SLE virus has been responsible for thousands of deaths, more than 10,000 severe illnesses, and no fewer than a million mild or subclinical infections [227, 228]. Only 1–2 % of SLE virus infections are symptomatic [210, 229, 230]. The ratio of asymptomatic to symptomatic infection ranges from 800:1 in children to 85:1 in adults older than 60 years [200, 231]. The infection incubation period ranges between 4 and 21 days. When the disease occurs, it may be classified into three clinical syndromes: constitutional symptoms and headache (febrile headache), aseptic meningitis, and fatal encephalitis [139, 200, 209]. Most cases start with fever, headache, nausea, myalgias, and sometimes respiratory or abdominal symptoms; most recover completely [231]. In those who develop advanced disease, following the acute febrile prodrome, there may be an acute or subacute appearance of meningeal and other neurologic signs and symptoms. Symptoms may include nuchal rigidity, disorientation, unsteady gait, vomiting, and diarrhea. Tremulousness involving the eyelids, tongue, lips, and extremities is observed. Cerebellar and cranial nerve signs are common [231, 232]. Apathy, confusion, and disorientation leading to coma may occur. Nearly one quarter of patients experience urinary symptoms (frequency, urgency, dysuria) [233]. The morality rate is approximately 8 %, ranging from approximately 2 % in the young to 22 % in the elderly who have comorbidities [139]. Advanced age is the most significant risk for developing both symptomatic disease and more severe encephalitis after infection [172]. People older than 60 years of age have the highest frequency of encephalitis [139]. Almost 90 % of elderly SLE patients develop encephalitis [230]. Longer-term sequelae such as asthenia, irritability, tremors, sleeplessness, depression, memory loss, and headaches typically last less than 3 years but may last longer. Persistent symptoms include gait and speech disturbances, sensorimotor impairment, psychoneurotic complaints, and tremors [234–236].

Clinical laboratory findings are nondistinct. Peripheral white blood cell count may be high and urine findings may include microscopic hematuria, proteinuria, and pyuria [231]. Inappropriate antidiuretic hormone secretion and hyponatremia may occur in a third of patients. Fewer than 200/mm^3 white blood cells are typically seen in the cerebral spinal fluid; polymorphonuclear cells predominate early with an eventual shift toward a lymphocytic pleocytosis. Protein levels may be elevated to 1.5–2.0 times normal. Electroencephalogram shows diffuse slowing and seizure

activity. Magnetic resonance imaging may show increased signal in the substantia nigra, while radionuclide brain scans and computed tomography have been normal [139, 237].

Diagnosis should be suspected if the patient presents with a compatible clinical syndrome in the summer or early fall, in an area known to have SLE virus circulation, with reports of similar cases with patients at the extremes of age. Although virus isolation has been documented from the liver, spleen, lung, kidney, and brain, isolation is very unusual from serum or CSF [238]. Polymerase chain reaction assays are being developed for diagnosis and surveillance [239–246]. Diagnosis most often is made using serologic assays testing acute and convalescent serum samples or a cerebral spinal fluid sample [21]. IgM antibodies in serum appear within the 4 days after infection, peak at 7–14 days, and then decline and disappear by day 60 but may persist up to a year in a small percentage of patients [139, 231, 247]. A fourfold change in serum antibody titer confirms infection, and presence of IgM antibody in a single serum is presumptive evidence. Hemagglutinin inhibition detects group-reactive antigens and may be a useful screening test. The presence of complement fixation antibodies in a single serum sample is presumptive evidence of a recent infection, but 20 % of patients with confirmed SLE virus infections do not develop complement fixation antibodies [139]. Detection of IgM antibodies in the cerebral spinal fluid by enzyme-linked immunosorbent assay (ELISA) provides a rapid and early diagnosis.

There is no licensed antiviral therapeutic to treat SLE. The current care standard is supportive focusing on controlling seizures, providing respiratory support, reducing cerebral edema, and managing metabolic derangements [231]. There is no licensed vaccine to prevent SLE. Personal protective measures and other vector avoidance practices are encouraged. Control in rural or an urban epidemics has been attempted by emergency application of mosquito control measures. Long-term control for urban and suburban localities depends on good sanitation with respect to drainage and adequate disposal of waste water. In more specific rural areas under irrigation, much can be accomplished through water management and directed application of insecticides to keep mosquito populations low.

Usutu Virus (USUV)

The USUV is an avian virus discovered in South Africa (1959) in a female mosquito (*Culex neavei*) [3, 248]. The virus has infectivity for numerous primary and continuous animal species and human cell lines [3]. The life cycle is complex, involving host bird species and *Culex* mosquitoes as primary vectors and humans, horses, and other mammals as incidental hosts. Geographic range initially includes Senegal, Central African Republic, Nigeria, Uganda, Burkina Faso, Cote d'Ivoire, and Morocco [249]. The virus emerged in Vienna, Austria, in 2001 associated with avian, mainly blackbird, mortality. Infection has recently been noted in a variety of central European birds in Austria, Hungary, Switzerland, United Kingdom, Spain, Germany, and Italy [250, 251]. USUV was initially discovered to be clinically relevant in 1981 when a man in the Central African Republic developed fever and rash following infection. In 2004, a 10-year-old child in Burkina Faso developed fever and jaundice following infection. In 2009, 2 immunosuppressed people (liver transplant, B-cell lymphoma) in Italy developed encephalitis [252, 253]. A recent serosurvey in Northeastern Italy demonstrated 4 of 359 donors had IgG evidence of USUV infection [254].

West Nile Virus (WNV)

WNV was first isolated in a febrile woman in the West Nile District of Uganda in 1937 [255]. Since its discovery in West Africa, outbreaks of WNV have occurred in many parts of the world, and WNV is now endemic in Africa, Europe, the Middle East, West and Central Asia, Oceania, and North America [256]. In the United States, the westward spread of WNV across the continent from the initial cases in New York over the course of about 5 years was an epidemiologic phenomenon that was closely monitored [257]. WNV now has become the leading cause of neuroinvasive arboviral disease in the United States [258].

Wild birds are the primary vertebrate reservoirs of WNV in endemic regions [259] and WNV has been found to be capable of infecting over 300 different species of birds [260]. In many instances, WNV has spread across continents and regions following bird migration patterns [261]. The virus is transmitted by mosquitoes usually of the *Culex* spp., though various spp. of *Aedes*, *Anopheles*, and Ornithodoros ticks can be infected by WNV [3]. Mammals are less important than birds in maintaining transmission cycles of the virus as viremia is too low in most of the mammal species to reinfect mosquitoes [262].

Nearly all humans are infected with WNV primarily by the bite of infected mosquitoes [257]. However, transmission of WNV to humans has also occurred through transplanted organs, and transfused blood, transplacental transmission [263], and transmission through breast milk may also be likely [264]. Most infections with WNV are asymptomatic. The typical incubation period is 2–14 days, and a self-limited febrile illness without neurologic involvement, known as West Nile fever, may occur in approximately 20–30 % of infected cases. The symptoms of West Nile fever may include malaise, eye pain, headache, myalgia, gastrointestinal discomfort, and rash. A maculopapular rash occurs in about half of the persons with West Nile fever but is less commonly reported in persons with neuroinvasive disease. About 1 in 150 cases may progress to severe disease and develop encephalitis, men-

ingitis, or acute flaccid paralysis. Long-term complications (1 year or more after infection) are common in patients recovering from severe WNV infection. Currently, supportive care is the only treatment available. Advanced age is the most important predictor of death [265]. The mortality rate among neuroinvasive disease is approximately 10 %, with increased risk for patients with compromised immune systems and advanced age and with underlying conditions such as diabetes mellitus.

Diagnosis of WNV is made primarily by the use of indirect antibody-capture ELISA or PCR. In most cases IgM will be produced within 4–7 days and may persist for more than a year [266]. ELISA for WNV may be performed on serum or CSF. Other serologic tests such as neutralization assays generally are less cross-reactive with other flaviviruses, but are not widely available for clinical diagnosis. Antigen detection assays are also being developed but are not widely used in the clinical setting. PCR is widely available and is very specific and sensitive.

There is no WNV vaccine available for use in humans, but a number of WNV vaccine candidates are in clinical trials. There are three WNV vaccines currently licensed for use in horses; two are killed virus vaccines, and one is a chimeric recombinant canarypox virus vaccine [262].

Yaounde Virus (YAOV)

The original source of YAOV was a pool of *Culex nebulosis* female mosquitoes collected in 1968 near Yaounde, Cameroon, Africa [3]. One month later the virus was isolated via intracerebral inoculation in mice. Complement fixation identified the virus as related to Usutu virus. Natural host range includes mosquitoes (*Culex* spp., *Aedes*, *Eretmapodites*), rodent, and bird. Injection in mice produced death. There are no known human cases [3].

Kokobera Virus Complex

Kokobera Virus (KOKV)

KOKV is a mosquito-borne virus that was originally isolated from *Culex annulirostris* at the Kowanyama (Mitchell River Mission) in northern Queensland in 1960 and named after a local Aboriginal tribe [267]. It is isolated throughout Australia and Papua New Guinea [268]. The reservoir for the virus is thought to be kangaroos, wallabies, and horses. Human infections with KOKV result in an acute polyarticular disease.

Stratford Virus (STRV)

STRV has a geographic distribution similar to KOKV from *Culex* species producing a febrile polyarticular illness. Originally classified with KOKV as part of the JEV serocomplex, serologic and sequencing of the virus demonstrated that STRV is closely related to KOKV and its classification into the KOKV complex [3].

New Mapoon Virus

New Mapoon virus was originally isolated as part of viral isolates obtained from mosquitoes in 1998 on Cape York Peninsula (located Far North Queensland, Australia) and in 2000 on Saibai Island (one of the Torres Strait Islands in Australia, between the Australian mainland and the island of New Guinea) and New Mapoon, Queensland [3]. Viruses were characterized by partial genomic sequencing, monoclonal antibody-binding assays, and polyclonal cross-neutralization tests. Two of these isolates were antigenically related to the KOKV complex but distinct. Sequencing demonstrated a distinct novel virus named New Mapoon virus.

Ntaya Virus Complex

Ilheus Virus (ILHV)

Ilheus virus (ILHV) was isolated from *Aedes serratus* and *Psorophora ferox* mosquitoes near Ilheus, Bahia, Brazil, in 1944 [269]. In the original study, *Aedes aegypti* was demonstrated as a competent vector for this virus. After its discovery, the virus was also isolated from a variety of other mosquito species and birds in Latin America. ILHV was described as producing a febrile illness in humans in Central and South America, but the burden of disease is not well studied. In November 2005, a patient in Bolivia was reported with ILHV who developed fever, malaise, asthenia, conjunctival injection, vesicular rash, facial edema, arthralgia, myalgias, bone pain, abdominal pain, headache, and earache [270].

Ntaya Virus (NTAV)

Ntaya virus was originally isolated from mosquitoes in Ntaya, Uganda [3]. Isolation has been made from mosquitoes in Uganda, Cameroon, and the Central African Republic and may be endemic in Nigeria, Kenya, and the Zambia [3]. Serologic surveys suggest that this virus may be widespread with antibodies to Ntaya virus in subjects in Tanzania, Egypt, and the Far East. In a study of returning travelers from Africa, three patients tested positive for Ntaya virus. Illness symptoms reported by the travelers included severe malaise, fever, headache, myalgia, and neurologic manifestations of dizziness, numbness, and weakness of the left leg and arm. In one traveler there was severe amblyopia and restriction of the peripheral visual fields.

Other Viruses Within the Ntaya Complex

Other viruses within this complex are primarily pathogens of poultry causing large epidemics. These include Bagaza virus (BAGV), Israel turkey meningoencephalomyelitis virus (ITV), and Tembusu virus (TMUV). All are spread by a variety of mosquitoes primarily, *Culex* spp. These viruses have the potential to produce human disease with serologic evidence of human infections though the burden of disease within the human population is not known and thus are

briefly described. BAGV which is closely related to ITV has been described as producing a febrile illness in humans with one study demonstrating a possible cause of human encephalitis in India. In an outbreak investigation of a severe duck illness in China, a new virus related to TMUV and BAGV was described named BYD virus [271].

Spondweni Virus Complex

Spondweni Virus (SPOV)

SPOV was first isolated in 1955 from mosquitoes, *Taeniorhynchus uniformis* collected in Tongaland, South Africa. The name was derived from the location they were collected, the district of Spondweni. A serosurvey of residents in Tongaland demonstrated evidence of infection to SPOV. Human infection was demonstrated in laboratory workers working with the virus characterized as a febrile illness with generalized aches and pains, headache rigors, and vertigo [272]. SPOV has been isolated from humans in Mozambique and Cameroon with serologic evidence of infection in humans in Angolal and Botswana [272]. The virus has been isolated from several mosquito species including *Mansonia uniformis*, *Aedes circumluteolus*, *M. africana*, *A. cumminsii*, *Eretmapodites silvestris*, *A. fryeri*, *and A. fowleri* [272]. In 1982 a case of acute SPOV infection was reported in a 40-year-old American man, who had worked in Bitou, located in southeastern Upper Volta (Burkina Faso), near the borders of Ghana and Togo [272]. Symptoms included severe headache, dizziness, nausea, muscle aches, eye pain, and sensitivity to light.

Zika Virus (ZIKV)

ZIKV was originally isolated from a caged febrile rhesus monkey in the Zika Forest, Entebbe, Uganda [273]. Subsequent studies revealed *Aedes africanus* as the primary vector and a serosurvey demonstrated evidence of human infection [274]. Human infection in a field worker and an experimental infection of a volunteer demonstrated that ZIKV could produce a severe febrile illness associated with headache, myalgias, and prostatitis symptoms [275]. Since its original isolation, ZIKV has been isolated from mosquitoes and a cause of human infections throughout equatorial Africa, Indonesia, Malaysia, and Cambodia. *Aedes aegypti* was found to be the primary vector in Southeast Asia [276]. In 2007, a large outbreak of ZIKV infection occurred in Yap Island, Micronesia [277]. In total there were 49 confirmed and 59 probable cases of ZIKV illness. Patients developed rash, fever, arthralgia, and conjunctivitis. The authors estimated that 73 % of Yap residents 3 years of age or older had been recently infected with ZIKV. *Aedes hensilli* was the predominant mosquito species identified. Currently ZIKV is widely distributed outside of Africa with cases or serologic evidence of infection in India, Malaysia, the Philippines, Thailand, Vietnam, and Indonesia. ZIKV was demonstrated to have evolved into an African and Asian lineage [278]. As noted earlier, ZIKV was documented to have been transmitted sexually from a scientist who was infected in Senegal and, upon returning to the United States, infected his spouse [62].

Yellow Fever Virus Complex

Banzi Virus (BANV)

BANV was first isolated in 1956 in a 9-year-old boy in Ndumu, South Africa [279]. The clinical manifestations of this virus was a nonspecific febrile illness. There have only been two acute cases of definitively diagnosed BANV infections, but seroprevalence studies across sub-Saharan Africa suggest BANV infections may be largely subclinical and underdiagnosed [3].

Bouboui Virus (BOUV)

BOUV is a flavivirus that has been isolated in a baboon in Senegal and in mosquitoes in Central Africa and Senegal. While BOUV has never been isolated in humans, seroprevalence studies (employing hemagglutination inhibition assays) involving over 4,000 patients in Central Africa have found 15 patients with serum antibodies to this virus. The clinical manifestations of this disease in humans are not known [3].

Wesselsbron Virus (WESSV)

WESSV is primarily an arboviral disease of sheep, cattle, and goats [280]. However, it has caused nine cases of human febrile disease in sub-Saharan Africa, sometimes with neurologic complications to include disturbances in speech, hearing, and/or vision [281]. While WESSV is primarily located in Africa, it has been isolated in mosquitoes in Bang Phra, Thailand [3].

Yellow Fever Virus (YFV)

YFV is the prototype member of the *Flaviviridae* family of viruses. The origin of YFV is speculated to have been Western Africa, although the disease was first distinguished from other tropical febrile diseases by the Mayans and the Spanish colonists in the Yucatan peninsula in 1648. During the eighteenth and nineteenth centuries, it was one of the great plagues of the world occurring along the eastern US seacoast, in Central America and South America, and in Africa throughout the tropical area [164, 165, 167]. Major epidemics occurred in many seaports of the United States, and the 1905 outbreak in New Orleans was particularly severe. The last US indigenous case occurred in 1911 and the last imported cases in 1924 [13, 214]. It never became established in Europe above the range of the vector, *A. aegypti* mosquitoes. YFV has never been reported from Asia and Australia, despite the endemic presence of *A. aegypti* in tropical Asia [282]. The historical significance of YFV was discussed in a previous section of this chapter.

The development of the YFV vaccine, Theiler's attenuated live virus vaccine introduced in 1937, represents the first successful vaccine against an arbovirus and forms the basis for the present-day product [283]. YFV is maintained in the environment in two cycles: an urban cycle involving human beings and *A. aegypti* mosquitoes and a sylvatic or jungle YFV cycle involving forest primates, principally monkeys, and forest canopy mosquitoes, with human infections tangential to the transmission cycle [284, 285]. In 1901, eradication efforts directed toward *A. aegypti* mosquitoes were launched under the direction of Dr. William Gorgas in Havana. These eradication efforts, with concomitant reduction of YFV, were extended throughout Central and South America in the early 1900s. The chain of urban *A. aegypti-transmitted* YFV was successfully broken by the eradication program. The last endemic focus of *A. aegypti*-transmitted urban YFV was in northeastern Brazil in 1934 [284]. The eradication of the vector, and the concomitant reduction in urban YFV cases in the Americas, historically represents one of the most successful public health campaigns against infectious diseases.

Today, jungle YFV persists in the Western hemisphere and is transmitted chiefly among monkeys, marmosets, and possibly other forest-dwelling animals, commonly causing fatal infections. The vectors are mosquitoes of the forest canopy, chiefly of *Haemagogus* spp. and, to a lesser extent, *A. leucocelaenus*, *Sabethes chloropterus*, and possibly *A. fulvus* in Brazil [285]. For the last few decades in South America, the vast majority of YFV cases were in males over 15 years of age whose occupations increase their exposure to YFV-infected mosquitoes in endemic forest and jungle areas [286, 287]. Up to 500 unvaccinated forest workers were infected in peak years. The majority of cases occur in the first 3 months of the year in South America [287, 288]. *A. aegypti* has now reinfested most of South and Central America and occupies habitats just adjacent to the areas where endemic YFV transmission occurs. A major threat is that this species could transmit YFV in an urban cycle.

In contrast to the endemic–sylvatic circulation of YFV in the Western hemisphere in the late twentieth century, YFV in Africa periodically explodes out of its sylvatic cycle to infect large numbers during major epidemics. During the decade 1980–1990, YFV reemerged as a major health problem in Africa and, as mentioned above, threatens to reemerge in South America. In Africa, two control strategies have been attempted during the last 40 years. The first was routine immunization programs, and the second was emergency control programs after the start of an outbreak. A routine, mandatory YFV immunization program was begun in the early 1940s in French West Africa, and the recurring pattern of epidemics in West Africa was interrupted in those immunizing countries. This strategy was abandoned in 1960, and the program switched to a post-outbreak, emergency immunization and control strategy. Since then, there has been a series of epidemics of varying severity [285]. The period 1986–1990 represented an extraordinarily active period of YFV. The worldwide total of 17,728 cases and 4,710 deaths (i.e., a case fatality rate of 26.6 %) represents the greatest amount of YFV activity reported to the WHO for any 5-year period since reporting began in 1948 [286, 287]. However, in Africa, numerous studies have shown that only a small percentage of African YFV cases are reported [287]. Due to the sylvatic cycle of jungle YFV, worldwide eradication is not considered possible. Despite numerous studies, the question of maintenance of YFV in nature remains somewhat obscure. Although a continual vertebrate–vector maintenance cycle is possible in some environments, in other areas overwintering and maintenance probably occur via other mechanisms. The laboratory and field studies that confirmed that YFV virus can be transovarially transmitted in many of its mosquito vectors suggest that this mechanism might play an important role in nature.

Yellow fever patients have a characteristic but nondiagnostic febrile disease with fever, headache, backache, nausea, variable epistaxis, and a lack of correlation between pulse and body temperature [289]. The clinical course is 2–4 days, followed by uneventful recovery or a remission period before development of severe yellow fever. Many tropical diseases, including a variety of arboviral infections, malaria, and relapsing tick fever, may present similar clinical syndromes, making a clinical diagnosis of suspected YFV difficult unless seen during a recognized epidemic. In a serious complication of the disease, the development of icterus occurs following a remission of the general manifestations. It develops as a yellowish tinge of the sclera, a very important diagnostic sign more easily seen in dark-skinned people, and only rarely becomes marked. Hemorrhagic signs and vomiting of blood characterize this more serious form of disease. They are more common preceding death, which usually occurs within 9 days of onset. Mortality rates vary widely and during epidemics reach from 20 to 80 % of the cases. Icteric YFV must be differentiated from infectious and serum hepatitis, leptospirosis, and poisoning.

Because of these uncertain clinical criteria, laboratory diagnostic tests must be used. Isolation and identification of YFV virus in blood samples or necropsy specimens or demonstration of specific antibody titer rises constitutes definitive diagnosis. While the virus generally grows well in standard cell cultures or suckling mice, identification of YFV virus is now usually performed by PCR. Other rapid diagnostic assays have shown promise for demonstration of YFV-specific antigen or IgG and IgM antibodies. Cross-reactivity with other flaviviruses has been a historical serologic problem. Demonstration of pathognomonic hepatic lesions in necropsy specimens is used when applicable, but needle biopsies of the liver have proved hazardous and the procedure is not generally recommended. No specific

therapeutic regimen is available for YFV, and treatment is chiefly supportive. Prevention is based both on protection from exposure and on vaccination. The 17D YFV vaccine was one of the earliest viral vaccines to be developed, and it has proved to be one of the safest and most efficacious live attenuated vaccines [214, 290].

Yellow fever in urban or jungle form is a continuing threat. The two forms are nonetheless the same virus and the same disease, distinguished on epidemiologic grounds. Human beings can be protected by immunization with 17D YFV vaccine (not advised for infants under 1 year of age). A list of the centers in the United States authorized to give the vaccination can be obtained from the Public Health Service (http://wwwnc.cdc.gov/travel/yellow-fever-vaccination-clinics/search).

Other Viruses in the Yellow Fever Virus Complex Not Pathogenic to Humans

These viruses include Edge Hill virus (EHV) [3, 267], Jugra virus (JUGV) [3], Saboya virus (SABV) [3], Sepik virus (SEPV) [291], and Uganda S virus (UGSV) [3]. These known viruses have been shown to cause illness in humans but by potential exposure as indicated by positive antibody titers.

10.1.4 Viruses with No Known Arthropod Vector

A number of flaviviruses have no known arthropod vector and no documented naturally occurring infection in humans and includes Entebbe bat virus (ENTV) [3], Yokose virus (YOKV) [3], Apoi virus (APOIV) [3], Cowbone Ridge virus (CRV) [292].

Jutiapa virus (JUTV) [3], Modoc virus (MODV) [293], Sal Vieja virus (SVV) [3], San Perlita virus (SPV) [3], and Carey Island virus (CIV) [3].

11 Unresolved Problems

The emergence of WNV in New York and its spread throughout the Americas and the emergence of DENV as a global health problem and recent outbreak in Florida have demonstrated the vulnerability of the United States to emerging viruses. Two studies by the Institute of Medicine dealing with emerging diseases warned that the threat posed by disease-causing microbes may be expected to continue and intensify in coming years [294, 295].

The natural life cycle of many arboviruses is multifaceted and, in addition to the virus, may include one or several reservoir or amplifying hosts and often an arthropod vector. A change affecting the interaction of these fundamental elements might lead to the emergence or reemergence of a viral disease. In some instances, viruses might emerge as the result of selection of new genetic strains and variants with increased infectiousness, virulence, or transmissibility. To control emerging viruses in general, and arthropod-borne viruses in particular, there is a need for expanded (1) basic and applied research that will help formulate coordinated strategies for anticipating, detecting, controlling, and preventing emergence or reemergence of viral diseases and (2) basic and applied research on the virus, the infective process, and the host response to infection, which will be useful in the development of vaccines and antiviral drugs.

Additional unresolved problems are discussed from several points of view, relating to the viruses, the vectors, the vertebrate hosts, and transmission cycles involving virus, vector, and host. The disease in the vertebrate host, which includes the host response to the pathogen, merits independent consideration. Problems relating to the epidemiology of each specific disease require a synthesis of many specific items. Finally, effective control exercised at the level of the virus, the vector, or the vertebrate requires thorough understanding of the epidemiologic background. Specific examples will help to illustrate problems.

11.1 The Viruses

Much progress has been made in recent years in cataloging the several hundred described arboviruses and determining the biochemical, growth, and morphological characteristics in intact vertebrates, in invertebrates, and in cell culture systems of vertebrate and invertebrate cells. However, further work is needed to understand the evolution and emergence of epidemiologically relevant strains. In particular, new research is needed on the nucleic acid homology that may exist among the numerous members of a given arbovirus grouping and on the mechanisms of recombination, reassortment, and selection of new virus strains with important virulence properties.

11.2 The Vectors

The factors that determine specific virus–vector associations are still being elucidated. The role of the vector in genetic conservation of the arboviruses, as genetic bottlenecks, and virus expansion into other vectors due to mutational events, such as in the case of chikungunya virus, is not well understood. Expanded research is needed before the principles governing virus–vector interactions are carefully delineated.

There is a continuing need for taxonomic refinements with respect to arthropods, such as the need for more information on both Old World and New World mosquitoes of the genera *Culex* and *Aedes*. This need is generated by the increasing realization of their involvement with a large number of arboviruses. The same remarks are pertinent for the

tick vectors. The need is equally great for more information on the biology, feeding preferences, longevity, flight range, and distribution of each arthropod species involved. The genetic constitution of each vector species is basic to an understanding of what constitutes a vector, both physiologically and behaviorally, and will become increasingly important as control of vectors through genetic manipulation is considered [118].

Unfortunately, in 1985, the Asian "tiger" mosquito, *A. albopictus*, was introduced in old tires imported from Japan to Houston, Texas. It has now spread to infest over 22 states, mostly in the South and Midwest, and has recently become established in several other countries. This mosquito is an aggressive, opportunistic feeder with a wide host range that includes man. It adapts well to forest or urban settings and it can vector many different arboviruses. In some areas, it already has replaced local mosquito species, and there is a concern it will transmit endemic viruses. Because of its potential as a new vector of endemic or emerging arboviruses in the United States and other countries, research on it should receive high priority.

11.3 The Vertebrate Hosts

For most of the arboviruses, the primary vertebrate host, i.e., the host that serves as the basic unit for propagation of the virus, is not man. For many of the arboviruses, the vertebrate hosts are not yet determined or are recognized on the most tenuous of evidence. Identification of the host(s) is a primary need. Following this, an emphasis should be placed on elucidating a biological profile of the hosts, including the full range of biological and ecological considerations, as well as the degree of host susceptibility to the virus.

11.4 Transmission Cycles Involving Virus, Vector, and Vertebrate

The problem of virus persistence in nature is a particularly baffling one. For example, there are many theories but few facts to explain how a given virus manages to overwinter or survive past a long dry season, when vectors may practically disappear and vertebrate populations decline (or go into hibernation).

Current theories hypothesize that the virus persists in vector populations that overwinter with some members harboring virus or the virus is in vertebrate populations that overwinter and some infected individuals respond to a reactivation stimulus. In other cases, existing data point to an important role for transovarial transmission, permitting passage of virus to generation after generation of a vector without the need for an intercalated vertebrate host. Several of the tick-transmitted viruses apparently utilize mechanisms of long persistence in ticks plus transovarial transmission of virus to exist in an endemic form in defined geographic areas. An excellent review of this topic is presented by Reeves [139] who discusses the epidemiologic problems of overwintering of arboviruses in northern countries and possible transport via infected vectors on migrating birds, with his discussion extending to the Old World as well as the New World viruses. A related paper by Lord and Calisher [112] discusses the transport of arboviruses in infected migrating birds along the Atlantic coast flyway of the United States. Further research in these areas is vitally needed to determine any point in the natural maintenance of the virus where intervention might lead to control or eradication of the endemic disease.

Studies of transmission cycles are tied closely with simulation of cycles by models with carefully defined parameters. Such models may permit computer manipulation and simulation of field conditions by varying the values applied to defined parameters, following which epidemic curves can be generated. Further work on models is needed, with the hope of eventual prediction of emergence and spread of disease.

11.5 Disease in the Vertebrate Host

Studies of the human response to arboviral infections are difficult, since the epidemics that provide numbers of cases for study usually occur unpredictably in time and often far from modern facilities required for detailed clinical investigation. Classically, studies of infection in the vertebrate host (including man) have been part of research programs in the fields of pathology. However, animal models are available for only a limited number of the arboviruses. The development of these models will be crucial for the development modern vaccines and antiviral drugs.

Recognition of disease in the vertebrate host, as well as worldwide surveillance of disease, requires further development of simple diagnostic techniques and standardization of these assays using accepted reference reagents.

11.6 Control

Virus vaccines are a highly cost-effective means of disease control; yet for the arboviruses, only an attenuated yellow fever (17D) vaccine is in use on an international scale. The recent WHO recommendation that this vaccine be included in the Expanded Program of Immunization (EPI) in YFV-endemic countries was a major step toward the control of YFV in Africa [200, 201]. The threat of emergence of YFV in South America has prompted some to call for

consideration of inclusion of YFV vaccine in selected EPI programs in South American countries.

In the case of JEV, an inactivated vaccine has proved highly successful and is in wide-scale use in parts of Asia. An inactivated vaccine for tick-borne encephalitis also has been successfully used for decades in central Europe. However, inactivated vaccines are often costly and need recurring reimmunizations to booster immunity. Advanced testing of the new attenuated JEV vaccine, now in partial use in China, should receive high priority. Research, safety testing, and standardized production studies needed to include such a vaccine in international immunization programs should be strongly supported.

Control at the vector level involves continuing work on methodology for control of arthropods. Development of resistance to various insecticides has impaired many control programs, and recent regulatory actions limiting the use of insecticides have further intensified the need for exploration of alternative methods for vector control.

Limited studies utilizing biological mosquito control (such as *Bacillus thuringiensis*) to control selected arbovirus vectors have been encouraging and may lead to widespread control strategies. Other approaches that need further research include those that introduce genes into a mosquito population relating to (1) increased insecticide susceptibility, (2) reduced capacity to support virus multiplication and/or to transmit virus, (3) alternatives in host feeding preferences, (4) reduction in numbers through mutations leading to reduction in reproductive success (sterile males, conditional lethal mutants), and (5) subversions of host feeding habits.

1 Historical Background

Jaundice or icterus and other diseases of the liver were described in the writings of a number of ancient societies including old Chinese, Greek, Roman, Babylonian, and Talmud literature. Jaundice was generally considered obstructive in origin, although large epidemics associated with military campaigns were described as early as the seventeenth century and continued through World War II [1–6]. Over the years and until discovery of the hepatitis A (HAV) and hepatitis B (HBV) viruses, many synonyms were used to describe viral hepatitis of undetermined origin, later referred to as HAV. These included among others the terms acute catarrhal jaundice, epidemic catarrhal jaundice, epidemic hepatitis, icterus epidemicus, infectious hepatitis, campaign jaundice, and MS-1 hepatitis. From the 1940s through the 1960s, extensive efforts to identify the agent(s) associated with viral hepatitis were unsuccessful [2, 6]. Epidemiologic evidence supported two types of hepatitis viruses: infectious hepatitis (later identified as HAV) and serum hepatitis (later identified as HBV). However, a clear distinction could not be made between the two agents until transmission studies were conducted in primates [1, 7–11]. Studies, conducted between 1940 and 1965, clarified clinical and epidemiologic distinctions and lack of cross-immunity between the two forms of viral hepatitis MS-1 and MS-2, later classified as HAV and HBV, respectively. Clinical studies in the late 1940s and onward established the efficacy of immune serum globulin (IG) in preventing infectious hepatitis A [1, 9, 10, 12].

The discovery of HBV in the early 1970s and development of serological assays further differentiated these two forms of viral hepatitis. However, the critical advance occurred in 1973 when HAV particles were identified through immune electron microscopy (IEM) in stool samples of patients with hepatitis

A [13]. The development of serological assays to distinguish between acute and resolved HAV infection during the next decade was pivotal in understanding the natural history, the epidemiology, and the pathogenesis of HAV infection [4]. The discovery of the hepatitis E virus (HEV) and the development of diagnostic assay for HEV enabled further distinction between HAV and HEV infections which share similar epidemiology and clinical characteristics [14]. Finally, the identification and characterization of the HAV genome has added power-full tool for the investigation of the phylogenesis and molecular epidemiology of HAV [15–18]. HAV was first grown in cell culture in 1979 [19], and vaccines developed from cell culture-derived attenuated virus have been shown to effectively prevent hepatitis A [20, 21].

2 Methodology Involved in Epidemiologic Analysis

2.1 Mortality

HAV infection has a low case fatality rate, and mortality from hepatitis A is a poor indicator of disease incidence. Although viral hepatitis has been included in the International Classification of Diseases (ICD) for decades, neither serological testing nor appropriate coding to distinguish different viral etiologies was available until 1980. The ICD-coded data on hepatitis A mortality has become more reliable in developed countries where serological testing is widely available. Because accurate serological testing is not widely available in developing countries, mortality statistics are unreliable and remain poor indicators of disease incidence.

2.2 Morbidity

Several factors have limited the usefulness of morbidity data in assessing the impact of HAV infection. In developed countries, the reporting of hepatitis A and hepatitis B as different diseases only started in the late 1970s, and it was not until 1980 that a diagnostic test for hepatitis A became available commercially. Furthermore, although viral hepatitis is a reportable disease in almost all countries, underreporting is assumed to reach >80 % even in developed countries [5, 22]. In less-developed countries, serological testing is not widely available, and each type of viral hepatitis is not reported separately. Consequently, it is difficult to make strict comparisons of reported rates of hepatitis A from different geographic areas.

In spite of these well-recognized limitations, cyclical patterns of increased disease incidence and trends of disease over time are reasonable indicators of the epidemiology of hepatitis A. Data derived from studies using serological testing to define the age-specific etiology of acute cases of viral hepatitis in specific locations can be combined with reported age-specific prevalence data to estimate the overall morbidity resulting from hepatitis A [23, 24].

2.3 Epidemiologic Studies

Epidemiologic studies that used serological assays to differentiate acute from resolved HAV infections have greatly increased the understanding of this disease. Recently, nucleic acid variation within the region of the HAV genome that codes for the capsid (surface) proteins has been used as a marker in epidemiologic studies [5, 17, 25].

The spread of HAV infection can be assessed through monitoring the overall and age-specific anti-HAV (IgG) seroprevalence in selected populations which also enables indirect measurement of incidence rates. Overall prevalence has been classified into high (≥90 % of population by age 10 years), intermediate (≥50 % by age 15 years with <90 % by age 10 years), low (≥50 % by age 30 years with <50 % by age 15), and very low (<50 % by age 30 years) [22].

A new classification is emerging regarding endemicity of HAV worldwide based on reported incidence of serologically confirmed acute HAV cases through detection of anti-HAV (IgM) antibodies [5, 22]. Accordingly, endemicity to HAV may also be classified as very low, with an estimated incidence of <5 cases/10^5; low, 5–15 cases/10^5; intermediate, 15–150 cases/10^5; and high, >150 cases/10^5. Cross-sectional studies of the prevalence of HAV infection in population samples stratified by age, and in some cases by socioeconomic status, have been completed in many parts of the world and provide the most accurate picture of HAV infection [23, 24, 26–28]. Serological testing of representative samples of acute hepatitis cases in children and in adults has been used to define the proportion caused by HAV. In less-developed countries, these data can be combined with reported age-specific rates of acute hepatitis to estimate disease incidence. Studies to define the risk of HAV infection in certain groups or populations have primarily been confined to persons traveling from countries with low HAV endemicity to regions with high rates of infection. Some data are available to define the current risk of infection in men who have sex with men (MSM), drug users, the developmentally disabled, children attending day care, persons working in day-care settings, or health-care workers [5]. Estimates on the national burden of HAV-associated disease should include data on patients with fulminant hepatitis and those with HAV-induced liver failure referred for liver transplantation.

Mechanisms or pathways of disease transmission have been defined by serological testing of persons ill or exposed in outbreaks and in some instances by analysis of genetic variation of HAV isolates [5, 17, 20]. Serological testing, or HAV-RNA detection and sequencing, has improved our

knowledge of the epidemiology of common-source outbreaks (i.e., through contaminated strawberries, shellfish, or lettuce), community-wide outbreaks, outbreaks associated with day-care centers and institutions for the developmentally disabled, and outbreaks occurring in hospitals.

2.4 Laboratory Methods

2.4.1 Isolation and Identification of the Virus

Primary virus isolation from clinical or environmental specimens (i.e., feces, water, shellfish, or strawberries) has become possible using various primary or continuous cell lines. However, because of the slow growth characteristics of HAV (up to 120 days), prolonged adaptation periods are required before either infectious foci or HAV antigen can be detected [19, 29]. HAV generally does not produce a cytopathic effect in cell culture, and detection of virus requires special time-consuming techniques such as the radioimmunofocus assay (RIFA), which uses radiolabeled antibody to detect infectious foci of HAV in fixed cells [29]. The inability to rapidly culture HAV has precluded the use of this method for the diagnosis of infection or for detection of HAV in environmental samples.

Immune electron microscopy (IEM) was used extensively in early studies to identify HAV [13] but has been supplanted by more sensitive techniques. These include immunoassays to detect HAV antigen [30, 31] and detection of HAV-RNA by polymerase chain reaction (PCR), the latter being the method of choice for detection of low levels of HAV in clinical and environmental samples [17, 25, 32–34]. However, the presence of HAV-RNA may not always equate with the presence of infectious virus [35].

2.4.2 Serological and Immunologic Diagnostic Methods

In the 1980s, immunoassays to detect antibodies to HAV structural antigens (anti-HAV) became available commercially, including those that detected both IgG and IgM antibodies (i.e., total anti-HAV often referred to as anti-HAV (IgG)) and anti-HAV (IgM), which allow the differentiation of past and current (within prior 6 months) infections [33, 36]. To better evaluate the effectiveness of hepatitis A immunization, quantitative assays for anti-HAV antibodies (IgG and IgM) with increased sensitivity have been developed. Cell culture assays that detect low levels of neutralizing antibodies have been used in the early phases of HAV vaccine development [31, 37]. An experimental assay for detection of an immune response to nonstructural HAV proteins has raised hopes to establish a method for differentiation between anti-HAV (IgG) response to acute HAV infection and response to immunization [38]. However, in contrast to HBV, no licensed immunoassays are yet available for this purpose.

3 Biological Characteristics of the Virus

HAV is a small (27–32 nm) non-enveloped RNA virus belonging to the family Picornaviridae. The virus has icosahedral symmetry, has a buoyant density of 1.33 g/cc, and contains a single-stranded positive-sense RNA of approximately 7,500 (Figs. 17.1 and 17.2). The virion is composed of at least three major structural viral capsid polypeptides: VP1, VP2, and VP3 (33,000–22,000 Da). Based on the nucleotide sequence, VP4, another viral capsid protein of approximately 2,500 Da, should be encoded but has not been identified in mature virions [20]. The genomic organization and replication of HAV appear similar to that of polio and other picornaviruses; viral RNA encodes a single large polyprotein from which structural and nonstructural proteins are subsequently cleaved [30, 40, 41].

When compared to other enteroviruses, HAV has essentially no nucleotide or amino acid homology, replicates more slowly in cell culture, and is more resistant to heat inactivation. Although HAV was initially classified in the genus *Enterovirus* (*Enterovirus* 72), it has been reclassified in a separate genus designated *Hepatovirus* [42].

HAV is stable in the environment, retaining infectivity in feces for at least 2 weeks and having only a 100-fold decline in infectivity over 4 weeks at room temperature [33, 34, 41, 43, 44]. The virus resists extraction by nonionic detergents, chloroform, or ether and retains infectivity in pH 1.0 at 38 °C for 90 min. HAV is more resistant than poliovirus to heat, being only partially inactivated at 60 °C for 1 h [34]. When suspended in milk at 62.8 °C for 30 min, 0.1 % infectivity remains, suggesting that pasteurization may not completely inactivate HAV and temperatures of 85–95 °C for 1 min are required to completely inactivate HAV in shellfish [34, 45, 46]. HAV is completely inactivated by formalin (0.02 % at 37 °C for 72 h) but appears to be relatively resistant to free chlorine, especially when the virus is associated with organic matter [34]. An outbreak of hepatitis A among swimmers suggested that if a prescribed free chlorine level of 0.3–0.5 ppm existed in the swimming pool, it failed to inactivate HAV in fecally contaminated water [47]. Only sodium hypochlorite, 2 % glutaraldehyde, and quaternary ammonia compound (QAC) with 23 % HC1 have been effective in reducing the titer of HAV by more than 10^4 on contaminated surfaces [48].

