elk is generally lower than in deer but can reach 10 % in parts of Wyoming. Known risk factors for CWD include sex and age of the animals, with adult male deer having the highest disease prevalence [203, 205]. Polymorphisms in the prion protein gene correlate with the incidence of CWD in deer and elk but remain less understood than the strong genetic influence described for scrapie in sheep [206–209]. The long-term effects of CWD infection on the dynamics of cervid populations are unclear. Epidemiologic modeling studies have predicted that CWD infection could have negative effects on the density of free-ranging cervid populations. These long-term effects may be influenced by variations in hunting management practices and persistence of the CWD agent in the environment [210, 211]. CWD infection in free-

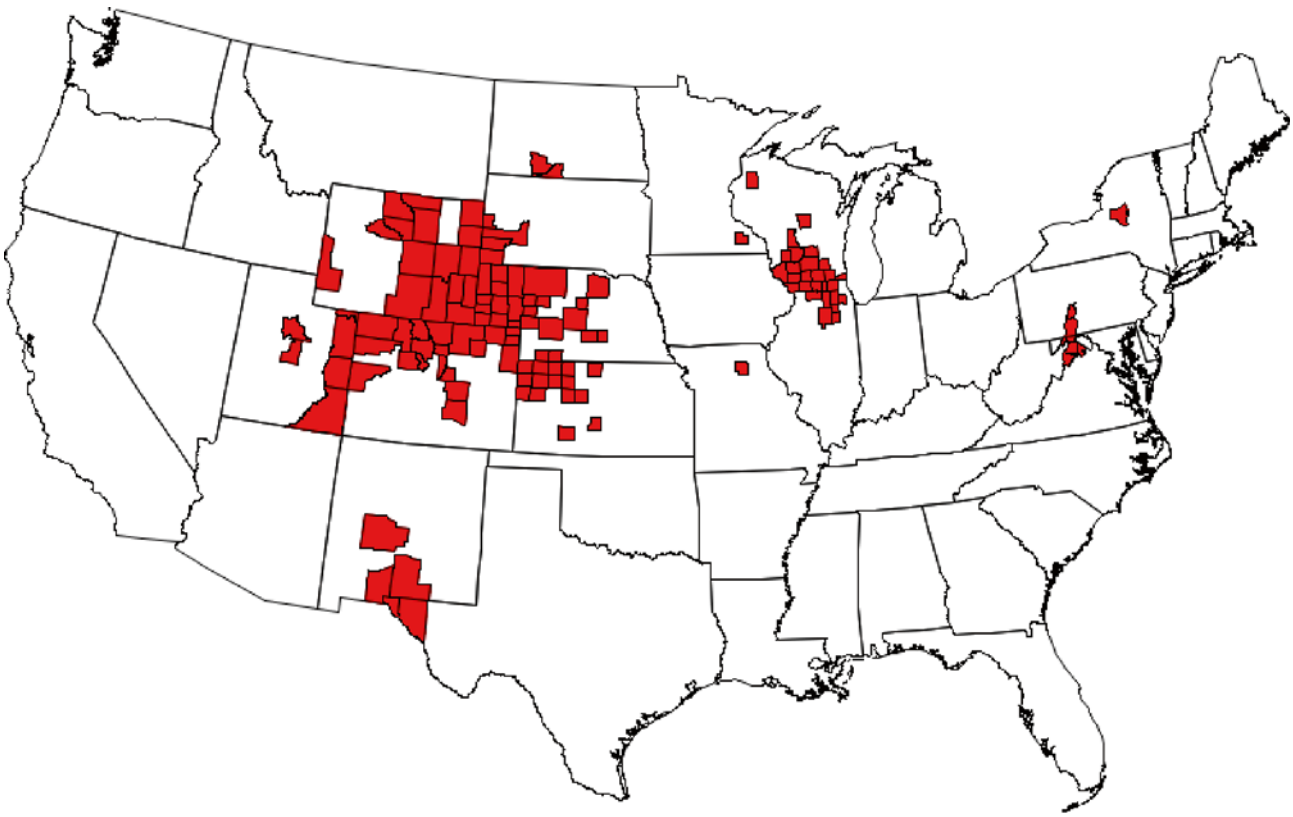

Fig. 47.5 Chronic wasting disease among free-ranging cervids by county, the United States, July 2012

ranging mule deer has been associated with large decreases in cervid populations in Boulder, Colorado, an area with a high rate of CWD infection [205]. Consistent with the clinical manifestations of the disease, deer with CWD are weaker and are preyed upon by mountain lions more readily than healthy deer [205]. They are also more likely to be involved in collisions with vehicles, further contributing to thinning of cervid populations [212].