HAV exists as a single serotype, and monoclonal antibodies that identify overlapping neutralization epitopes react with virus isolates from all parts of the world [41]. The single immunodominant neutralization epitope appears to be highly conformational and is composed of several sites located on VP1 and VP3 [34, 41, 49, 50]. There are seven known HAV genotypes, defined by sequence of the VP1/P2a junction region of a global collection of viruses [17, 26]. Genotypes are defined by a sequence variability of ~15 % in these regions, while subgenotypes differ by 7.0–7.5 %. Four

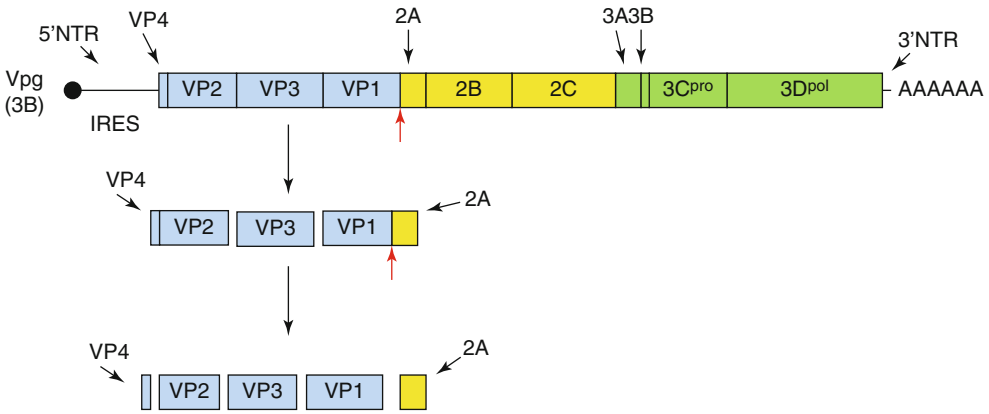

Fig. 17.1 HAV genome organization. On top a scheme of the HAV genome is shown. The positive-strand (messenger-sense) RNA genome contains a single open reading frame encoding a polyprotein that is proteolytically processed by the viral protease $3C^{pro}$. A yet-to-be-identified cellular protease cleavage in VP1-2A is indicated by a *red arrow*. Structural proteins (*P1*) are indicated in blue; nonstructural proteins (*P2* and *P3*) are indicated in *yellow* and *green*, respectively (Reproduced by permission reference Cristina and Costa-Mattioli [39])

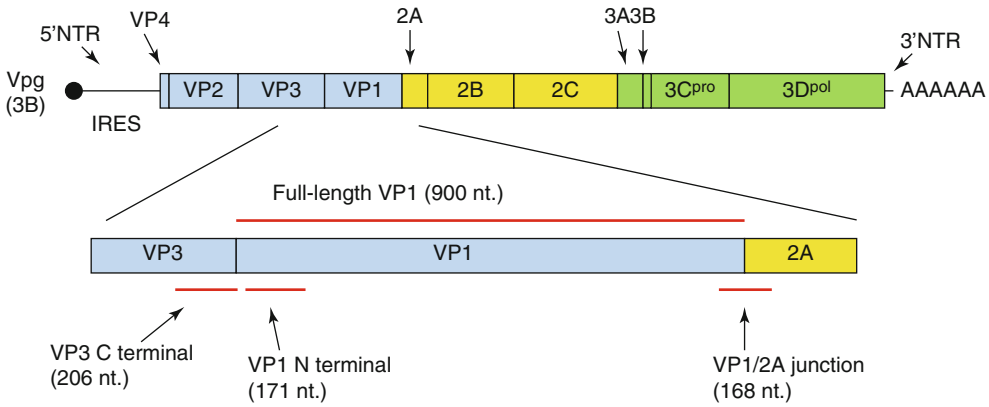

Fig. 17.2 HAV genome regions used for genetic analysis. The *thick red lines* below the genome scheme indicate the different genomic regions used to characterize the different HAV isolates (Reproduced by permission reference Cristina and Costa-Mattioli [39])

genotypes, namely, I, II, III, and VII, were identified in infected humans, while genotypes IV, V, and VI have been found in infected nonhuman primates. Recently, the seven HAV genotypes have been re-classified into six genotypes while genotype VII is now defined as a subgenotype of genotype II [18]. The identification of the various HAV genotypes and subgenotypes has significantly enhanced the ability to investigate the molecular epidemiology of hepatitis A outbreaks and particularly its transmission routes [17, 25].

Besides man, the host range of HAV includes nonhuman primates (marmosets, tamarins, owl monkeys, chimpanzees) that have been infected experimentally and have served as animal models of human HAV infection [51–53]. In addition, several species of Old World monkeys have been shown to be infected with an HAV that is serologically similar to the human virus but genetically distinct and that does not appear to infect humans [7, 34, 54].

In 1979, cell culture of HAV in fetal rhesus monkey kidney cells was achieved only after the virus was passaged multiple times in marmosets [19, 34]. Since then, HAV has been cultivated directly from clinical or environmental samples, but long adaptation periods (4–10 weeks) have been required for detection of significant amounts of HAV antigen in infected cells. The lack of a cytopathic effect allowed serial passage of virus that ultimately produced strains that replicate more rapidly and produce higher virus yields [34]. HAV that has been adapted to grow efficiently in cell culture appears to have mutations in the 2B and 2C areas of the genome that codes for nonstructural proteins [34]. In addition, cytopathic variants of HAV have been isolated, and similar to polio, these variants produce plaques in cell culture and have proven useful in laboratory studies [34, 55].

4 Descriptive Epidemiology

4.1 The Changing Epidemiology of HAV and the Impact on Global Burden of Infection

Prior to identification of its specific viral etiology and the development of diagnostic tests, hepatitis A was presumed to be the cause of most sporadic and epidemic hepatitis worldwide. Large epidemics of hepatitis A occur in developing countries and

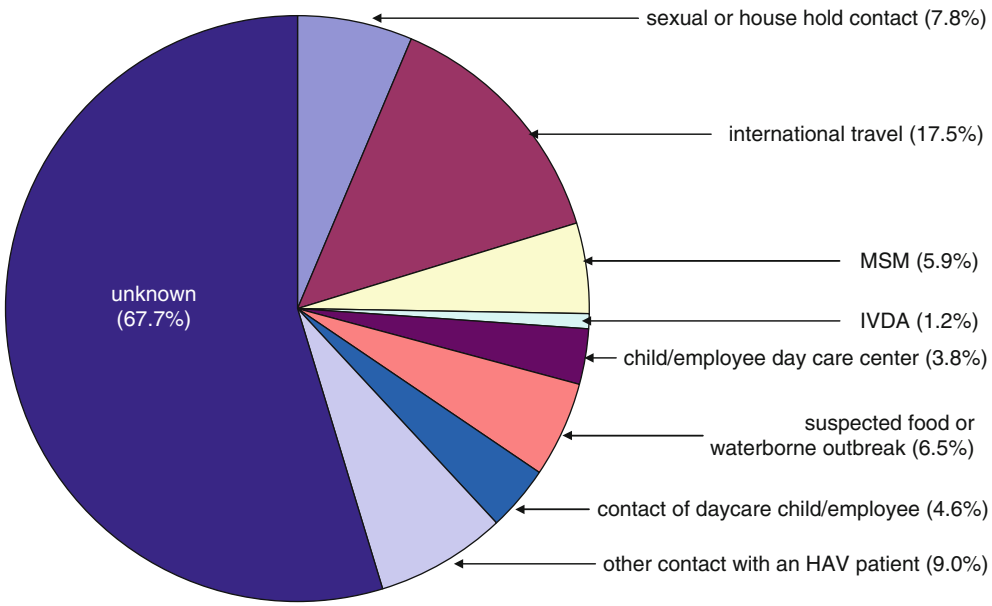

Fig. 17.3 Epidemiologic risk groups for acute hepatitis A virus infection obtained from reported cases in the United States in 2007. *MSM* men who have had sex with men, *IVDA* intravenous drug abuse (Modified from reference Daniels et al. [61])

especially in countries in transition from high to intermediate endemicity of HAV. However, it appears that hepatitis E is also an important cause of epidemics of hepatitis that involved large numbers of people, especially in India and central Asia [3, 56].

Data on the global incidence of disease (GID) and global burden of disease (GBD) of acute HAV infection is incomplete, with an assumed underreporting rate of ≥80 % [28, 57–61]. The WHO has recently completed a preliminary survey for reassessment of the GBD of HAV disease. Estimates suggest an increase in the number of symptomatic acute hepatitis A as well as subclinical cases globally from 177 million in 1990 to 212 million in 2005 and deaths due to hepatitis A to increase from 30,283 in 1990 to 35,245 in 2005 [22, 23]. Increased numbers of cases were estimated to occur in the age groups 2–14 years and >30 years. An epidemiologic shift from high to intermediate endemicity of HAV is now being recognized worldwide. As a result, more adults in such areas of transition escape exposure to HAV in early childhood and become susceptible to infection during outbreaks. This change in susceptibility to HAV infection is paradoxically associated with an increase in disease incidence rates in the presence of improved socioeconomic and sanitary conditions. An example for the potential consequences of such a shift in endemicity was clearly demonstrated during the massive 1988 outbreak of hepatitis A in Shanghai where >300,000 individuals contracted HAV infection within a short period [62, 63].

HAV infection is mainly spread through the fecal–oral route as well as through contaminated water and food. Shellfish are able to ingest and concentrate HAV and as a result become a reservoir for spread of the virus [63, 64]. Transmission occurs mainly through common-source outbreaks (i.e., food- and waterborne) as well as person-to-person contact. HAV is very rarely transmitted through blood products or medical procedures. Epidemiologic risk groups include populations of low socioeconomic status living under crowded conditions, household contacts of infected individuals, children visiting day-care centers and kindergartens, international travelers from countries with low endemicity to areas with intermediate or high endemicity, MSM, intravenous drug users, patients with chronic liver disease, food handlers, caretakers of nonhuman primates, and patients with blood clotting disorders. The clinical expression of HAV infection is highly age dependent. Serological studies have confirmed that less than 10 % of infected children under age 6 will become jaundiced, whereas in adults and children above age 5, infection may cause jaundice in 50–90 % of cases [65–68].

The increased incidence of HAV infection in adults has had an impact on the magnitude and severity of the disease as recently reported from Korea [68, 69] and Brazil [70]. Furthermore, in countries in transition, pockets of intermediate endemicity may exist within the same areas of high endemicity. Despite the observed low attack rates of clinical hepatitis, especially in areas of high but also in countries with intermediate endemicity in transition, HAV infection has been identified as a leading cause of fulminant hepatic failure in a growing number of countries including Korea [71], Argentina [70, 72, 73], and Brazil [70].

The major risk groups for contracting HAV infection reported by the US Centers for Disease Control and Prevention (CDC) for the year 2007 are shown in Fig. 17.3 [61].

4.2 Prevalence and Incidence

The age-specific prevalence of anti-HAV (IgG) antibodies worldwide can be used to define several patterns and risks of infection [23] (Fig. 17.4).

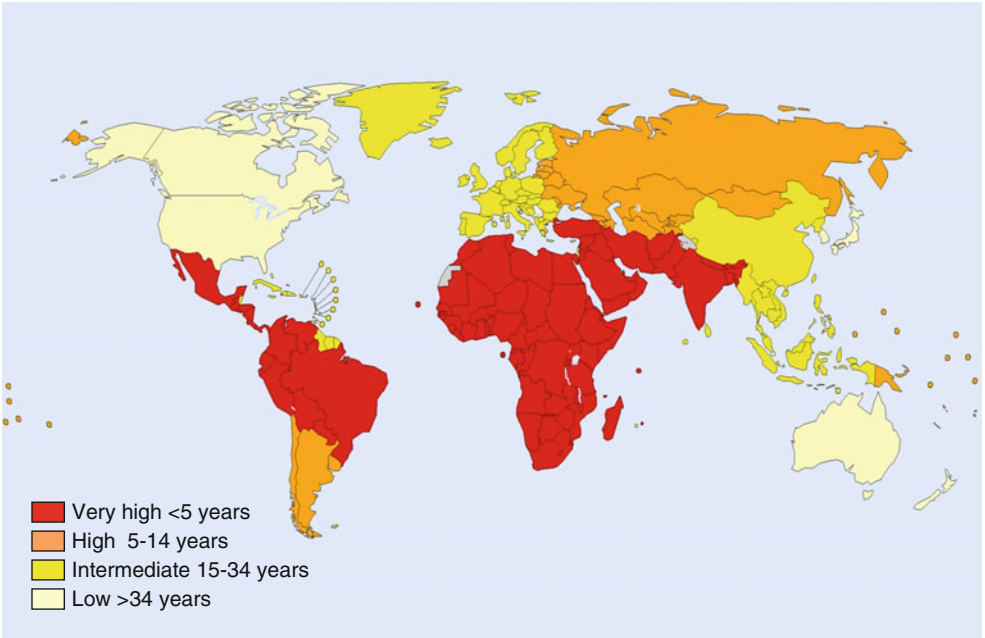

Fig. 17.4 Global risk map of HAV immunity in 2005. Age at midpoint of population immunity to HAV (Reproduced from BioMed Central, reference [74])

Many data on the global prevalence of HAV are outdated and recorded between the late 1970s and early 1990s prior to major shifts in endemicity. Areas with a very high endemicity of infection primarily consist of less-developed and developing nations of Asia, Africa, South and Central America, the Pacific Islands and certain populations in southern regions of Eastern Europe [26]. In these countries and until recently within ethnically defined populations or regions also in the United States, the prevalence of past HAV infection in adults has reached 90 % or higher; almost all older children had serological evidence of prior infection, and most children became infected by the age of 10 years [24, 75, 76]. However, persons of upper socioeconomic status residing in these regions have not become infected until they were adolescents or young adults.

In more developed counties in Western Europe (excluding northern regions) and some countries in Asia, the endemicity of HAV infection was already intermediate to low in the prevaccine era, and the prevalence of anti-HAV (IgG) varied widely [24, 27]. During the 1980s in countries such as Greece, Italy, and Taiwan, prevalence of past HAV infection in adults reached 80–90 %; while in children under age 10, the prevalence was only 20–30 %. The major increase in prevalence of infection occurred between 10 and 19 years [77–79]. In several Western European countries and the United States and prior to introduction of mass vaccination, anti-HAV (IgG) prevalence in young adults varied from 30 to 70 % but was less than 10 % in children under age 10, while low socioeconomic status was associated with high rates (endemicity) of past infection [80].

In some northern European countries, endemicity of HAV infection is very low. In several regions in the United States and in Japan, HAV infection is disappearing, and the endemicity of infection is considered low or very low. Until recently, in some US states, 30–60 % of US adults >40 years old had serological evidence for past HAV infection. In contrast, the prevalence of infection is less than 10 % in young adults and almost nil in children. In both very-low- and low-endemicity areas, there is evidence that a cohort effect accounts for the high prevalence of infection among older adults, indicating that HAV infection was much more common in the past, especially among persons who were born prior to World War II [24]. The epidemiology of HAV infection is rapidly changing in countries and regions which introduced mass or universal vaccination against HAV in babies and young children [5, 23, 81, 82]. Consequently, in such regions and countries, assessment of prevalence and incidence of HAV infection should be divided into pre- and postvaccination periods. For example, in the United States, endemicity of HAV is shifting from intermediate to low and very low prevalence of infection in populations previously considered at risk [83] as also shown in Israel [84] and some regions in Spain, Italy, and Australia [5]. The impact of rising socioeconomic conditions, improved sanitary conditions, and vaccination of children against hepatitis A is clearly shown in surveillance of incidence which has markedly dropped in age groups 5–39 years according to data obtained by the US Centers for Disease Control (CDC) [61, 83] as shown in Fig. 17.5.

4.3 Epidemic Behavior and Contagiousness

Rates of hepatitis A are not inherently stable, and periodic widespread epidemics may occur in high, intermediate, and

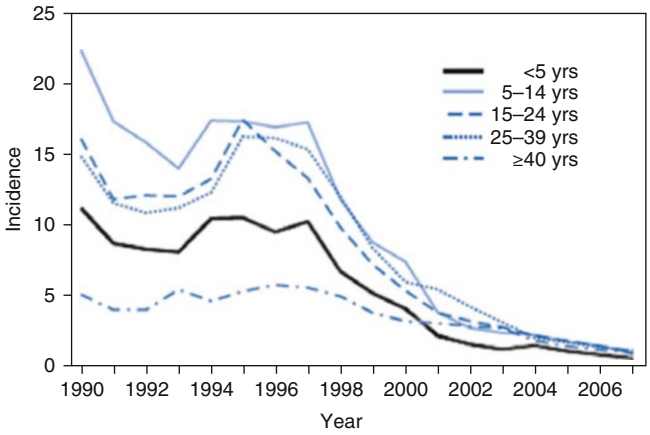

Fig. 17.5 US CDC report on decline of hepatitis A incidence between 1990 and 2007 [85]

even low endemicity areas and produce cyclical patterns of infection. However, over the past 20–40 years, nationwide epidemics of hepatitis A have gradually declined in most countries with a low endemicity of infection, while epidemic cycles continue to occur in countries with either a high or intermediate endemicity in transition. Determinants of the cyclical recurrence of epidemics include the age-specifc proportion of the population susceptible to infection, the interepidemic rate of HAV infection and the likelihood that HAV will be introduced into the susceptible population. Several patterns appear to produce these epidemic cycles: (1) high rates of asymptomatic infection in children under age 5 who serve as a reservoir for spread of infection to susceptible older children, a pattern observed in American Indian populations [86]; (2) periodic introductions of HAV into largely susceptible isolated populations where epidemics occur due to living conditions that facilitate virus transmission and where the high attack rate results in the disappearance of hepatitis A during interepidemic periods, a pattern observed in Alaskan Native villages and some Pacific Island populations [87, 88]; and (3) the periodic introduction of HAV through vehicles such as food in populations where the standard of living has improved and a large proportion of the young adult population remains susceptible, a pattern observed in Shanghai, China, during the 1988 hepatitis A epidemic [63]. Smaller outbreaks continue to play a role in disease transmission in the United States and elsewhere [89]. Common-source outbreaks related to contaminated water, shellfish harvested from sewage-contaminated areas, or food contaminated by an infected food handler have been recognized for many years [34, 90–95]. Outbreaks among MEM and drug users have been recognized in recent years, with infections in the latter probably occurring from person-to-person spread or occasionally from common-source contamination of illicit drugs, although HAV has rarely been transmitted parenterally [96–99]. In addition, outbreaks may occur among adult contacts (parents, caretakers) of diapered children in day-care settings [100, 101].

4.4 Geographic Distribution

As described previously, HAV infection occurs worldwide with endemicity patterns defined by the socioeconomic development of the individual nation and impact of vaccination campaigns. Published world maps on the prevalence of HAV infection have been useful to convey public health messages as shown in Fig. 17.4. Yet most data on the global prevalence of HAV infection are decades old. Consequently, as the socioeconomic status of the population increases, endemicity declines and the median age of infection increases, such maps require frequent updating. Recently, it was suggested that world maps should also use the age at midpoint of population susceptibility as a standard indicator for the level of HAV endemicity within the world regions [74]. In the least-developed countries, HAV transmission occurs exclusively during early childhood, almost the entire population becomes infected before age 10 years, and clinical disease is recognized only in older children. As hygiene/sanitation standards improve, the age of infection shifts progressively to include older children and young adults, particularly in upper socioeconomic groups. This may result in higher rates of clinical disease, and common-source outbreaks and/or nationwide epidemics appear if a substantial proportion of adults remain susceptible to infection. As sanitation and socioeconomic conditions improve further, the infection frequency in all age groups and overall rates of disease decrease; clinical disease is recognized in older children and young adults, and localized outbreaks may occur. Finally, in some developed countries, infection rates decline in all age groups, and cases of disease occur primarily as importations from areas having a high endemicity of infection.

4.5 Temporal Distribution

Long-term follow-up data from Europe and the United States have shown a marked change in patterns of reported incidence of disease in the past 50 years. Prior to and immediately following World War II, hepatitis rates were high, and nationwide epidemics, presumably of hepatitis A, occurred at 6- to 10-year intervals. In addition, seasonal fluctuations of the disease occurred, with peaks in the late summer and early fall. Following World War II, disease rates began to decrease in northern Europe and epidemic cycles disappeared, as did seasonal variation in disease rates. In the United States, improvement in overall socioeconomic conditions, sanitation, and hygienic standards and introduction of universal vaccination in states at risk have led to a reduction

of epidemic cycles which gradually are waning. The reported incidence of acute hepatitis A in the United States has declined by 92 %, from 12.0 cases per 100,000 population in 1995 to 1.0 case per 100,000 population in 2007 [61]. In the European Union (EU), though figures may vary among countries, the overall incidence of hepatitis A has decreased from 15.1 per 100,000 population in 1996 to 3.9 per 100,000 in 2006 [89].

4.6 Age

In the United States and prior to introduction of HAV vaccination, children aged 5–14 years have had the highest attack rates as shown in community-wide outbreaks affecting specific ethnic or low socioeconomic groups [86, 102, 103]. A bimodal distribution has been seen in day-care outbreaks, with children aged 5–9 years and adults 25–35 years most commonly affected [65]. In recent years, the overall incidence of hepatitis A declined among all age groups in the United States, but the greatest decrease recorded between 2001 and 2007 was among children <5 years of age. However, asymptomatic infection is common among young children, and symptomatic cases in children aged <5 years represent only a limited proportion of infections that occur in this age group [61]. In 2007, rates were highest for persons aged 25–39 years (1.3 cases per 100,000 population) [61].

During 1999–2006 and following the introduction of universal vaccination in 17 US states, the overall seroprevalence of anti-HAV (IgG) was 34.9 % as reported by the National Health and Nutrition Examination Survey (NHANES) [83]. During this period, US-born children living in vaccinating states had a higher seroprevalence (33.8 %) than children in non-vaccinating states (11.0 %). Seroprevalence among children increased from 8.0 % during 1988–1994 to 20.2 % during 1999–2006. For US-born children aged 6–19 years, the strongest factor associated with seroprevalence was residence in vaccinating states. Among US-born adults aged >19 years, the overall age-adjusted seroprevalence of anti-HAV (IgG) was 29.9 % during 1999–2006, which was not significantly different from the seroprevalence during 1988–1994 [83].

Similar age-specific prevalence patterns occur in regions which initiated mass vaccination campaigns in Europe and Australia [104]. In countries with a low or very low endemicity of infection, the disease and the prevalence of anti-HAV(IgG) are largely limited to adults, since the majority of infections are imported. Seroprevalence rates vary considerably in various African, Asian, and South American countries where HAV endemicity is either high or in transition [26]. In populations with a high endemicity of infection, cases occur primarily in children, as all adults are immune as a result of infection in childhood.

4.7 Sex

Until 2002, rates of acute hepatitis A had consistently been higher among males than among females at a ratio of almost 2:1; however, by 2007, overall rates had declined more among males than among females, and the reported incidence in males was 1.1 cases per 100,000 population, compared with 0.9 cases per 100,000 population among females [61].

4.8 Race

Hepatitis A occurs in all racial groups, and race per se is not believed to predispose to infection except when related to socioeconomic status or country of origin [101]. Hepatitis A rates in the United States have differed historically by race; the highest rates occurred among American Indian/Alaska Natives and the lowest rates among Asians/Pacific Islanders. In 2007, rates among American Indian/Alaska Natives dropped from >60 cases per 100,000 population before 1996 to 0.5 cases per 100,000 population. Rates for Hispanics decreased 94 %, from the peak of 24.1 cases per 100,000 population in 1997 to 1.4 cases per 100,000 population in 2007 [61].

4.9 Occupation

There does not appear to be an increased risk of HAV infection associated with a particular occupational group, although outbreaks of hepatitis A have occurred in persons working with certain nonhuman primates and sewage workers. Employment in a day-care center is a reported source of infection, but no studies have shown that this occupational group has an increased risk of infection compared to the general population. Susceptible persons from low endemic countries who work in or travel to countries with a high endemicity of HAV infection are at risk of infection, and this risk increases the longer they reside in the country [105, 106]. Outbreaks of hepatitis A in health-care workers are rare [107, 108]. Studies of health-care workers have shown that they are not at increased risk of infection [109, 110].

4.10 Military and Other Settings

Hepatitis A among military personnel stationed in low endemicity countries does not appear to differ from that in the

surrounding community. Outbreaks caused by contaminated food, exposure to children in day-care centers, and sporadic disease from person-to-person contact have been reported. However, prior to the availability of HAV vaccines, hepatitis A posed a risk among troops deployed to parts of the world where HAV infection is of high or intermediate endemicity. However, in recent years, American troops sent to regions with high or intermediate HAV endemicity are immunized prior to deployment. Consequently, the crude incidence of HAV in the US military is very low at 1.37/100,000 person-years, and the rate of hospitalization for HAV infection has declined sharply [111].

5 Mechanisms and Routes of Transmission

Studies in experimentally infected nonhuman primates and in humans have shown that HAV is excreted in large quantities (up to 10^8 infectious units per ml) in feces during the late incubation period and first week of clinical illness. Some studies suggest that children may shed virus longer than adults, but there is no evidence of chronic virus excretion [112–114]. Fecal shedding of HAV has been reported in patients with relapsing HAV infection [115]. Viremia occurs from the middle of the incubation period into the early clinical illness; infectivity titers of serum are 10^3- to 10^6-fold lower than those of feces. Virus is also present in saliva with an infectivity that may be 10^4 lower than serum [114, 116]. These physical data are firmly supported by epidemiologic data that have implicated the fecal–oral pathway as the predominant route of HAV transmission and occasionally demonstrated blood-borne transmission. Ingestion of infectious feces or vomits transferred from person to person or ingestion of contaminated food or water is the major route of HAV transmission. Blood-borne transmission occurs rarely and can lead to secondary outbreaks among health-care workers due to inapparent fecal–oral spread of the virus [117, 118]. Transmission among MSM has been well documented; whether this occurs through sexual contact or simply by non-sexual intimate contact is not certain [96, 119]. Finally, HAV-RNA was identified in breast milk of infected nursing mothers but without evidence for HAV transmission to their babies [35].

Common-source outbreaks have occurred from contamination of food and various sources of water, including streams, individual wells, or community supplies [34, 41, 120]. Food-borne outbreaks usually result from contamination by a food handler during the disease incubation period, and poor hygiene and diarrhea enhance the risk of transmission [90]. Implicated foods are usually handled extensively after cooking and/or are eaten uncooked. Such foods have included salads, sandwiches, glazed or iced pastries, and in the past some dairy products [34, 90, 121]. Outbreaks have been reported throughout the world when filter-feeding bivalve mollusks (clams, oysters, mussels) harvested from sewage-contaminated waters have been eaten with little or no cooking [34, 91, 122]. In addition, outbreaks have occurred from foods contaminated at the time of harvest or processing that are subsequently served raw and have included lettuce, strawberries, and raspberries [34, 92, 93]. Nevertheless, during the 1990s, in the United States, disease traceable to contaminated food or water constituted less than 5 % of the overall disease burden [102].

Direct person-to-person transmission by the fecal–oral route accounts for most infections in all parts of the world. Susceptible household contacts have a 10–20 % risk of acquiring infection from a family member with acute illness [123, 41]. Person-to-person transmission is the predominant pathway in the day-care setting, in community-wide outbreaks, and among homosexual men. The common denominator of close contact in settings with less than optimal hygiene accounts for the ease of HAV transmission.

Transmission in the day-care setting has received close study and provides a model for person-to-person disease transmission [65]. In centers enrolling children in diapers, hepatitis A outbreaks may be common and involve transmission not only among young children but also among adult contacts in the center, at home, or in the community. Infected children are rarely jaundiced, but they transmit HAV to adult contacts who are more likely to become symptomatic and comprise 70–80 % of recognized cases. Adult contacts of 1- to 2-year-old children are at highest risk of infection; risk of transmission decreases with increasing age of the child, and contacts of older children (age 5–6 years) are not commonly affected. In centers not enrolling children in diapers, outbreaks are uncommon, and spread following the introduction of infection is limited. HAV spreads rapidly but silently among mobile, fecally incontinent children in day care and subsequently to their contacts.

The day-care model indicates that asymptomatic HAV-infected children are highly infectious and efficiently spread disease. Among persons without an apparent source for their HAV infection, almost 50 % have a child less than 5 years of age residing in the household. This suggests that much community-acquired hepatitis A may be acquired from inapparently infected young children.

Transmission of HAV by blood or blood products occurs infrequently and represents a very rare cause of posttransfusion hepatitis, i.e., in patients with blood coagulation disorder receiving multiple blood products [97, 117, 118]. Outbreaks of hepatitis A in hospitals have been traced to an index case (often an infant) who acquired infection through transfusion. Transmission to hospital staff exposed to feces

through breaks in infection control practices has occurred in neonatal intensive care units, with silent transmission among infants and high attack rates among hospital staff [117, 118].

6 Pathogenesis and Immunity

6.1 The Viral Life Cycle

The virological, immunologic, and clinical events that occur during HAV infection have been characterized in experimentally infected nonhuman primates and naturally infected humans [124, 125]. The incubation period may range from 14 to 45 days, with a median of 28 days observed in common-source exposures. Studies in experimentally infected nonhuman primates suggest that the incubation period is lengthened with the inoculation of a lower dose of virus or shortened when inoculated parenterally but that the clinical severity of disease is not dependent on dose and route of inoculation [114, 126]. Infection usually occurs through ingestion of HAV-contaminated food or fluid when HAV penetrates the gut mucosa reaching the liver through the portal circulation. HAV was demonstrated in intestinal crypts by immunofluorescence but replication was not verified. HAV has a specific tropism for hepatocytes which are the primary site of replication [125, 127]. HAV entry into hepatocytes is mediated most probably through a surrogate putative mucin-like glycoprotein receptor. Another hypothesis suggests that HAV enters the liver cell as a virus–IgA complex through the asialoglycoprotein receptor [128]. The virus replicates in the liver and is then shed into the bile and feces and to a lesser degree into the bloodstream. Upon hepatocyte cell entry, host cell ribosomes bind to the viral uncoated RNA. HAV-RNA is then translated into a major protein of 2,225 amino acids. This large polyprotein is divided into three regions: the P_1 region encoding for the structural proteins VP_1, VP_2, and VP_3 and the P_2 and P_3 regions encoding for the nonstructural proteins involved in viral replication (Fig. 17.1). HAV-RNA can be detected in body fluids and feces, using nucleic acid amplification and sequencing techniques (Fig. 17.2). Such methods, mainly used by research laboratories, have been utilized for studies on the genetic organization of HAV infection [4, 17].

HAV antigen is found primarily in the cytoplasm of hepatocytes but can also be found in liver macrophages (Kupffer cells). HAV appears in hepatocytes prior to detection in feces and prior to the onset of liver enzyme elevations. HAV is excreted via the biliary system into the feces where it appears in high concentrations from 1 to 2 weeks prior to onset of clinical illness. Virus excretion begins to decline at the onset of clinical illness, and in most persons, it has decreased substantially 1 week later. A modest proportion (< 33 %) of those infected may continue to excrete virus during the second and third week of illness, and children may excrete virus for longer periods than adults [112, 113, 118]. Between 5 and 20 % of cases may experience a relapse of symptoms and ALT rise, 2–8 weeks after the initial illness, and virus excretion may occur during this time [112, 115, 129]. Viremia is present from the middle of the incubation period until early in the clinical illness and during relapse [129].

In tissue culture, HAV can replicate and be released without cell damage. No cellular injury occurs during the high rate of viral replication that occurs early in the infection. The mechanism of hepatic cell injury induced by HAV is not fully understood, but available evidence suggests that it is immune mediated. The immune response to wild-type HAV infection involves the cellular, humoral, and innate limbs of the immune system.

6.2 Cellular Immune Response in Acute Hepatitis A

Infection with HAV leads to a cellular immune response which is involved in the immunopathogenesis of HAV infection and the induction of hepatocyte injury [130–138]. Despite the proven tropism of HAV for liver cells, the virus is not cytopathic, and liver cell injury occurs through activation of HAV multi-specific cytolytic T cells [137]. Inflammatory cell infiltrates isolated from liver biopsies of patients with hepatitis A contain CD_8-positive T cells which can specifically lyse hepatitis A virus-infected target cells in an histocompatibility leukocyte antigen (HLA) class I-restricted manner [130]. Although there is only limited information on involvement of the innate immune system in HAV infection, there is evidence that secretion of interferon gamma by activated T cells may facilitate the expression of HLA class 1 determinants on the surface of infected liver cells. Cytolytic T-cell epitopes residing on the structural protein of HAV may be involved in cytolysis of HAV-infected hepatocytes [134, 135, 137]. Little is known about the role of T-helper cells in mounting an immune response to HAV. One putative CD_4 T-cell helper lymphocyte epitope was identified on the VP3 102–121 sequence [132]. There is also some evidence that nonspecific immune mechanisms, including natural killer cells (NK) and lymphokine-activated killer cells (LAK), are involved in the induction of hepatocellular injury even before the initiation of cytotoxic T lymphocyte injury [133]. Finally, impaired function of CD4+/CD25+ regulatory T cells has been linked to the

frequent resolution of acute hepatitis A with spontaneous recovery [136].

6.3 Humoral Immune Response in Acute Hepatitis A

HAV infection generates a humoral immune response directed mainly against structural HAV proteins (Fig. 17.6). Diagnosis of acute hepatitis A is established through detection of anti-HAV (IgM) antibodies. Postinfection and postvaccination immunity is established through detection of total anti-HAV consisting mainly of IgG antibodies [17, 67, 139]. Presence of total anti-HAV antibodies in the absence of anti-HAV (IgM) antibodies signifies immunity against HAV and exclusion of acute HAV infection. Commercially available enzyme-linked immunoassays (EIA) are used for detection of anti-HAV (IgM) antibodies (directed against HAV capsid proteins). EIAs are also used for detection of total anti-HAV antibodies which consist mainly of anti-HAV (IgG) antibodies and referred to as such in this chapter. Anti-HAV (IgM) assays utilize the principle of direct binding of anti-HAV (IgM) in the test sample to anti-human IgM-coated matrix or particles. Qualitative competitive inhibition assays for measurement of total anti-HAV (IgG) antibodies are used in routine clinical practice. Experimental quantitative sensitive assays containing calibrators standardized against a WHO reference serum have been used in the assessment of anti-HAV (IgG) response to immunization.

Symptoms and signs of the acute infection usually occur within 2–4 weeks of exposure. IgM, IgG, and IgA anti-HAV antibodies appear shortly before or during the onset of symptoms [17, 126]. Anti-HAV (IgM) antibodies are detectable in symptomatic and asymptomatic patients alike. In symptomatic patients, anti-HAV (IgM) antibodies appear within 5–10 days before symptoms, or at the early phase of alanine aminotransferase (ALT) elevation, and persist for a period of about 4 months (range 30–420 days) (Fig. 17.6) [129, 140, 141]. In patients with relapsing hepatitis A (3–20 % of patients), anti-HAV (IgM), viremia, and shedding of HAV in the feces may reappear intermittently for up to 6 months and occasionally even longer [33, 126, 129, 140]. False-positive anti-HAV (IgM) may rarely be present >1 year postinfection or in patients with hyperglobulinemia [33, 67].

Anti-HAV (IgG) antibodies are usually detectable at the onset of symptoms, and their titer rises slowly parallel to the decrease in titer of anti-HAV (IgM) antibodies (Fig. 17.6). Anti-HAV (IgG) antibodies generated through natural infection provide protection against rechallenge with HAV and signify long-term immunity against hepatitis A apparently for life, irrespective of whether the infection was symptomatic or subclinical [17, 142]. Immunity to HAV is established by convention once anti-HAV (IgG) antibodies rise to a titer above 10–20 mIU/ml, depending on the immunoassay used for detection. However, the absolute lower limit of protective antibody level has not been determined [143].

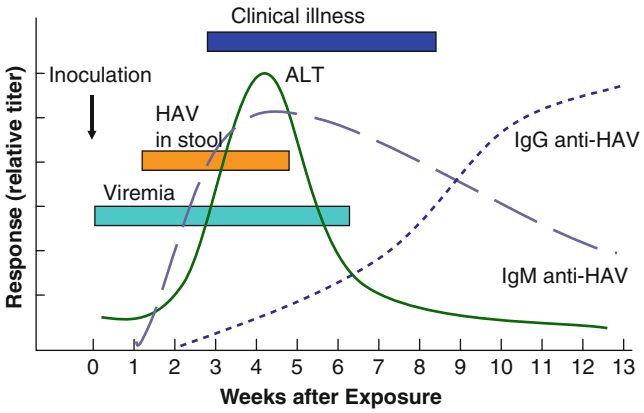

Fig. 17.6 Timeline of clinical and laboratory manifestations of acute hepatitis A. The sequence of events includes HAV viremia (*green-blue*) and shedding of infectious HAV in feces (*orange bar*), followed by increase in serum alanine aminotransferase (*ALT*) (*green line*) and the appearance of anti-HAV (*IgM*) (*gray*) and total, mainly anti-HAV (*IgG*) antibody responses (*blue dotted line*). IgM antibody declines within 3 months but can be detected in some patients as late as 6–12 months postinfection as well as in relapsing patients by sensitive assays. Data were obtained during the course of experimental infection in chimpanzees inoculated IV with human strain HLD2 (Modified from references Nainan et al. [17, 126])

Qualitative assays for total anti-HAV antibodies are used for prevalence studies and may be used for assessment of immunity pending and following vaccination. However, this method does not enable a distinction between immunity generated by "natural," wild-type HAV infection and vaccine-induced immunity. Such a differentiation may be possible in part through quantitative IgM and total anti-HAV measurements using modified, more sensitive (and experimental) immunoassays, since the humoral response to immunization is generally weaker compared to the response to wild-type HAV infection [139, 144]. The inability to distinguish clearly between these two situations led to an attempt to develop an antibody assay against nonstructural proteins of the P_2 and P_3 regions of the HAV genome, for differentiation of the humoral immune response against replicating virus from the response to a killed-inactivated HAV vaccine [145, 146]. However, at present, these tests remain a research tool only.

There are also other sensitive but also more time-consuming methods, compared to the commercially available assays for identification of neutralizing antibodies against hepatitis A. These assays, which are mainly used as a

research tool, include the radioimmunofocus inhibition assay (RIFIT), HAVARNA, and radioimmunoprecipitation assay [139].

The role of secretory immunity in hepatitis A remains unclear. Anti-HAV (IgA) antibodies have been detected in the saliva and feces of experimentally infected animals and humans [145, 146].

7 Patterns of Host Response and Clinical Outcome

7.1 Clinical Features

Acute HAV infection causes an acute necro-inflammatory process in the liver which normally resolves spontaneously. The clinical spectrum of acute disease is comparable to that of other types of viral hepatitis and ranges from few or no symptoms to fulminant hepatitis [147, 148]. However, in contrast to HBV and hepatitis C virus (HCV) infection, HAV infection does not lead to chronic liver disease. An important feature of HAV infection includes the relationship of age to clinical expression. Children under age 6 generally have mild, often nonspecific, symptoms that may include nausea and/or vomiting, malaise, diarrhea in 50–70 %, and fever or dark urine in 30–50 % [65]. Among those under age 3, fewer than 5 % become icteric, compared to 10 % of those aged 4–6 years. Data are less complete for children aged 6–14 years but suggest that symptom patterns are comparable to those of adults.

In adults, symptoms include malaise, fatigue, anorexia, vomiting, abdominal discomfort, diarrhea, pruritus, and less commonly fever, headaches, arthralgia, and myalgia [148]. Five clinical patterns are recognized: (1) asymptomatic HAV infection, often present in children under the age of 5 years; (2) symptomatic HAV infection with the appearance of dark urine and sometimes clay-colored stools, often accompanied or followed by jaundice; (3) cholestatic hepatitis characterized by pruritus, prolonged elevation of alkaline phosphates, gamma-glutamyl transpeptidase, bilirubinemia, and weight loss; (4) relapsing hepatitis A infection manifested by reappearance of the clinical, biochemical, and virologic markers of acute hepatitis A after initial resolution; and (5) fulminant hepatitis, which frequently resolves spontaneously under conservative care but which occasionally may require liver transplantation.

Extrahepatic manifestations of acute hepatitis A may occur and include skin involvement, vasculitis, pancreatitis, neuritis, encephalitis, carditis, glomerulonephritis, pneumonitis, hemolysis (especially in patients with glucose-6-phosphate dehydrogenase (G6PD) syndrome), cryoglobulinemia, and aplastic anemia [5, 41, 149]. Other post-icteric manifestations may occur in a minority of patients including prolonged fatigue, right upper quadrant discomfort, fat intolerance and indigestion, weight loss, emotional instability, and prolonged indirect bilirubinemia. Acute HAV infection resolves spontaneously in >99 % of infected individuals. Relapsing hepatitis A with subsequent complete resolution has been reported in 3–20 % of patients with clinical hepatitis A [129].

Fulminant hepatitis A is rare, with a wide range of estimated rates as low as 1:10,000 or more in immunocompetent individuals. About 70 % of fulminant hepatitis A patients experience a relatively high spontaneous survival rate; the remaining patients either die or require emergency liver transplantation. In the United States, hepatitis A accounted for 3 % of cases of fulminant hepatitis referred for liver transplantation. The Acute Hepatic Failure Study group reported in 2008 that only 29 % of 31 US patients with fulminant hepatitis A underwent liver transplantation [59, 150]. Recent reports from South America and Korea have raised concern that the current incidence of fulminant hepatitis A may be rising [59, 70, 71, 73]. Immunosuppressed patients and patients with chronic liver disease such as chronic hepatitis C and B are at an increased risk of developing severe or fulminant hepatitis [151]. Mortality in fulminant hepatitis is rare. Following the massive outbreak of hepatitis A in Shanghai, there were 47 death among >300,000 infected patients. Fatality in HBsAg+Chinese patients reached 0.05 % as compared to 0.015 % in non-HBV carriers [62]. In Western countries, reports suggest a case fatality ratio in age groups <40 years of ~0.3–0.6 %. In age groups >50 years and older, case fatality may rise to 1.8–5.4 % (these data were obtained prior to introduction of liver transplantation for HAV-associated liver failure) [11, 66, 81, 148, 152–154]. Risk factors associated with development of fulminant HAV infection are poorly understood [155]. Familial clustering of fulminant HAV cases and putative sequence variations have been suggested as potential risk factors [156–158] but await confirmation.

Hepatitis surveillance in the United States has shown the fatality rate among reported cases to be age dependent. The highest rates were recorded among children under age five (1.5 per 1,000 cases) and in persons over age 40 (27.0 per 1,000 cases), especially among those with underlying chronic liver disease [24].

7.2 Diagnosis of Acute Viral Hepatitis A

Diagnosis of hepatitis A requires demonstration of hepatocellular liver injury by standard biochemical tests (e.g., ALT, AST, bilirubin) and the presence of anti-HAV (IgM) antibodies. The intensity of hepatocellular injury (and clinical symptoms) is variable and ALT levels may rise to thousands of units accompanied by bilirubinemia and jaundice or remain very low, unicteric and undetected, especially in young children. Historically, in situation of major outbreaks,

documentation of hepatocellular injury and bilirubinemia has been used to classify such events as HAV induced provided one or more index cases were serologically positive for anti-HAV (IgM). Because of the higher frequency of nonspecific symptoms or anicteric infection in young children, the index of suspicion should be high in particular circumstances (i.e., those exposed in day-care centers), and testing for liver enzymes or anti-HAV (IgM) should be considered when an adult contact of a child has hepatitis. Clinical symptoms are inadequate to distinguish hepatitis types, and virus-specific serological testing must be done for all cases of presumed viral hepatitis. Commercially available anti-HAV (IgM) tests remain positive in virtually all cases tested within 2 months of the disease, often remaining detectable for up to 6 months after onset, and thus allow for the diagnosis based on a single acute or early convalescent serum specimen. Testing for anti-HAV (IgG) will not differentiate acute from past infection, but is useful for identifying immunity as a result of prior infection or immunization. Measurement of plasma HAV-RNA levels by PCR is not used in routine clinical diagnosis but remains an important tool for investigation of the molecular epidemiology of HAV and used especially in situations of outbreaks [15, 17].

8 Control and Prevention

There are three measures for protection against HAV infection: (1) improvement in personal hygiene, sanitation, and socioeconomic status; (2) passive prophylaxis with immunoglobulin (IG); and (3) active immunization with formaldehyde-inactivated or live-attenuated vaccines.

8.1 Personal Hygiene and Sanitation

Personal hygiene and environmental sanitation to prevent transmission through fecal contamination of food and water or by personal contact have been the primary means to control hepatitis A in any setting. Improved sanitation is presumed to have lowered the incidence of infection and disease in developed countries.

8.2 Passive Prophylaxis Against Hepatitis A with IG

Since the late 1940s and until recently, administration of human immunoglobulin (IG) prepared from pooled human plasma through ethanol fractionation [159] and containing high concentration of anti-HAV (IgG) antibodies has been used as an efficient means for pre- and postexposure prophylaxis against HAV infection [12, 143, 160]. The protective efficacy of IG is well documented [143, 161, 162], but duration of protection is limited to 12–20 weeks following intramuscular injection of 0.02 and 0.06 ml/kg weight, respectively. Preexposure prophylaxis is achieved within hours of injection. Postexposure administration is ~85 % effective when administered as close as possible to exposure and no later than 14 days [143]. The mechanism of protection against hepatitis A conferred by IG is not fully established, but most probably involves neutralization of circulating virus and possibly prevention of uptake of virus through the gut mucosa and hepatocytes.

Administration of IG is considered very safe, although contraindicated in patients with IgA deficiency. Interference with live-attenuated vaccines such as measles, mumps, rubella (MMR), and varicella requires special caution. Coadministration of IG with an active hepatitis A vaccine may blunt the initial quantitative anti-HAV (IgG) antibody response after the first vaccine dose [163, 164]. This effect, which is similar to the effect of passively transferred maternal anti-HAV (IgG) antibodies, is of minor significance, and such vaccines respond well to a booster dose given 6 months after the primary immunization. Finally, although administration of IG for pre- and postexposure short-term prophylaxis is highly efficacious, the use of immunoglobulin worldwide is now declining for a number of reasons: (a) nonspecific IG preparations increasingly fail to contain adequate amounts of anti-HAV (IgG) [165–168]; (b) cost of specific HAV IG preparations is high [167, 169]; (c) duration of IG-mediated protection against HAV infection lasts only several months as compared to hepatitis A vaccines [143]; and (d) hepatitis A vaccines have already been shown to induce very rapid pre- as well as postexposure protection against HAV following the first out of the two recommended doses [20, 37, 162].

8.3 Active Pre- and Postexposure Prophylaxis Against Hepatitis A

8.3.1 Serological Measurement of Protection

A positive (qualitative) test for anti-HAV (IgG) antibodies signifies immunity to hepatitis A. The lowest protective level against challenge with HAV is unknown. The reported minimal serum levels of anti-HAV (IgG) antibodies required for protection against HAV in humans vary between 10 and 20 mIU/ml depending on the immunoassay used for detection and regardless of whether these antibodies emerged following "natural" wild-type HAV infection or following vaccination [31, 139]. Clinical experience suggests that protection against hepatitis A following passive immunization with IG or active vaccination may still be present even in the absence of detectable anti-HAV antibodies using standard immunoassays [81]. Low levels of anti-HAV (IgM) antibodies may be detectable by a conventional assay for a few

weeks in ~20 % of recipients of HAV vaccines [37]. Therefore, anti-HAV (IgM) antibody assays cannot be used for reliable distinction between acute hepatitis A and anti-HAV response to vaccination.

8.4 Active Immunization

All HAV vaccines contain HAV antigens derived from cell cultures of attenuated HAV strains adapted to grow in human and nonhuman mammalian cells. Viral attenuation is associated with a number of mutations generated through serial passage of wild-type HAV [4, 5, 17, 170]. Comparison of the nucleotide sequence of complementary DNA (cDNA) cloned from wild-type virus with attenuated HM-175/7 MK-5 HAV strain revealed a small number of nucleotide changes distributed throughout the genome [170]. Most attenuated virus strains used for vaccine production are grown in human diploid MRC-5 fibroblasts, and the nucleotide and amino acid sequences of the virus are about 95 % identical among different strains. Cell culture-derived HAV antigen is purified, inactivated by formaldehyde, and adsorbed to aluminum hydroxide for the following vaccines: HAVRIX®, VAQTA®, and AVAXIM®). The HAV antigen in EPAXAL® is formulated in influenza-reconstituted virosomes. VAQTA®, HAVRIX®, EPAXAL®, HEALIVE®, and the Chinese Lv-8 inactivated HAV vaccine are at present preservative-free (Table 17.1). In addition to monovalent HAV vaccines, formaldehyde-inactivated combination vaccines have been developed in Europe against HAV and HBV or HAV and typhoid [5, 174–179].

Two live-attenuated hepatitis A vaccines were developed in China containing the H2 and LA-1 strains [172, 180, 181] used in a single-dose immunization schedule. Both these vaccines as well as two formaldehyde-inactivated vaccines, administered in two doses, were tested in clinical trials and integrated into the Chinese EPI in 2008 [172, 181] (http://www.who.int/wer/2010/wer8530/en/index.html).

Formaldehyde-inactivated hepatitis A vaccines are highly immunogenic and safe, providing rapid, protective immunity to hepatitis A within 2–4 weeks after primary immunization. A second dose is usually administered within 6–12 months after the priming injection, but the interval may be extended to 18–36 months depending on vaccine type. Long-term, most probably lifelong immune memory and protection after a complete vaccination has been predicted [104, 173, 182] and already documented for at least 17 years [182, 183]. Consequently, booster doses are not recommended in vaccinees who completed a two-dose vaccination schedule [104, 182, 184].

The immunogenicity of inactivated hepatitis A vaccine is blunted somewhat by preexisting antibodies, which occurs when vaccine is coadministered with IG [185, 186] or when given to infants of previously infected HAV immune mothers [187]. Yet, the clinical consequences of this phenomenon are most likely negligible in view of a recent report that vaccine-induced anti-HAV (IgG) seropositivity in children vaccinated <2 years of age persists for at least 10 years regardless of maternal anti-HAV (IgG) status [188].

8.4.1 Preexposure Prophylaxis Through Active Immunization

Inactivated hepatitis A vaccines have been licensed in Europe, Asia, Australia, and the Americas. The high efficacy of these vaccines in preventing hepatitis A in children has been shown in two pivotal placebo-controlled clinical trials conducted in Thailand and the United States demonstrating a 99 % efficacy after three doses and 100 % after two doses of aluminum hydroxide-formulated vaccines, respectively [18, 19]. In a third study a single dose of an inactivated vaccine formulated in virosomes was shown to provide complete protection against the disease [189]. Several factors have a marginal impact on blunting of anti-HAV (IgG) antibody levels following immunization. These include overweight, older age, smoking, as well as passively transferred anti-HAV (IgG) antibodies from pregnant mothers to their newborns. Lower sero-protection rates following vaccination have been reported in human immunodeficiency virus-infected patients as well as solid organ and stem-cell transplant recipients. As observed with other vaccines, anti-HAV (IgG) levels were reported to be higher in females as compared to males, following a priming and booster dose of the vaccine [5]. HAV vaccines have an excellent safety and tolerability record and are interchangeable [5, 81].

As more information has become available on the extraordinary immunogenicity, effectiveness, and safety of hepatitis A vaccines, immunization strategies have shifted from vac-

Table 17.1 Attenuated hepatitis A virus strains used for production of formaldehyde-inactivated hepatitis A virus vaccines

Attenuated HAV strain	Trade name	Adjuvant	HAV antigen dose/injection		Manufactures	Reference
			Pediatric	Adult

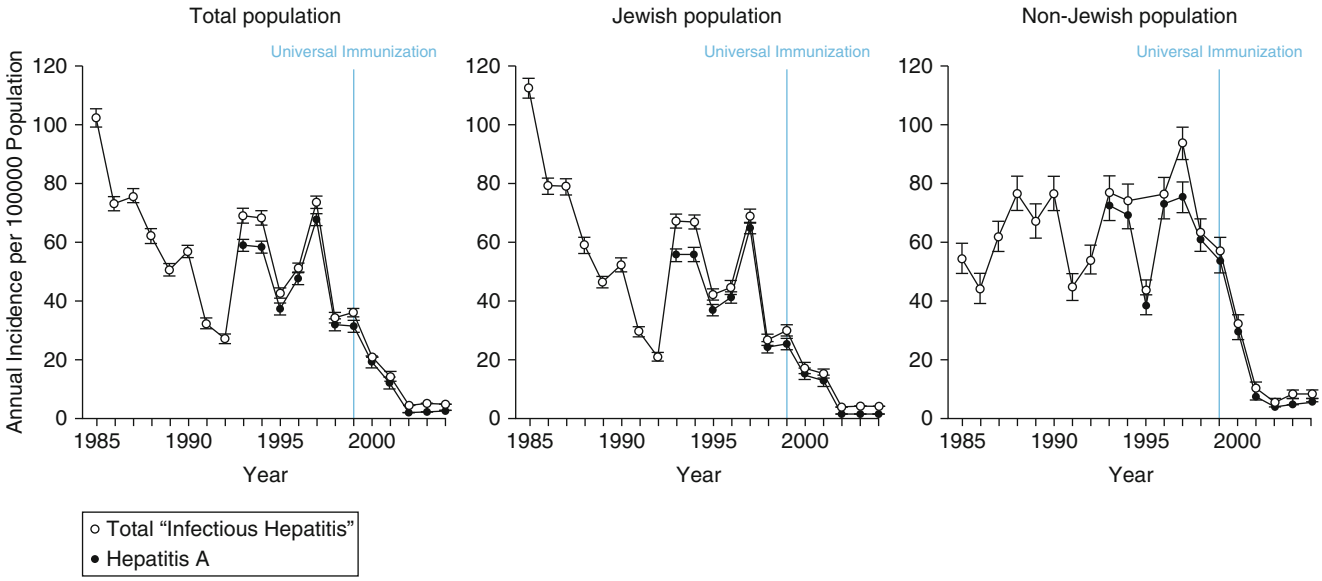

Fig. 17.7 The impact of universal vaccination against hepatitis A of 18-month-old toddlers on the incidence rates in the Jewish, the Arab, and the overall population in Israel. Data obtained by passive and active surveillance. Between1985 and 2004, acute hepatitis cases were classified as "infectious hepatitis" (including A, B, C, and nonspecified). Afterward, between 1993 and 2004, data include only serologically confirmed hepatitis A cases (Reproduced by permission from reference Dagan et al. [84])

cination of individuals belonging to specific risk groups to mass vaccination campaigns and then to universal vaccination, which is however still restricted to a limited number of countries [61, 81, 82, 84, 104, 190].

Following the licensure of HAV vaccines, four immunization strategies have been evaluated for preexposure prophylaxis. First, early efforts were aimed at immunization of individuals at increased risk, which included international travelers to areas of HAV endemicity, MSM, intravenous drug users, patients with chronic liver disease, food handlers, day-care center staff, caretakers of nonhuman primates, and patients with blood clotting disorders. This policy is still valid but has no or little public health impact on the herd immunity at large.

The second strategy included regional mass vaccination of pediatric populations at risk. Three demonstration projects conducted in the United States in native Americans in Alaska, in native American Indians, and in Butte County, California, led to a 94–97 % reduction in incidence of symptomatic acute hepatitis [82]. Consequently, in 1999, the US Advisory Committee on Immunization Practices (ACIP) issued a recommendation to introduce universal hepatitis A vaccination into routine childhood vaccination (two doses in children >2 years old and catch-up at the age of 10–12 years) in 17 states in the United States with an annual incidence of >20 cases/100,000. Postimmunization surveillance revealed that, despite variable first vaccine coverage of 50–80 %, a progressive decline in reported incidence of hepatitis A was observed from 21.1 cases/100,000 to 2.5 cases/100,000, which represents an 88 % drop (Fig. 17.5) [61, 82, 83]. Similar projects were introduced in Puglia, Italy, in 1997 [191]; in Catalonia, Spain, in 1998 [192]; and in North Queensland, Australia, in 1999 [193], leading to a 90–97 % decline in the reported incidence in these regions. The results of these highly successful vaccination projects in selected geographic regions worldwide suggested that mass vaccination of children in communities at risk is effective and will lead to herd immunity even under moderate coverage.

These early projects paved the way for the introduction of the third immunization strategy, namely, universal vaccination against HAV in selected countries with intermediate endemicity in transition. At present, 11 countries have embarked on the road toward universal HAV vaccination in babies. In 1999, Israel, a country with intermediate HAV endemicity in transition, became the first country to introduce universal HAV vaccination given in two doses to toddlers at 18 and 24 months of age. At a vaccination coverage of 90 and 85 % for the first and second dose, respectively, the annual incidence of hepatitis A dropped sharply within 2–3 years of program initiation. An overall decline of 95 % in incidence was documented not only in babies but also in the unvaccinated adult population (Figs. 17.7 and 17.8) [84]. Thus, immunization of ~3 % of the population annually led to a marked decrease in attack rates of HAV infection in all age groups until the age of 44 years and a shift from a state of intermediate HAV endemicity to very low endemicity with an annual incidence of ~2.5 cases/100,000.

In the United States, the public health objective of hepatitis A vaccination is the reduction of disease incidence and possibly eradication of HAV infection through routine infant

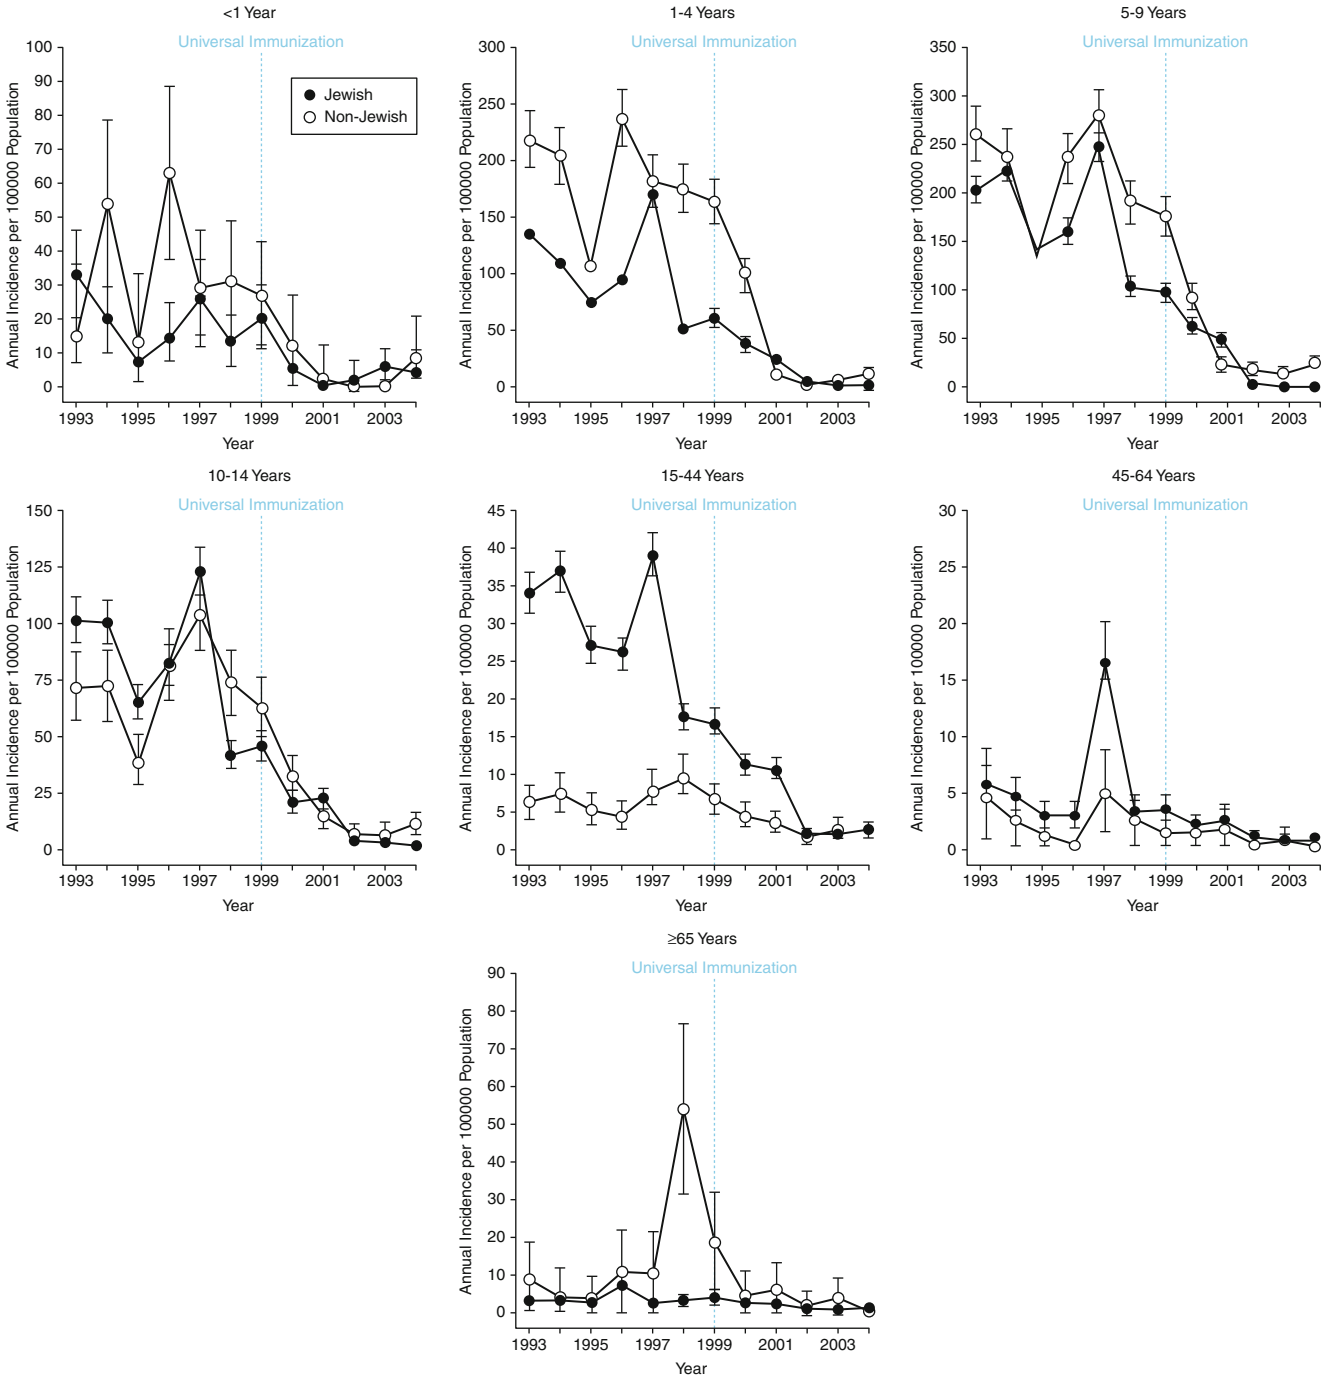

Fig. 17.8 Annual age-specific incidences of reported hepatitis A disease among the Jewish and non-Jewish populations in Israel, 1993–2004. Error bars indicate 95 % confidence intervals (Reproduced with permission from reference Dagan et al. [83])

immunization [187]. Major progress in this direction has already been achieved [83] (Fig. 17.5).

The fourth strategy for preexposure prophylaxis includes immunization with only a single dose of an inactivated HAV vaccine. The rationale for this strategy is based on the cumulative experience that anti-HAV (IgG) sero-protection rates may reach 88 % in vaccinees within 2 weeks after a single vaccine dose rising to 97–100 % at weeks 4–6 [37, 194, 195]. In 2005, public health authorities in Argentina began an experimental universal immunization program in 12-month-old babies [196]. The original baseline incidence of HAV in Argentina dropped from 70.5 to 173.8 cases/100,000 between 1995 and 2004 to ~10 cases/100,000 in all age groups within a few years, representing a >80 % decrease in incidence. These results also confirmed the experience gained in mass and universal immunization programs

elsewhere that effective immunization of toddlers will lead to widespread herd immunity. It remains, however, to be seen if a single-dose immunization strategy will indeed provide long-term protection against HAV or whether a booster dose will be required after all [197].

The ultimate success of routine infant immunization to eliminate HAV transmission is dependent on the availability of an affordable vaccine that potentially can be combined with other antigens and provides long-term protection. Such a strategy would also be appropriate for countries with an intermediate and high endemicity of infection where most persons become infected during childhood.

8.4.2 Postexposure Prophylaxis

Evidence obtained in a number of clinical trials suggested that postexposure immunization against hepatitis A may also have similar effectiveness as IG, provided that immunization is started within 2 weeks of exposure. Support for this impression was initially obtained from the hepatitis A efficacy trial conducted in the United States where the HAV vaccine was administered during an HAV outbreak and no new cases of acute hepatitis were identified from day 17 onward after vaccination [20]. A similar experience was obtained in Slovakia [198], in Israel, and in Italy where a 79 % protective efficacy of postexposure immunization was documented in Italian household contacts of acute hepatitis A cases [199]. In Israel, as in Slovakia, prompt intervention with an active vaccine in a community outbreak of hepatitis A led to effective control of an epidemic within 2 weeks of starting the intervention, in contrast to the relatively poor performance of IG [200]. Final proof for the use of inactivated HAV vaccines for postexposure prophylaxis was obtained in a pivotal study conducted in Kazakhstan [162]. In this controlled clinical trial, 1,090 household and day-care contacts (2–40 years old) of index cases with acute hepatitis were randomized to receive hepatitis A vaccine or IG. Transmission of HAV, confirmed by anti-HAV (IgM) testing, occurred in 4.4 and 3.3 % of the study groups respectively (RR 1.35; 95 % CI = 0.70–2.67). Consequently, the US ACIP is now recommending postexposure immunization with an active HAV vaccine in 2–40-year-old individuals at risk [201]. Altogether, the use of hepatitis A vaccines instead of IG for postexposure prophylaxis has a number of advantages, including induction of long-term protection against HAV, ease of administration, and acceptance at a similar cost per dose [169].

9 Unresolved Problems

Despite the availability of efficacious and safe hepatitis A vaccines for more than 20 years, hepatitis A still remains a frequent and debilitating disease affecting millions of individuals annually. The continuous improvement in sanitary and socioeconomic conditions in many countries and in regions within individual countries has led to a shift in prevalence of HAV infection from high to intermediate and even low endemicity. Consequently, a growing population of adolescents and young adults becomes susceptible to HAV infection. Hepatitis A is a vaccine-preventable disease, and vaccination of babies is the most efficient means for the control of the infection. Yet, at present only a few countries at risk have embarked on the route toward implementation of universal vaccination. The demonstrated effectiveness of hepatitis A immunization holds the potential for the eventual eradication of HAV infection. Elimination of HAV transmission occurs when a critical level of herd immunity is present in the population. As recently stated in a 2012 WHO position paper on hepatitis A, "Countries should collect and review the information needed to estimate their national burden of hepatitis A" [22]. In addition to surveys estimating age-specific prevalence of anti-HAV (IgG) antibodies, this may require examining vital registration systems, acute disease surveillance, and health information systems capturing fulminant hepatic failure cases and/or causes for liver transplantation. Economic evaluation, including cost-effectiveness analyses of relevant immunization strategies, can serve as a useful additional element for decision making.

Acknowledgments This chapter is an extensively revised and updated version of the chapter printed in the 4th edition of this book authored by HS Margolis, MJ Alter, and SC Hadler.

Hepatitis E Virus

18

Xiang-Jin Meng

1 Introduction

Although evidence for the existence of a new form of enterically transmitted non-A, non-B viral hepatitis came from serological studies of waterborne epidemics of hepatitis in India in 1980 [1, 2], the identity of the virus was not known until 1990 when the genomic sequence of the hepatitis E virus (HEV) was determined [3]. The diseases caused by HEV are characterized by explosive outbreaks of acute hepatitis in developing countries and sporadic and clustered cases in industrialized countries [4, 5]. The identification of various animal strains of HEV has broadened the appreciation of the host range and diversity of the virus [6] and also provided unique homologous animal model systems to study HEV replication and pathogenesis. Hepatitis E is now a recognized zoonotic disease, and pigs and likely other animal species are reservoirs for HEV [7]. A vaccine has recently been licensed for use in China, although it is not yet available in other countries [8]. Promising antiviral agents have also been identified.

2 Historical Background

The epidemiological features of the large waterborne outbreaks of hepatitis in India in the 1950s and 1970s such as the 1955–1956 Delhi, the 1975–1976 Ahmadabad, and the 1978 Kashmir epidemics resembled hepatitis A in terms of the mode of spread, incubation period, and clinical and biochemical features [9]. In fact, the 1955–1956 Delhi epidemics were initially reported as due to hepatitis A [10]. However, diagnostic markers of acute hepatitis A were not detected in the 1978 Kashmir epidemic [1] or retrospectively in the earlier outbreaks [2]. In addition, these outbreaks displayed unique clinical features that were distinct from that of hepatitis A, such as the high attack rate among young adults and high mortality rate in pregnant women [11]. This led to the recognition of a new form of epidemic non-A, non-B, or enterically transmitted non-A, non-B hepatitis [1, 2]. The term hepatitis E was designated only after the etiological agent responsible for these outbreaks was identified in 1990 [3].

In 1983, Mikhail Balayan (a Russian virologist) successfully transmitted the disease to himself. He had experienced prior infection with the hepatitis A virus (HAV) and thus was immune to HAV, when he voluntarily ingested a suspension of the stool samples collected from non-A, non-B hepatitis patients [12]. About 36 days after ingestion of the stool suspension, he developed severe acute hepatitis but acute diagnostic markers for hepatitis A and B were not detected in his sera, thus indicating a new agent was responsible for the hepatitis. Immune electron microscopy identified 27–30 nm viruslike particles in samples of his stool; they provided the first direct evidence for the existence of a new enterically transmitted viral hepatitis agent. Acute viral hepatitis was further transmitted to cynomolgus macaques by intravenous inoculation of monkeys with the stool suspension collected from the infected volunteer, and viruslike particles were visualized from the feces of the experimentally infected monkeys [12]. A nonhuman primate model was subsequently established for the study of the disease [13, 14].

In 1990, the agent responsible for the enterically transmitted non-A, non-B hepatitis was successfully cloned and sequenced and designated as hepatitis E virus (HEV) [3]. Subsequently, the development of diagnostic tests based on recombinant HEV antigens or peptides enabled the study of the HEV epidemiology [15]. In 1997, the first animal strain of HEV, swine hepatitis E virus (swine HEV), was discovered and characterized [16], leading to the recognition of hepatitis E as a zoonotic disease [6, 7, 17] and significantly expanding our understanding of the natural history and ecology of this pathogen [4–6, 18].

3 Methods for Epidemiologic Analysis

3.1 Mortality

Prior to the identification of the causative agent, the sources of mortality data were primarily studies of large waterborne outbreaks of acute hepatitis that were negative for hepatitis A and B diagnostic markers [19]. With the development of serological and molecular diagnostic assays specific for HEV, the mortality data are now based on patients that are positive for anti-HEV antibodies or HEV RNA [20, 21]. The mortality associated with HEV infection is typically less than 1 % in the general population, but it can reach up to 25 % in infected pregnant women especially during the third trimester [4, 5, 22]. Among the recognized hepatitis viruses, the high mortality observed during pregnancy is unique to HEV.

3.2 Morbidity

The main sources of morbidity data have been investigations of outbreaks and sporadic cases of acute viral hepatitis [19]. Due to the lack of accurate etiology-specific data for acute viral hepatitis, the morbidity data for hepatitis E are not very reliable [23]. Investigations of acute viral hepatitis disease outbreaks using specific serological assays to detect IgG and IgM anti-HEV and PCR-based assays to detect HEV RNA help produce more accurate morbidity data regarding hepatitis E. Unfortunately, many sporadic cases of acute viral hepatitis are not routinely tested for hepatitis E and thus are not reported. Due to the lack of an FDA-approved diagnostic assay, underdiagnosis of hepatitis E in the United States and many other industrialized countries has further limited the available morbidity data.

3.3 Serological Survey

The seroprevalence of HEV infection has been primarily inferred from serological studies of archived samples and from reported outbreaks of the disease worldwide [24–27]. The seroprevalence data from the retrospective studies should be interpreted with caution due to the potential sampling bias of the convenient samples, the duration of IgG anti-HEV response in infected individuals, and the variations of different serological assays. Age- and geography-matched seroprevalence studies in special high-risk populations such as pig handlers, swine veterinarians, organ transplant recipients, and HIV-infected patents have also been reported [28–31]. The prevalence of HEV infection has been investigated prospectively in the placebo groups in conjunction with vaccine clinical trials [32–34], which provided a more accurate estimate of HEV seroprevalence.

3.4 Laboratory Diagnosis

Immune electron microscopy is insensitive for the detection of HEV particles and thus is of little value in the laboratory diagnosis of HEV infection [4, 35]. Specific serological assays to detect IgA, IgG, and IgM anti-HEV have been developed [36, 37] and are commercially available in some countries in Asia and Europe and recently in the United States. However, a considerable variation in the specificity and sensitivity of these assays has been reported [38, 39]. The available serological diagnostic assays primarily use the recombinant ORF2 capsid protein expressed in bacterial or baculovirus expression system as the antigen, although a mixture of both ORF2 and ORF3 proteins is also used as the antigen in some assays. Some commercial serological assays are approved for HEV diagnosis by regulatory agencies in Asia and Europe, although none has been approved by the FDA. When serum samples are collected during the acute stage of HEV infection, IgM anti-HEV is detectable in up to 90 % of the acute cases within 1–4 weeks after the onset of the disease [4, 15, 40, 41], but in <50 % of cases 3 months after the onset of the disease [15, 42]. A rising IgG anti-HEV titer in samples collected 2–4 weeks apart after the onset of the disease can also aid in the diagnosis of hepatitis E [4, 15, 40]. The duration of IgG anti-HEV persistence in infected individuals varies from <1 year in some pediatric patients to 2–14 years in some adult patients [40, 41, 43].

RT-PCR has been successfully used to detect HEV RNA from outbreaks and sporadic cases of hepatitis E [44–48]. Real-time PCR assays have also been developed to detect and quantify HEV genomes [49, 50]. By using a panel of known HEV-containing plasma samples, the performance of 20 conventional or real-time RT-PCR assays from different laboratories worldwide was evaluated for the detection of HEV RNA [51]. Significant variations in the sensitivity (100–1,000-fold difference) and specificity of these PCR-based assays were observed, indicating the need for a standardized PCR-based diagnostic assay for HEV. The existence of at least four recognized and two putative genetically distinct genotypes of mammalian HEV [18, 52] further stresses the need for a standardized universal RNA-based detection assay for HEV.

4 Biological Characteristics

4.1 Physical and Biochemical Properties

The buoyant density of HEV virion is 1.35–1.40 g cm^{-3} in CsCl and 1.29 g cm^{-3} in glycerol and potassium tartrate gradients. The HEV virion is sensitive to low-temperature storage (between −70 °C and +8 °C) and iodinated disinfectants [4, 18]. It is more heat labile than is HAV: HEV was about

50 % inactivated at 56℃ and almost totally inactivated (96 %) at 60℃ for 1 h [53]. Liver suspensions containing HEV remained infectious after incubating at 56 °C for 1 h, although the virus is completely inactivated by boiling or stir-frying the HEV-contaminated livers for 5 min [54].

4.2 Morphology

The HEV virions are nonenveloped icosahedral particles with a diameter of approximately 27–34 nm [52] (Fig. 18.1). The capsid is formed by capsomers consisting of homodimers of a single capsid protein forming the virus shell. Each capsid protein contains three linear domains forming distinct structural elements: S (continuous capsid), P1 (three-fold protrusions), and P2 (two-fold spikes). Each domain contains a putative polysaccharide-binding site that may interact with cellular receptors [56, 57]. Native $T=3$ capsid contains flat dimers, with less curvature than those of $T=1$ viruslike particles [58].

4.3 Antigenic Properties

It is thought that there exists only a single serotype of HEV, with antigenic cross-reactivity among strains in different genotypes [52]. Antibodies cross-reactive to human HEV strain capsid proteins have been reported in various animal species, but the viruses responsible for the antigenic cross-reactivity were genetically identified only in swine, chickens, deer, mongoose, rats, and rabbits [6, 18]. Common antigenic epitopes in the capsid protein between avian and mammalian HEV strains and among different animal strains of HEV have been identified [59–61].

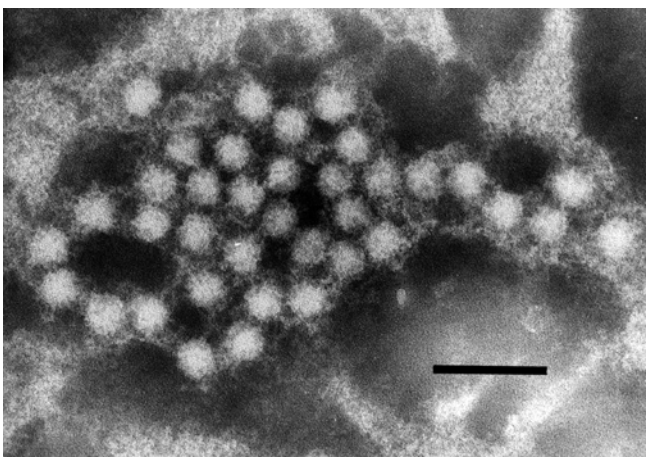

Fig. 18.1 An electron micrograph of a strain of hepatitis E virus particles (30–35 nm diameter). Negative staining, bar = 100 nm (Reproduced with permission from Haqshenas et al. [55] the Society for General Microbiology)

4.4 Genome Organization and Genotypes

The HEV genome is organized into a short 5′ noncoding region (NCR), three open reading frames (ORFs 1, 2, and 3), and a 3′ NCR [62]. ORF2 overlaps ORF3, but neither overlaps with ORF1 [63]. A cap structure has been identified in the 5′ end of the viral genome and may play a role in the initiation of HEV replication [64]. A bicistronic subgenomic mRNA encoding both ORF2 and ORF3 proteins has been identified [65]. The 5′-NCR is only about 26 nt long and may play a role in the initiation of HEV replication. The 3′-NCR contains a *cis*-reactive element. ORF1 encodes the nonstructural polyprotein, ORF2 encodes the major capsid protein, and ORF3 encodes a small phosphoprotein with a multifunctional C-terminal region [62].

Currently HEV is the only species in the genus *Hepevirus* within the family *Hepeviridae*, and avian HEV from chickens is classified as a floating species within the family [52]. There exist at least 4 recognized and two putative genotypes of mammalian HEV (Fig. 18.2): genotype 1 (Burmese-like Asian strains), genotype 2 (a single Mexican strain and some African strains), genotype 3 (strains from sporadic human cases mostly from industrialized countries, and animal strains from pig, deer, rabbit and mongoose), and genotype 4 (strains from sporadic human cases in Asia and swine strains) [52]. The strain of HEV recently identified from rats in Germany [67] and the United States [68] appears to be a new genotype, as does the recently identified HEV strain from wild boars in Japan [69]. The HEV strains from chickens [55] and cutthroat trout [70] likely represent different genera.

4.5 Gene Expression and Replication of HEV

The mechanisms of HEV replication and gene expression are largely unknown. The recent reports on the development of improved cell culture systems for HEV may aid in understanding the mechanisms of HEV replication in the future [71, 72]. The ORF1 encodes a nonstructural polyprotein that is important for viral replication, although it remains unknown if the polyprotein functions as a single protein or as individually cleaved smaller proteins [5, 52]. Functional activities such as methyltransferase [64, 73], guanylyltransferase [73], deubiquitination [74, 75], NTPase and 5′ to 3′ RNA duplex-unwinding activities [76], and RNA 5′-triphosphatase [77] have been experimentally demonstrated in the ORF1 protein. A proline-rich hypervariable region in the ORF1 protein is dispensable for viral replication both in vitro and in vivo and is functionally exchangeable between HEV genotypes [78, 79]. The ORF2 encodes the viral capsid protein that contains a typical

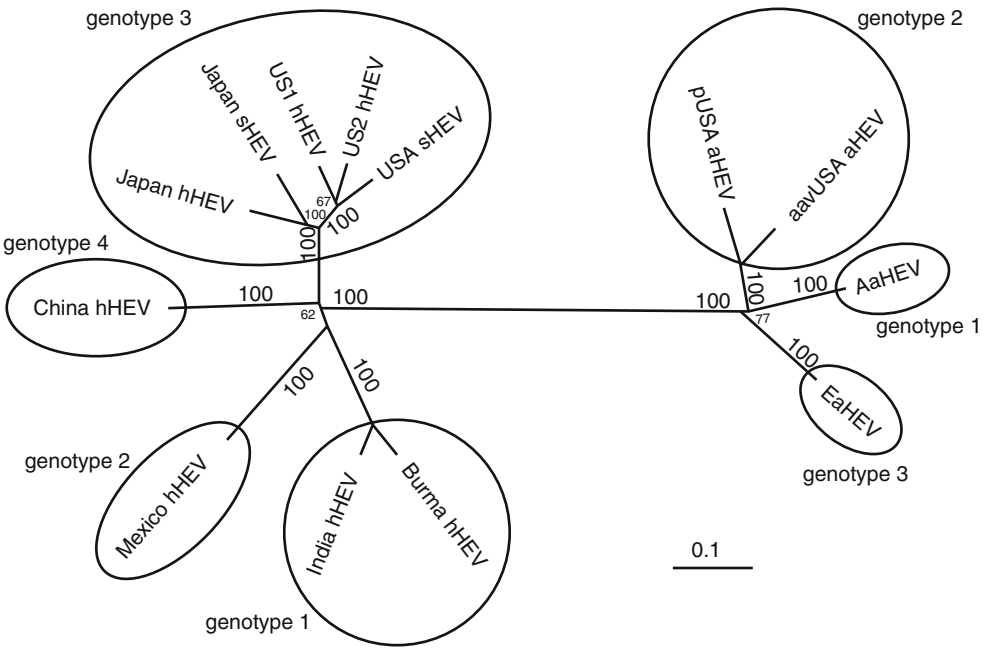

Fig. 18.2 A phylogenetic tree of mammalian and avian strains of hepatitis E viruses. The four recognized genotypes of mammalian H*epeviruses* and the three recognized genotypes of avian hepatitis E virus are indicated (Reproduced with permission from Bilic et al. [66] the Society for General Microbiology)

signal peptide sequence and three potential glycosylation sites. Mutations within the glycosylation sites prevent the formation of infectious virus particles [80–82]. The ORF2 capsid protein contains neutralizing epitopes and is the target for vaccine development [82]. The ORF3 encodes a small cytoskeleton-associated phosphoprotein [83]. The N terminus of ORF3 binds to HEV RNA and forms a complex with the capsid protein, whereas the C terminus is multifunctional and may be involved in virion morphogenesis and pathogenesis [62, 84].

HEV is thought to enter the host through the gastrointestinal epithelial cells. HEV replication in small intestines has been experimentally demonstrated [85, 86]. The capsid protein attaches to cell surface heparan sulfate proteoglycans (HSPGs), specifically syndecans, in Huh7 human liver cells [87], although a specific cellular receptor for HEV is unknown. The capsid protein is co-translationally translocated across the ER membrane [88]. After uncoating, viral genomic RNA is released to cytoplasm where transcription, translation, and virus replication occur [62, 89]. During HEV replication, an intermediate negative-sense genomic RNA is produced to serve as the template for the production of positive-sense progeny viral genomic RNA as well as the subgenomic RNA for the translation of ORF2 and ORF3 proteins [62, 89]. Negative-sense, replicative, viral RNA has been detected in the livers and gastrointestinal tissues of experimentally infected animals [85, 86]. A conserved double stem-loop RNA structure identified in the ORF1 and ORF2 junction region of HEV genome is critical for virus replication, and both the sequence and the stem-loop structure in the junction region play important roles in HEV replication [90]. The mechanisms of HEV assembly and release remain largely unknown. The ORF3 protein is responsible for virion egress from infected cells [84, 91].

4.6 Host Range and Cross-Species Infection

Genetic identification of HEV strains from several animal species including pig [16], chicken [55], mongoose [92], deer [93], rabbit [94, 95], rat [67, 68], and fish [70] and the demonstration of cross-species infection by some animal strains of HEV [61, 96, 97] have significantly expanded the host range and genetic diversity of HEV (Table 18.1). The strains of human HEV genotypes 1 and 2 have a more limited host range and are restricted to humans, whereas genotype 3 and 4 strains can infect across species barriers. Genotype 3 and 4 strains of swine HEV infected nonhuman primates [96, 97], and conversely genotypes 3 and 4 strains of human HEV infected pigs [98, 99]. Cross-species infection of HEV has also been reported in other animal species. Wistar rats were reportedly infected by human HEV isolate [100]. Avian HEV from chickens infected turkeys but failed to infect rhesus monkeys [101], suggesting that avian HEV may have a more limited host range and may not infect humans. The HEV strains from rabbits infected pigs [61], and genotypes 1 and 4 human HEV also reportedly infected rabbits [102].