5.1 CWD Transmission in the Natural Host

Horizontal transmission of the CWD agent is a major mechanism of disease spread in the wild. CWD prions can enter the environment through shedding from diseased animals and from decomposing carcasses. The CWD agent is shed from infected deer in urine, feces, saliva, blood, and antler velvet, and shedding can occur during the preclinical phase of CWD or from clinically affected animals [213, 214]. CWD prions are present in many organs and tissues of an infected cervid, including skeletal muscle, cardiac muscle, fat, lymphoid tissues, and peripheral and central nervous system tissues [209, 215, 216]. Ingestion is an effective route of CWD agent transmission among cervids and lesions in the oral cavity can facilitate entry of the agent enhancing the transmission of CWD [217, 218]. Prions bind to a range of soils and soil minerals and retain the ability to replicate [219–223]. Ingestion and inhalation of soil by cervids has been hypothesized to play an important role in CWD transmission [224, 225]. Nasal inoculation has been shown to be an efficient route of prion transmission [226, 227]. Consistent with the role of the environment in CWD transmission, exposure of CWD-naïve deer to drinking water, feed buckets, and bedding used by CWD-infected deer resulted in the naïve deer developing CWD [228].

5.2 Interspecies CWD Transmission

Human prion disease with evidence of a link with CWD has not been identified despite several epidemiologic investigations of suspected cases [202, 229–232]. Consistent with this observation, in vitro prion conversion assays indicate that the efficiency of human PrP^C conversion by CWD prions is low. In addition, transgenic mice expressing human PrP^C are not susceptible to CWD infection [233–235]. However, the CWD agent has been transmitted to squirrel monkeys by intracerebral and oral routes of inoculation, while cynomolgus macaques, which are genetically closer to humans, are resistant to CWD infection [236]. Transmission of CWD to non-cervid species has not been observed under natural conditions. Raccoons, opossums, and coyotes who may scavenge CWD-infected carcasses have not been shown to be infected with CWD in Wisconsin [237]. Transmission of CWD to cattle has not been observed in experimentally controlled environmental exposure studies [209]. However, CWD has been transmitted to cattle, sheep, goats, mink, ferrets, voles, and mice by intracerebral inoculation [209, 238–240]. Limitations of the aforementioned negative transmission studies include the small number of animals inoculated, which would be unlikely to identify low transmission rates, and the fact that strain variations have not been fully accounted for. Compelling evidence suggests the existence of distinct CWD strains which may influence host range, pathogenicity, and the zoonotic potential of CWD [241–243]. Currently, knowledge about the natural distribution and prevalence of CWD strains in free-ranging cervids is very limited. Interactions of the CWD agent with the environment particularly soil may alter CWD strain properties or exert selective pressure on different strains, further complicating the interpretation of CWD transmission studies [219]. Although the negative transmission studies provide reassurance indicating the existence of a substantial species barrier protecting humans from CWD transmission, the animal model studies should be interpreted with caution. Epidemiologic surveillance is ongoing to monitor the zoonotic transmission of CWD to individuals who hunted in areas where the disease has been endemic for decades. Although these studies have not detected any evidence of CWD transmission to humans, long-term follow up is necessary because of the long incubation period associated with any potential zoonotic transmission.

6 Prion Diseases of Humans Associated with Genetic Mutations

One of the intriguing properties of prion diseases in humans is the fact that they can be both infectious and heritable. The inherited or genetic forms of prion diseases are associated with insertion, deletion, or point mutations of the open reading frame of the prion protein gene [113, 244]. At least 24 different point mutations of the prion protein gene have been described in association with human prion diseases [113, 245]. These genetic prion diseases have widely varying clinical and neuropathologic manifestations and account for 10–15% of prion diseases in humans. Historically, genetic forms of prion diseases, in part based on their phenotypical expression, are classified as familial CJD, GSS, and FFI. They mostly follow an autosomal dominant inheritance pattern and have high penetrance. Beginning in 1989, many types of insertion mutations associated with markedly heterogeneous phenotypes have been reported in familial clusters.