Table 18.1 Animal reservoirs and host range of the hepatitis E virus (HEV)

Genotypes	Natural hosts	Epidemiological features in humans
Mammalian HEV		
Genotype 1	Humans	Epidemic outbreak
Genotype 2	Humans	Epidemic outbreak
Genotype 3	Humans, domestic and wild pigs, deer, mongoose, rabbits	Sporadic cases
Genotype 4	Humans, domestic and wild pigs, cattle[a], sheep[a]	Sporadic cases
Putative genotype 5	Rats	Non-transmissible to humans
Putative genotype 6	Wild boars	Unknown
Avian HEV		
Genotype 1	Chickens (Australia, Korea)	Non-transmissible to humans
Genotype 2	Chickens (USA, Canada)	Non-transmissible to hum ans
Genotype 3	Chickens (Europe, China)	Non-transmissible to humans
Fish HEV		
Cutthroat trout virus	Brown, Apache, and Gila trouts	Non-transmissible to humans

[a]Not independently confirmed

5 Descriptive Epidemiology

5.1 Incidence and Prevalence

The incidence of hepatitis E in the general population is unclear as there are few such studies to determine the disease incidence [103]. A prospective study of a cohort of 1,134 randomly selected individuals with 1,172 person-years of follow-up in southern Bangladesh revealed that the overall incidence of HEV infection was 64 per 1,000 person-years over an 18-month period [104]. Based on surveys of clinical diseases, the incidence of hepatitis E during outbreaks was estimated at 1,400–1,650 per 100,000 population during large outbreaks in India and Nepal [19]. In 2005, a large outbreak of 1,611 cases of hepatitis E was reported in Hyderabad, India, with an attack rate of 40 per 100,000 population. A significantly higher attack rate (203 per 100,000 population) was found in neighborhoods supplied by water lines that crossed open sewage drains than in neighborhoods supplied by non-crossing water pipes (38 in 100,000 population) [105]. Another large outbreak of 2,621 cases of acute hepatitis E was reported in refugee camps in Darfur, Sudan, with an attack rate of 3.3 % and a case fatality rate of 1.7 % [106]. In industrialized countries, the incidence of sporadic or clustered cases of acute hepatitis E is difficult to determine but appears to have been on the rise in recent years [107, 108]. Whether the increased incidence of sporadic cases of acute hepatitis E is due to increased awareness of the disease and availability of diagnostic tests or due to actual increase in disease incidence remains debatable. The majority of the sporadic or clustered cases are caused by zoonotic genotypes 3 and 4 strains of HEV [6, 18].

The prevalence of anti-HEV antibodies is very high in some developing countries: for example, more than 70 % of the general populations in Egypt are positive for IgG anti-HEV antibodies [20]. Interestingly, IgG anti-HEV prevalence in some industrialized countries is much higher than expected: for example, in some regions of the United States, up to 30 % of the blood donors were tested positive for IgG anti-HEV antibodies [28, 30, 109].

5.2 Epidemic Behavior

The sources of infection appear to be different for epidemics and sporadic cases. HEV-contaminated drinking water is the main source for epidemics [4], which typically occur in small towns and villages, refugee camps, as well as in cities of developing countries lacking modern sanitation [9, 19, 110]. The outbreaks are often associated with inadequate water treatment, contamination of water supplies with fecal materials, and poor sanitary conditions such as washing hands in a group basin and storage of drinking water in large-mouthed vessels [105, 106, 111]. Person-to-person spread of hepatitis E, although uncommon, does occur during an epidemic [112]. The epidemic cycle is believed to be similar to hepatitis A with an occurrence of 7–10-year cycles [19]. It has been reported that a second epidemic of hepatitis E occurred in a village that had experienced a prior outbreak 30 years earlier [113], suggesting a loss of protective immunity over time in the community. Most outbreaks are associated with contamination of well water or leakage of untreated sewage into city water treatment plants [19]. Attack rates are higher in villages that rely on river water as compared to villages that rely on wells or ponds [114]. For villages relying on river water, the peak of epidemics is associated with the rise in the level of the river during rainfall [19, 114]. HEV RNA has been detected in sewage samples from an HEV-endemic region of India

during a time when no HEV outbreak was being reported, suggesting that HEV infection and fecal viral excretion may be common in HEV-endemic regions throughout the year even during nonepidemic periods. [115].

The sources for sporadic cases of hepatitis E appear to be contaminated animal meats, shellfish, and direct contacts with infected animals [6, 18, 116]. In the United States, having a pet in the home and consuming liver or other organ meats more than once per month were significantly associated with increased odds of HEV seropositivity [109].

5.3 Geographic and Temporal Distribution

Seroepidemiological studies revealed that HEV infection is distributed worldwide [34, 117] (Fig. 18.3). Large explosive epidemics of hepatitis E occur primarily in the developing countries of Asia, Africa, and Latin America [111, 118–122]. Outbreaks are more common in geographic regions with hot climates but are rare in temperate climates [34, 117]. Sporadic or clustered cases have been reported in developing countries as well as in many industrialized countries [4]. As

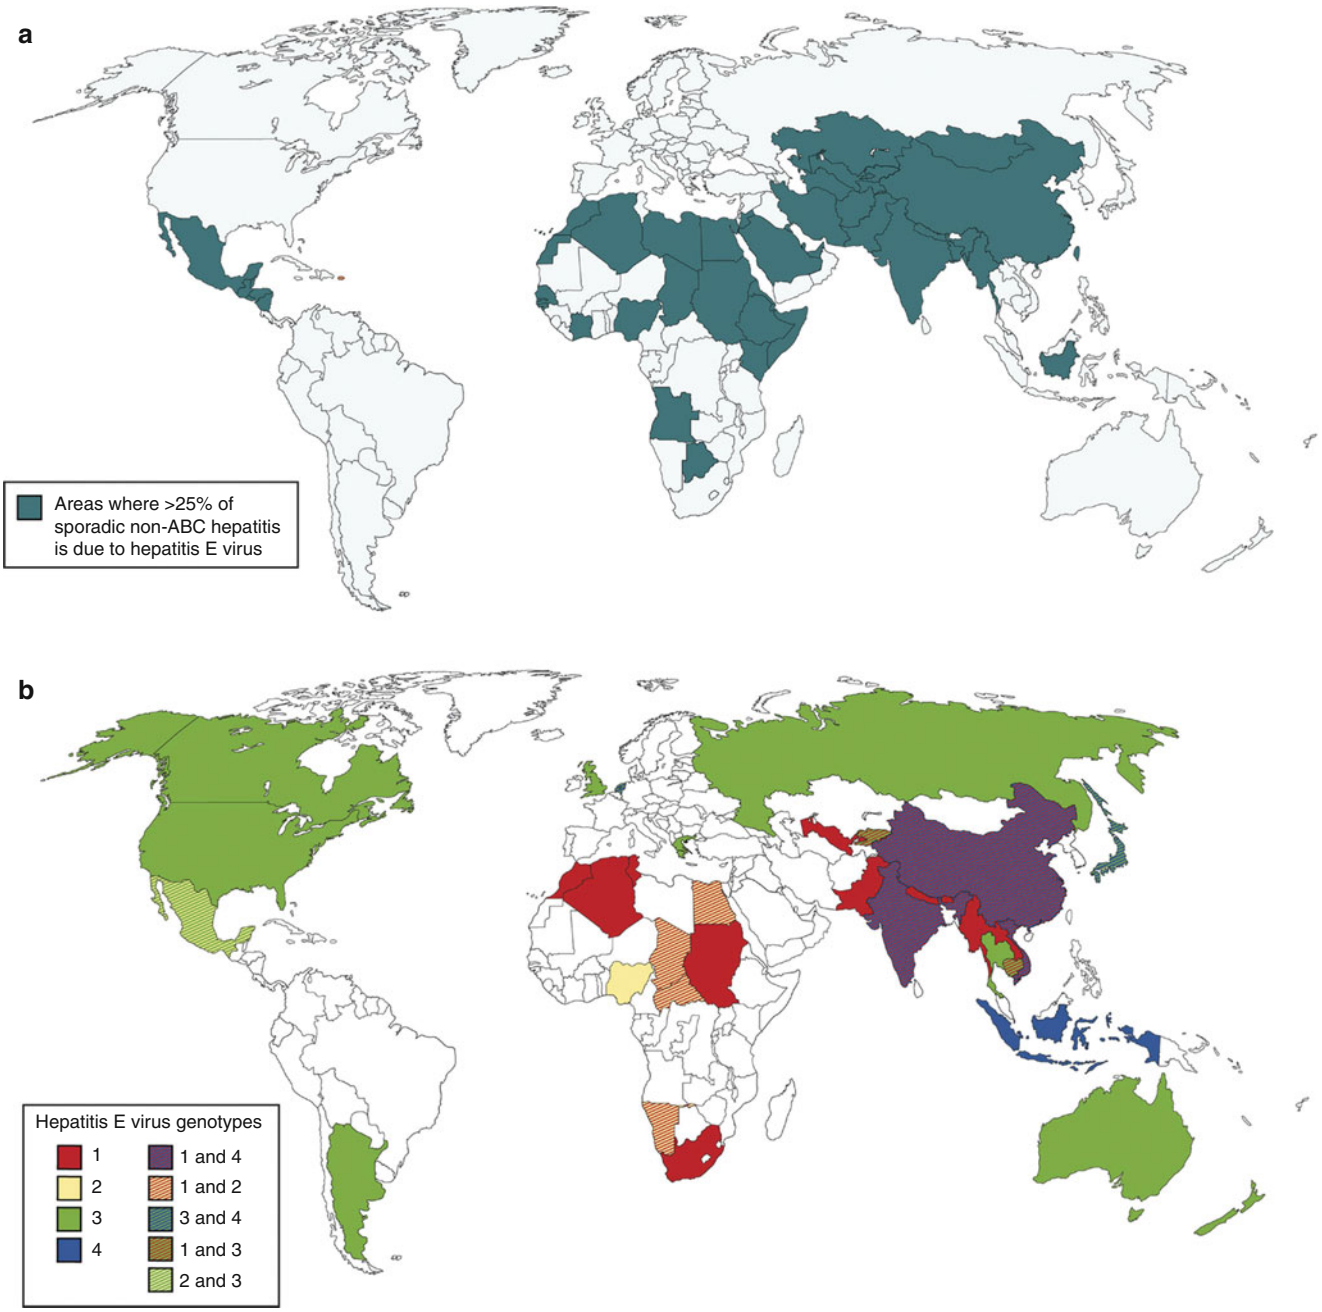

Fig. 18.3 Worldwide prevalence of hepatitis E virus (HEV) (**a**) and the global geographic distribution of the different HEV genotypes (**b**) (Reproduced with permission from Wedemeyer et al. [117] the American Gastroenterological Association)

a fecal-orally transmitted disease primarily through contaminated water or water supplies, the frequency of hepatitis E outbreaks rises in seasons with monsoon rains and flooding. A unique riverine ecology of HEV transmission has been reported in Southeast Asia [123]. Significantly higher prevalence of HEV infection has been associated with the use of river water for drinking and cooking, personal washing, and disposal of human excreta [123, 124]. In Indonesia, unusually dry weather led to decreased dilution of HEV in river water and thus contributed to the risk of epidemic HEV transmission. However, in Vietnam the risk of HEV infection increased with river-flooding conditions and contamination [123, 124]. In the United States, individuals from traditionally major swine states appear more likely to be seropositive for IgG anti-HEV than those from traditionally non-swine states: for example, subjects from Minnesota, a major swine state, are approximately five to six times more likely to be seropositive for IgG anti-HEV than those from Alabama, which is traditionally not a major swine state [30].

5.4 Occupation

Pigs are reservoirs for HEV [7], and therefore pig farmers, swine veterinarians, and other pig handlers in both developing and industrialized countries have been shown to be at an increased risk of HEV infection [28, 30]. An investigation of the 295 swine veterinarians from 8 US states with available age- and geography-matched normal blood donors revealed that swine veterinarians were 1.51 times more likely to be IgG anti-HEV positive than normal blood donors [30]. Veterinarians who reported having needle sticks while performing procedures on pigs were about 1.9 times more likely to be seropositive than those who did not. Similarly, swine workers in North Carolina had a 4.5-fold higher IgG anti-HEV prevalence rate (10.9 %) than the control subjects (2.4 %) [125]. In Moldova, approximately 51 % of pig farmers were positive for IgG anti-HEV, whereas only 25 % of control subjects with no occupational exposure to swine were seropositive. In Thailand, the prevalence of IgG anti-HEV in swine and poultry farmers was significantly higher than that in government officers [126]. Human populations with occupational exposure to wild animals have also been found to have an increased risk of zoonotic HEV infection. For example, field workers from the Iowa Department of Natural Resources had significantly higher seroprevalence of IgG anti-HEV than normal blood donors [127].

Sewage workers in India were found to have a significantly higher seroprevalence of IgG anti-HEV (56.5 %) than the control subjects (19 %), and the IgG anti-HEV seropositivity significantly increased in sewage workers with >5 years in the occupation [128]. However, a cross-sectional study in Switzerland did not clearly identify sewage work as a high-risk occupation for HEV infection [129].

5.5 Age, Sex, Race, and Other Factors

The highest attack rate of clinical disease is in young adults of 20–29 years of age [15], although the seroprevalence of IgG anti-HEV is age dependent [130]. The seroprevalence of IgG anti-HEV and the clinical attack rate are low in young children <15 years of age with the exception in epidemic settings [4, 42, 130, 131]. In Pune, India, an HEV-endemic region, HEV infection is rare in children and the prevalence does not peak (33–40 %) until early adulthood [130]. In Japan, an investigation of sera of 1,015 individuals collected in 1974, 1984, and 1994 showed that age-specific profiles of IgG anti-HEV prevalence remained unchanged, with a peak at 40–49 years, suggesting ongoing silent HEV infection during the 20-year period studied [132] (Fig. 18.4). Age, socioeconomic status, and well water were significant independent variables for HEV infection in India [133]. In

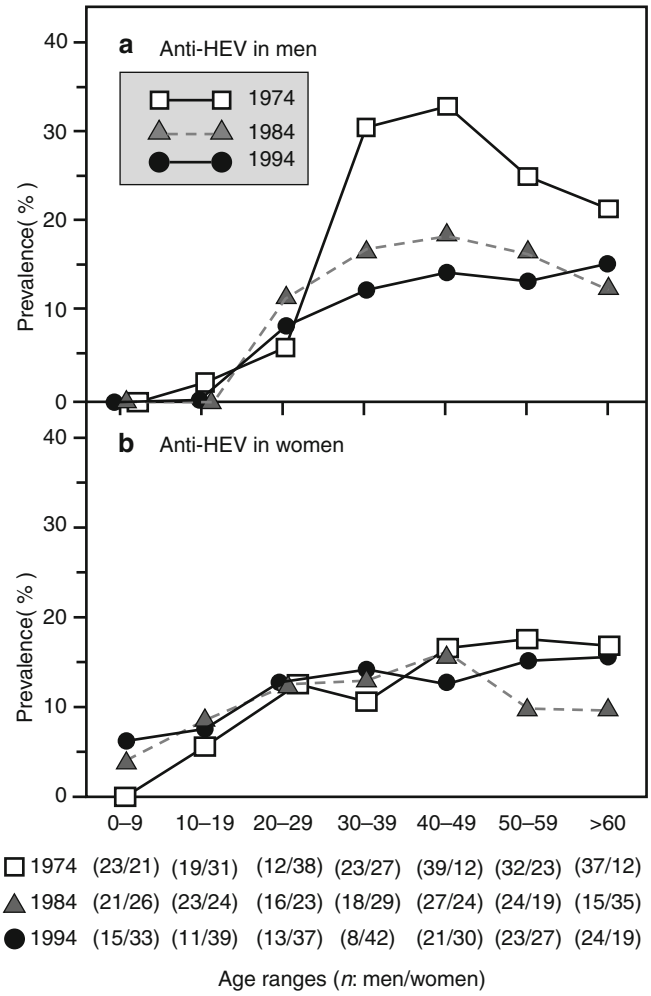

Fig. 18.4 Age- and sex-specific prevalence of IgG anti-HEV at three different times in an industrialized country. Numbers of men (**a**) / women (**b**) tested in each age group and year are indicated below in parentheses (Reproduced with permission from Tanaka et al. [132] John Wiley and Sons)

Pakistan, the attack rate was significantly higher in individuals 11–30 years of age (15.3 %) than in children <11 years of age (1.4 %) [134]. In a large hepatitis E outbreak in 2004 in refugee camps in Darfur, Sudan, the risk factors included age of 15–45 years (OR = 2.13) and drinking chlorinated surface water (OR = 2.49) [106].

No significant differences in IgG anti-HEV prevalence between males and females have been observed [4, 42, 130, 131], although individuals with symptomatic HEV infection had male-to-female ratios ranging from 1:1 to 3:1 [19, 132]. The higher rate of disease in men in certain outbreaks may reflect the fact that men from rural areas worked outside the village whereas women stayed at home in local villages [19, 132] (Fig. 18.4). A higher mortality of up to 28 % was observed in infected pregnant females [22, 114, 135, 136]. Racial difference in HEV infection is not evident. However, in a large seroepidemiological survey among US-born individuals, it was found that males, non-Hispanic whites, and individuals residing in the Midwest and/or in metropolitan areas had the highest IgG anti-HEV seroprevalence [109].

6 Mechanisms and Routes of Transmission

The main route of HEV transmission is fecal-oral. Under experimental conditions, however, infection of nonhuman primates or pigs with HEV via oral inoculation proved to be difficult [137], even though the animals could be readily infected by HEV via the intravenous route of inoculation. Chickens were successfully infected via the oral route of inoculation with an avian strain of HEV. Other routes such as vertical, blood-borne, foodborne, and zoonotic transmissions have also been reported.

6.1 Fecal-Oral Waterborne Transmission

Contaminated water supplies are major sources of HEV infections. Historically, waterborne transmission is characteristic of hepatitis E outbreaks in humans. Raw sewage water contamination of drinking water and contaminated well or river water used for washing and drinking purpose are the main sources of HEV transmission in developing countries. Zoonotically infected pigs and other animals may excrete large amounts of HEV in feces [18]; thus, HEV-containing animal manure and feces could contaminate irrigation or coastal water with concomitant contamination of produce or shellfish. Strains of HEV of both human and swine origins have been detected in sewage water [138, 139].

6.2 Foodborne Transmission

Sporadic and clustered cases of acute hepatitis E have been linked to the consumption of raw or undercooked pig livers and pork products. HEV RNA was detected in approximately 2 % of the pig livers sold in local grocery stores in Japan [46] and 11 % in the United States [140]. The contaminating virus in commercial pig livers remains infectious [140]. The virus sequences recovered from pig livers in grocery stores are closely related, or identical in some cases, to the viruses recovered from human hepatitis E patients [46]. Sporadic cases of hepatitis E including a fulminant hepatic failure case were linked to the consumption of raw or undercooked wild boar meats [141, 142]. In France, raw pig liver sausages (figatelli) were the source for some sporadic cases of hepatitis E [44]. In Japan, a cluster of 4 cases of acute hepatitis E were linked to the consumption of raw deer meats in two families [93, 143]. The viral nucleotide sequence recovered from the leftover frozen deer meat was 99.7–100 % identical to the viruses recovered from the four human patients [93, 143, 144]. Additionally, cases of hepatitis E have been linked to the consumption of shellfish [145, 146]. Taken together, the available data provided compelling evidence of foodborne transmission of HEV.

6.3 Zoonotic Transmission

The increased risk of HEV infection to persons in pig-handling occupations was noted above. In addition, potential transmissions of hepatitis E from a pet cat [147] and a pet pig [148] to human owners have been reported. Zoonotic transmission of hepatitis E to individuals who consume infected pig and deer meats and pork products has also been documented [44, 93, 142].

6.4 Vertical Transmission

There have been reports of HEV transmissions from the mother to the fetus leading to premature birth, increased fetal loss and acute hepatitis in the newborns, and high neonatal mortality [135, 149–151]. An investigation of 62 pregnant women with jaundice in the third trimester of pregnancy showed that vertical HEV transmission occurred in 33.3 % of the cases [135]. In a study of mother-to-child HEV transmission, 3/6 (50 %) of the cord blood samples tested were positive for HEV RNA [150]. Although HEV RNA has been detected in the colostrum of HEV-infected mothers, breast-feeding appears to be safe for the infants, but transmission may occur postpartum through close contact with infected mothers [152].

Although vertical HEV transmission has been reported in patients, experimental evidence of vertical HEV transmission in animal models is still lacking. For example, infectious HEV was detected in egg whites from eggs of chickens experimentally infected with an avian strain of HEV, but evidence of complete vertical transmission is absent [153]. In another study, gilts (female pigs pregnant with their first litter) inoculated with a genotype 3 HEV became infected and shed virus in feces; however, vertical transmission was not detected in the fetuses [154]. Similarly, pregnant rhesus macaques experimentally infected with HEV failed to transmit the virus to the offspring [155].

6.5 Blood-Borne Transmission

Numerous reports have documented the transmissions of hepatitis E through blood transfusions in patients from both developing and industrialized countries [156–161]. A small proportion of blood donors in Japan are viremic for HEV and thus pose a potential risk for transfusion-associated hepatitis E [162, 163]. Among the 41 blood donors with elevated ALT levels in Japan, HEV RNA was detected in 8 serum samples (20 %) [164].

7 Pathogenesis and Immunity

7.1 Pathogenesis

The pathogenesis of HEV is not well understood. After oral ingestion of the virus, HEV is believed to first replicate in the gastrointestinal tract and then spread to its target organ, the liver, through viremia. Evidence of HEV replication in the liver has been documented in nonhuman primates, pigs, and chickens experimentally infected with human and swine HEVs. After replication in the liver, the virus is released to the gallbladder from hepatocytes and then is excreted in feces. In addition to livers, HEV replication has also been identified in extrahepatic tissues including small intestines, colon, and hepatic and mesenteric lymph nodes [85, 86], although the clinical and pathological significance of these extrahepatic sites of virus replication remains unknown.

Earlier studies in human volunteers provided some clues on the course of HEV infection in humans [12, 165]. Fecal virus shedding and viremia precedes the onset of clinical and biochemical hepatitis, and virus shedding ends when the level of serum liver enzyme returns to baseline [4, 117] (Fig. 18.5). Pregnancy increased the severity and mortality of the disease, although the mechanism of fulminant hepatitis E during pregnancy remains unknown. Histological changes include focal necrosis with minimal infiltration and moderate inflammation of Kupffer cells and leukocytes [4, 19]. In pigs experimentally infected with a genotype 3 human HEV [98], mildly-to-moderately enlarged hepatic and mesenteric lymph nodes were observed from 7 to 55 days postinoculation. Mild-to-moderate multifocal lymphoplasmacytic hepatitis and focal hepatocellular necrosis were observed. In chickens experimentally infected with an avian strain of HEV, gross lesions include subcapsular hemorrhages and slightly enlarged right intermediate lobe of the livers. Foci of lymphocytic periphlebitis and phlebitis were the characteristic histological lesions in livers [166].

7.2 Immunity

The immune response to HEV infection is characterized by a transient appearance of IgM HEV antibodies followed by long-lasting IgG antibodies [4, 40] (Fig. 18.5). The HEV capsid protein is immunogenic and induces neutralizing antibodies and protective immunity. The capsid proteins of mammalian and avian HEV strains share common antigenic epitopes, and all HEV strains identified thus far appear to belong to a single serotype. Protection against hepatitis E has been demonstrated in passively or actively immunized cynomolgus monkeys [167]. It has also been demonstrated that passive transfer of anti-HEV immunity from immunized mothers to their offspring occurs both by transplacental and lactation routes [168]. The characteristics of cell-mediated immune response against HEV infection are largely unknown. The HEV-specific IFN-γ responses were found to correlate strongly and significantly with the presence or absence of IgG anti-HEV in experimentally infected chimpanzees as well as in seroconverted human subjects [169].

8 Patterns of Host Response

8.1 Clinical Features

The incubation period ranges from approximately 2 weeks to 2 months. The clinical presentation of acute hepatitis E is often indistinguishable from other types of acute viral hepatitis. Patients generally have jaundice, anorexia, dark urine, and hepatomegaly, and approximately 50 % of the patients also have abdominal pains and tenderness, nausea, vomiting, and fever [4, 19]. Not all HEV-infected individuals develop overt clinical disease, and in industrialized countries a significant proportion of individuals are seropositive for HEV antibodies with no known history of hepatic disease [28, 30]. Hepatitis E is a dose-dependent disease: exposure to a higher dose of virus may lead to manifestation of clinical symptoms of hepatitis E, whereas patients exposed to a lower virus dose generally had only subclinical infections [4].

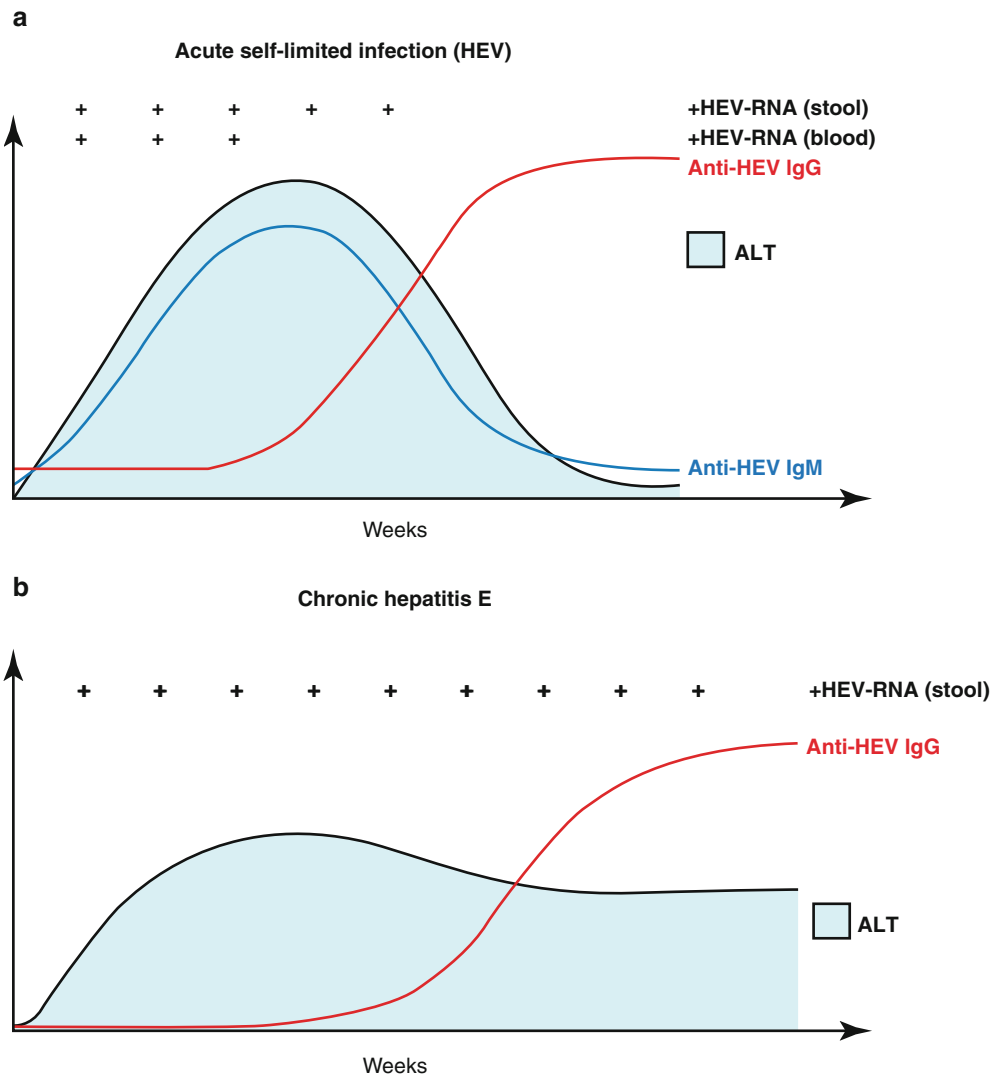

Fig. 18.5 A diagram of serological, virological, and clinical courses of acute and chronic hepatitis E in humans. The detection and appearance of viral RNA in blood and stool samples, serum IgG anti-HEV antibodies, and levels of alanine aminotransferase (ALT) levels during the course of acute (**a**) or chronic (**b**) HEV infection are schematically depicted (Reproduced with permission from Wedemeyer et al. [117] the American Gastroenterological Association)

8.2 Hepatitis E and Pregnancy

An important feature of HEV infection is the observed high mortality during pregnancy, particularly in certain regions in India, where HEV infection causes severe hepatitis and acute liver failure (ALF), leading to death in a significant proportion of infected pregnant women [22, 151]. For example, it was reported that the case fatality among the HEV-positive pregnant women was 27 % and that approximately two-thirds of the infected pregnant women had preterm deliveries in India [135]. In Pakistan, the hepatitis E attack rate among the 162 pregnant females was 22 %, compared to only 11 % in nonpregnant females of childbearing age [134]. Other studies, however, question the mortality data during pregnancy since the severity of hepatitis in pregnant women was found to be similar to that in nonpregnant women. For example, a study of 2,428 pregnant women in Egypt did not link HEV exposure to liver disease history, although the authors of the study concede that the predominant HEV strain(s) in Egypt could be less virulent than those in South Asia [20]. In India, a large retrospective study showed that HEV-related ALF was independent of the sex or the pregnancy status of the patients: case fatality was 51 % in HEV-related ALF in pregnant patients and 54.7 % in non-HEV-ALF in pregnant patients [21]. Aggarwal has suggested that, in aggregate, pregnant women appear to be at an increased risk of developing HEV-associated ALF but that once ALF develops, the risk of death is similar in pregnant and nonpregnant women and boys and men [151].

Under experimental conditions, pregnant sows experimentally infected with a genotype 3 HEV at various stages of gestation did not develop clinical signs of hepatitis or elevation of liver enzymes [154]. Similarly, pregnant rhesus monkeys experimentally infected with a genotype 1 HEV did not develop more severe hepatitis than the nonpregnant

monkeys [155]. The socioeconomic status, hormonal changes and immunological status during pregnancy, and the existence of coinfecting agents may explain the observed geographical difference of HEV-associated mortality during pregnancy.

8.3 Chronic Hepatitis E in Immunocompromised Individuals

Hepatitis E is generally regarded as a self-limiting acute viral hepatitis that does not progress to a chronic infection [4]. However, recent studies revealed that chronic HEV infections do occur, more often than previously thought, especially in immunocompromised individuals such as organ transplant recipients and HIV-infected patients. For example, eight of the 14 HEV-infected patients who received organ transplants developed chronic hepatitis E with persistently elevated aminotransferase levels, viremia, and chronic hepatitis lesions [170]. Numerous other studies also documented chronic hepatitis E in liver, kidney, heart, and kidney-pancreas transplant recipients [161, 170–177]. Additionally, chronic HEV infections have also been reported in individuals with HIV infection [178–181]. Under experimental conditions, prolonged viremia and fecal virus shedding were also observed in a few animals experimentally infected by HEV [99, 166, 182]. Taken together, these recent studies indicated that acute HEV infection in immunocompromised individuals can progress to a chronic infection and can rapidly progress into cirrhosis as well.

8.4 HEV Infection and Neurological Diseases

Increasing evidence indicates that neurologic disorders are an emerging clinical manifestation of HEV infection. In a kidney transplant patient chronically infected by HEV, peripheral nerve involvement with proximal muscular weakness in the four limbs, with central nervous system involvement and bilateral pyramidal syndrome, was reported [183, 184]. HEV RNA was detected in the serum and cerebrospinal fluid of the patient. In the United Kingdom and France, among the 126 patients with genotype 3 HEV infection, 7 patients (5.5 %) developed neurologic symptoms including 3 with inflammatory polyradiculopathy, 1 with Guillain-Barré syndrome, 1 with bilateral brachial neuritis, 1 with encephalitis, and 1 with ataxia/proximal myopathy [183]. In France, meningitis with diffuse neuralgic pain or polyradiculoneuropathy was associated with HEV infection in 2 adults [185]. Additionally, several cases of Guillain-Barré syndrome in different countries have been linked to HEV infection [186, 187].

9 Control and Prevention

Protection of water system from fecal material contamination, practicing good hygiene, and avoiding drinking water of unknown purity or consuming raw or undercooked animal meats are important preventive measures [4–6, 18, 19, 188]. Washing hands thoroughly after handling infected animals is also an effective measure to prevent zoonotic HEV transmission [18].

A recombinant vaccine against HEV has recently been licensed for use in China, although it is not yet available in other countries [8, 33]. Other experimental recombinant HEV vaccines based on the recombinant capsid protein of HEV also appear to be very promising [32]. The efficacies of the recombinant HEV vaccines were 100 % for a bacteria-expressed recombinant vaccine [33] and 95.5 % for a baculovirus-expressed recombinant vaccine [32]. However, the efficacies of these vaccines against the novel strains of HEV including the emerging animal strains with zoonotic potential will need to be evaluated.

Pegylated interferon and ribavirin have been shown to clear HEV infection and improve liver histology in patients [173, 179, 189]. Ribavirin monotherapy inhibits HEV replication and induces a sustained virus inhibition in patients with chronic HEV infections [173, 177, 190, 191]. Pegylated-interferon-α-2a also induced a sustained virological response in an HEV-infected hemodialysis patient [189]. In addition, in vitro treatment of A549 cells persistently infected with a genotype 3 HEV with IFN-α for 72 h showed a dose-dependent reduction in the levels of HEV RNA [192]. Other experimental antivirals such as short hairpin RNA (shRNA) [193], RNAi [194], and proteasome inhibitors such as MG132 [75] have also been shown to inhibit HEV replication in vitro and thus could serve as potential therapeutic agents against HEV.

10 Unresolved Problems

Hepatitis E is an important but extremely understudied disease. The life cycle of HEV remains largely unknown in large part due to the lack of a robust cell culture system for HEV. However, several recently identified cell lines that support more efficient HEV replication should aid in future studies of the HEV life cycle. Identification of a specific cellular receptor for HEV will help establish a more efficient cell culture system. The mechanisms of HEV transcription, translation, and genome replication need to be delineated. One of the most pressing issues regarding HEV epidemiology is the elucidation of the now poorly understood ecology and natural history of this virus. The existence of IgG anti-HEV in various animal species suggests that more animal species are likely infected by HEV. Unfortunately, the virus

has been genetically identified only from a few animal species. Therefore, genetic identification and characterization of animal strains of HEV will help our understanding of the epidemiology, transmission routes, host range, and reservoirs of this important pathogen.

The relatively high prevalence of IgG anti-HEV in individuals from industrialized countries suggests that the occurrence of hepatitis E in those locations is underestimated, since sporadic cases of hepatitis E may go undiagnosed. The lack of an FDA-approved diagnostic assay for HEV further contributes to the underdiagnosis of hepatitis E in the United States and likely other industrialized countries. Therefore, there is an urgent need for standardized serological and molecular diagnostic assays with improved sensitivity and specificity. The association of HEV infection with chronic hepatitis in immunosuppressed individuals opens new avenues for research into the mechanism of chronic HEV infections. The mechanism of extrahepatic disease manifestation of neurological symptoms in HEV-infected patients also requires in-depth research in the future. The relationship between pregnancy and severe hepatitis E remains controversial. Although the current licensed and experimental vaccines appear to be promising, it will be important to evaluate the efficacies of the vaccines against the emerging novel strains of HEV including the zoonotic strains. Development of vaccines against the animal strains of HEV in their respective animal hosts may minimize the risks of zoonotic transmission and increase food safety.

Influenza Viruses

19

John J. Treanor

1 Introduction

More than 80 years after the recognition of influenza virus as the cause of the syndrome of influenza, or grippe, influenza continues to be a major cause of acute respiratory illnesses. These illnesses rival acute gastroenteritis as causes of morbidity and mortality throughout the world. Although the majority of cases of influenza are not identified by laboratory methods, a variety of direct and indirect methods have attributed a substantial proportion of the overall burden of acute respiratory illness directly to influenza. This burden includes both deaths and hospitalizations, which occur most commonly at the extremes of age and in persons with other underlying heart or lung diseases and in pregnancy, as well as an enormous burden of transiently disabling illness in all ages that result in substantial economic and productivity losses.

Infection with influenza virus stimulates a coordinated response of the innate, and cellular and humoral adaptive, immune response that leads to effective and long-lived resistance to reinfection with the same strain of virus. However, influenza viruses uniquely subvert this immune response through rapid evolution of the viral surface glycoproteins resulting in antigenic changes that allow infection in the presence of immunity to prior strains. Relatively minor antigenic changes, traditionally referred to as "antigenic drift," typically result in new viruses that cause the familiar seasonal epidemics of acute influenza. In addition, influenza A viruses occasionally and unpredictably undergo major changes in antigenicity referred to as "antigenic shift" that lead to worldwide, more severe epidemics, or pandemics of influenza. In many cases, it appears that pandemics viruses emerge from the enormous gene pool of influenza A viruses in migratory waterfowl. Surveillance for these viruses in birds, and their transmission to domestic poultry, swine, other mammals, and ultimately man, has therefore become an object of intense interest in recent years.

Two specific forms of influenza control approaches have been developed in the 80 years since the discovery of these viruses, vaccines, and antiviral agents. In theory, developing effective vaccines for influenza should be straightforward. However, the same antigenic variation that circumvents natural immunity also has confounded efforts to develop effective influenza vaccines, and currently available live or inactivated vaccines must be reformulated and readministered annually to keep pace with these antigenic changes. Despite intense effort over many decades, a truly universal influenza vaccine has never been successfully developed, although recent progress in influenza immunology has increased optimism along these lines. Nevertheless, the current vaccines do provide a substantial measure of protection and are important tools for reducing the overall disease burden of influenza.

The same high rate of evolution of influenza viruses has also complicated efforts to develop antiviral agents. Two viral proteins, the influenza A virus M2 protein and the neuraminidase (NA) protein of influenza A and B viruses, are the targets of the current classes of antiviral agents, the M2-inhibitors (amantadine and rimantadine) and NA-inhibitors (zanamivir and oseltamivir), respectively. Both classes of drug have been shown to reduce the duration of illness and viral shedding in acutely infected individuals and to reduce the rate of hospitalization and death when used relatively early in the course of illness. However, the rapid development of antiviral resistance has significantly impacted the utility of these agents. At the moment, essentially all current influenza A viruses are completely resistant to the M2 inhibitors, and there has been frequent development of resistance to the NAI oseltamivir, particularly in the N1 neuraminidases. The use of multiple antiviral agents with synergistic activities may represent a strategy to reduce the emergence of resistance.

DOI 10.1007/978-1-4899-7448-8_19,

In this chapter, we will briefly review the history of influenza throughout. We will then describe the classification and the basic virology of these agents and consider the data used to estimate their yearly impact on human health. We will review the basics of the immune response to influenza and the characteristics of illness induced by these viruses and then discuss the current approaches to prevention and control.

2 Historical Background

The characteristics of influenza epidemics, such as the high attack rates, explosive spread of disease, and characteristic cough and fever, have allowed identification of past influenza epidemic throughout history. Older studies identified probable influenza epidemics occurring at an average interval of 2.4 years between 1173 and 1875 [1]. The greatest pandemic in recorded history occurred in 1918–1919 when, during three "waves" of influenza, 21 million deaths were recorded worldwide, among them 549,000 in the United States [2].

William Farr introduced the concept of "excess mortality" in his vivid description of the London epidemic of 1847 [3]. Frost [4] first used this concept in the United States to describe the 1918 influenza epidemic, but it was Selwyn Collins who systematically used excess mortality as an index for recognition of influenza epidemics [5, 6]. Collins estimated baseline mortality by calculating weekly arithmetic means, and Serfling refined the baseline estimate by deriving a regressin function to describe seasonal variation in baseline mortality [7], the basic methodology which is still in use today for assessing excess mortality.

The first influenza virus was isolated from chickens with fowl plague in 1901, but it was not recognized that this was an influenza A virus until 1955. Shope isolated the swine influenza virus in 1931 [8, 9]. Influenza A virus was first transmitted from humans to ferrets and recognized as the cause of influenza in 1933 [10]. Influenza B virus was isolated by Francis in 1939 [11] and influenza C virus by Taylor in 1950 [12]. The discovery by Burnet in 1936 that influenza virus could be grown in embryonated hens' eggs allowed extensive study of the properties of the virus and the development of inactivated vaccines [13]. Animal cell culture systems for the growth of influenza viruses were developed in the 1950s [14]. The phenomenon of hemagglutination, which was discovered by Hirst in 1941, led to simple and inexpensive methods for the measurement of virus and specific antibody [15].

Evidence of the protective efficacy of inactivated vaccines was developed in the 1940s [16]. The use of live vaccines for influenza was first suggested shortly after the virus was discovered [17], but the first live vaccine was not licensed in the United States until 2003, approximately 70 years later. Finally, four antiviral agents in two classes have been approved for prevention and treatment of influenza. These include the so-called M2 inhibitors, amantadine in the mid-1960s, rimantadine in 1993, and the neuraminidase inhibitors zanamivir and oseltamivir in 2000.

3 Biological Characteristics

Influenza viruses are members of the Orthomyxoviridae family of viruses and are enveloped, single-stranded, negative-sense RNA viruses. The viruses are further divided into types A, B, and C based on substantial differences in proteins and genomic structure. Types A and B influenza are causes of seasonal epidemics of acute respiratory disease in children, adults, and elders. Type C influenza is primarily a minor cause of mild respiratory illness in children.

Type A influenza viruses are further subdivided into subtypes based on antigenic and sequence differences in the two major surface glycoproteins: the hemagglutinin (HA) and neuraminidase (NA). To date, a total of 16 distinct HA subtypes have been identified, designated H1 to H16, and nine distinct NA subtypes, N1 to N9. Recently, a new, unique influenza virus was detected in yellow-shouldered bats in Guatemala [18]. Preliminary characterization of this virus suggests that its HA and NA should be designated H17 and N10, although crystal structure suggests that the N10 neuraminidase does not actually have neuraminidase activity [19].

While influenza A viruses of the H1N1, H2N2, and H3N2 subtypes have caused substantial disease in humans, the natural hosts of influenza A viruses are probably migratory waterfowl, in which a genetically diverse ecology of all known HA and NA subtypes have been found. These avian species thus are thought to act as a reservoir of genetic diversity of influenza A viruses and as the source of emerging pandemic influenza viruses (discussed below). Avian influenza viruses are frequently transmitted from waterfowl to domestic poultry, where they can cause widespread epidemics of severe or fatal disease. Transmission of influenza A viruses also commonly occurs to pigs, horses, mink and ferrets, and marine mammals, in which the viruses can become established and maintained for years. Influenza in each of these populations is typically limited to certain subtypes, with H1 and H3 viruses in pigs, H7 and H3 viruses in horses, and H7 in marine mammals. Recently, influenza A has also been described in felines and dogs.

Influenza B viruses do not exhibit the same type of antigenic and genetic variation in the HA and NA, and therefore do not have subtypes. However, since 2001, two antigenically lineages of influenza B viruses, termed the "Victoria" lineage and the "Yamagata" lineage, have cocirculated in humans [20]. In contrast to influenza A viruses, influenza B

viruses appear to be limited to humans, although isolation of influenza B from seals has been described [21]. Possibly for this reason, influenza B viruses have not been responsible for pandemics of influenza.

An important feature of influenza viruses is that the genome is segmented. Each gene segment is responsible for the synthesis of one or more viral proteins. Both influenza A and B viruses contain eight gene segments, although the specific proteins assigned to each gene segment differ between these two types. The consequences of this are that when a cell is infected with two different influenza viruses, the resulting progeny virus can in theory contain any combination of gene segments from the two parent viruses, meaning that 256 possible combinations of genes can be derived from reassortment event between two influenza viruses. However, some combinations may not be compatible [22], and all combinations are probably not equally likely. Genetic reassortment has been demonstrated to play an important role in the generation of pandemic influenza A viruses and has also been taken advantage of for the construction of attenuated live influenza vaccines.

Influenza viruses enter the cell by attachment of the viral hemagglutinin to sialic-acid-containing receptors on the cell membrane, followed by internalization of the virus into an acidic endosome. In the acidic environment of the endosome, the HA undergoes a conformational change that liberates a fusion peptide and results in fusion of the viral envelope with the endosomal membrane. At the same time, the third envelope protein, the M2 protein, acts as an ion channel allowing H+ions to enter the virion from the endosome. This in turn allows the viral gene segments to leave the virion and enter the cytoplasm, a process known as uncoating.

Viral gene segments are transported to the nucleus, where the viral polymerase complex, comprised of the proteins PB1, PB2, and PA, directs the synthesis of the plus sense messenger RNA as well as synthesis of negative-sense copies that will serve as progeny genomic RNA. The polymerase proteins also may play a role in disruption of host cell protein synthesis. Because replication takes place in the nucleus, some mRNA are spliced, giving rise in the case of influenza A viruses to the M2 protein from the M gene segment, and the NS2, or NEP (nuclear export protein) from the NS gene segment. Alternative start codons also give rise to a number of additional proteins from the polymerase genes of influenza A viruses including PB1-F2 [23] and PA-X [24], which may play roles in pathogenesis.

Negative-sense daughter virion RNAs are encased in nucleoprotein, associated with one copy of the polymerase complex and transported to the cytoplasm for assembly at the cell surface. Envelope proteins are glycosylated and transported to the cell surface. Virions bud from selected lipid rafts at the cell surface, acquiring an envelope derived from the cell membrane and decorated with HA, NA, and small amounts of M2 protein. Finally, the NA removes sialic acid from receptors on the cell surface or on the viral envelope, allowing the progeny viruses to leave the infected cell.

4 Descriptive Epidemiology

The epidemiology of influenza is characterized by seasonal epidemics of acute respiratory disease, punctuated, in the case of influenza A, at random intervals by worldwide epidemics of varying levels of severity, referred to as pandemics. Both of these events are felt to be driven by antigenic variation. In the case of seasonal epidemics of influenza, it is felt that population immunity drives the selection of mutations in the immunologically critical HA and NA proteins that result in sufficient antigenic differences from previously circulating viruses to allow the selected antigenic variant to efficiently replicate and infect individuals who have developed immunity to previous viruses of the same subtype. Because these antigenic changes are relatively minor and are generally the result of a few mutations in critical antibody epitopes, this process is frequently referred to as antigenic drift.

In contrast, radical changes in the HA and NA result in the emergence of viruses that are able to spread rapidly in populations with little or no effective immunity, resulting in pandemics with high attack rates and, usually, high levels of morbidity and mortality (Fig. 19.1).

Classically, pandemics involve the replacement of influenza A viruses of one subtype with influenza A viruses of a different subtype. For example, the most severe pandemic of influenza in recently recorded history was the so-called Spanish flu pandemic of 1918, due to a virus of the H1N1 subtype (the pandemic occurred before influenza virus was discovered and before the recognition of subtypes but was classified as H1N1 retrospectively). Subsequent seasonal epidemics of influenza were due to H1N1 viruses with various degrees of antigenic change, most remarkably in 1947 when a pseudopandemic was experienced due to an H1N1 virus (A/Fort Monmouth/47) with enough antigenic change from previous viruses that it was initially characterized as a new influenza A virus, so-called A' influenza [25]. H1N1 viruses continued to cause seasonal epidemics in man until 1957, when an influenza virus with an entirely new H and N subtype, A/Japan/57 (H2N2), emerged to cause a second pandemic of the twentieth century, the Asian flu. Initially, these viruses were referred to as strain A2, until the modern typing system was developed and they were categorized as H2N2 viruses. For reasons that are unclear, H1N1 viruses ceased to circulate in man after the emergence of H2N2 viruses.

H2N2 viruses then underwent antigenic drift resulting in seasonal influenza until 1968 when these viruses were

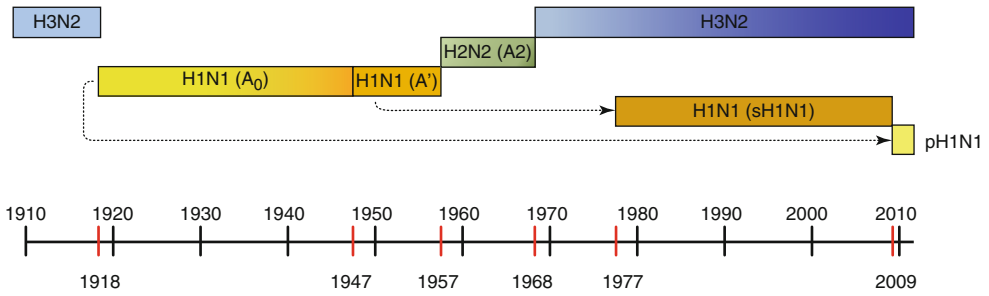

Fig. 19.1 Schematic diagram of the subtype circulation of influenza A viruses in man. The pandemic of 1918 was caused by a virus of the 1918 subtype, which may have been introduced from an unknown animal reservoir. Pandemics of 1957 and 1968 were reassortment events between previous human and avian viruses (see text). In 1977 and 2009, novel H1N1 viruses which were antigenically related to previous H1N1 viruses (*dotted lines*) were introduced into the population

replaced by the new subtype H3N2 viruses or the so-called Hong Kong flu. This virus represented a slightly different circumstance in that while the HA was a new subtype, the NA was retained from the previous H2N2 virus. Several studies have suggested that residual immunity to the retained N2 component of the H3N2 viruses substantially ameliorated the severity of this pandemic worldwide [26]. Again, for unclear reasons, the emergence of H3N2 viruses coincided with the disappearance of the previous H2N2 viruses, which have not circulated in man since then. Studies of the serologic reactivity of banked sera (so-called seroarcheology) have suggested that an H3 virus, possibly of the H3N8 subtype, may have also caused a pandemic in 1889–1891 [27].

H1N1 viruses reemerged in 1977 and resulted in a relatively more mild pandemic referred to as the Russian flu (A/USSR/77). This virus was genetically and antigenically identical to influenza A viruses that had circulated in man in 1950, and the mechanism that led to the preservation of this virus over the subsequent 27 years has never been fully explained. As expected, disease was largely restricted to younger persons born after 1957 who had not been previously exposed to H1N1 viruses, and the overall impact of this pandemic was much less severe than previous pandemics. In addition, the emergence of the H1N1 viruses did not result in the disappearance of the previous H3N2 virus. These H1N1 viruses cocirculated with the H3N2 viruses until 2009, when a new variant of H1N1 virus emerged from swine and replaced the previous H1N1, but not H3N2 viruses.

4.1 Emergence of Pandemic Viruses from Birds

Extensive surveillance studies have identified influenza A viruses of all 16 HA subtypes and all 9 NA subtypes in migratory waterfowl. In these birds influenza A causes mild illness or may be shed asymptomatically at high levels and for long duration in the feces. These birds may transmit influenza to other animals, including domestic poultry, horses, swine, and marine mammals, which may in turn transmit these viruses to man. Comparisons of sequence data from animal and human influenza viruses isolates have suggested that the 1918 virus was introduced into humans from such an animal population. In contrast, the 1957 and 1968 pandemic influenza viruses were reassortant viruses that derived some genes from previously circulating human viruses, while deriving the HA and sometimes NA genes from an avian influenza virus [28].

Because of the likely role of avian influenza viruses in the generation of emerging pandemics, there has been intense interest in recent outbreaks involving transmission of avian influenza viruses to man, with resulting disease. Most of these transmission events have been quite limited, with small numbers of persons affected, relatively mild disease, and little or no evidence of person-to-person transmission. In most cases, virus has been transmitted to humans from infected domestic poultry, but cases have also occurred in association with marine mammals and possibly wild birds.

Subtype H7 viruses have been responsible for several small outbreaks. Human infections with H7 AI viruses have generally been sporadic and mild in nature, with infected individuals presenting with mild flu-like illness and/or conjunctivitis [29, 30]. Human cases have typically been associated with outbreaks in birds, although one case of human H7 infection was reported in a laboratory worker who was sneezed upon by a seal that was infected with an H7N7 influenza virus [31]. The largest known cluster of H7N7 infections of humans occurred in 2003 in association with an outbreak of highly pathogenic avian influenza in commercial poultry farms in the Netherlands [32, 33]. While almost all cases in this outbreak were mild or subclinical, there was one confirmed fatal case in a 57-year-old otherwise healthy veterinarian, who developed pneumonia [33].

A new outbreak of influenza illness due to viruses of the H7N9 subtype has been recognized in western China since the spring of 2013 [34]. In contrast to previous H7 disease which has been predominantly mild respiratory illness with conjunctivitis, cases in this outbreak have been more severe, with hospitalizations and an approximately 20% case fatality rate [35]. Cases have been mostly recognized in older adults, for unknown reasons, and fatalities have largely occurred in individuals with underlying heart of lung disease , somewhat similar to seasonal influenza [36]. Almost all cases have direct contact with poul-

try, mostly in live bird markets. Because H7N9 viruses are not highly lethal in poultry, outbreaks in markets are much harder to recognize and control, which may be contributing to the persistence of this outbreak in affected areas.

Subtype H9 viruses have rarely caused human disease. H9N2 virus was isolated from two children in Hong Kong with mild febrile pharyngitis in 1999 [37]. Retrospective serologic cohort studies of individuals exposed to these two H9N2-infected children did not suggest person-to-person transmission [38]. Subsequently, H9N2 infection has been detected from five individuals with typical influenza in China [39] and from a child with a relatively severe influenza in Hong Kong.

The greatest concern has been for H5N1 viruses, which were first recognized in humans in 1997 [40] and which have continued to cause substantial numbers of human cases since that time. From 2003 to October 1, 2012, a total of 608 laboratory-confirmed human cases of H5N1 infection had been reported to the WHO, of which 359 cases were fatal. Cases have ranged in age from 3 months to 75 years with the median age being 20 years. Half of all cases have been in people aged less than 20 years and 90 % of cases have been in those less than 40 years of age. The median duration from onset of illness to hospitalization has been 4 days (range of 0–18 days). The case fatality rates have been the highest for those in the 10–19-year age group, lowest for people 50 or older, and in between for children aged <10 years [41].

Most cases have had close contact with ill poultry in the week before the onset of illness. Activities like plucking and preparing diseased birds, playing with birds, especially asymptomatically infected ducks, and handling fighting cocks are risk factors for infection [42]. Other apparent modes of acquisition have included eating undercooked poultry or drinking raw duck blood or exposure to contaminated water [43]. However, instances of person-to-person transmission have been rare. Fifteen family clusters of infection involving ≥2 family members were documented between January 2004 and July of 2005 [44], with the largest cluster identified thus far involving seven confirmed cases in family members of a woman who died of an acute respiratory illness [45]. In addition, there is one well-documented transmission of virus from an ill child in Thailand to her mother [46].

4.2 Emergence of Pandemic Viruses from Swine

Domestic swine have also been recognized as a potential source of pandemic influenza viruses in man. Genomic data have suggested that influenza A (H1N1) viruses were introduced into swine populations at around the same time that H1N1 viruses emerged in man in 1918 [47]. Since that time, these H1N1 viruses, or classic swine viruses, continued to be maintained in domestic swine where they caused minor illnesses and underwent relatively little antigenic evolution. During this time, swine were also occasionally infected with influenza A viruses from humans and from birds and have always been considered to represent a potential "mixing vessel" in which reassortment between human and avian influenza viruses could occur. This concept was strengthened by the recognition that the swine respiratory tract contains abundant receptors of both the α2-3 and α2-6 types favored by avian and human viruses, respectively [48].

In the late 1990s, one such reassortment event has been recognized leading to a unique virus containing polymerase genes of both swine and avian influenza virus origin. This unique combination of genes, referred to as the triple reassortant cassette, apparently increased the frequency with which these viruses underwent reassortment with other variants in swine populations. These viruses were also occasionally transmitted to humans, typically in the context of state agricultural fairs. While most of the resulting disease was relatively mild, occasional severe disease and deaths were reported, primarily in pregnant women. However, person-to-person transmission was not observed.

This situation changed in early 2009, when cases of swine-origin influenza A H1N1 viruses were first recognized in the United States and rapidly spread throughout the world [49]. The virus responsible for this pandemic was determined to be a quadruple reassortant virus derived from the triple reassortant virus by the addition of M and NA genes from a swine virus of Eurasian lineage (Fig. 19.2). The exact circumstances that led to this event remain mysterious, but it appears that the M1 protein derived from the Eurasian M gene conferred on these viruses an enhanced ability to transmit from person to person [50].

The age distribution of cases in the resulting pandemic displayed the relative sparing of older adults that has been observed in previous pandemics and might be explained by the exposure of older adults to antigenically similar viruses in their childhood [51]. Thus, the bulk of the disease occurred in adolescents and young adults. As a result, the estimated number of excess deaths due to the pandemic in 2009 was estimated to be only 12,000 in the United States, which, while substantial, was considerably less than often experienced during seasonal influenza, especially in years predominated by H3N2 viruses. However, as many of these deaths occurred in young people, the impact on years of life lost was much greater and overall more representative of the impact of the pandemic.

Since the emergence of the pH1N1 viruses, influenza surveillance activities have increased their focus on domestic swine, and a new potential pandemic threat in the form of quadruple reassortant viruses with the same internal genes as the pH1N1 but containing variant H3 HA genes has been recognized [52]. Antigenically, these viruses resemble human H3 viruses that circulated in the early 1970s [53]. Approximately 300 cases of human disease have been identified, almost all as the result of transmission from swine to humans during agricultural fairs. As expected, almost all of these cases have occurred in children. There has been little evidence of person-to-person spread, but there remains a need for continued vigilance regarding this possibility.

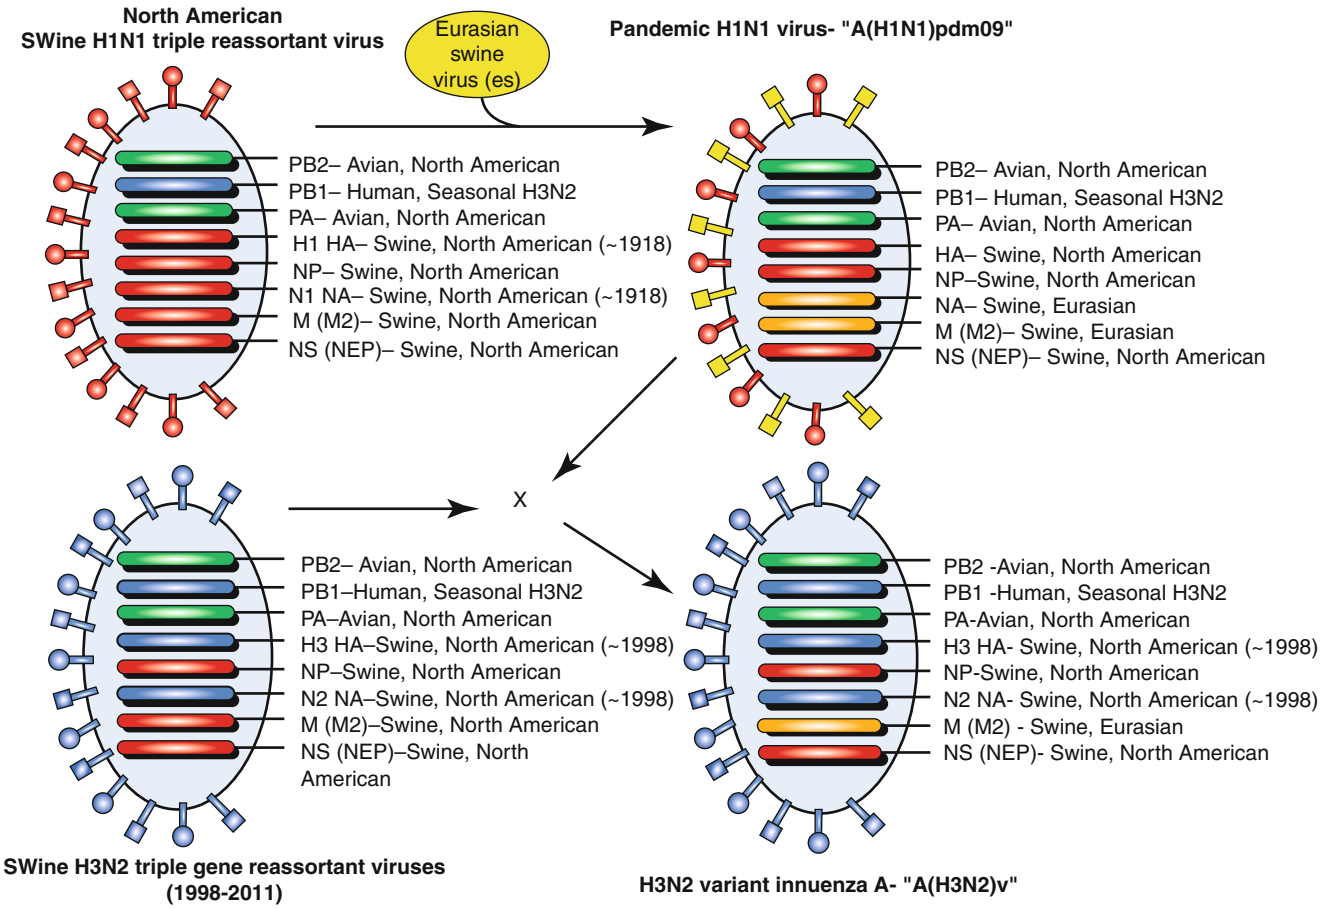

Fig. 19.2 Current swine-origin viruses are the result of a complex series of reassortment events. Both current pH1N1 viruses and H3N2v viruses derive the M gene from a Eurasian swine lineage

4.3 Seasonal Influenza

Influenza epidemics during the interpandemic period generally display a marked seasonal periodicity in regions with temperate climates, with the majority of disease activity occurring between November and April in the Northern Hemisphere and between May and September in the Southern Hemisphere (Fig. 19.3).

Seasonal periodicity is also observed in tropical climates, with increased activity during periods of low absolute humidity, although influenza can occur throughout the year and seasonal fluctuations are not as marked [54]. The reasons for these seasonal changes are not entirely clear but might be the result of more favorable environmental conditions for virus survival [55]. Studies in a model of transmission of influenza in guinea pigs have also supported a role for conditions of cold temperature and dry humidity in facilitating transmission [56]. Colder temperatures are also associated with behavioral changes that may increase transmission, such as indoor crowding or school attendance.

4.3.1 Disease Impact

Influenza epidemics are regularly associated with excess morbidity and mortality, usually expressed in the form of excess rates of pneumonia- and influenza-associated (P&I) hospitalizations and deaths during epidemics. In order to estimate the disease burden of influenza, observed P&I events during periods of influenza epidemic activity are compared with an expected seasonal baseline derived from a time-series regression model, and the excess event rate attributable to influenza is calculated. Because not all influenza-related deaths are manifested as pneumonia, P&I mortality statistics may underestimate the true impact of influenza on the population [57]. Although less precise, seasonal excess all-cause mortality is probably a more accurate reflection of the total burden of influenza.

From 1979 to 1991, these methodologies have led to estimated rates of influenza-associated hospitalizations ranging from 55,000 to 431,000 annually, with an overall average of 226,000 hospitalizations attributable to influenza [58]. Estimates of influenza-associated deaths have increased in

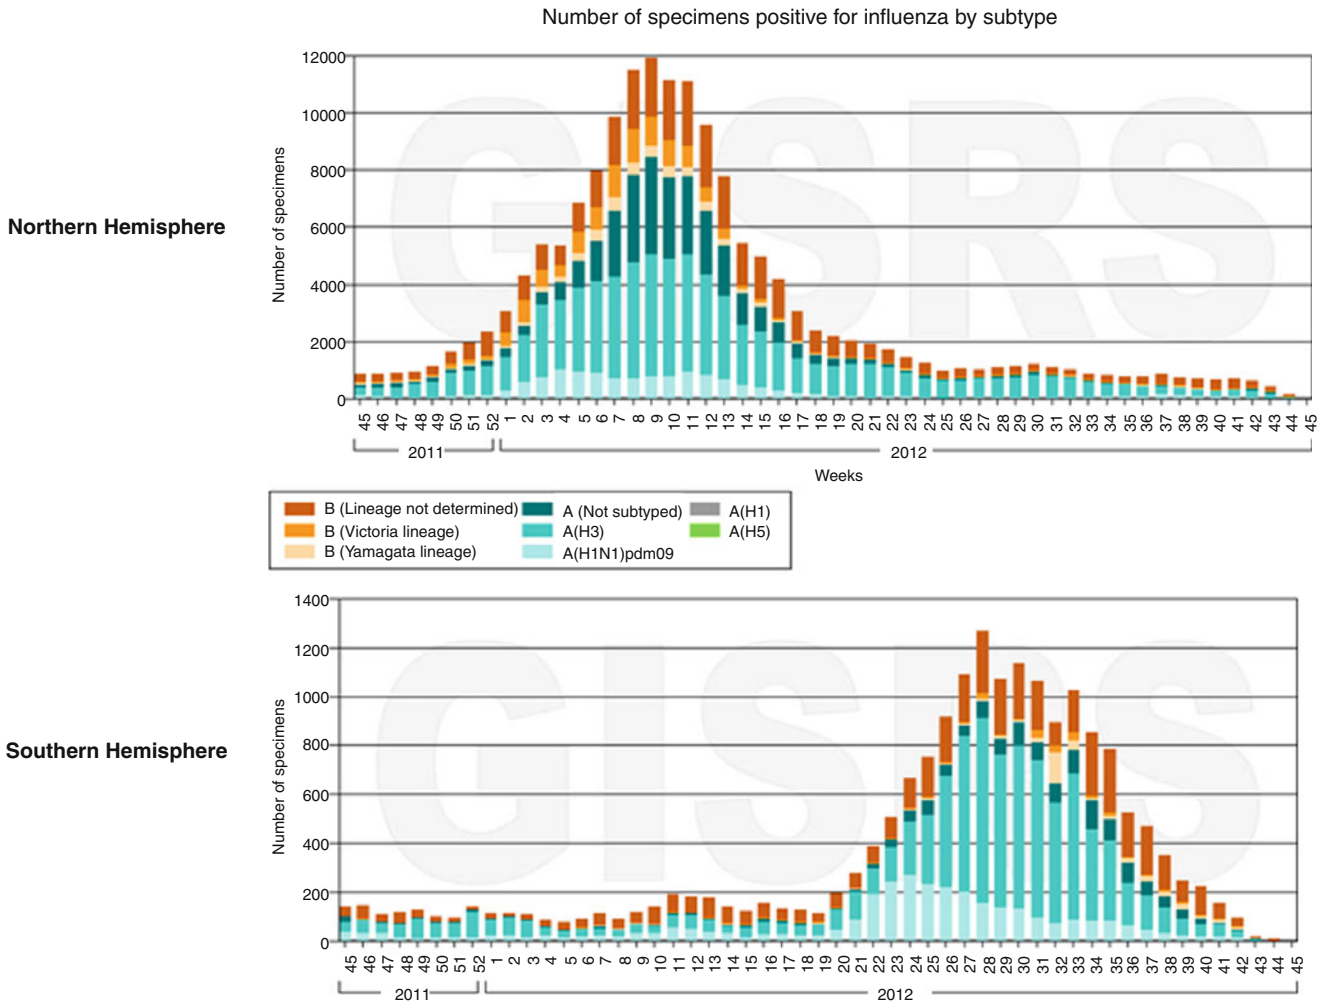

Fig. 19.3 Representative example of the global circulation of influenza in the northern and southern hemisphere. In temperate climates, influenza peak activity occurs in months with cooler, drier climate conditions

recent decades, possibly because of the increasing numbers of older, at-risk members of the population. Recent estimates suggest an average of approximately 8,000 excess P&I-associated deaths annually, but much higher numbers of all-cause mortality associated with influenza, with an average of 36,000 deaths annually with a range as high as 51,000 deaths in the United States [59]. Generally, the level of excess mortality is highest in years when influenza A (H3N2) viruses predominate [60] and lower in years with predominant H1N1 activity, possibly reflecting age-related susceptibility to these two subtypes.

Excess morbidity and mortality are particularly high in those with certain high-risk medical conditions, including adults and children with cardiovascular and pulmonary conditions such as asthma, or those requiring regular medical care because of chronic metabolic disease, renal dysfunction, hemoglobinopathies, or immunodeficiency, and in individuals with neurologic conditions that compromise handling respiratory secretions [61]. Influenza also results in more severe disease and significant mortality in individuals with human immunodeficiency virus (HIV) infection [62, 63].

The increased risk of influenza during pregnancy was dramatically demonstrated during the 2009 pandemic [64]. Previous studies had identified an increased risk of hospitalization associated with influenza epidemics during pregnancy, especially in the second and third trimester and in the immediate postpartum period [65]. Several groups at increased risk for severe influenza-related disease and deaths were recognized during the 2009 H1N1 pandemic. Women in each stage of pregnancy, or in the immediate post partum period, were clearly over represented among those admitted to hospitals and ICUs. This observation was perhaps not surprising as pregnancy has long been recognized as a risk factor for influenza mortality during previous pandemics and to a lesser extent during seasonal influenza as well. The mechanism(s) by which pregnancy enhances the risk of

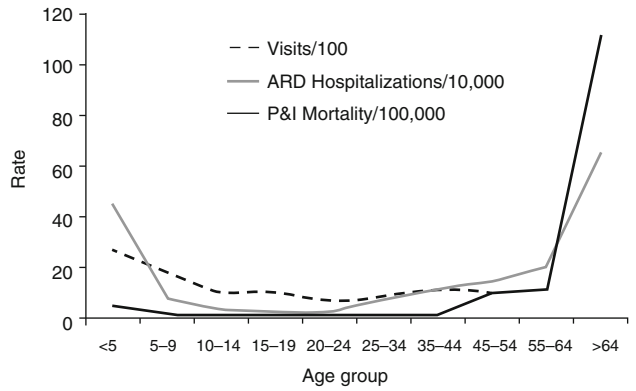

Fig. 19.4 Age-related annual incidence of acute illness visits, hospitalizations, and deaths during the interpandemic era in Houston, Texas (Data from Couch et al. [66])

influenza is not clear but might include the increased cardiovascular demands of pregnancy as well as hormonally mediated changes to the innate and adaptive immune response.

Obesity also emerged as a risk factor for influenza morbidity and mortality that had not been recognized in previous seasonal epidemics or pandemics. While compromise to respiratory mechanics as a direct result of extreme obesity undoubtedly plays a role, there is also evidence to support a detrimental role of adipose tissue in the inflammatory response that might also enhance the influenza disease process. As a result of these observations, obesity is not recognized as an important factor for targeting influenza vaccine.

Influenza is usually associated with a U-shaped epidemic curve (Fig. 19.4). Attack rates are generally highest in the young, whereas mortality is generally highest among older adults [66, 67], in part because the prevalence of high-risk conditions is greater in this group. Influenza is also recognized as an important health problem in young children. Rates of influenza-related hospitalizations are particularly high in healthy children under 2 years of age, where rates approach those of older children with high-risk conditions [68–70]. In addition, a high rate of secondary complications, particularly otitis media and pneumonia, occurs in children with influenza infection [71]. Outpatient clinic visit rates for laboratory-documented influenza have been observed at 50–95 and emergency room visit rates of 6–27 per thousand person years in children under five [72]. While rare, influenza-related deaths occur each year in previously healthy children [61]. Notably, many of these deaths occur in children who were not recognized to have high-risk conditions prior to their illness.

Much of the impact of influenza is related to the malaise and consequent disability that it produces, even in young, healthy individuals. It has been estimated that a typical case of influenza, on average, is associated with 5–6 days of restricted activity, 3–4 days of bed disability, and about 3 days lost from work or school [73]. The average number of medical visits for cases in which medical attention was sought was from 1.1 to 3.6 per year, depending on severity of the outbreak and age of the patient. In children, outpatient visits are 10–250 times more common than hospitalizations [72]. It is worth noting that direct medical costs of illness account for only about 20 % of the total expenses of a case of influenza, with a major proportion (30–50 %) of the economic impact due to loss of productivity [74]. In one study, influenza in schoolchildren resulted in 37 missed school days by children and 20 days of missed work by parents, per 100 children [75]. Influenza is also associated with decreased job performance in working adults [76] and reduced levels of independent functioning in older adults [77]. Data from the Tecumseh Community Health Study have been used to estimate that influenza is responsible for 13.8–16.0 million excess respiratory illnesses per year in the United States among individuals less than 20 years of age and for 4.1–4.5 million excess illnesses in older individuals [78].

5 Mechanisms and Routes of Transmission

Influenza viruses are transmitted from person to person via the respiratory route. Three potential modes of transmission have been suggested [79]. Coughing and sneezing could generate small particle aerosols (<10 um mass diameter) which can remain suspended in air for many hours and could transmit infection to individuals at a substantial difference. Larger particles or droplets will typically fall to the ground within 3 m of the infected person and would be expected to infect individuals in direct contact. Finally, viral particles could land on surfaces, where influenza viruses remain infectious [80, 81] and could infect others through indirect contact. There is substantial evidence for all three modes of transmission in experimental studies and epidemiologic observations, but the relative roles of each mode of transmission are uncertain and remain controversial, with obvious implications for infection control practices and for potential interventions to mitigate pandemics.

Small particle aerosols are generated by infected humans, and influenza genome can be detected in these small particles by polymerase chain reaction techniques [82, 83]. It has not been proven that these aerosols contain significant amounts of infectious virus, but experimental studies in humans have shown that vary small amounts (~5 infectious particles) may be sufficient to infect humans by the aerosol route [84, 85]. Aerosol transmission has also been demonstrated in animal models in which infected and exposed ferrets or guinea pigs are separated by several meters, with transmission occurring in the direction of airflow [56, 86].

Airborne transmission has also been implicated in multiple observations of outbreaks where an airborne route of transmission appears to be the most plausible explanation for the characteristics of the outbreak. The most often cited such

outbreak occurred in a commercial airliner that was delayed for approximately 4½ h with a poorly functioning ventilation system. The risk of transmission of influenza A from the index case to other passengers was related to the amount of time passengers spent on the aircraft and not on their seating proximity to the index case. Since most of the passengers did not have direct contact with the index case, airborne transmission appears to be likely [87]. In a well-investigated hospital outbreak, nosocomial cases occurred significantly less frequently in a hospital ward where the air was treated with UV light than in an otherwise similar ward without UV light treatment [88]. In an outbreak in a long-term care facility, there appeared to be an association between the risk of nosocomial influenza and the air handling systems in several wards [89].

Additional observations consistent with airborne transmission were made during an early study of zanamivir prophylaxis of influenza in families. In this study [90], subjects who received short-term prophylaxis with inhaled zanamivir were protected compared to placebo recipients, but recipients of zanamivir administered by nasal spray were not. In addition, the combination of nasal and inhaled zanamivir was no better than inhaled zanamivir alone.

In most of these outbreaks, there are alternative explanations for the observations that could at least partially explain the epidemic behavior without requiring aerosol transmission [91], and the real role of aerosol transmission remains controversial. If aerosol transmission plays a dominant role in influenza, then health-care workers would need to wear filtering face masks, and patients would require negative pressure isolation, to prevent nosocomial transmission of influenza. This has prompted several studies that have attempted to evaluate the role of facemasks in infection prevention in hospitals. In one large, randomized trial, nursing staff who were randomly assigned to wear N-95 respirators had the same rate of influenza as staff assigned to wear simple surgical masks while caring for patients with influenza [92]. This study suggests that airborne transmission does not play a major role at least in nosocomial influenza, although it has been pointed out that cases in the N-95 group could have been acquired outside the hospital and that compliance with these masks is frequently poor. In contrast, hand hygiene and simple surgical masks were reported to be modestly effective in the prevention of influenza transmission in households [93] suggesting that in this setting, droplet spread was the predominant modality.

6 Pathogenesis and Immunity

6.1 Pathogenesis

Once virus is deposited on the respiratory tract epithelium, it can attach to and penetrate columnar epithelial cells if not prevented from doing so by specific secretory antibody (IgA), by nonspecific mucoproteins to which virus may attach, or by the mechanical action of the mucociliary apparatus. After adsorption, virus replication begins, leading to cell death by inhibiting cellular protein synthesis and disrupting other cellular functions and by inducing apoptosis. Virus release continues for several hours before cell death ensues. Released virus then may initiate infection in adjacent and nearby cells, so within a few replication cycles, a large number of cells in the respiratory tract are releasing virus and dying as a result of the virus replication. The time between the incubation period and the onset of illness and virus shedding varies from 18 to 72 h depending in part on the inoculum dose [94].

Quantitation of virus in respiratory tract specimens from otherwise healthy young adults reveals a characteristic pattern (Fig. 19.5). Virus is first detected just before the onset of illness (within 24 h), rapidly rises to a peak of 3.0–7.0 log10 TCID50/mL, remains elevated for 24–48 h, and then rapidly decreases to low titers [95]. Usually, virus is no longer detectable after 5–10 days of virus shedding. However, because of the relative lack of immunity in the young, more prolonged shedding of higher titers of virus is expected in children.

fections of healthy adults, the severity of illness correlates well with the quantities of virus shed, suggesting that a major mechanism in the production of illness is cell death resulting from viral replication. Although the clinical manifestations of influenza are dominated by systemic symptoms, viral replication is limited to the respiratory tract. Instead, systemic symptoms are probably due to the release of potent cytokines, such as type I interferons, tumor necrosis factor, and interleukins (ILs), by infected cells and responding lymphocytes [95]. In fact it has been suggested that an overly vigorous cytokine response to infection may contribute to the high fatality rate seen with H5N1 influenza [96, 97].

Bronchoscopy of individuals with typical, uncomplicated acute influenza has revealed diffuse inflammation of the larynx, trachea, and bronchi, with mucosal injection and edema [98, 99]. Biopsy in these cases has revealed a range of histologic findings, from vacuolization of columnar cells with cell loss to extensive desquamation of the ciliated columnar epithelium down to the basal layer of cells [99]. Individual cells show shrinkage, pyknotic nuclei, and a loss of cilia. Viral antigen can be demonstrated in epithelial cells [100]. Generally, the tissue response becomes more prominent as one moves distally in the airway [99]. Epithelial damage is accompanied by cellular infiltrates primarily composed of lymphocytes and histiocytes. Histologic findings on autopsy in more severe cases show extensive necrotizing tracheobronchitis, with ulceration and sloughing of the bronchial mucosa [101], extensive hemorrhage, hyaline membrane formation, and a paucity of PMN infiltration. Patients with secondary bacterial pneumonia have the changes characteristic

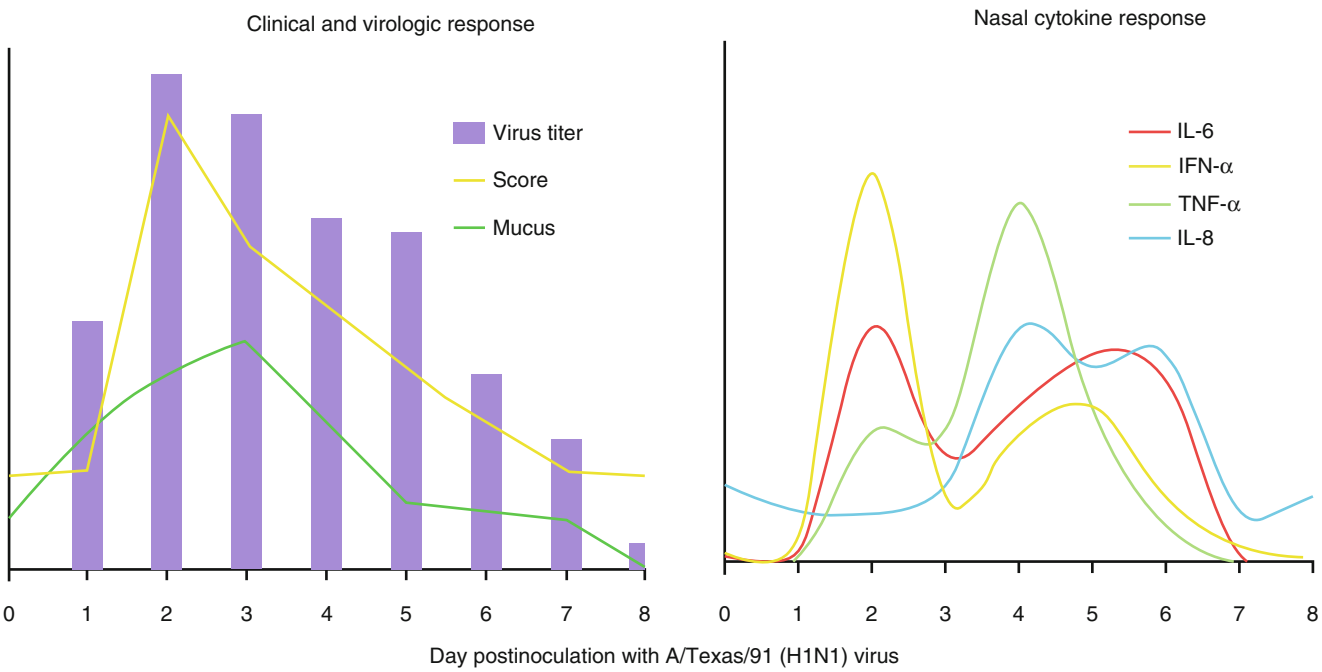

Fig. 19.5 Time course of influenza in healthy adults who were experimentally infected with influenza A/Texas/91. Symptoms are temporally correlated with the peak of virus shedding and production of a variety of cytokines (Data adapted from Hayden et al. [95])

of bacterial pneumonia in addition to the tracheobronchial findings of influenza. Recovery is associated with rapid regeneration of the epithelial cell layer and with pseudometaplasia.

Abnormalities of pulmonary function are frequently demonstrated in otherwise healthy, nonasthmatic young adults with uncomplicated (nonpneumonic) acute influenza. Demonstrated defects include diminished forced flow rates, increased total pulmonary resistance, and decreased density-dependent forced flow rates consistent with generalized increased resistance in airways less than 2 mm in diameter [102, 103], as well as increased responses to bronchoprovocation [102]. In addition, abnormalities of carbon monoxide diffusing capacity [104] and increases in the alveolar-arterial oxygen gradient [105] have been seen. Of note, pulmonary function defects can persist for weeks after clinical recovery. Influenza in asthmatics [106] or in patients with chronic obstructive disease [107] may result in acute declines in forced expiratory vital capacity (FVC) or forced expiratory volume in 1 s (FEV1). Individuals with acute influenza may be more susceptible to bronchoconstriction from air pollutants such as nitrates [108].

Primary viral pneumonia is an uncommon but frequently severe complication of acute influenza. In this situation, virus infection reaches the lung either by contiguous spread from the upper respiratory tract or by inhalation. The trachea and bronchi contain bloody fluid, and the mucosa is hyperemic [109]. Tracheitis, bronchitis, and bronchiolitis are seen, with loss of normal ciliated epithelial cells. Submucosal hyperemia, focal hemorrhage, edema, and cellular infiltrate are present. The alveolar spaces contain varying numbers of neutrophils and mononuclear cells admixed with fibrin and edema fluid. The alveolar capillaries may be markedly hyperemic with intra-alveolar hemorrhage. Acellular hyaline membranes line many of the alveolar ducts and alveoli [109]. Pathologic findings seen by biopsy of lung in nonfatal cases are similar to those described in fatal cases [110].

Bacterial superinfection is a well-recognized complication of influenza that may account for a substantial proportion of morbidity and mortality, especially in adults. For example, the frequency of pneumococcal hospitalizations has been shown to increase in association with influenza epidemics [111]. Consequently, the spectrum of disease and pathophysiology of bacterial superinfection has been studied intensively, and a number of factors have been identified in viral respiratory disease that could play a role in increasing the risk of bacterial infection. Uncomplicated influenza is associated with significant abnormalities in ciliary clearance mechanisms [112]. In addition, increased adherence of bacteria to virus-infected epithelial cells has been demonstrated [113]. The disruption of the normal epithelial cell barrier to infection and loss of mucociliary clearance undoubtedly enhance bacterial pathogenesis. In addition, influenza infection may upregulate certain cell surface receptors involved in bacterial adherence [114]. Alterations in PMNs and mononuclear cells may also contribute to enhanced bacterial infection.

6.2 Immunity

Epidemiologic and experimental observations in humans have shown that infection with influenza virus results in long-lived resistance to reinfection with the homologous virus. In addition, variable degrees of cross-protection within a subtype have been observed [115]. Infection induces both systemic and local antibody, as well as cellular immune responses, each of which plays a role in recovery from infection and resistance to reinfection (Fig. 19.6) [116].