6.1 Familial CJD

Patients with familial CJD generally have clinicopathologic phenotype similar to sporadic CJD. The disease has a

dominant inheritance pattern, and over half of affected family members carrying the mutation eventually die of CJD [2]. Familial CJD has been reported among family clusters in many countries, including from Canada, Europe, Japan, Israel, the United States, and several Latin American countries [2, 113, 244, 246–250]. The largest familial cluster was reported among Jews of Libyan and Tunisian origin, in rural Chile, and in Slovakia. It is most frequently associated with a mutation substituting glutamic acid with lysine at codon 200 of the prion protein gene. Arguably, familial CJD associated with codon 200 mutation is the most common heritable form of prion disease in humans. Perhaps the next relatively common form of familial CJD is associated with a mutation at codon 178 substituting aspartic acid with asparagine. This mutation has been reported in families originating from England, Finland, France, Hungary, and the Netherlands [245, 251]. A pedigree analysis of the original Finish family indicated that codon 178 mutation could have a disease penetration rate of 100 % [252]. Familial CJD with codon 178 mutation occurs when the mutant allele coding for asparagine at codon 178 also codes for valine at codon 129 [2, 253]. Compared with sporadic CJD patients, familial CJD patients with codon 178 mutation tend to have illness onset at an earlier age (mean, 46 years). About 12 other less frequent mutations with phenotypical expressions resembling familial CJD have been reported from many countries.

6.2 Gerstmann-Sträussler-Scheinker Syndrome

GSS bears the names of the three physicians who first described the disease in 1936 [56]. The original Austrian family spanning many generations reported by these physicians was later shown to carry the codon 102 mutation, which we now know is the most common form of GSS. Since its first report, the term GSS is used to describe a heterogeneous group of inherited human prion diseases that are characterized by a long duration of illness (median: ~5 years but sometimes exceeding 20 years) and the presence of numerous PrP-amyloid plaques, primarily in the cerebellum.

At least 13 different types of prion protein gene mutations or a combination of mutations in at least 56 kindred or families have been reported in association with the GSS phenotype. Familial clusters with the GSS phenotype have been reported from Canada, Europe, Japan, Israel, Mexico, and the United States [2, 245]. Many of the GSS mutations are associated with a greater degree of variability in the disease phenotype than other inherited forms of prion diseases. The most frequent GSS mutation results in a substitution of leucine for proline at codon 102 of the prion protein gene and is coupled with methionine at the polymorphic codon 129 of the mutant allele [254]. Patients with this mutation commonly manifest with cerebellar dysfunction, including ataxia and dysarthria, movement disorders, and possibly dementia and akinetic mutism. In some patients with the GSS 102 mutation, the illness can last for up to 6 years.

GSS with codon 105 mutations substituting proline for leucine or serine has been reported in several Japanese families. Patients predominantly have spastic paraparesis associated with cerebellar dysfunction and dementia and a neuropathologic picture of numerous amyloid plaques with neurofibrillary tangles and absence of spongiform changes. A large US family of German descent followed up for decades with an illness resembling GSS has been shown to have a mutation at codon 117 substituting alanine for valine [255]. Patients in this family cluster predominantly presented with dementia and pyramidal and extrapyramidal signs with minimal signs of cerebellar dysfunction. Arguably the largest and perhaps most studied family cluster with GSS was identified in the US state of Indiana with over 70 affected family members identified over 6 generations, and a total of over 1,000 family members involved in the investigation [256–263]. Many patients in this cluster had a mutation at codon 198 substituting phenylalanine for serine. At least six additional mutations of the prion protein gene have been reported in patients manifesting with a phenotype resembling GSS.

6.3 Fatal Familial Insomnia

The name FFI was first used in 1986 to describe a patient who predominantly presented with insomnia and autonomic dysfunction and had a history of other family members in several generations who had died of a similar illness [264–266]. Neuropathologic studies in FFI predominantly show marked involvement of the thalamus, resulting in a clinical phenotype characterized often by intractable insomnia and autonomic nervous system dysfunction, including abnormalities in temperature regulation, increased heart rate, hypertension, and sexual and urinary dysfunction [266–272]. The neuropathologic lesions are more severe in the thalamus than other regions of the brain. FFI is primarily associated with a mutation at codon 178 of the prion protein gene resulting in a substitution of aspartic acid with asparagine in combination with methionine at the polymorphic codon 129 of the mutant allele. The mutation seems to follow an autosomal dominant inheritance pattern. FFI has been identified in Australia, Canada, Japan, the United States, and several European countries. Recently, patients with no prion protein gene mutations but having clinical and pathologic manifestations indistinguishable from that seen in FFI patients have been reported. These seemingly sporadic cases with no family history of a similar disease are now recognized as sporadic fatal insomnia (sFI) and are classified as one of the subtypes of sporadic CJD [273, 274].