6.2.1 Systemic Antibody Responses

Infection with influenza virus results in the development of antibody to the influenza virus envelope glycoproteins HA and NA, as well as to the structural M and NP proteins. Some individuals may develop antibody to the M2 protein as well [117]. The antibody response is more rapid after reinfection. Peak antibody responses after primary infection are seen at approximately 4–7 weeks and decline slowly thereafter. Antibody titers can sometimes be detected years after exposure, for example, persons born before 1968 frequently have detectable titers of antibody against H2 viruses. The mechanisms that allow such persistent antibody are not known.

As implied by the name, the HA protein of influenza is defined by the ability to hemagglutinate red blood cells, a function which is directly related to binding to cellular receptors. Thus, antibody that can block hemagglutination, or so-called hemagglutination-inhibiting antibody (HAI), has been studied intensively and is generally accepted as a surrogate for virus neutralization and protection against infection. Serum antibody to the HA has been demonstrated to have a protective role against influenza infection and disease in both animal models as well as in experimental infection of humans and in epidemiologic observations. An increased risk of laboratory-documented influenza among those with the lowest titers of preexposure HAI or neutralizing antibody is a consistent finding of most but not all studies. However, there is considerable uncertainty about the actual level of HA antibody that is the best predictor of protection, with estimates ranging from HAI titers of 1:8 to 1:160 or higher [118]. Given the substantial variation from laboratory to laboratory in the estimation of the HAI titer on the same set of samples [119], the inability to use an absolute value for protection is not unexpected. In addition, the amounts of antibody needed to mediate protection could vary by population, degree of exposure, age, and specific influenza type or subtype, although this has not been analyzed comprehensively.

B cells secreting HA-specific antibody that binds to the stem region rather than the head of the HA have been detected in the blood of individuals experiencing infections with novel influenza viruses such as pH1N1 or H5N1 [120, 121].

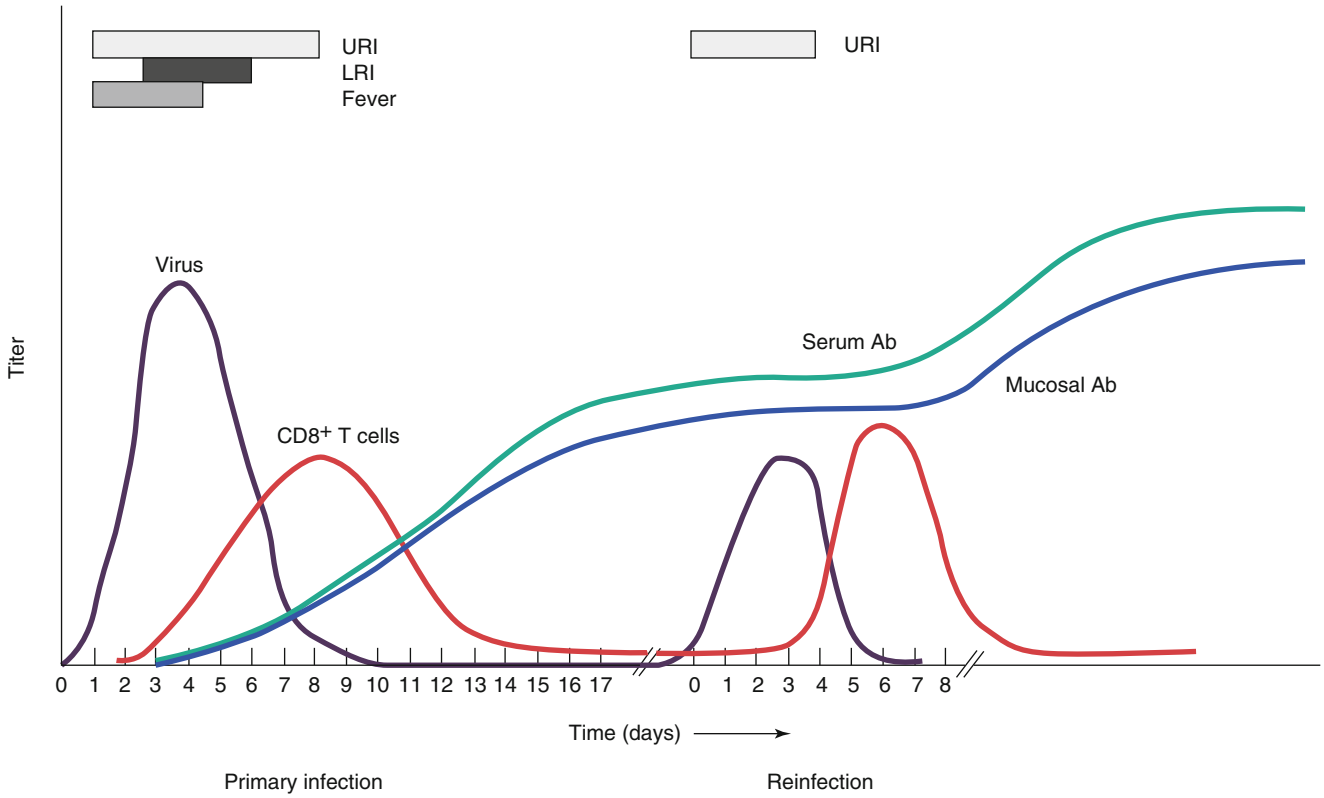

Fig. 19.6 Immune response to influenza infection and reinfection (Adapted from Subbarao et al. [116])

These antibodies exhibit neutralizing activity in some assays but do not inhibit hemagglutination. Stalk-binding antibody can be detected in serum as well [122]. Because the stalk region is well conserved, these antibodies can be cross-neutralizing among HA subtypes and have increased interest in the potential creation of a universal influenza vaccine.

In contrast to anti-HA antibody, anti-NA antibody does not neutralize virus infectivity but instead reduces efficient release of virus from infected cells, resulting in decreased plaque size in in vitro assays [123] and in reductions in the magnitude of virus shedding in infected animals [124, 125]. Observations on the relative protection of those with anti-N2 antibody during the A/Hong Kong/68 (H3N2) pandemic [26, 126], as well as experimental challenge studies in humans [127], have shown that anti-NA antibody can also be protective against disease and results in decreased virus shedding and severity of illness but that it is infection permissive [128].

Antibody to other influenza viral proteins has also been evaluated for potential protection. Antibody to M2 reduces plaque size in vitro, and passive transfer studies in mice have also suggested that antibody to the M2 protein of influenza A viruses may be partially protective if present in large enough amounts [129]. The mechanism of protection in vivo is related to mediation of antibody-dependent cytotoxicity [130]. Antibody to internal viral proteins such as M or NP is also cross-reactive among type A viruses, but they are non-neutralizing. Studies in mice have suggested that such non-neutralizing but cross-reactive antibody may mediate protection under some circumstances [131]. The mechanism by which antibody to viral proteins that are not exposed on the surface can mediate protection is unclear.

6.2.2 Mucosal Antibody Responses

Both natural viral infection and live attenuated vaccines have been found to induce significant mucosal antibody responses. Nasal HA-specific IgG is predominantly IgG_1, and its levels correlate well with serum levels of HA-specific IgG_1, suggesting that nasal IgG originates by passive diffusion from the systemic compartment [132]. Nasal HA-specific IgA is predominantly polymeric and IgA_1, suggesting local synthesis. Studies in mice and ferrets have emphasized the importance of local IgA antibody in resistance to infection, particularly in protection of the upper respiratory tract. Studies in humans have also suggested that the resistance to reinfection induced by virus infection is mediated predominantly by local HA-specific IgA, whereas that induced by parenteral immunization with inactivated virus depends also on systemic IgG [133]. Importantly, either mucosal or systemic antibody alone can be protective if present in high enough concentrations, and optimal protection occurs when both serum and nasal antibodies are present [134, 135].

6.2.3 Cellular Immune Responses

The induction of cellular immune response to influenza virus infection has been studied intensively in murine models, and such studies suggest that B cell, CD4+ T cell, and CD8+ T cell responses all can play a role in protection against disease and recovery from infection. A large number of HLA class I-restricted (CD8+ T cell) and HLA class II-restricted (CD4+ T cell) epitopes have been described, and in situations where those epitopes are on relatively well-conserved influenza proteins such as the polymerase, NP, and M proteins, the cellular responses are cross-reactive between subtypes, but not between types A and B.

Cellular immune responses to influenza vaccination and infection have not been studied as extensively in humans, but B cell (memory B cell and antibody-secreting cell), CD4+ T cell, and CD8+ T cell responses in peripheral blood have been described after infection or vaccination [136]. It can be difficult to capture the peak of the response and detectable increases in antigen-specific cells may only be seen on a few days after exposure. Generally, the peak cellular response occurs somewhere between 5 and 14 days depending on the status of the subject and the nature of the response. As seen in murine models, a major component of the cellular response is directed at conserved peptides to which the subject has already been exposed during previous infections or vaccinations.

Antibody-secreting cells (ASC) appear in blood and tonsils as early as 2 days after vaccination and are detected in the blood of adults and older children more frequently than in young children after immunization [137]. An increase in cytotoxic T lymphocytes, directed primarily at the conserved internal proteins, has been shown in healthy adults with a peak at 14 and 21 days after vaccination and return to baseline at 6 months. An increase in HA-specific CD8+ T cells on day 7 after vaccination has also been detected by tetramer staining in adults receiving inactivated influenza vaccine [138].

An important role of the cellular immune response in recovery from influenza infection in humans is strongly supported by the observation of prolonged illness and viral shedding in individuals who are lymphopenic as a result of disease or chemotherapy. However, it has been difficult to develop specific markers of T cell immunity as correlates of protective immunity. Activated T cells, in the form of granzyme B-positive T cells, have been associated with protection in older subjects [139]. In the human challenge model, early studies identified the early induction of virus-specific cytotoxic T cells as measured by cytochrome release assays as correlated with reductions in the duration and level of virus replication in adults [140]. In a subsequent study done many years later by the same group, prechallenge CD4+ T cells, but not CD8+ T cells, correlated with relatively lower levels of viral shedding and symptoms following experimental

infection [141]. In a large study of the efficacy of live attenuated vaccine in children, it was shown that higher levels of influenza-specific T cells assayed by gamma-interferon ELISPOT was associated with a decreased risk of PCR-documented influenza [142]. The development of more sophisticated markers that can specifically identify reactive cells in peripheral blood will help to define the role of cellular immunity in protection, but the field remains limited by the lack of convenient access to compartments other than peripheral blood in humans.

7 Patterns of Host Response

Typical uncomplicated influenza often begins with an abrupt onset of symptoms after an incubation period of 1–2 days. Many patients can pinpoint the hour of onset. Initially, systemic symptoms predominate, including feverishness, chilliness or frank shaking chills, headaches, myalgia, malaise, and anorexia. Usually, myalgia or headache is the most troublesome symptom, and the severity is related to the height of the fever. Respiratory symptoms, particularly cough and sore throat, are usually also present at the onset of illness. The predominance of systemic symptoms is a major feature distinguishing influenza from other viral upper respiratory infections. Older adults may simply present with high fever, lassitude, and confusion without the characteristic respiratory complaints, which may not occur at all. Generally there is a wide range of symptomatology in healthy adults, ranging from classic influenza to mild illness or asymptomatic infection.

Two manifestations of pneumonia associated with influenza are well recognized: primary influenza viral pneumonia and secondary bacterial infection. The syndrome of primary influenza viral pneumonia was first well documented in the 1957–1958 pandemic, predominantly among persons with cardiovascular disease, especially rheumatic heart disease with mitral stenosis, and to a lesser extent in others with chronic cardiovascular and pulmonary disorders [109]. The illness begins with a typical onset of influenza, followed by a rapid progression of fever, cough, dyspnea, and cyanosis. Secondary bacterial pneumonia classically presents after a brief period of improvement [143, 144], although most patients do not fit this classic pattern. Bacteria frequently associated with influenza include *Streptococcus pneumoniae* or *Haemophilus influenzae* and, notably, an increased frequency of *Staphylococcus aureus*. An increased frequency of community-acquired, methicillin-resistant *S. aureus* has been seen in children and adults following influenza outbreaks [145].

In addition to pneumonia, other pulmonary complications of influenza include croup [146] and exacerbations of chronic bronchitis or asthma [147, 148]. Recognized non-pulmonary complications include myositis and myoglobinuria [149], myocarditis and pericarditis [150, 151], toxic shock syndrome [152, 153], Guillain-Barré syndrome and transverse myelitis [154], and Reye's syndrome particularly in children who have been given aspirin to treat fever.

8 Control and Prevention

8.1 Antiviral Drugs

Two classes of antiviral drugs have been used clinically to treat and prevent influenza. The adamantanes amantadine and rimantadine are related primary symmetrical amines whose mechanism of action involves inhibition of the M2 ion channel activity of susceptible viruses. The function of the M2 ion channel in viral replication is to acidify the interior of the virion, disrupting the interaction between the matrix and nucleoproteins and allowing the ribonucleoproteins to be transported to the nucleus, where replication occurs [155]. Similar ion channels have been described for influenza B and C viruses; however, at clinically achievable levels, these drugs are active against only influenza A.

Amantadine and rimantadine are effective in the therapy of both experimentally induced and naturally occurring influenza A, with more rapid decrease in fever, more rapid improvement in symptoms, and decreased shedding of virus [156, 157]. Rimantadine has also been shown to be effective in the treatment of influenza A in children [158].

Drug resistance has been a factor in limiting the use of these antiviral agents. Resistant viruses emerge frequently in treated individuals, particularly children, in whom subpopulations of resistant virus can be detected following treatment in virtually all cases [159]. Resistance is the result of single point mutations in the membrane-spanning region of the M2 protein, and it confers complete cross-resistance between amantadine and rimantadine [160]. Resistant virus can be transmitted to, and can cause disease in, susceptible contacts. Prolonged shedding of resistant viruses may occur in immunocompromised patients, particularly children, and may continue even after therapy is terminated [161], consistent with the relative fitness of these resistant viruses. While previously rare, a rapid increase in the prevalence of de novo resistance to M2 inhibitors was noted in 2005, and essentially all H3N2 viruses are now resistant to these agents [162, 163]. Although previously circulating seasonal H1N1 viruses remained sensitive to these agents, the emerging pH1N1 viruses are also completely resistant to the M2 inhibitors, which now lack activity against all strains of influenza virus currently circulating.

The neuraminidase inhibitors act by inhibiting the functioning of the influenza virus neuraminidase, which is critical in allowing newly formed viruses to egress from the cell

and spread to other cells [164]. The two licensed inhibitors, zanamivir and oseltamivir, have shown very similar results in clinical trials. Both drugs reduce the duration of symptoms and enhance the return to normal activities when used within the first 36 h of symptoms in otherwise uncomplicated influenza in healthy adults [165–168]. Both drugs have also been shown to be effective in reducing the duration and severity of influenza in children [169, 170].

Antiviral resistance to these agents has also been detected both in treated and untreated individuals. Mutations within the catalytic framework of the NA that abolish binding of the drugs have been described [171, 172]. The specific mutations conferring resistance are dependent on the specific NA, that is, common resistance mutations in N1 (e.g., H274Y) are different than the ones seen in the N2 (e.g., R292K or E119V) or influenza B (e.g., D198N). In addition, depending on the location of the mutation, these viruses may be specifically resistant to only one inhibitor [173]. Resistance mutations in the NA may be associated with altered characteristics of the enzyme with significantly reduced activity [174, 175].

Some resistant viruses appear to have reduced fitness, with reduced levels of replication, attenuation in animals, and reduced ability to be transmitted from animal to animal [176–179]. Drug resistant viruses were also isolated very infrequently from oseltamivir-treated individuals in clinical trials, being seen in less than 2 % of treated adults and detected in 5.6 % of children [169]. However, subsequent studies have demonstrated that resistant viruses can be detected in up to 18 % of treated children when using sensitive PCR techniques to pick up minor subpopulations [180].

Beginning in 2006, spontaneously resistant H1N1 viruses carrying the H274Y mutation began to be detected in viruses from individuals who did not have a history of exposure to oseltamivir [181]. By 2008, all H1N1 viruses isolated in the United States were resistant to oseltamivir. The mechanism that led to the selection of seasonal H1N1 clades resistant to oseltamivir as the predominant circulating H1N1 viruses is unclear. However, the emerging pH1N1 virus has remained largely susceptible to oseltamivir.

8.2 Vaccines

Two types of influenza vaccines are currently licensed and are used in various countries, inactivated influenza vaccines (IIV) and live attenuated influenza vaccines (LAIV). Shortly after these vaccines were introduced, it was recognized that their efficacy might depend on the antigenic match between the strain(s) contained within the vaccine and the circulating viruses [182], and since that time, the vaccines have been continuously reformatted to keep pace with the ongoing evolution of influenza viruses. Since 1977, influenza vaccines have contained a representative A/H3N2, A/H1N1, and B virus, so-called trivalent influenza vaccine. As mentioned above, two antigenically distinct lineages of influenza B viruses have cocirculated in humans since 2004, and quadrivalent formulations of vaccine are currently being considered.

8.2.1 Safety

IIV are chemically inactivated and have been administered either as the so-called "whole-virus" preparations or as detergent-disrupted and partially purified "split product" or "subunit" vaccines. Hundreds of millions of doses of IIV are administered each year, and the safety of these vaccines has been repeatedly confirmed. For example, no increase in clinically important medically attended events has been noted among over 251,000 children <18 years of age who were enrolled in one of the five health maintenance organizations within the Vaccine Safety Datalink, the largest published post-licensure population-based study of vaccine safety [183]. The most common adverse events reported following immunization with IIV are tenderness and/or pain at the injection site. Most injection site reactions are mild and rarely interfere with daily activities. Systemic reactions following immunization of adults with inactivated vaccine are uncommon. In placebo-controlled clinical trials in younger and elderly adults, rates of systemic reactions were similar among groups given inactivated vaccine or placebo [184, 185]. However, whole-virus IIV are associated with fever in children [186] and are not recommended in this age group.

Recently, an increased frequency of fever and febrile seizures was observed among young children given one specific IIV during the 2010 influenza season in Australia [187]. The reasons for this unexpected reactogenicity are unclear, but preliminary studies have suggested that this vaccine preparation stimulated unusually high cytokine responses in in vitro assays. In addition, concomitant immunization of young children with IIV and pneumococcal conjugate vaccine (PCV) was shown to be associated with an increased risk of developing febrile seizures.

Immediate hypersensitivity reactions (hives, wheezing, angioedema, or anaphylactic shock) following inactivated vaccine can also occur, and vaccine is considered contraindicated for persons who experienced a previous anaphylactic reaction following vaccine. Clinical protocols have been proposed to administer inactivated vaccine to persons who are at high risk for severe or complicated influenza who also have a history of immediate hypersensitivity to eggs, if the benefit of immunization is judged to outweigh the risk [188].

Several unusual syndromes have been associated with IIV. The Guillain-Barré syndrome (GBS), an acute inflammatory demyelinating polyneuropathy, was associated with the 1976 swine influenza vaccination campaign, with an increased risk of approximately 1 per 100,000 vaccinees. More recent studies have suggested a statistically significant

but very slight increased relative risk of GBS within 7 weeks of influenza vaccination [189]. The oculorespiratory syndrome (ORS) is a syndrome of red eyes, facial edema, and/or respiratory symptoms such as coughing, wheezing, sore throat, hoarseness, difficulty breathing, or chest tightness that develop within 2–24 h after vaccination, associated with a specific influenza vaccine used in Canada, but not elsewhere [190]. The specific mechanism underlying this phenomenon is unknown.

Although not studied as extensively, LAIV also appear to be quite well tolerated. Nasal symptoms (runny nose, nasal congestion, or coryza) and sore throat have been the most frequently identified adverse symptoms following LAIV. Children under 8 have had slightly increased rates of low-grade fever, runny nose, and abdominal symptoms in the 7 days following vaccination compared to placebo recipients. However, when considering all the pediatric studies in aggregate, no consistent symptom was significantly more common in LAIV compared to placebo recipients. In older children, 11 to <16 years of age, sore throat was observed slightly more frequently in LAIV recipients than IIV recipients.

In larger studies, wheezing has been associated with LAIV in young children, although occurring at low rates. In the largest trial, medically significant wheezing within 42 days of vaccination was reported in 3.8 % of children <2 years old after receipt of LAIV compared to 2.1 % in those who received IIV [191]. Wheezing generally occurs in the youngest, previously unvaccinated children following the first dose of vaccine. Because of this observation, LAIV is currently approved for use in the United States for children ≥2 years old who do not have a history of asthma.

LAIV can be recovered from nasal secretions of about half of adult recipients, although generally shedding of LAIV by adults is of low titer and short duration [192]. Although young children shed much higher levels of vaccine virus, no transmission of LAIV from vaccine recipients to susceptible contacts was detected in studies of young children involved in day-care-like settings where LAIV and placebo recipients played together for up to 8 h a day for 7–10 days after vaccination. In the largest study, 197 children between 8 and 36 months of age were randomized to receive LAIV or placebo, and vaccine virus shedding was assessed for 21 days after vaccination. Although 80 % of LAIV recipients shed at least one vaccine strain, for a mean of 7.6 days, clear evidence of transmission was detected in only one placebo recipient [193].

8.2.2 Efficacy and Effectiveness

The ability of influenza vaccines to prevent influenza has been assessed in numerous clinical studies which vary greatly in design, populations, and endpoints. These studies have included prospective, randomized controlled studies, in which case they are referred to as efficacy studies, as well as a wide variety of nonrandomized cohort and retrospective study designs which assess vaccine effectiveness. Endpoints evaluated in these studies have included both laboratory-confirmed influenza and non-laboratory-confirmed respiratory illnesses. In this regard, it has been recognized that studies that utilize a serologic definition of influenza infection may overestimate the efficacy of influenza vaccine, since it will be harder to demonstrate postvaccination to post-season antibody increases in the vaccinated group [194].

Randomized studies of IIV efficacy against laboratory-confirmed influenza have mostly been conducted in healthy adults. These studies have shown a wide range of efficacy, from approximately 40–80 %, with lower levels of efficacy typically seen in years with apparent antigenic mismatch. A recent meta-analysis of 8 randomized, controlled trials in healthy adults during 2004–2008 estimated the pooled efficacy of IIV against culture-confirmed influenza to be 59 % (95 % CI 51–67) among those aged 18 through 64 years [195]. The role of antigenic mismatch in the efficacy observed in these trials is unclear, and some studies in young adults have demonstrated high levels of efficacy (76 %) despite a degree of antigenic mismatch. Recent studies using virus culture and/or PCR endpoints have demonstrated similar levels of efficacy for both egg-grown and cell culture-grown IIVs [196].

Relatively few placebo-controlled trials of the efficacy of LAIV have been conducted in adults. In the human challenge model, cold-adapted and inactivated influenza vaccines were of approximately equal efficacy in the prevention of experimentally induced influenza A (H1N1), A (H3N2), and B. The combined efficacy in preventing laboratory-documented influenza illness due to the three wild-type influenza strains was 85 % for LAIV [197]. In a randomized, controlled study in healthy persons aged 1 through 64 years, of whom most of the participants were adults, the efficacy of a pre-licensure, bivalent preparation of LAIV for preventing culture-confirmed influenza A illness in adults was 85 % (95 % CI 70–92 %) for H1N1 and 58 % (95 % CI 29–75 %) for H3N2 [198]. LAIV was also evaluated in a large study against clinical endpoints performed in 4,561 healthy working adults [199]. In this study, the effectiveness of LAIV-T in preventing severe febrile respiratory illness of any cause during the influenza season was 29 %.

Relatively few recent prospective trials have assessed IIV efficacy in children. In one randomized, controlled trial in healthy children aged 6 through 23 months, vaccine efficacy was 66 % (95 % CI 34–82) in the first year, but efficacy could not be assessed in the second year due to a very low influenza attack rate (efficacy −7 %: 95 % CI −247–67) [200]. Immunization of asthmatic children has also been shown to reduce the incidence of influenza. More recently, the efficacy of IIV against PCR-confirmed influenza was assessed in a randomized, placebo-controlled trial in healthy children

between the ages of 6 and 72 months [201]. The efficacy of IIV against all influenza strains was 43 % compared with the placebo group.

LAIV was demonstrated to be efficacious in the prevention of influenza in a pivotal 2-year, randomized placebo-controlled trial conducted in 1,314 children aged 15 to <72 months [202]. The efficacy against culture-confirmed influenza illness in the first year of this trial was 95 % (95 % C.I. 88–97 %) for influenza A/H3N2 and 91 % (95 % C.I. 79–96 %) for influenza B. In the second year of the trial, the H3 component of the vaccine (A/Wuhan/93) was not a close match with the predominant H3 virus that season, A/Sydney/95. However, the efficacy of LAIV against this variant was 86 % (95 % C.I. 75–92 %) [203]. Overall, the efficacy of LAIV to prevent any influenza illness during the 2-year period of surveillance in this field study was 92 % (95 % C.I. 88–94 %). The overall efficacy of LAIV against culture-confirmed influenza among children 6 to <36 months who were attending day care was recently shown to be 85 and 89 % in the first and second year of the study, respectively [204]. Significant protection against flu-associated acute otitis media also was demonstrated (>90 % in both years). Studies done in Asia have reached similar conclusions, with an efficacy of LAIV compared to placebo of between 64 and 84 % over multiple seasons, depending on the antigenic match with the vaccine [205].

Although annual vaccination of elders and other high-risk persons has been recommended for many years, there are very few randomized trials demonstrating efficacy in these groups, in part because the existing vaccine recommendations make it difficult to do studies using a placebo group. In the most commonly referenced study, TIV was 52 % (95 % CI 29–67) efficacious in preventing serologically documented influenza illness in a population of adults 60 years of age and older [184]. When the groups were further stratified by age, efficacy estimates against serologically documented influenza illness were 57 % (95 % CI 33–72 %) in those 60 through 69 years old but only 23 % (95 % CI −51–61 %) in those ≥70 years old.

In a recently reported randomized, double-blind, placebo-controlled clinical trial of LAIV among community-dwelling ambulatory adults ≥65 years old, the overall efficacy of LAIV against viruses that were antigenically similar to the vaccine was 42 % [206], similar to the protection seen with inactivated vaccine. However, LAIV is not currently licensed for use in individuals over 49 years of age.

Monitoring influenza vaccine efficacy on an annual basis by conducting randomized placebo-controlled studies would clearly be a very difficult undertaking and is probably not possible in children, elders, and other high-risk groups. Therefore, a number of observational study designs have been used for this purpose. Many recent studies have utilized a test-negative, case–control design, in which individuals meeting a particular case definition are tested for influenza using a highly sensitive and specific diagnostic test, and the vaccination exposure of test-positive cases and test-negative controls is determined [207]. Large surveillance networks for this purpose have been established in Canada, the United States, Europe, and Australia for purposes of making interim and end-of-season estimates of vaccine effectiveness.

Studies using this design have shown variable results with estimates generally ranging from as low as 20 %, or in some cases, no effectiveness, to as high as 70 % [195]. While the various networks vary in their study design and the specific selection criteria for subject inclusion, a few overall generalizations can be stated. Failure to detect VE has typically occurred in studies with very low prevalence of influenza in the study population, or in years with substantial antigenic mismatch between the vaccine and circulating strains, most often involving influenza B lineage mismatch. The relationship of antigenic mismatch with vaccine effectiveness for influenza A/H1N1 and A/H3N2 viruses is not as consistent, but even in situations of antigenically matched viruses, VE remains in the 50–60 % range [208]. In some cases, viruses recovered from subjects in studies with low vaccine effectiveness have been shown to have substantial changes on a HA sequence level despite appearing well matched by traditional HAI tests [209].

Most studies have not enrolled enough subjects in a single season to make age-specific estimates of VE. However, there is a trend towards decreased VE in elderly, not surprising given their diminished immune response to vaccination. After accumulating cases over several seasons, it was recently possible to use the same test-negative case–control design to demonstrate VE of approximately 60 % against influenza-related hospitalization in a population of community-dwelling older adults [210].

While the use of a study design in which testing is performed without knowledge of vaccination status may eliminate some biases related to health-care access and health-seeking behavior, the results are influenced by the accuracy of the diagnostic testing, since errors in assignment to the case or control group will bias VE towards nil. Recently, in a study done in children, it was demonstrated that using the test-negative case–control approach, estimates of VE were substantially higher when children with documented infections with viruses other than influenza were used as a control group, rather than using all children who were test negative for influenza [211].

A larger body of data exists from nonrandomized or observational studies of vaccine effectiveness. These studies have suggested that influenza vaccination can reduce pneumonia and influenza (P&I) hospitalizations and death among the elderly regardless of whether they have other conditions that place them at high risk for complications following influenza [212]. While post-licensure observational studies are

important tools for monitoring vaccine effectiveness, such studies relating to the elderly are particularly challenging to perform and interpret. Frailty selection bias (a higher baseline risk of hospitalization and death among unvaccinated vs. vaccinated subjects) and nonspecific endpoints may overestimate vaccine effectiveness in cohort studies [213].

Infants less than 6 months of age are at substantial risk for influenza-related morbidity but are too young to receive influenza vaccine. One strategy to protect vulnerable infants is maternal immunization, with protection mediated by both transfer of maternal antibody and reduced potential for contact with an influenza-infected mother. In a randomized study of maternal immunization, infants born to mothers immunized with influenza vaccine had substantially lower rates of laboratory-documented influenza in the first 6 months of life than did infants born to mothers immunized with pneumococcal vaccine [214]. Similarly, in a retrospective case–control study, the frequency of influenza immunization was substantially lower in the mothers of infants hospitalized with PCR-confirmed influenza than in mothers infants hospitalized who were PCR negative, with an estimated protective effect of 92 % [215].

There has been considerable interest in potential strategies to protect such individuals indirectly by preventing illness and viral transmission within highly susceptible populations that probably play a role on community transmission, such as schoolchildren. Several studies have suggested that this may be possible. During the 1968 pandemic, it was observed that the incidence of respiratory illness during the period of influenza A circulation was among unvaccinated adults was substantially lower in a community in which schoolchildren were immunized than in a comparison community with no school immunization. Influenza B was not contained in the vaccine, and during a subsequent influenza B epidemic, there was no difference in adjusted respiratory illness rates in adults in the two communities [216]. In a recent study, closed agricultural communities of Hutterites were randomized to vaccination of schoolchildren with influenza vaccine or with hepatitis A vaccine as a control. In the subsequent influenza A epidemic, the rate of laboratory-documented influenza A in unvaccinated adults residing in school-vaccinated communities was reduced by 61 % (95 % CI 8–83 %) compared to adults in unvaccinated communities [217]. Observations in Japan, where it appeared that substantial fluctuations in overall influenza-related mortality (occurring mostly in the elderly) were directly related to the rate of school-aged influenza vaccination, also support a potential role for school vaccination in protection of elders [218].

8.2.3 Adjuvants

For many years, licensed inactivated influenza vaccines have been administered without adjuvants. However, it is clear that the immune response to vaccination and the protective effects of vaccine are suboptimal, particularly in some groups at high risk for influenza-related complications including young children and elders. Thus, there has been significant interest in the potential use of adjuvants to enhance the protective effects of vaccination. Although influenza vaccines adsorb well to aluminum salts, these compounds have not been effective adjuvants for influenza, for unknown reasons. Early studies suggested that water in oil emulsions using mineral oil could very substantially improve antibody responses in military recruits allowing the use of lower doses [219]. However, the use of these adjuvants was restricted by substantial local side effects including the development of sterile abscesses at the site of administration; [220] the use of peanut oil appeared to reduce the observed toxicity [221].

Subsequently, oil-in-water emulsions based on the metabolizable oil squalene have been shown to substantially improve immune responses with an excellent safety profile. While there is relatively little effect on the immune response to seasonal vaccines in healthy adults [222], the oil-in-water emulsion MF59 results in an approximately 50 % increase in antibody titers in older adults [223], and MF59 adjuvanted seasonal IIV has been licensed for use in elders in Italy for several years. Recently, a large randomized trial in young children compared MF59-adjuvanted IIV with unadjuvanted IIV over two seasons. Absolute efficacy against all influenza strains was 86 % in the group given IIV-MF59 and 43 % in the group given unadjuvanted IIVs when compared with the placebo group [201].

Oil-in-water emulsions have demonstrated especially striking improvements in the antibody responses to candidate H5 pandemic vaccines. These studies have shown higher titers of antibody against the vaccine virus, as well as against antigenic variants, the development of B cells that recognize a larger variety of HA epitopes, and broadened and more vigorous CD4 T cell responses [224, 225].

8.2.4 Comparisons of Inactivated and Live Influenza Vaccines

While relatively few randomized direct comparisons of the efficacy of live and inactivated vaccines have been performed, the available studies are consistent with the observed effects of age and prior influenza experience on immunogenicity. When these vaccines have been compared in young children 12 months through 59 months of age, LAIV has shown consistently superior protection, with an approximately 50 % greater protective efficacy than inactivated vaccine [191, 226]. Studies conducted in healthy young children have generally concluded that LAIV may be more efficacious than IIV, including both against viruses which are well matched antigenically to the vaccine virus and those which are antigenically drifted [191].

In contrast to young children, studies that have directly compared the vaccines in adults have suggested that the

vaccines have similar efficacy or that IIV vaccine is slightly more efficacious than live vaccine. In one 3-armed study, the efficacy of LAIV compared to placebo for prevention of laboratory-confirmed influenza in healthy adults was 57 %, while the efficacy of the IIV was 77 %, but the difference between the two vaccines was not statistically significant [227]. In a subsequent season in the same population, the absolute efficacies of IIV and LAIV were 68 and 36 %, respectively [228]. Similar results have been reported from a retrospective study evaluating the effectiveness of IIV and LAIV against medical visits for pneumonia- and influenza-related diagnoses in the US military [229]. Generally, rates of such visits were lower in recipients of IIV, except for personnel who had not been vaccinated in previous years, in which there was not apparent difference in the effectiveness of the two types of vaccines. In a recent effectiveness study that included both LAIV and IIV recipients, there was no clear-cut difference in effectiveness between the two vaccines [208].

9 Unresolved Problems

Despite many years of research and vast energies devoted to uncovering its mysteries, influenza remains an enigma and effective strategies for its control are elusive. Influenza vaccines, including unadjuvanted inactivated vaccines of various formulations and live attenuated vaccines based on cold-adapted master donor viruses, have clearly been demonstrated to reduce the risk of influenza in selected populations. However, these vaccines have never been shown to have any substantial impact on the overall disease burden of influenza. In part, this is a problem of inconsistent supply and limited uptake, compounded by the need for annual reformulation and administration, but in part this also reflects our growing recognition of the limited effectiveness of these vaccines and an incomplete understanding of the nature of protective immunity.

Development of more effective vaccines, perhaps to include broadly cross-protective vaccines, is an obvious goal. The specific types of immune responses that could contribute to more effective vaccination are unclear, and the best strategies for generating these responses remain to be determined. Many exciting new discoveries have recently been revealed, and multiple innovative approaches for new vaccines and adjuvant systems are underway. Each of these pathways will need to carefully balance safety and efficacy in the context of the existing very safe but modestly effective options.

Antiviral agents are another strategy to mitigate the impact of seasonal and pandemic influenza, but their real utility in this disease has also been quite limited. The rapid emergence of resistance is a major obstacle facing effective use of antiviral strategies, but the basic pathogenesis of influenza creates an extremely narrow time window for antiviral intervention in most cases, further complicating antiviral therapy. Novel approaches that focus on modifying the host or the host innate immune response may offer one alternative that might overcome some of these problems.

Although it should be recognized that the cumulative disease burden of seasonal influenza is generally larger than that of pandemic influenza, the threat of a severe influenza pandemic represents another unresolved issue in the field. Extensive efforts have been devoted to comprehensive surveillance for novel influenza viruses and potential pandemic threats in a wide variety of domestic and wild animal populations, and our understanding of the ecology of influenza is expanding rapidly. However, our ability to actually predict the emergence of any specific pandemic remains extremely limited.

Noroviruses, Sapoviruses, and Astroviruses

20

Ben A. Lopman, Jan Vinjé, and Roger I. Glass

1 Introduction

Acute gastroenteritis (AGE) is among the most common diseases of humankind affecting people of all ages and particularly those at the extremes of life: children and the elderly. In developing countries, AGE remains one of the most important causes of death in children [1] and has been associated with a cycle of malnutrition and problems of impaired neurocognitive development [2]. In developed countries, the disease is an important cause of doctor visits and hospitalization of children, and a less frequent but persistent problem for adults and the elderly, all at appreciable medical cost [3, 4]. Prior to 1970, an etiology could be specified for fewer than 15 % of episodes of AGE, but since that time, more than 50 different infectious agents and toxins have been identified to cause the disease. This wealth of new information has challenged investigators and public health professionals to understand the relative importance of each agent, assess its contribution to human health, and consider prospects for prevention and control. Control has focused on understanding routes of transmission of each pathogen and determining whether public health interventions could interrupt their spread or investigating whether natural immunity to repeat infection might provide an opportunity to consider prevention with vaccines. Many of the infectious agents of AGE have been discovered in epidemics where a common illness has led to the identification of a single point source of infection. However, patients with these infections also present individually as "sporadic cases" in clinics and hospitals, where despite careful questioning, their illnesses cannot be linked to an outbreak or to other common cases or exposures.

Noroviruses and sapoviruses belong to two separate genera of the family *Caliciviridae* [5]. These single-stranded RNA nonenveloped viruses are highly infectious agents transmitted through a variety of routes including person-to-person; contact with fecally contaminated food, water, or environmental surfaces; or possibly via airborne droplets. In the United States, noroviruses are now recognized to be the most common cause of outbreaks of AGE, the most common cause of sporadic AGE across all ages, and the most common cause of foodborne disease [6]. They are also an important cause of healthcare-associated infections in both long-term and acute care settings. In addition to accounting for the high burden of AGE, noroviruses are often detected in people without the occurrence of symptoms, particularly among people in resource-poor settings [7]. Immunity is complex and incompletely understood but generally regarded to be short-lived [8]. The sapoviruses, which initially were thought to cause AGE in children, are now recognized to cause outbreaks in people of all age groups including the elderly [9]. Astroviruses are non-enveloped, single-stranded RNA viruses in the family *Astroviridae*. Although astroviruses have been detected in all age groups, most infections are in children <2 years of age and tend to be relatively mild, rarely requiring hospitalization [10].

Over the past two decades, this new appreciation of the major burden of norovirus and sapovirus AGE has been brought about by laboratory advances in the molecular detection of these viruses and their genetic characterization. In the 1990s, the prototype Norwalk virus and its close relative, Southampton virus, were cloned and sequenced [11, 12],

paving the way for the development of new molecular diagnostic tests based upon RT-PCR detection and sequencing of virus directly from fecal specimens [13–15]. Furthermore, expression of the capsid proteins meant that serologic assays could be performed with antigens that could be replenished in the laboratory [16] rather than relying on immunoassays that required fecal specimens for antigen and paired sera collected from human volunteers. Genetic factors associated with resistance to infections and acquired immunity both play a role in susceptibility to infection and disease. With this in mind, and because of the great difficulty in controlling most outbreaks through routine public health interventions, vaccines for norovirus are currently a priority for development.

Unfortunately, there are currently few specific interventions to prevent the spread of these viruses. Management of outbreaks is based on identifying, where possible, the means of spread, be it from person to person or from fecally contaminated food and water, and then intervening with control measures to interrupt that spread. Treatment is supportive and based on oral rehydration solution (ORS) or intravenous fluid replacement in cases of severe dehydration. Recent advances have led not only to major changes in our recognition of the importance of these viruses in human health but also novel approaches to their control through public health measures and the potential future use of vaccines.

2 Historical Background

The history of noroviruses and our understanding of the viruses that cause AGE track directly with the development of modern diagnostic methods to detect and characterize these viruses. Each advance in diagnostics has furthered our understanding of the epidemiology of the virus and expanded our appreciation of the role that these viruses play in human health. Consequently, over the past 40 years, noroviruses have emerged from being an obscure and rarely detected viral cause of outbreaks of AGE to become the most common cause of these outbreaks and of sporadic episodes of AGE in developed countries and a common pathogen in developing countries. In the 1940s, investigators suspected viruses to be possible causes of AGE because volunteers administered bacteria-free stool filtrates from patients suffering from AGE developed the disease [17]. Unfortunately, they were unable to isolate a pathogen. Most episodes and outbreaks of AGE, one of the most common illnesses of humans, went without an etiologic diagnosis and were defined with descriptive terms – diarrhea of weaning, travelers' diarrhea, winter vomiting disease, or idiopathic diarrhea. The first major breakthrough occurred in 1972 when Kapikian discovered a virus-like particle by immune electron microscopy (IEM) in the fecal specimen of victims linked to an outbreak of AGE at a school in Norwalk, Ohio, which had been investigated by CDC epidemiologists 4 years earlier [18]. The discovery of the Norwalk virus opened a golden era for electron microscopists to discover new viral pathogens in fecal specimens and use IEM to characterize the patient's immune response in acute and convalescent sera. A stream of other enteric viruses were then discovered – rotaviruses, astroviruses, "classic caliciviruses," as well as antigenically distinct variants of Norwalk virus, named according to the location where first identified (e.g., the Hawaii agent, the Snow Mountain agent, the Sapporo virus, the Taunton agent) [19–21]. Other viruses were seen in fecal specimens in the absence of a corresponding serologic response, a *sine qua non* of a true infection – parvoviruses, reoviruses, enteroviruses, and picobirnaviruses. Thus began the journey to discover the relevance of each of these viruses to cause disease and to public health. Viruses found in stool were first classified by their morphologic appearance by EM. Noroviruses were first classified simply as "small round-structured viruses" (SRSVs) to distinguish them from small round viruses (SRVs) without a distinct surface structure such as parvovirus and enterovirus. Differentiating between variant SRSVs required IEM using human paired sera specimens, but few research groups had the human reagents or skills needed to distinguish one SRSV from another.

Following their discovery, the Norwalk-like viruses began to be linked to the majority of outbreaks of AGE where another bacterial or parasitic pathogen could not be found [22]. The frequency of detection depended initially upon the skill of the microscopist. Because no animal model for norovirus infection was available, a long series of human volunteer challenge studies was conducted to assess immunity to infection [23, 24] and cross-protection between strains [25] and to develop novel immunoassays using fecal specimens and paired acute and convalescent sera from human volunteers. Virus was often not seen in fecal specimens from patients directly implicated in outbreaks. Therefore, serologic assays, both radioimmunoassay (RIA) and an enzyme immunoassay (EIA), were developed using human reagents (stool for antigen and paired sera) to monitor the immune responses of those involved in outbreaks [26, 27]. At CDC, for more than a decade, these assays became the diagnostic tests of choice [28]. The application of serology greatly increased the number of outbreaks of AGE that were attributed to the Norwalk virus. Of note, however, was that some people with documented exposure to the contaminated food or water did not become ill or seroconvert, suggesting a role for innate or acquired immunity. Also, some people involved in outbreaks of norovirus did not seroconvert to stool filtrates from Norwalk volunteers; however, they did respond to human reagents developed from volunteers challenged with an inoculum from patients infected with antigenically distinct Norwalk-like viruses such as the Snow Mountain agent

or the Hawaii agent suggesting serotype differences in susceptibility and immunity to disease [25]. A laboratory diagnosis of norovirus was rarely sought in patients routinely hospitalized for diarrhea because no simple diagnostic test was commercially available, and few had a history of exposure in an outbreak. Noroviruses remained almost exclusively agents of outbreaks of AGE and were not associated with sporadic illness leading to hospitalization [28].

All this changed in the early 1990s when the Norwalk and Southampton viruses were cloned and sequenced [11, 12, 29], an advance that revolutionized the field. These discoveries led immediately to the development of molecular assays that were more sensitive, specific, and reproducible than electron microscopy and that used chemical reagents that could be produced or purchased rather than biological reagents obtained from human volunteers. Molecular characterization immediately placed the Norwalk virus and the Norwalk "family of viruses," i.e., the other SRSVs, into a separate genus, *Norovirus*, in the family *Caliciviridae*. The Sapporo virus and related viruses with typical calicivirus morphology were grouped in their own genus *Sapovirus* [5]. Knowledge of the sequence meant that individual strains could be identified and traced within and between outbreaks allowing for the identification of common source exposures [30, 31]. Furthermore, strains previously characterized simply by the location where they had been found, or studied for antigenic differences by IEM, could now be sequenced and classified into genogroups and genotypic clusters [32]. When reverse transcription polymerase chain reaction (RT-PCR) was applied to examine fecal specimens from a large collection of outbreaks of AGE in the United States, Europe, Australia, and Japan, which had gone without an etiologic diagnosis, more than 80 % could be attributed to a norovirus, making it the most common cause of outbreaks of AGE [28, 33, 34]. Knowledge of sequence allowed new studies of the molecular epidemiology of the virus and facilitated tracing transmission of a single strain to a common source, such as fecally contaminated shellfish or foods prepared by a single sick food handler [30, 35, 36]. Similarly, outbreaks caused by foods irrigated with sewage (e.g., raspberries transported in a worldwide distribution chain) had a mixture of viruses representing multiple sources of contamination [37, 38].

The cloning of a number of HuCVs cleared the way for their single capsid protein to be expressed in different vectors [11, 12, 29]. When the Norwalk virus capsid gene was introduced into a baculovirus expression system, it formed viruslike particles (VLPs) that were indistinguishable by EM from natural virus [11]. VLPs could be used as antigens in immunoassays to monitor the immune response to specific infections, to differentiate between strains of virus, and to consider as potential vaccines [39]. They also provided targets to study the structure of related viruses and consider novel targets for drugs. Noroviruses can genetically be grouped into at least six different genogroups of which viruses from GI and GII viruses being the most common [6, 40]. GII viruses have caused the majority of all norovirus outbreaks over the past decade worldwide [41].

Traditionally, public health laboratories studied noroviruses almost exclusively in the context of outbreaks reported to them. However, AGE is responsible for both mild disease leading to doctor and clinic visits and severe disease leading to hospitalizations and some deaths [3, 42, 43]. That few of these patients are directly linked to an outbreak suggested a role for noroviruses as a cause of sporadic AGE. A national cohort study in England was the first to widely apply RT-PCR for noroviruses to study patients with AGE in the community [44–46]. Norovirus was identified as the most common cause of disease among adults and second only to rotavirus as the causative agent among children. A study of the etiology of AGE in adults hospitalized or treated in the emergency room in three sites in the United States yielded similar results: noroviruses were the most common cause of diarrhea in US adults [47]. With the advent and widespread use of rotavirus vaccine in the United States, norovirus has become the most common cause of medically attended gastroenteritis [48]. Application of molecular diagnostics have now demonstrated noroviruses and sapoviruses to be common in children and adults as well and a major cause of AGE in low- and middle-income countries [49].

In a parallel trajectory, astroviruses were first discovered in 1975 through electron microscopic examination of stools from an outbreak of pediatric diarrhea [50, 51]. The modern standard for laboratory diagnosis is real-time RT-PCR [52, 53]. In the pediatric population, astroviruses are consistently associated with acute diarrhea, though at substantially lower levels than the noroviruses [54].

3 Epidemiology

Noroviruses are now recognized to be one of the most common pathogens causing AGE in a wide range of settings, ages, and risk groups. In the United States, they are the most common cause of AGE in the community, the most common cause of outbreaks of AGE, and the most common cause of foodborne disease outbreaks [3, 55, 56]. Following the introduction of routine rotavirus immunization in the U.S., noroviruses are now the most common cause of pediatric gastroenteritis requiring medical care [48]. They also cause the great majority of outbreaks of AGE in institutional settings such as nursing homes, hospitals, and chronic care facilities in industrialized countries [57]. Sapoviruses are a less common cause of AGE in all age groups and in a wide variety of settings as well. For norovirus, sapovirus, and astrovirus, our more complete appreciation of the burden of disease has developed over the last decade, largely due to the availability of more sensitive and specific diagnostic tests.

3.1 Methods for Epidemiological Analysis

3.1.1 Epidemics and Outbreak Investigation

Data from the United States and Europe have demonstrated that norovirus is responsible for approximately 50 % of all reported AGE outbreaks (range 36–59 %) [58]. These generally occur throughout the year, although there is a seasonal pattern of increased activity during the winter months (Fig. 20.1) [58]. Outbreaks occur in various settings; they are propagated by nosocomial transmission in hospitals and nursing homes, foodborne spread in restaurants and aboard cruise ships, and waterborne outbreaks, all affecting people of all ages. Although initial reviews of norovirus outbreaks in the United States implicated contaminated food as the main vehicle of infection [59], newer reports suggest that the majority involve person-to-person transmission [55, 60–62]. Moreover, given the high infectivity and environmental stability of noroviruses, transmission during outbreaks may involve multiple routes [63], and contaminated fomites, surfaces, and droplets may also act to perpetuate outbreaks [64–66].

HuCV infections often come to the attention of public health authorities in the form of outbreaks, and these events present an opportunity to learn about transmission of the virus. In the United States, thousands of outbreaks have been identified and investigated over the past four decades, and a few have provided critical clues to understand transmission. The original Norwalk virus outbreak occurred in an elementary school and provided important initial observations. It was clear that the virus was highly infectious with primary and secondary attack rates of 50 and 30 %, respectively [18, 67]. The incubation period was determined to be short at <48 h, and occurrence in both students and teachers implied a lack of protective immunity with age. Other outbreak investigations from the 1980s demonstrated that norovirus could be transmitted by drinking water [10], as well as recreational water use [68]. Transmission by contaminated oysters was demonstrated to be an important route of transmission, as were a range of other foodborne exposures (e.g., to leafy greens, raspberries, and foods prepared by ill food handlers) [69–72]. The role of norovirus in healthcare facilities, including nursing homes, also becomes apparent from these early investigations [73]. Outbreak investigation led to the observation that norovirus can also be transmitted directly by apparent airborne or droplet spread [74–77], not only directly from person to person. More recent investigations have provided compelling evidence of environmentally mediated transmission [78, 79] and even by unusual fomites such as reusable shopping bags [80, 81]. An other outbreak started from a contaminated food product, subsequently spread by person to person among players on opposing football teams, and went on to attack the roommates of the players several days later; it demonstrated the potential for multiple transmission routes in a single outbreak [82]. While astroviruses primarily cause sporadic disease, outbreaks have been reported in a range of settings and may be a fairly common cause of nosocomial gastroenteritis in children's hospitals [83].

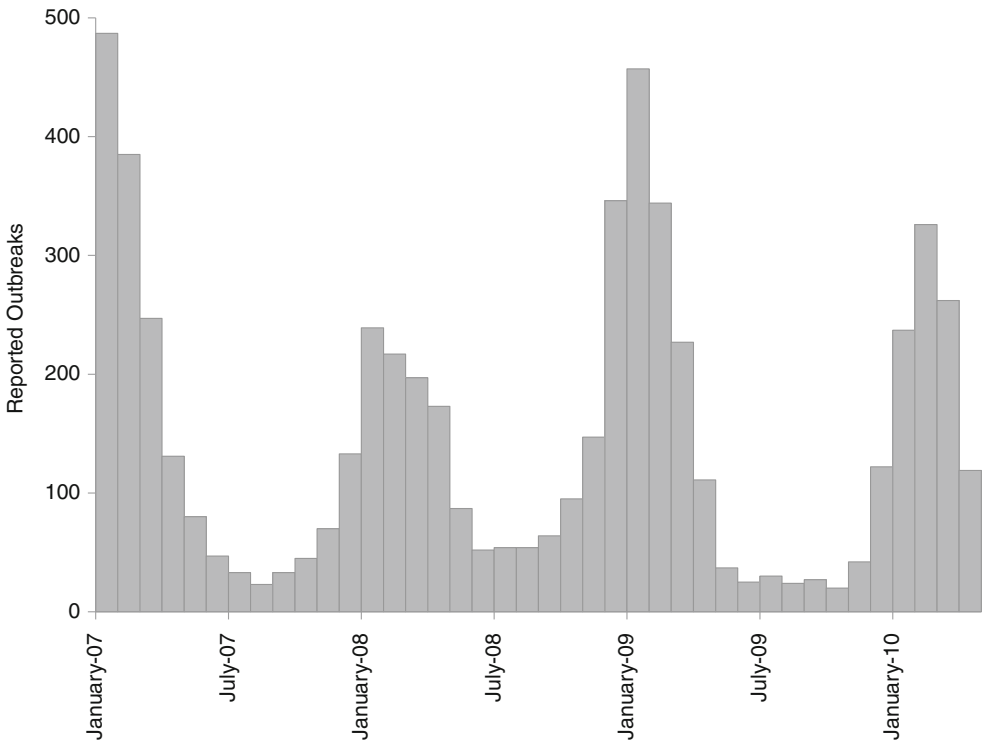

Fig. 20.1 Suspected and confirmed norovirus outbreaks reported by 30 US states, January 2007–April 2010 (Adapted from Yen et al. [55])

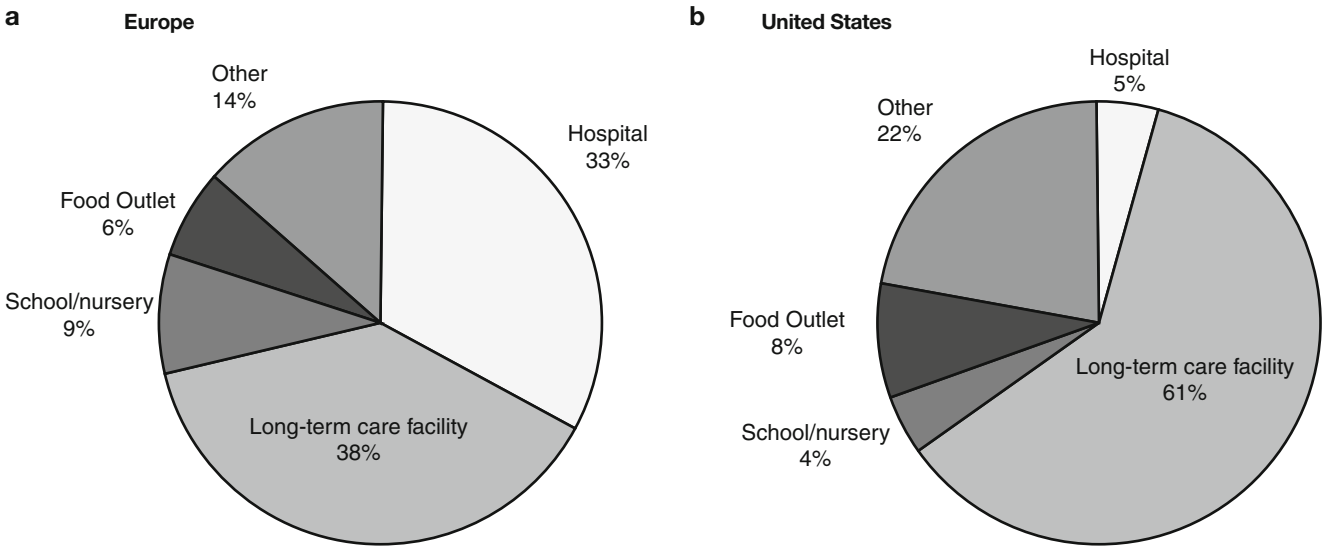

Fig. 20.2 Setting of reported outbreaks of norovirus AGE in (**a**) Europe, 2004 [33], and the (**b**) United States, 2006–2008 [89]. In both settings, the majority of outbreaks occur in healthcare settings; in Europe many more outbreaks are reported from acute care hospitals

Periodically, the number of norovirus outbreaks has increased at the same time that new genogroup II genotype 4 (GII.4) strains have emerged, likely because these new variants escape immunity in the population [84, 85]. These emergent GII.4 strains rapidly replace circulating strains and can sometimes cause unusually severe seasons, as occurred in 2002/2003 and 2006/2007 [41, 86, 87]. GII.4 variants predominate across all settings, though the role of GI and other GII genotypes appears to be greater in settings that involve foodborne or waterborne transmission compared to the GII.4 viruses [88].

A major difference in the reported epidemiology of norovirus between the United States and most other high-income countries lies in the frequency of outbreaks in acute care (hospital) settings. In Europe approximately one-third of reported outbreaks occur in hospitals compared with 4 % in the United States (Fig. 20.2) [90]. It is not known whether this difference in reported outbreaks represents a real difference in the epidemiology of outbreaks, an underreporting of hospital outbreaks in the United States, or differences in infection control practices in hospitals.

Recently, more sophisticated statistical and modeling studies have used data from traditional outbreak investigations to examine issues of virus transmission. Transmission models have been fit to demonstrate the important role that vomiting plays in the spread of norovirus [91]. By using methods that reconstruct the most likely transmission trees [92], Sukhrie and colleagues found that in healthcare settings, people with symptoms are far more likely to transmit infection than those who remain asymptomatic, and patients are more important to virus transmission than staff [93, 94].

Outbreaks of sapovirus-associated AGE have been reported in settings similar to those of noroviruses – schools [95], child care facilities, [96] hospitals [97], long-term care facilities, and occasional foodborne outbreaks [98, 99]. The broad age range of individuals affected in these outbreaks demonstrates that sapovirus infection is not restricted to young children as was previously thought. Although the molecular epidemiology of sapovirus is less well studied than norovirus, strains belonging to four different sapovirus genogroups (GI, GII, GIV, GV) have been observed to infect humans. Two of these viruses, GI.2 and GIV, have been most commonly associated with outbreaks in Europe, Asia, and North America primarily affecting older adults [9, 100, 101].

Similar to the norovirus and sapovirus, astrovirus outbreaks may occur in a range of settings including long-term and acute care facilities, schools, and child care centers [102]. However, such outbreaks appear to be much less common than those caused by norovirus.

Few studies have quantified the direct healthcare or societal costs due to the noroviruses, but given how common these infections are, the direct healthcare costs and the indirect costs to society are likely to be substantial. Most studies to date have only quantified the cost of outbreaks, as opposed to endemic disease, for which the cost must be much greater. For example, an outbreak in a single 946-bed US hospital cost an estimated $650,000 [103]. During the 2002–2003 season, the cost to the English National Health Service of nosocomial AGE outbreaks was estimated at $184 million [57]. Norovirus foodborne disease in the United States costs an estimated $2 billion annually [4].

3.2 Surveillance

There are some major limitations to what can be learned from individual outbreak investigations since published reports likely represent a biased sample of events in terms of disease severity [104, 105] and provide limited insight into the efficacy of control measures and the full burden of disease [106]. In most countries, AGE from norovirus is not a notifiable cause of disease; surveillance has focused on the recognition of outbreaks, many of which would not be reported in the peer-reviewed literature. What constitutes an outbreak can be hard to define; as a result, the data collected by any given surveillance system may in part reflect the definitions used, the size of the outbreaks reported, and the focus of the surveillance effort. For example, in the United States, outbreaks linked to food historically were prioritized for reporting, whereas in England and Wales, surveillance targeted outbreaks occurring in National Health Service hospitals, thereby emphasizing nosocomial spread [107]. When more broad-based assessments have been conducted, the profile of outbreaks in the United States has been consistent with those from other industrialized countries where a majority occur in healthcare settings and are spread by person-to-person transmission [55]. In response to this surveillance gap, CDC has recently developed the National Outbreak Reporting System (NORS) as an integrated national surveillance system for all enteric disease outbreaks [108]. Launched in February 2009, NORS now provides the framework through which all outbreaks of enteric disease, regardless of transmission mode, may be reported from state and local health departments to the CDC. CDC also coordinates a norovirus outbreak surveillance network known as CaliciNet, also launched in 2009 [109]. State and local public health and food regulatory agency laboratories upload sequences of norovirus outbreaks to allow rapid comparison to potentially link outbreaks with a common (e.g., food) source as well as to identify emerging norovirus strains (e.g., GII.4 Sydney in late 2012).

Large reviews of surveillance datasets have been published from a number of countries including England and Wales, [61, 110] some European countries (as part of the Foodborne Viruses in Europe group) [33, 90], Australia, and New Zealand [111, 112]. These broad-based surveillance systems have consistently demonstrated that the majority of reported outbreaks occur in healthcare settings (including nursing homes or hospitals) and are predominantly spread from person to person while at the same time identifying an important role for food in disease transmission. Systems dedicated to the surveillance of outbreaks in healthcare settings have shown a large burden of disease, in both acute and long-term care settings, as well as a high degree of severe disease and economic burden [112, 113]. Regional or state-wide surveillance reports have also been useful for understanding patterns of disease when national surveillance systems are incomplete or do not exist [114, 115].

3.2.1 Etiologic Studies and Endemic Disease

Globally, norovirus is estimated to account for 12 % (95 % CI 9–15 %) of community- or clinic-based AGE cases and 11 % (95 % CI 8–14 %) of emergency department- or hospital-based cases [49]. These proportions are similar in developing and developed country populations [49]. In the United States, norovirus causes an estimated 21 million cases of AGE [3], 1.7 million outpatient visits [116], 400,000 emergency care visits, 70,000 hospitalizations [42], and 800 deaths annually across all age groups (Fig. 20.3) [43]. The burden of hospitalizations and death surges by approximately 50 % in those years when novel GII.4 variant strains emerge [86, 87, 117]. Although symptomatic norovirus infections are usually mild and self-limiting in otherwise healthy adults, they may be fatal among the elderly [118] and immunocompromised persons [119]. Excess mortality associated with norovirus has been documented in a number of countries as well [120, 121].

Etiologic studies of norovirus can be grouped into two categories: (1) community-based cohort/case–control studies or (2) healthcare facility-based studies, with the former being much less common. Community-based cohort studies are expensive and logistically complicated to conduct, but when conducted, have established norovirus to be the most common cause of AGE in the community [46, 54, 122]. In England and the Netherlands, these studies have estimated the incidence of norovirus in the general population to be 4.1 and 4.6 cases per 100 person-years [46, 54, 122], with regional studies providing generally consistent results [116, 123]. This means that with a life expectancy of ~80 years, a person will experience an average of three to five episodes in their lifetime. Incidence is approximately five times higher in children under the age of 5 years [46]. The incidence of norovirus at the general practitioner (primary care) level has been estimated at 0.49 per 100 person-years in England and 0.62 in northwest Germany, suggesting about one in ten who are ill with AGE seeks medical care [46, 54, 123].

Community-based studies of the incidence of sapoviruses have been less common. In England and Wales, the incidence of sapovirus-associated illness in the community was estimated at 2.6 cases per 100 person-years [54]. Estimates from a study of a Healthcare Management Organization population in the state of Georgia yielded similar results, 9 and 1 cases per 1,000 population, respectively [116]. A prospective study of Finnish children <2 years of age reported sapoviruses in 9 % of sporadic gastrointestinal illness compared with rotavirus in 29 % and norovirus in 20 % [124].

As noted earlier, astroviruses are also comparatively less common than norovirus. In the England and Wales study, incidence across the age range (at 0.5 per 100 person-years)

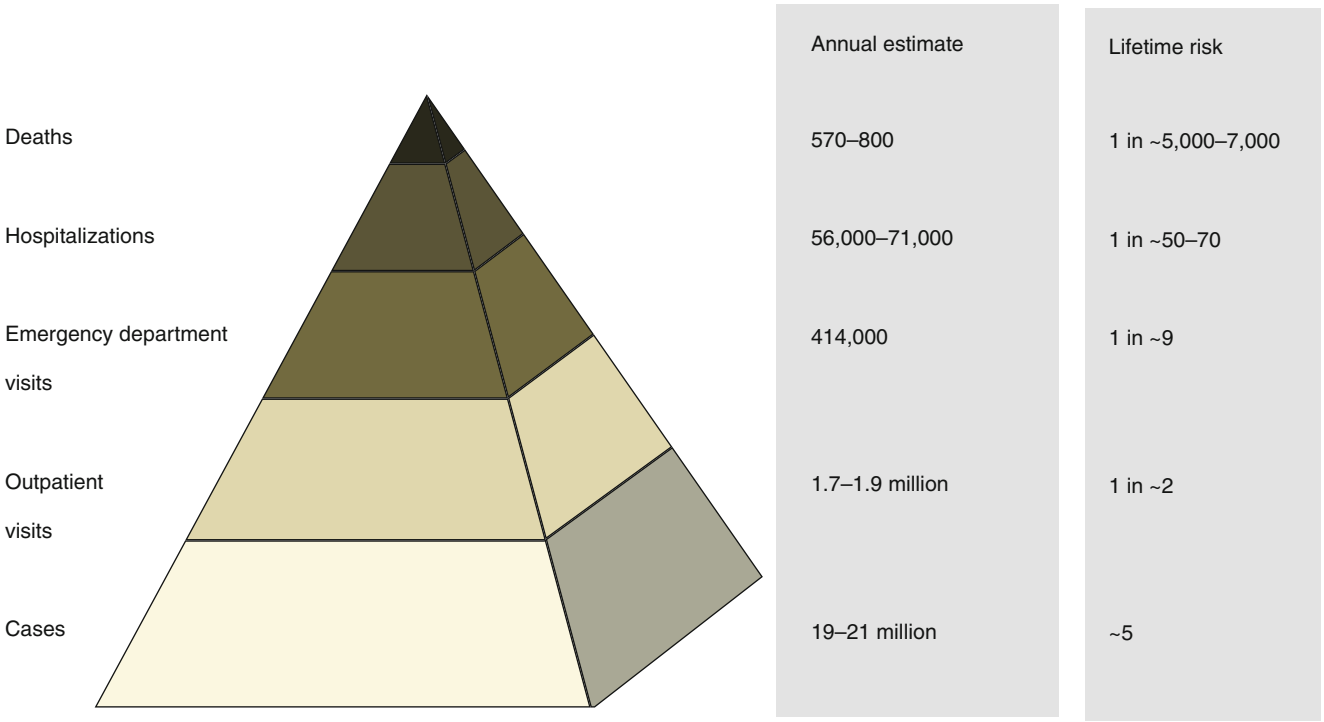

Fig. 20.3 Annual cases, outpatient visits, emergency room consultations, hospitalizations, and deaths from norovirus annually in the United States. Lifetime risk estimate based on a life expectancy of 80 years and US population of 300 million [125]

was about one-tenth and one-fifth of the incidence of norovirus and sapovirus, respectively, in 2008/2009, while in a recent study in the United States, the classical human astroviruses caused about one-fourth of the norovirus cases [54, 126]. Astroviruses are usually detected in <10 % of young children treated for gastroenteritis in outpatient clinics or in hospitals [127, 128].

The only nationally comprehensive estimate of the burden of disease due to human caliciviruses and the associated disability-adjusted life years (DALYs) exists for the Netherlands. This assessment included the incidence of cases in the community that did not seek healthcare, those visiting a general practitioner, hospitalizations and deaths that were derived from cohort studies, and surveillance data and literature. In total, these yielded an estimate of 1,622/100,000 (95 % CI 966–2,650) disability-adjusted life years in a population of 16.5 million [129]. This burden is similar to that of disease due to *Salmonella spp*. in the same population. While endemic disease-related costs have not been comprehensively assessed, norovirus-associated hospitalizations specifically have been estimated at nearly $500 million annually in the United States [42].

3.2.2 Severe Disease Outcomes

Although norovirus AGE is typically a mild self-resolving illness in healthy adults, it can lead to severe dehydration, hospitalization, and, in rare cases, death. These severe outcomes are more common in vulnerable populations such as young children and the elderly residing in long-term care facilities (LTCFs) or hospitals [105, 107]. In nearly all instances of norovirus-associated death reported in the literature, the decedents had other serious underlying heath conditions, such as immunosuppression [130–133]. Data from passive surveillance systems and outbreak investigations provide estimates of norovirus case hospitalization in the range of 0.1–5 hospitalizations per 1,000 cases [61, 107, 110, 112, 134]. A large systematic review of published outbreak reports estimated norovirus-associated hospitalization and mortality rates at 7 and 0.7 per 1,000 cases, respectively [105]. However, severity may be overestimated when based on published outbreak reports since the larger and more severe outbreaks are more likely to be investigated and reported.

It has been challenging to isolate the risk factors leading to hospitalization and death because the mode of transmission, population affected, and genotype causing the outbreaks are highly correlated. Specifically, GII.4 outbreaks are predominant in healthcare facility outbreaks, which affect vulnerable individuals (i.e., the elderly) and are typically spread from person to person [135, 136]. A review of over 800 outbreaks has highlighted that hospitalizations and deaths were much more likely to occur in healthcare outbreaks and, somewhat surprisingly, in GII.4 virus-associated outbreaks, independent of those factors that could be analyzed. This suggests that in addition to increased vulnerability of certain population groups, there is increased severity

associated with GII.4 viruses. GII strains are shed at higher levels [137], may be more likely to induce vomiting [138], and cause more severe disease in children; [139] this genogroup thus appears to demonstrate a consistent pattern of higher virulence. The relatively high hospitalization rates in long-term care facilities and mortality in all healthcare settings underscore the vulnerability of populations affected by outbreaks in these settings.

3.2.3 Risk Factors

Consistently, the strongest risk factors for community disease are proxies for contact with an infectious person. For both young children and older children/adults, reporting a symptomatic household member, especially a child, is a strong predictor of disease [122, 123, 140, 141]. It appears that young children frequently bring infection into the household, and older children/adults acquire many of their infections within the household [141, 142]. Foreign travel is also a risk factor; [141, 143] the increased risk may be attributable to changes in behavior while traveling or exposure to a different spectrum of norovirus strains. Although outbreak investigations frequently attribute norovirus AGE to contamination of food during preparation by a range of mechanisms and in a range of settings, food-related risk factors have not shown consistent associations with disease in community-based studies [122, 141]. In fact, consumption of raw fruits and vegetables, often considered potential vehicles for transmission, is generally associated with a protective effect [141]. Other potential factors such as recreational water exposure and animal contact have also been associated with reduced risk [122, 123, 141]. Taken together, the unexpected relationships observed in these studies suggest that these putative risk factors are correlated with other lifestyle factors that may actually be protective against norovirus or that frequent exposure results in immunity. The foods consistently associated with disease are oyster and other shellfish harvested from areas where the seabeds are contaminated with sewage [141, 144]. However, in most populations, consumption of these products is not common, and this exposure likely accounts for only a small fraction of disease.

4 Mechanisms and Routes of Transmission

Norovirus is extremely contagious, with an estimated infectious dose as low as 18 viral particles [145]. In contrast, approximately five billion infectious doses are contained in each gram of feces during peak shedding. Humans are the only known reservoir for human norovirus infections. Transmission occurs via fecal-oral and vomit-oral pathways by four general routes: direct person-to-person, foodborne, waterborne, or through environmental fomites (Fig. 20.4). Because humans are the only known reservoir for human norovirus, sapoviruses, or astroviruses, in a sense, all transmission is ultimately person to person. From that perspective, foodborne, waterborne, and environmental transmission are "special cases" of person-to-person spread.

4.1 Direct Person-to-Person Spread

Direct person-to-person transmission is believed to be the primary mode of spread in most outbreaks [55, 61] and in sporadic disease [141, 146]. The proportion of outbreak spread primarily by person-to-person transmission is highest in settings with close contacts. Direct person-to-person transmission is reported as the primary route in >90 % of norovirus outbreaks in hospitals, long-term care facilities, and schools [61]. GII and, specifically, GII.4 viruses are more commonly associated with person-to-person transmission [62] or found in settings where person-to-person transmission is common [135, 136]. Furthermore, there is a strong wintertime seasonality of person-to-person outbreaks [55, 147–149], a pattern not clearly seen for norovirus spread by other routes of transmission [61]. However, when new strains of GII.4 emerge by escaping population immunity, aberrant seasonal patterns may occur, [41, 87, 150, 151] highlighting the importance of host factors (i.e., population immunity) in transmission [152]. The most consistently identified risk factors for transmission are all related to the exposure of a symptomatic contact (see Sect. 3.2.3). Although infection in asymptomatic individuals is common, the importance of these shedders in person-to-person spread is unclear. However, based on current evidence, it appears that disease symptoms, especially vomiting, are fundamental to disease transmission [91, 93, 94, 153].

4.2 Foodborne Disease

Norovirus is the most common cause of foodborne disease outbreaks in the United States [154, 155], accounting for >50 % of foodborne disease outbreaks with known causes reported to CDC during 2006–2008 [154, 155]. Foodborne transmission most frequently occurs by contamination from infected food handlers during preparation and service. Only a small dose of virus is needed to cause infection, and thus infected food handlers can contaminate large quantities of product, especially when they put their hands into large-volume liquids (e.g., salad dressing), which allow for mixing. In one example, an estimated 3,000 cases of AGE were traced to icing prepared by an ill baker and put on a variety of bakery products [71]. Unlike with direct person-to-person transmission, the role of both pre- and post-symptomatic shedding has been clearly linked with onward transmission

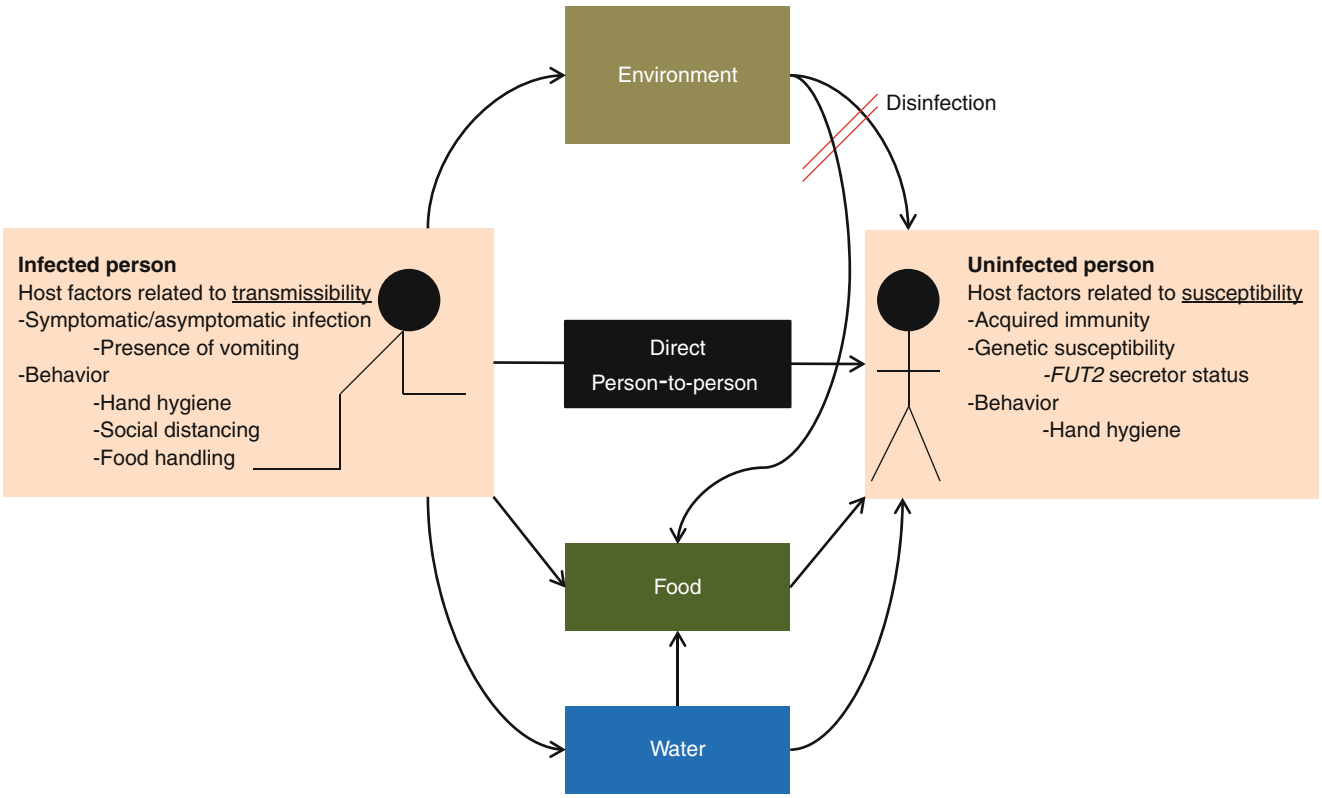

Fig. 20.4 Routes of transmission of norovirus from infected to uninfected people (Reproduced with permission from Current Opinion in Virology [7]). Norovirus transmission can occur via a range of transmission routes. Characteristics and behaviors of the infected host and potential susceptible individuals may mitigate the risk of transmission. This simple schematic is not meant to depict all the intricacies of each pathway but rather to highlight the interaction of the various routes and to illustrate that all pathways require shedding of virus from infectious hosts. Different control measures may be targeted at each *arrow*; here, the role of environmental disinfection is highlighted. Certain practices (such as hand hygiene) may reduce transmission through all pathways, while targeted interventions (such as exclusion of ill food handlers from work) may reduce transmission through specific pathways

[156–158]. Foodborne astrovirus outbreaks have been reported, [159] though this route of transmission, relative to person-to-person spread, is not well defined.

Food can become contaminated with norovirus at any point along the farm-to-fork continuum, including production, processing, and preparation. Thus, a variety of products have been implicated in outbreak investigations, especially those foods irrigated with or grown in fecally contaminated water and eaten raw, such as leafy vegetables, fruits, raspberries, and shellfish [31, 108, 154, 160–163]. Because gross sewage contamination will contain a collection of viruses circulating in the community, multiple norovirus genotypes are often detected in such outbreaks.

4.3 Environmental Transmission

Many factors may facilitate environmental transmission of norovirus. They include a large human reservoir, [3, 46, 116, 122] high levels of shedding [164, 165] (which can be asymptomatic and prolonged [164, 166, 167]), small infectious dose, [145] and widespread contamination by vomitus [65, 77, 91, 164, 165, 167–169]. The viruses are relatively stable in the environment, [149, 167, 170] resistant to disinfection, [171, 172] and can contaminate a range of fomites [65, 165, 168, 173, 174]. The most convincing evidence of environmental transmission comes from outbreaks where groups in a common setting with no known direct contact have been sequentially affected [175]. Such transmission has occurred aboard airplanes and cruise ships, [78] [63] in a concert hall, [176] and from the use of a reusable grocery bag [80]. In all these examples, the environment or fomites likely became contaminated by airborne transmission following an episode of vomiting. Widespread contamination of environments during outbreaks has been documented, particularly in hospital settings where virus has been detected on surfaces of many different objects – switches, televisions, cellular phones, public phones, water taps, toilet light switches, microwave ovens, keyboards, bed frames, and chairs [165, 168]. The role of this contamination is nevertheless

unclear because noroviruses are hardy: outbreak strains have been detected on environmental surfaces during non-outbreak periods, and the converse has also been observed [173, 177]. Although the highest levels of contamination probably occur on surfaces directly contaminated by vomitus or feces, virus has been detected on mantle pieces and light fittings, located above 1.5 m in a hotel affected by an outbreak [65].

4.4 Waterborne Transmission

Sewage-contaminated water is also a recognized route of transmission [178–180]. Norwalk virus can remain infectious in groundwater for at least 2 months and can be detected for over 3 years [170, 181]. Drinking water or ice may become contaminated with norovirus and result in outbreaks in food service settings. The same contaminated water can cause disease directly through drinking and when used in food preparation [182]. Recreational and drinking water can become contaminated from septic tank leakage and sewage or from breakdowns in municipal treatment plants, resulting in large community outbreaks [183–185] [186]. However, outbreaks have even been reported from wells built in compliance with regulations when groundwater becomes contaminated by septic systems or percolation of sewage through unusual geologic formations [187]. For reasons that are not clear, most waterborne outbreaks are associated with GI noroviruses [88, 188]. However, in contrast to these epidemiological observations, some laboratory data suggest that GII viruses are more stable in water as well as on surfaces [181, 189]. Waterborne transmission of astrovirus has also been documented [190]. Because they often result from gross contamination, waterborne outbreaks are also more commonly associated with mixed infections with multiple noroviruses or even multiple pathogens [88].

5 Biological Characteristics

Noroviruses are a group of nonenveloped, single-stranded RNA viruses with an icosahedral symmetry classified into the genus *Norovirus* of the family *Caliciviridae*. Other genera within this virus family include *Sapovirus*, which also causes AGE (AGE) in humans, as well as *Lagovirus*, *Vesivirus*, and *Nebovirus*, which are not pathogenic for humans [5]. Upon approval by the calicivirus study group of International Committee on the Taxonomy of Viruses (ICTV), novel caliciviruses detected in rhesus monkeys and swine may be accepted as additional genera [191, 192]. By structural analysis, the Norwalk VLP capsid is formed with 180 capsid molecules organized into 90 dimers with a T =3 icosahedral symmetry (where T is triangulation number), [193] using two distinct dimer types to form the higher-order structure [194]. Noroviruses cannot be classified by serotypes, since it cannot be grown in cell culture and neutralized with antisera, but can be divided into at least five genogroups (G), designated GI–GV, based on amino acid identity in the major structural protein (VP1) [195]. Viruses from at least one additional genogroup have been recognized in dogs [40, 196]. The strains that infect humans are found in genogroups GI, GII, and GIV, whereas the strains infecting cows and mice are found in GIII and GV, respectively (Fig. 20.5a). Although interspecies transmission of noroviruses has not been documented, strains that infect pigs are found in GII [197], and a GIV norovirus was discovered recently as a cause of diarrhea in dogs [196], suggesting the potential for zoonotic transmission. On the basis of phylogenetic analysis of the complete VP1, noroviruses can be further classified into genotypes, with at least nine genotypes belonging to GI and 21 genotypes belonging to GII (Fig. 20.5a). At least since 2001, GII.4 viruses have caused the majority of viral AGE outbreaks worldwide [41, 198]. Recent studies have demonstrated that these viruses evolve over time through serial changes in the VP1 sequence, which allow evasion of immunity in the human population [117]. Sapoviruses are divided into at least seven different phylogenetic clusters, four (GI, GII, GIV, and GV) of which include viruses that infect humans, while GIII, GVI, and GVII have only been found in swine [199]. Detection of additional sapovirus genogroups in mink and recently in bats illustrates the enormous genetic variability and host range of viruses within the *Sapovirus* genus (Fig. 20.5b).

Astroviruses, first discovered in 1975 [200, 201], are nonenveloped, single-stranded RNA viruses in the family Astroviridae. Astroviruses are 28 nm in diameter with a smooth edge and may have a characteristic 5- or 6-pointed starlike appearance in the center (Greek, *astron* = star). Since then eight serotypes of human astrovirus (classical human astroviruses) have been identified and characterized. Serotype 1 is the most common, though multiple serotypes can co-circulate during the same season. Greater serotype diversity may be found in developing countries [202, 203]. In addition, viruses belonging to two other phylogenetic clades (MLB and VA) have been detected in human stools, some of which has been directly linked to AGE in children [204, 205].

6 Pathogenesis

The primary replication site for noro- and sapoviruses has not been established. It is likely that these viruses replicate in the upper intestinal tract because volunteers who develop

gastrointestinal illness following oral administration of virus have histopathologic lesions on biopsies from the jejunum [19, 206]. Pigs infected with porcine sapovirus demonstrate blunting and shortening of the villi of the proximal small intestine [207]. Interestingly, the same characteristic jejunal lesion has also been observed in volunteers who were fed Norwalk or Hawaii virus but did not become ill [208–210]. Increased mononuclear infiltrates in the lamina propria and villous blunting in intestinal biopsies of pediatric patients compared with uninfected controls have been reported [211]. Levels of small intestinal brush border enzymes (trehalase and alkaline phosphatase) are significantly decreased compared with baseline and convalescent-phase values [206]. It has been proposed that abnormal gastric motor function is responsible for the nausea and vomiting associated with noroviruses [208], but the precise mechanism responsible for illness is not known. Astrovirus infection appears to be restricted to villous enterocytes and the exposed epithelium. Histological damage and inflammation is generally mild [212], and the specific mechanism by which astrovirus causes diarrhea is not known [102, 213].