6.4 Codon 129 Polymorphism

The prion protein gene in humans exhibits a polymorphism at codon 129 which codes either for methionine or valine. Approximately 40 % of predominantly Caucasian populations are homozygous for methionine, 50% heterozygous with methionine and valine, and 10 % homozygous for valine. Methionine and valine homozygosity seem to be overrepresented among sporadic CJD (84 %) and hGH-associated CJD (67 %) patients, indicating that it may influence disease susceptibility in some individuals [121]. To date, all variant CJD patients who have been tested are homozygous for methionine at codon 129 [180, 181]. Heterogeneity at codon 129 seems to be protective against CJD, but when disease occurs the incubation period is usually prolonged in some iatrogenic CJD patients. The polymorphism also markedly influences the clinicopathologic phenotype of sporadic CJD and several inherited prion diseases. The most striking example of this influence is the phenotype associated with codon 178 mutation that substitutes aspartic acid with asparagine. Patients who have this mutation in combination with methionine on the mutant allele at codon 129 present with the FFI phenotype, whereas patients who have valine at codon 129 of the mutant allele present with the familial CJD phenotype [253]. The codon 129 polymorphism may also influence the age at onset and duration of illness in some prion diseases.

7 Scrapie

Scrapie was first reported in the 1730s in England but has been identified in many countries since then. Although it was recognized as a distinct clinical entity of sheep over 250 years ago, many aspects of the disease including its natural origin in flocks and the precise means by which it usually spreads remain uncertain. Experimentally, the disease was first transmitted by intraocular inoculation of scrapie brain extracts.

Scrapie transmission may occur by different postulated mechanisms. A commonly cited source of transmission, for example, is the placenta and amniotic fluid of scrapie-infected ewes. These tissues are known to harbor the infectious agent and can cause scrapie when fed to other sheep. They may contaminate pastures and barns that, in turn, may remain potentially infectious for years. Another possible source of spread is feces because prion replication occurs in gut lymphoid tissues after oral inoculation in sheep and goats. The importance of oral transmission is supported by experimental studies that detected prions in sheep tonsils examined early during the incubation period. Other poorly defined scrapie transmission mechanisms include: (a) the vertical transfer of the scrapie agent and (b) the possible chance occurrence of scrapie caused by hypothesized rare, spontaneous changes in the animal's cellular prion protein.

Scrapie occurs endemically in many countries, including in Europe and North America. Australia and New Zealand have sizable sheep populations but are generally recognized as free of the disease. To protect their "scrapie-free" status, these countries have established extensive safeguards to prevent the introduction of scrapie into their herds from imported animals.

The breed of sheep and polymorphisms of the prion protein gene can greatly influence susceptibility to scrapie [275–277]. Experimental transmissions with scrapie-infected tissues, for example, have confirmed the differing susceptibility to scrapie of different breeds of sheep. Other studies of Suffolk sheep in the United States indicated that susceptibility to scrapie was highly correlated with a polymorphism in the prion protein gene at codon 171 (glycine or arginine); the presence of arginine confers resistance to the disease [278, 279].

7.1 Atypical Scrapie

A new prion disease of sheep was identified in Norway in 1998 (Nor98) and has since been identified in several countries worldwide [280–287]. This new form, commonly referred to as atypical scrapie, differs from the classic form of scrapie in several important ways. The electrophoretic migration of Nor98/atypical scrapie PrP^{Sc} is characterized by lower molecular weight PrP^{Sc} species than that of the classic form [288, 289]. The distribution of PrP^{Sc} in sheep infected with Nor98/atypical scrapie is largely localized to the CNS in contrast to classic forms of scrapie that have a more widespread distribution. Interestingly, Nor98/atypical scrapie is mainly found in sheep with prion protein genotypes that correspond with relative resistance to the classic strains of scrapie [290–293]. Atypical scrapie occurs in older animals compared to classic forms of scrapie, and the incidence of disease is similar in infected flocks compared to the general population, suggesting that animal-to-animal transmission is not a prominent feature of Nor98/atypical scrapie [281, 294–296].

The etiology of Nor98/atypical scrapie is unclear. The predominance of PrP^{Sc} distribution in the CNS, the occurrence of disease in older animals, and the lack of clear evidence of animal-to-animal transmission have led to the hypothesis that Nor98/atypical scrapie may be a spontaneous prion disease with an etiology similar to sporadic CJD [281]. In addition, transmission of Nor98/atypical scrapie to transgenic mice expressing ovine prion protein produces a disease phenotype that is distinct from BSE-infected mice suggesting that Nor98/atypical scrapie is not due to transmission of BSE to sheep [285, 297, 298]. However, recent data indicate that Nor98/atypical scrapie is experimentally transmissible via oral inoculation and that extraneural tissues that are PrP^{Sc} negative as assessed by immunodetection techniques contain significant amounts of prion infectivity when tested using animal bioassays [299]. The implications of these findings are twofold. First, the conditions exist for transmission of Nor98/atypical

scrapie between individual animals (peripheral distribution of agent and oral susceptibility) suggesting that a spontaneous etiology is not the only mechanism of disease occurrence. Second, disease surveillance is based on immunodetection of PrP^{Sc}; therefore, the incidence of disease may be underreported. Clearly much work is needed to resolve the etiology and transmission history of this newly emerging prion disease of sheep.

8 Diagnostic Tests for Prion Diseases

In general, infecting prions can be detected in high concentrations in central nervous system tissues, particularly the brain. Their presence outside of the brain in peripheral tissues varies by the host species and infecting prion strains. In many prion diseases, confirmatory diagnosis requires testing of brain tissues by one of the widely used diagnostic methods, including histopathology using H&E staining, immunohistochemistry after labeling with antibodies directed to certain epitopes of the prion molecule, Western blot techniques, or rapid diagnostic tests developed for BSE screening such as prionics and biorad. Most of these diagnostic methods require protease digestion of biological samples to degrade native PrP^{C} that could interfere with the test results. They rely on the resistance of PrP^{Sc} to protease digestion to detect its presence. In contrast, confirmation-dependent immunoassay (CDI), a test developed by researchers at University of California, San Francisco, does not rely on the protease-resistant nature of PrP^{Sc} to be used as a diagnostic tool [300, 301]. The high-affinity antibodies used in CDI recognize confirmation-dependent epitopes of PrP^{Sc} to distinguish it from that of PrP^{C}.

8.1 Prion Amplification in In Vitro Systems

Current prion diagnostic tests, such as immunohistochemistry and Western blot, mainly rely on the immunodetection of endogenous PrP^{Sc} that is present in the host. They are very specific in the diagnosis of prion diseases but have limited sensitivity of detection of low amounts of PrP^{Sc}. The ability to detect low amounts of PrP^{Sc} would allow for an earlier diagnosis of prion diseases and potentially from easily accessible tissues (e.g., blood) that may harbor low levels of PrP^{Sc} compared to the brain. Recent promising studies have developed in vitro means of prion conversion that allow for the amplification of low levels of PrP^{Sc} to an abundance that is in the range of detection of current immunodetection technologies. In these in vitro systems, the natural properties of prions to recruit and convert PrP^{C} are exploited by mimicking the in vivo prion replication process to amplify and detect even minute amounts of prions in biological samples [302]. Byron Caughey and colleagues first demonstrated in a cell-free system that PrP^{C} could be converted to a PK-resistant form in the presence of PrP^{Sc} [303, 304]. This cell-free conversion assay was useful for understanding the nature of the prion agent, prion strain properties, and the species barrier effect [303]. Cell-free conversion reactions were not very efficient; therefore, such assays had limited ability to be used as diagnostic tools for prion diseases. Claudio Soto and colleagues subsequently developed a system they termed protein misfolding cyclic amplification (PMCA) to increase the efficiency of in vitro conversion assays [305–308]. PMCA utilizes incubation of uninfected brain homogenate that contains PrP^{C} with a biological sample that contains PrP^{Sc} resulting in the conversion of PrP^{C} to PrP^{Sc}. The PrP^{Sc} acts like a seed and elongates into an oligomer by attracting PrP^{C} molecules and incorporating them into the growing oligomer. The rate of conversion is limited by the availability of seeds actively recruiting PrP^{C}. To accelerate the process, a sonication step was introduced to fragment the growing oligomer into smaller units that would serve as multiple seeds to recruit even more PrP^{C}, thereby amplifying the conversion reactions. Serial rounds of incubation and sonication result in a highly efficient in vitro conversion process [307]. PMCA has been shown to amplify PrP^{Sc} from samples containing a single infectious dose to levels that are easily detectible by Western blot analysis. Real-time quacking-induced conversion (RTQuIC) is a modification of PMCA methodology and utilizes recombinant PrP^{C} that has single PrP^{Sc} molecule sensitivity and detects PrP^{Sc} using thioflavin T fluorescence resulting in real-time detection of PrP^{Sc} formation allowing for a more rapid assay [303, 304, 309, 85]. Other promising in vitro technologies include the amyloid seeding assay and the surround optical fiber immunoassay. As with all other highly sensitive diagnostic tests (e.g., PCR), care must be taken to minimize contamination, and in an aspect that is unique to prion diseases, the spontaneous conversion of PrP^{C} to PrP^{Sc} must be controlled for. With these controls in place, PMCA, RTQuIC, and other tests developed using similar methodologies have the potential to be highly sensitive and accurate prion diagnostic tests.