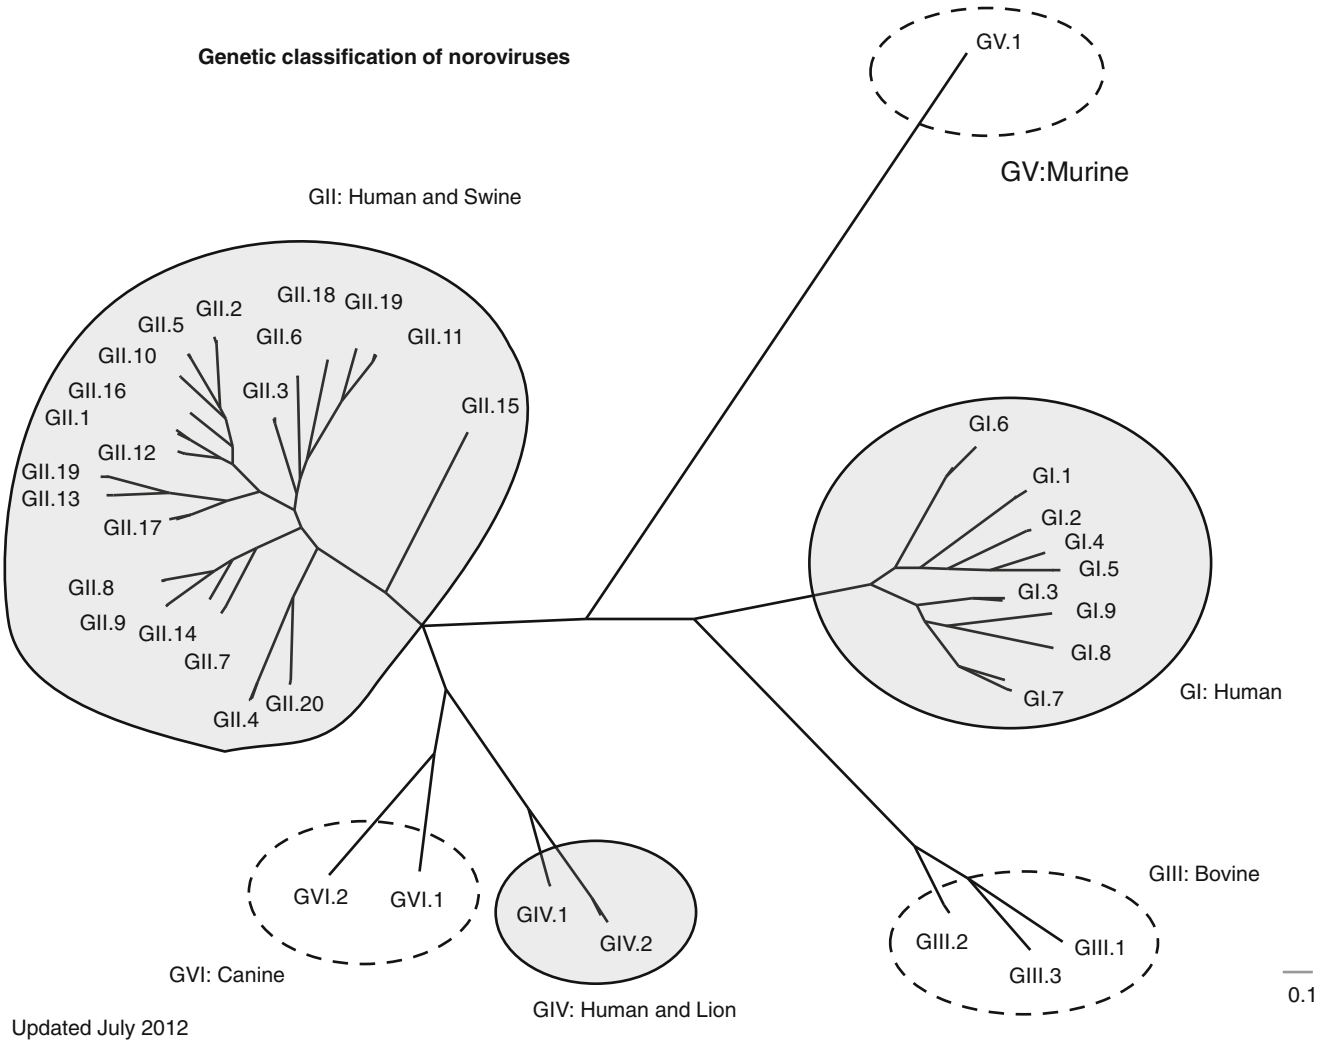

Fig. 20.5 Genetic classification of (**a**) noroviruses and (**b**) sapoviruses based on phylogenetic analysis of sequences of the major capsid protein VP1. Noroviruses can be grouped into six different genogroups (GI–VI) of which *GI* (9 genotypes), *GII* (18 of the 21 genotypes), and *GIV* (1 of the 2 genotypes) can infect humans. Strains belonging to *GIII*, *GV*, and *GVI* infect bovine, murine, and canine species. (**b**) Sapoviruses can be grouped into at least seven different genogroups (GI–VII) with several additional viruses (mink sapovirus and bat sapovirus) that are tentative new genogroups. Sapoviruses in *GI* (5 genotypes and 1 unassigned), *GII* (3 genotypes and 2 unassigned), *GIV* (1 genotype), and *GV* (1 genotype) can infect humans. The scale bar of 0.1 reflects the number of amino substitutions per site (Data analysis and graphs were developed by Everardo Vega, CDC)

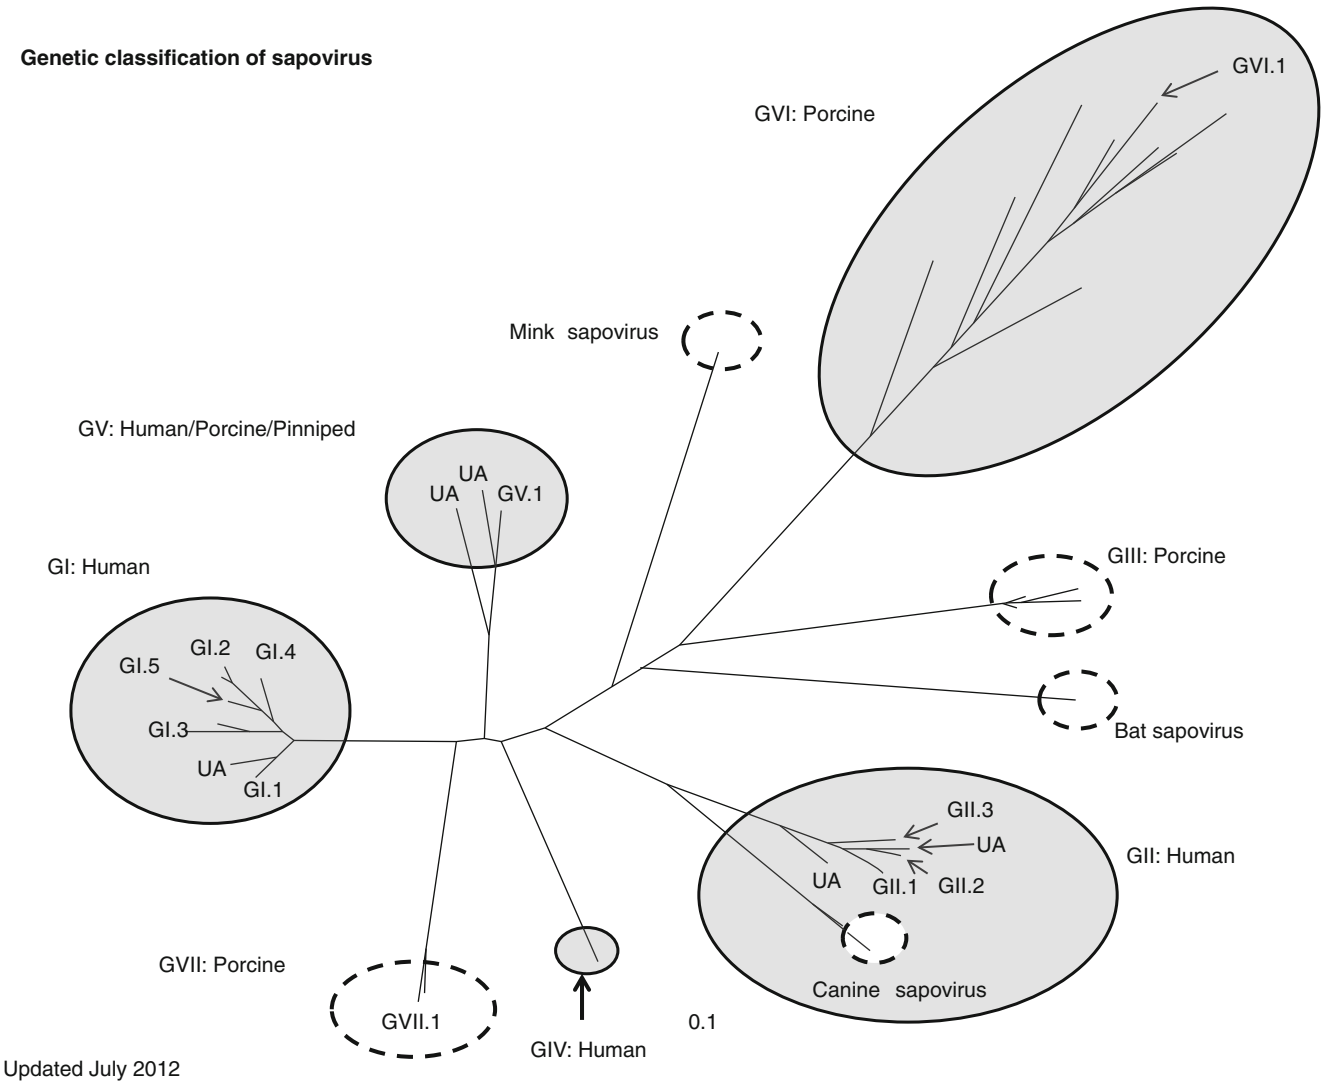

Fig. 20.5 (continued)

7 Patterns of Host Response

Protective immunity to norovirus appears to be different from other enteric viral pathogens and is incompletely understood. Although seroepidemiological studies have shown an antibody prevalence to norovirus of >80 % by age 20, adults consistently demonstrate a high degree of susceptibility to both naturally occurring and experimentally administered noroviruses. In a classic study from the 1970s, 50 % of adult volunteers infected with Norwalk virus consistently developed illness following challenge [25, 214]. In human challenge studies, infected volunteers were susceptible to reinfection with the same strain as well as to infection with heterologous strains [23, 25, 215, 216]. In addition, individuals with preexisting antibodies were not protected from infection unless repeated exposure to the same strain occurred within a short period. Two of these studies demonstrated that homologous antibody protection might last anywhere from 8 weeks to 6 months [23, 216]. Because preexisting antibodies among challenged volunteers did not confer immunity in all individuals and because some persons remained uninfected despite significant exposure, both innate host factors and acquired immunity have been hypothesized to contribute to the susceptibility to infection [23]. However, the infectious dose of virus given to volunteers in these challenge studies was several thousand-fold greater than the small dose of virus capable of causing human illness, and thus immunity to a lower, more natural challenge dose might be greater and more cross-protective. A mathematical modeling study suggests the duration of protective immunity may be on the order of 4 to 8 years [217].

Histo-blood group antigens (HBGAs), including H type, ABO blood group, and Lewis antigens, are a diverse family of carbohydrates expressed on mucosal surfaces. Several

studies indicate that they act as putative receptors or co-receptors for noroviruses. Although there is no evidence that binding to HBGA is mediating viral entry, there is a strong correlation between polymorphic expression of HBGA and human susceptibility to norovirus infection [8]. Genetic resistance to norovirus infections has been associated with mutations in the *FUT2* (or "secretor") gene, which encodes an α1,2-fucosyltransferase; in the homozygous state, null mutant alleles (FUT2–/–) lead to the absence of the α1,2-linked fucose residue on the H-type carbohydrate structures, which characterize the so-called non-secretor phenotype [218]. The most frequent null allele (se428) is characterized by the 428G > A nonsense mutation, and homozygous non-secretors (FUT2–/–) represent up to 20 % of the European population [219]. Results from two landmark studies of human volunteers who were challenged with Norwalk virus demonstrated that non-secretors were not infected by the virus and none of the volunteers showed an increase in anti-Norwalk virus antibodies or had detectable RNA in feces, while secretors (FUT2+/+ or FUT2+/–) excreted the virus and developed a strong antibody response [8, 220]. In addition, both volunteer studies demonstrated that FUT2-positive individuals of the B blood group type were less likely to be infected than A or O individuals but, if infected, more likely to remain asymptomatic. Thus, alleles at the *FUT2* locus determine sensitivity or resistance to the Norwalk virus strain, and the polymorphism at the ABO locus modulates sensitivity within the secretor-positive group. HBGAs are differentially expressed in humans, and several conserved amino acids of the P2 domain of VP1 are important for HBGA binding [221]. The expression of HBGAs has been shown to be associated with strain-specific susceptibility to norovirus infection [8, 222–224]. However, specific binding profiles are not genotype or genogroup exclusive [225] suggesting a host-pathogen coevolution driven by carbohydrate-protein interactions. For GII.4 viruses, single amino acid replacements seem to drastically alter the binding capacity of the VLP [226]. Overall no single norovirus strain seems to be able to cover the whole spectrum of human HBGAs diversity, although collectively, they are likely to be able to infect nearly everyone. The only notable exception is the subgroup of individuals who have a rare genotype, either FUT2–/– or FUT3–/– [218], who may be completely resistant.

Recent studies have reported that innate immunity plays an important role in the control of murine norovirus infection, but little is known about cell-mediated immune responses against noroviruses [227, 228]. A study using oral immunization of human volunteers with Norwalk viruslike particles showed an increase in interferon-γ (IFN) in the absence of IL-4 production, suggesting a dominant Th1 pattern of cytokine production [229]. This dominant Th1 response was confirmed in a study of 15 volunteers infected with Snow Mountain virus, who experienced significant increases in serum IFN-γ and IL-2, but not IL-6 or IL-10, on day two after challenge [224]. Interestingly, in an in vitro study using a Norwalk virus replicon-bearing cells, IFN-α efficiently cleared the NV replicon in a dose-dependent manner at comparable levels to hepatitis C virus, indicating a potential therapeutic application of IFN to norovirus infection [230].

Because diarrheal disease caused by astrovirus is largely restricted to children, immunity is believed to be long lasting; however, little is known regarding the specific immune responses that result in immunity to astroviruses. $CD4^+$ T cells may be involved in the anti-astrovirus response [231] and animal models point to a possible role for the innate immune system [232].

8 Control and Prevention

Efforts to prevent norovirus and sapovirus disease are directed at interrupting the person-to-person transmission cycle, even in the case where contaminated food or water can be identified. Most gastroenteritis viruses are transmitted via the ingestion of infectious fecal (or, less commonly, vomitus) material. Therefore, standard sanitation and hygienic precautions are key. These include frequent hand hygiene, environmental disinfection, proper disposal of fecal or vomit-soiled materials, and limited contact with ill persons. Even when these precautions are put firmly in place, our ability to control outbreaks remains limited [233].

8.1 Hand Hygiene

The single most important method to prevent norovirus infection and control transmission is appropriate hand hygiene [234, 235]. Washing with soap and water is the preferred method to prevent norovirus transmission, with alcohol-based hand sanitizers useful only as an adjunct when hands are not visibly soiled [236]. Plain soap and water reduces the number of microbes on hands via mechanical removal of loosely adherent microorganism [234]. In finger pad studies, soap and water used for 20 s have been shown to reduce norovirus by 0.67–1.20 $\log_{10}$ by RT-PCR assay [235]. The use of alcohol-based hand sanitizers remains controversial, due to both inconclusive in vitro finger pad studies [171, 235, 237] and epidemiological studies where higher rates of infection have been detected during outbreaks in long-term care facilities that use alcohol-based hand sanitizers [238], though the reasons for association in this one study are debated [239].

Surrogate viruses such as murine norovirus (MNV) or feline calicivirus (FCV) and porcine sapovirus are typically used since norovirus cannot be cultured, so its infectivity cannot be directly assessed. Additionally, detection and quantification of viral RNA is not necessarily a reliable

means of estimating the effectiveness of hand sanitizers against human norovirus [171]. Studies on disinfectant and hand sanitizers using MNV and FCV have given contradictory results [237, 240]. The sensitivity of FCV to low pH and the relatively high susceptibility of MNV to alcohols suggest that disinfectants that are effective against both surrogate viruses may be more likely to be effective against human norovirus [171].

8.2 Exclusion and Isolation

Considering the highly infectious nature of norovirus, exclusion and isolation of infected individuals are often the most practical means of interrupting transmission of virus and limiting contamination of the environment. This is true in settings where people reside or congregate such as long-term care facilities, acute care hospitals, cruise ships, and college dormitories as well as in the case of infected food handlers.

Unfortunately, empirical evidence for the effectiveness of exclusion and isolation strategies is limited; [241] these strategies are based on general infection control principles rather than direct evidence. The principle underpinning isolation is to minimize contact with persons during the most infectious periods of their illness. This includes the acute phase of illness, a period following recovery while the person is still shedding virus at high levels, and, in some situations in healthcare facilities, exclusion of exposed and potentially incubating individuals. Isolation of well persons (i.e., quarantine) may be useful during outbreaks in long-term care facilities and hospitals to help break the cycle of transmission and prevent additional cases.

In healthcare facilities, ill patients may be cohorted together in an isolatable unit, with the same dedicated nursing staff providing care only for infected individuals [242]. Ill patients should not generally be transferred to unaffected units in the facility – except in the case of medical necessity and after consultation with infection control staff. Analogously, passengers with AGE on cruise ships may be asked to remain isolated in their cabins during their illness and for a period of 24–48 h after recovery. To minimize the risk of spread from incubating or asymptomatically infected patients and staff in healthcare facilities, such individuals should not be transferred to or work in unaffected areas, typically for 48 h after exposure. In certain situations, units in a healthcare facility may be closed to new admissions to prevent the introduction of new susceptible patients, though guidelines differ on this point [236, 243–245]. Ill staff members in healthcare facilities as well as infected food handlers should be excluded during their illness and for 24–48 h following resolution of symptoms [108].

8.3 Food Handling

Food may also be potentially contaminated with enteric viruses during production if growing or irrigation waters are contaminated with human feces; thus, shellfish should be adequately cooked and fresh produce washed thoroughly before consumption [108].

8.4 Environmental Decontamination

Chemical disinfection is a central approach inactivate norovirus [246, 247]. The US Environmental Protection Agency maintains a list of approved products for norovirus disinfection (http://www.epa.gov/oppad001/list_g_norovirus.pdf) based on their efficacy against FCV. Notably, FCV exhibits different physiochemical properties than human norovirus and therefore might not reflect a similar disinfection efficacy profile. Largely due to the uncertainty from in vitro studies, CDC recommends chlorine bleach solution at a concentration of 1,000–5,000 ppm (5–25 tablespoons household bleach [5.25 %] per gallon of water) for disinfection of hard, nonporous, environmental surfaces whenever feasible [108, 172]. In healthcare settings, cleaning products and disinfectants used should be EPA registered and have label claims for use in healthcare settings [108]. Hand hygiene (discussed above) is also a key part of the environmental transmission cycle since contaminated hands can transfer virus to touched surfaces, and hands may be a vehicle for transferring virus from contaminated surfaces back to humans [175].

8.5 Vaccination and Treatment

No specific treatment exists for most AGE viruses, so treatment is supportive and includes therapy for dehydration and electrolyte imbalances. First-line treatment should be oral rehydration solutions, while severe dehydration or shock may warrant intravenous fluid therapy. Antiemetics, antimotility agents, and antibiotics are generally not recommended [248]. Certain compounds with antiviral properties have shown promise in laboratory studies, but their value in the clinic remains uncertain given the short and acute infection caused by caliciviruses.

No vaccines for noroviruses are currently available, but a number of norovirus vaccines are at various stages of development. The product furthest developed is based on recombinant virus-like particles (VLPs) produced by the expression and spontaneous self-assembly of the major capsid protein VP1. An intranasally delivered formulation was shown to be safe and immunogenic in phase 1 and 2 trials [249]. In a challenge study, where participant were vaccinated and

subsequently exposed to homotypic Norwalk virus, the vaccine was shown to be effective against disease and, to a lesser extent, infection [250]. A number of remaining questions and challenges include whether efficacy in the community against commonly circulating viruses can be achieved, whether more vulnerable groups (children and the elderly) will be protected, and whether duration of protection will be long enough to be clinically useful [251].

9 Unresolved Problems

A number of issues remain unresolved, hamper our understanding of norovirus, and preclude a solid basis to develop effective prevention and control strategies. Most fundamental is our inability to grow norovirus in a cell-culture system [252]. This limitation has restricted development of infectivity assays and our ability to differentiate infectious virus from inactivated particles. That capability could ultimately lead to a better understanding of the biology of noroviruses. Second, a perplexing result from many studies is the high level of asymptomatic infection, mainly in children, but occasionally in older age groups [44]. These findings raise questions about the interpretation of diagnostic results as well as the role of asymptomatic infection in transmission. For example, considering the long duration of asymptomatic shedding, we do not know how long infected food handlers or healthcare workers should be excluded from work. Finally, and most importantly, the burden of the noroviruses among economically poor populations in developing countries remains to be fully understood.

Orthopoxviruses: Variola, Vaccinia, Cowpox, and Monkeypox

21

Brett W. Petersen, Kevin L. Karem, and Inger K. Damon

1 Introduction

1.1 Biological Characteristics

Poxviruses are a family of large, complex DNA viruses characterized by their unique ability to replicate entirely within the cytoplasm of infected cells [1]. The *Poxviridae* family is divided into the subfamilies *Chordopoxvirinae* and *Entomopoxvirinae* which infect vertebrate and insect hosts, respectively. Orthopoxviruses are members of the *Chordopoxvirinae* subfamily along with seven other genera: *Parapoxvirus, Avipoxvirus, Capripoxvirus, Leporipoxvirus, Suipoxvirus, Molluscopoxvirus,* and *Yatapoxvirus*. Four species of orthopoxviruses are known to infect humans: variola (smallpox), vaccinia (smallpox vaccine), cowpox, and monkeypox.

Due to their large size compared to other animal viruses, poxviruses were the first viruses to be seen with a microscope [1, 2]. With the increased resolution of electron microscopy, orthopoxvirus virions appear brick shaped with slightly rounded edges [1, 3]. The mature virion (MV) is the most basic infectious form of poxvirus and consists of a dumbbell-shaped core surrounded by a single lipid membrane bilayer [1, 4] (Fig. 21.1).

The orthopoxvirus genome is located in the viral core within a nucleoprotein complex (nucleosome) [4]. It consists of a single, linear, covalently closed double-stranded DNA molecule with inverted terminal repetitions (ITRs) at each of the two ends. The genomes of most orthopoxviruses are ~200 kbp in length and contain a guanine plus cytosine content of ~36 % [1]. The complete genomic DNA sequences of many orthopoxviruses, including representative strains all of

the viruses described in this chapter, have been determined and described previously [5–8].

During virion morphogenesis, a minority of MV undergo further processing with the addition of a second outer lipid membrane bilayer to form an extracellular enveloped virion (EV). Both MV and EV are infectious particles but are thought to have different mechanisms of binding and entering cells. MV binding to cell glycosaminoglycans or laminin is mediated by four viral proteins associated with the single MV membrane [9]. While the binding protein(s) of EV has yet to be identified, it is believed that the second outer membrane is disrupted to expose the MV membrane prior to entry [9, 10]. Subsequently, membrane fusion is initiated by 11–12 transmembrane proteins on the MV surface, a process that can occur directly with the cell plasma membrane or with the membrane of an endocytic vesicle [9, 10]. When fusion occurs at the plasma membrane, the viral entry and fusion proteins now embedded in the cell membrane also mediate the formation of syncytia with adjacent cells and cell to cell spread of virus [10]. Once inside the cell, viral replication commences and occurs completely within the cytoplasm. For this reason, poxvirus virions contain a nearly complete RNA polymerase system that enables primary transcription of viral genes without the use of the cell's nuclear machinery [1]. This early gene expression provides nonstructural proteins needed for DNA replication as well as gene expression of intermediate and late genes. The intermediate and late genes encode structural proteins required for virion assembly in addition to early transcription factors that are packed together with RNA polymerase in assembling virions [1]. In total, orthopoxvirus genomes contain approximately 200 genes of which half encode proteins that are ultimately packaged into virions [4].

1.2 Patterns of Host Response

At present, there is an incomplete understanding of the patterns of host response that occur in human orthopoxvirus infections. Of the four orthopoxviruses that infect humans, vaccinia virus has been the best studied as a model for understanding poxvirus biology. Vaccinia virus has also been exploited as a vaccine due to the ability of orthopoxviruses to induce cross-reactive antibodies that protect against infection from other orthopoxvirus species. Neutralizing antibodies to orthopoxviruses generally appear within the first week of illness and can remain present beyond 20 years [11, 12]. In contrast, hemagglutination-inhibition and complement-fixation antibodies become detectable 16–18 days after infection with levels decreasing after 1 year [2, 13]. The development of such antibodies has been associated with protection in studies of both animals and humans [14–17]. However, in addition to humoral responses, cell-mediated and T-cell responses also appear to be important in the development of immunity against orthopoxviruses [18]. To thwart these host responses, poxviruses have developed numerous mechanisms to evade the immune system [19, 20]. Many of these disrupt the innate immune system by targeting mediators of inflammation such as interferons, tumor necrosis factors, interleukins, complement, and chemokines [19, 21–27]. Further studies using DNA microarrays to evaluate gene expression profiles in response to infection with variola, vaccinia, and monkeypox viruses confirmed the absence of interferon and tumor necrosis factor responses and other factors with critical roles in the activation of the innate immune response [28, 29]. This complex interplay between the host response and viral immune evasion mechanisms has made it difficult to establish a direct correlate of immunity despite technological advances [4]. Historically, the presence of a "take," i.e., demonstrable lesion or scar at the administration site of smallpox vaccine, was used as evidence of successful vaccination against smallpox and protection against disease. However, this practice can mistake a bacterial superinfection of the inoculation site or vaccination with bacillus Calmette-Guérin (BCG) vaccine with protection [4]. Furthermore, an alternate correlate of protection would be useful for more recently developed highly attenuated smallpox vaccines that do not produce visible lesions. Continued research is needed to better elucidate the patterns of host response and correlates of immunity for orthopoxvirus infections.

2 Smallpox

2.1 Historical Background

Smallpox is one of the oldest described human diseases. Examinations of several mummies from ancient Egypt, including that of the pharaoh Ramses V, suggest that smallpox may have occurred in humans over 3,000 years ago [2]. Early written records containing detailed descriptions of smallpox also exist including those of Ko Hung from China in 340 AD, Ahrun from Alexandria in 622 AD, and the Persian scholar Al-Razi in 910 AD [2]. Periodic epidemics of smallpox likely plagued primitive civilizations until their populations became sufficiently dense to establish endemicity [2]. By the mid-eighteenth century, smallpox had become endemic on all continents with the exception of Australia [2]. Throughout the centuries, smallpox caused untold human suffering and loss of life. Even as late as the 1950s, over 150 years after Edward Jenner introduced vaccination, smallpox was estimated to produce 50 million cases worldwide each year [30]. Subsequently, a global eradication campaign was initiated by the World Health Organization (WHO) in 1959 to rid the world of this ancient scourge. The success of these efforts culminated in the identification of the last known case of naturally occurring smallpox in Somalia in 1977.

In 1980 the WHO's General Assembly officially declared smallpox eradicated, and recommendations for routine vaccination against smallpox were discontinued. All known stockpiles of variola virus were collected and consolidated and are currently stored in two locations at the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia, United States, and the State Research Center of Virology and Biotechnology VECTOR in Novosibirsk, Russia. Following eradication, smallpox was allegedly developed as a biological weapon by the Soviet Union and produced in large quantities [31]. This revelation, along with other intelligence concerns, has led to the belief that unauthorized stocks of smallpox may exist and could be used as a biological weapon by terrorists or rogue nations. Though the likelihood of this happening is believed to be low, efforts to be prepared, utilizing a smallpox response research and development program, for the possible reemergence of smallpox into human circulation are ongoing [32, 33].

2.2 Methods for Epidemiologic Analysis

Given the eradication of the disease, all epidemiologic data on smallpox is historical in nature. However, the widespread nature of the disease prior to eradication provided numerous cases for study. Among the largest and most systematic clinical and epidemiologic analyses of smallpox in hospitalized patients were those done by Thomas F. Ricketts, A. Ramachandra Rao, James P. Marsden, and Cyril W. Dixon [2, 34]. The work of Ricketts, Rao, and Dixon was based on personal examination of hundreds of patients with smallpox hospitalized in London, England; Madras, India; and Tripolitania (modern-day Libya), respectively [35–37]. Similarly, Marsden's experience in the London smallpox hospitals provided insights into the epidemiology of the milder form of smallpox variola minor [2, 38]. Further studies evaluating the epidemiology of smallpox in nonhospital settings were also undertaken during the global eradication campaign [39, 40]. Currently, smallpox surveillance is focused on strengthening and maintaining the capacity to identify the disease in the event that human infection reoccurs. Smallpox is a nationally notifiable disease in the United States, and the CDC has developed a clinical algorithm to evaluate the risk of smallpox in patients with acute vesicular or pustular rash illnesses, to assist in developing a differential diagnosis, and to help inform the need for diagnostic testing [41, 42]. To increase capacity for diagnostic testing, the Laboratory Response Network (LRN) was established by the CDC with collaboration from multiple partners including the Association of Public Health Laboratories and the Federal Bureau of Investigation [43, 44]. The LRN provides laboratory diagnostic testing for smallpox in addition to other potential biological warfare agents.

2.3 Descriptive Epidemiology

The host range of variola virus was restricted to humans, and there are no known animal or insect reservoirs [2]. However, recent genetic analyses suggest that the disease may have emerged from a rodent-borne variola-like ancestor in Africa [45, 46]. Among humans, smallpox cases occurred in all ages, genders, races, and ethnicities. Indeed, smallpox has been described as a disease of "princes and peasants" due to its indiscriminate nature in inflicting disease upon all people [47]. Two principal forms of disease were distinguished epidemiologically: variola major and the less severe variola minor (including a biologically distinct virus type alastrim). Outbreaks of variola major produced case fatality rates up to 30 %, while those for variola minor were generally less than 1 % [2, 4]. Population studies including both vaccinated and unvaccinated subjects revealed that case fatality rates were highest in the very young and older age groups [40, 48]. Pregnant women also had extraordinarily high case fatality rates from smallpox (34.3 % overall and nearly 70 % for unvaccinated pregnant women) and were particularly susceptible to hemorrhagic smallpox [2, 49–51]. Secondary attack rates of 30–80 % among unvaccinated contacts within households were similar for both variola major and minor [4]. The age distribution during outbreaks of smallpox depended largely on the immunization or disease-convalescent status of the population affected. Children generally had the highest attack rates in smallpox outbreaks in most areas including the United States, Europe, and Asia as most adults had acquired immunity through either vaccination or previous smallpox infection [52]. In contrast, the age distribution of cases was generally proportional to the age distribution of the population in rural areas where vaccination was less common and adults were more likely to be vaccine naïve and susceptible to disease [40, 52]. Smallpox outbreaks exhibited a seasonal pattern with the highest incidence of cases occurring during the winter and early spring [40, 53]. This observation was consistent with the findings that other orthopoxviruses (i.e., vaccinia) survived better under conditions of low temperature and humidity [54].

2.4 Mechanisms and Routes of Transmission

The most common route of transmission of smallpox was from person to person primarily via respiratory-salivary droplets expelled from the oropharynx of infected individuals. Transmission generally occurred following direct face-to-face contact, though rare occurrences involving airborne dissemination over longer distances have been documented [55]. Common features linked to these occurrences included primary cases with extensive rash and cough, low humidity, and hospital ventilation favoring the formation of air currents

[55]. Transmission of smallpox also occurred through direct contact with active rash lesions or other sloughed exudative materials, though this route of transmission was uncommon [2]. Smallpox was also rarely transmitted via contaminated fomites, e.g., soiled clothing or bed linens [2, 34]. Lastly, smallpox infection by direct inoculation occurred among nursing mothers, postmortem workers, and fabric workers (particularly those working with lace) or more commonly through variolation – a technique for immunizing patients by purposefully infecting them with material from the pustules of smallpox patients with mild smallpox disease [2]. Variolation was practiced widely before the advent of vaccination.

Peak viral shedding is seen during the rash phase of illness; consequently, almost all transmission occurred during the time when rash is present [56, 57]. As such, the majority of smallpox transmission occurred within households, hospitals, and other health-care settings. Large outbreaks in schools were uncommon, and transmission on trains, planes, or buses was also rare [58, 59]. Despite containing significant amounts of virus, scabs were not found to be particularly infectious presumably due to the encasement of viral particles within the protein-fibrin matrix [2].

2.5 Pathogenesis and Immunity

Infection with smallpox began with entry of the virus through the respiratory mucosa or alveoli. The clinical course of ordinary smallpox then began with an asymptomatic incubation period generally lasting 10–14 days (range of 7–17 days). Illness onset generally occurred suddenly with fever and malaise. Temperatures rose to 38.5–40.5 °C and were variably accompanied by headache, backache, abdominal pain, vomiting, and pharyngitis [2]. These prodromal symptoms lasted approximately 2–3 days before the first appearance of lesions [2]. The rash developed in a centrifugal pattern with lesions appearing first and in highest numbers on the oropharynx, face, and extremities before spreading to the trunk. Those on the oropharynx quickly ulcerated as a result of the lack of stratum corneum, releasing high titers of virus into the saliva [58, 60]. The presence of lesions on the palms and soles of the hands and feet was also characteristic (Fig. 21.2). Lesions progressed from macules to papules to vesicles over the course of 4–5 days. Vesicles were often umbilicated and evolved to pustules within a day or two (Fig. 21.3).

Pustules were described as round, tense, firm to the touch, and deep seated within the dermis. At any given time, lesions exhibited the same stage of development in any one area of the body [4]. Lesions typically began to crust on the eighth or ninth day of rash with scab formation and sloughing around day 14 post rash onset. Resolving skin lesions left pitted scars which were particularly evident on the face due to the destruction of the sebaceous glands, shrinking granulation tissue, and fibrosis [2]. In fatal cases, death usually

Fig. 21.3 Umbilicated smallpox lesions on the trunk (From the US CDC PHIL Image ID 284. Credit: CDC/James Hicks. This image is in the public domain and thus free of any copyright restrictions)

occurred during the second week of illness. The exact cause of death in smallpox remains unclear, and the pathogenesis may have differed depending on whether the clinical manifestations were hemorrhagic, flat, or "malignant" as opposed to the ordinary type [34]. In some cases reviewed retrospectively, mortality was attributed to some combination of renal failure, shock secondary to volume depletion, and respiratory compromise induced by cytopathic effects of the virus [61]. Toxemia associated with viral antigens in plasma and immune complexes of antigen and antibody have also been proposed to be contributing factors [2, 58].

During the eradication of smallpox, the WHO established four main clinical types of disease based on disease presentation and rash burden: ordinary, modified, flat, and hemorrhagic [62]. The most common type was ordinary smallpox which accounted for approximately 85 % of cases in outbreaks of variola major. The clinical presentation of ordinary smallpox followed the description above and, as classified by WHO for epidemiologic description, was further subdivided based on the density of rash lesions on the face and body. In ordinary confluent, the rash was confluent on the face and arms, whereas ordinary semiconfluent demonstrated a confluent rash on the face only. Ordinary discrete was characterized by areas of normal skin between pustules on the face and body. These subdivisions had prognostic value as higher rash burden portended a higher likelihood of death; confluent, semiconfluent, and discrete ordinary smallpox had case fatality rates of 62, 37, and 9 %, respectively, in unvaccinated individuals [2, 36]. Modified smallpox was similar to ordinary smallpox apart from being "modified" by previous vaccination to produce disease with a milder prodrome, fewer lesions, and an accelerated clinical course. This type accounted for 5–7 % of cases and was not fatal [2, 62]. In contrast, flat smallpox occurred at a similar frequency but was usually fatal in both vaccinated and unvaccinated individuals [2, 36]. The lesions of flat smallpox were slow to mature and generally remained as soft, velvety vesicles without pustulation [30]. Most cases of flat smallpox were seen in children and may have been associated with deficient cellular immune responses though no studies were undertaken to confirm this [2]. Lastly, hemorrhagic smallpox was a rare (<1 % of cases) but deadly form involving extensive bleeding into the skin and mucous membranes that almost invariably led to death within a week of disease onset [4]. This type occurred mostly in adults (particularly pregnant women) with equal frequencies in vaccinated and unvaccinated individuals [2]. Variola infection without the development of rash was thought to occur rarely in previously vaccinated individuals exposed to smallpox cases and was referred to as variola sine eruptione. Patients typically presented with sudden onset of fever, headache, and sometimes backache that resolved within 48 h and showed evidence of acute infection by high or rising antibody titers and occasionally viral isolation [2].

A similar system for subdividing smallpox into categories with prognostic value was described by Dixon [34, 37]. He defined a total of nine types of smallpox, each with associated mortality estimates. Fulminating smallpox (purpura variolosa) was the first and most deadly type with a mortality rate of nearly ~100 %. This type of smallpox was characterized by a hyperacute course leading to death within 4–5 days after onset of symptoms. Illness began with fever, prostration, and anxiety accompanied by early hemorrhages, particularly of the mucous membranes. The absence of any vesicular eruption was a distinct clinical feature making differentiation from other acute hemorrhagic catastrophes difficult. The second and third types of smallpox were termed malignant confluent and malignant semiconfluent. Malignant smallpox typically began with a high initial fever during the first 3–4 days of illness that defervesced before reappearing during the fourth to twelfth days of illness. The rash of malignant smallpox was soft, velvety, hot, and tender with a slow evolution. Vesicular lesions were rare though hemorrhaging could occur late in the skin as well as the mucosa. The prognosis depended largely on the distribution of the rash with 70 % mortality in patients with confluent rash on the face and arms (malignant confluent) as opposed to 25 % mortality in patients with confluent rash on the face only (malignant semiconfluent). Benign confluent and benign semiconfluent were the fourth and fifth types of smallpox described by Dixon. These types were distinguished primarily by the distinctive rash of ordinary smallpox that followed a centrifugal distribution and progressed through the macular, papular, vesicular, and pustular stages. As with malignant smallpox, the rash of benign semiconfluent extended to the face only compared to the face and arms in patients with benign confluent and conferred a mortality benefit (10 vs. 20 %, respectively). Lastly, Dixon described four types of less severe smallpox that differed primarily in the number of lesions; the discrete type exhibited over 100 (but no areas of confluence), 20–100 in the mild type, less than 20 in the abortive type (often without pustulation), and no lesions in variola sine eruptione. Death was uncommonly encountered in these types of smallpox with only discrete smallpox manifesting a 2 % mortality rate.

Variola minor infections produced disease that was clinically identical to the ordinary or modified types of smallpox with typical prodrome and rash [38]. Prior to eradication, variola major and minor could only be distinguished in outbreak settings by the difference in case fatality rates, whereas virologic differentiation is now possible for certain biologically discrete viruses causing minor disease (i.e., alastrim) [2, 58].

Survivors of smallpox were thought to be protected for life [2, 13]. In contrast, complete protection is not lifelong following smallpox vaccination. Vaccine-induced immunity is most effective in the first 1–3 years following vaccination

when preexposure vaccine efficacy may approach 100 %, and substantial protection may endure for up to 15–20 years [4, 63, 64]. Postexposure vaccination was also effective in preventing and/or ameliorating disease when given to contacts of patients with smallpox. Such postexposure prophylaxis appeared to be most effective when given as soon as possible following exposure and particularly in previously vaccinated individuals; vaccination beyond 3 days after exposure appeared to be less effective based on interpretations of data from the eradication era [65–68].

3 Vaccinia and Cowpox

3.1 Historical Background

The disease known as "cowpox" was so named because of the pustular lesions it produces on the teats of milking cows. During the 1700 s, rural Europeans observed that milkmaids (and others exposed to cows) were rarely afflicted with the scars of smallpox, and it was hypothesized that exposure to cowpox induced resistance to infection with smallpox. In 1798, Edward Jenner published the first scientific evidence that cowpox could be used prophylactically to produce immunity against challenge with smallpox. This concept of preventing disease through inoculation was later termed "vaccination" by Louis Pasteur using the Latin word for cow (vacca) to honor the work of Jenner. Initially, poxviruses taken from or grown on a wide range of species including cows, horses, goats, sheep, pigs, and buffaloes were used [2]. However, smallpox vaccination quickly gained acceptance, and by the twentieth century, almost all smallpox vaccines contained vaccinia virus. Recent genotypic analysis suggests that vaccine strains of vaccinia virus are most closely related to cowpox viruses from continental Europe [69]. Regardless of its precise origin, the use of vaccinia virus in combination with surveillance and monitoring led to the eradication of smallpox in 1980.

3.2 Methods for Epidemiologic Analysis

Early interest in the epidemiology of vaccinia stemmed primarily from its use as a routine childhood vaccine for the prevention of smallpox. In particular, considerable attention has been paid to describing the adverse events associated with vaccinia when used as a smallpox vaccine. Two studies conducted by the Centers for Disease Control in 1968 were among the most comprehensive to evaluate the incidence of adverse events following childhood smallpox vaccination with vaccinia virus. The first study relied on passive reporting of patients with suspected complications of smallpox vaccination to seven separate national surveillance systems [70]. The second study actively surveyed physicians in ten states to solicit reports of complications of smallpox vaccination [71]. Not surprisingly, the adverse event rates calculated using the active surveillance from the ten statewide surveys were higher than those calculated from the passive national surveillance [70, 71]. More recently during 2002–2004, adverse events were monitored, while the United States Department of Defense (DOD) and Department of Health and Human Services (DHHS) increased efforts to vaccinate service members and civilians to enhance preparedness against the possibility of a bioterrorism event involving smallpox. In contrast to those persons vaccinated during the 1968 studies, these populations involved adults that were highly screened for predisposing conditions associated with higher rates of adverse events (e.g., eczema, immunodeficiency, or therapeutic immunosuppression). As such, overall rates of adverse events were much lower in both the DOD and DHHS programs when compared to historical rates [72–74]. One exception was the identification of myopericarditis and cardiac ischemic events at higher rates than anticipated based on historical data [73, 75].

With respect to cowpox, the most detailed epidemiologic analysis is based on a series of 54 human cases investigated between 1969 and 1993 [76]. Limited epidemiologic information has also been gleaned from outbreaks and case reports of naturally acquired as well as laboratory-associated cowpox infections [77–85].

3.3 Descriptive Epidemiology

The vast majority of cases of vaccinia virus infection and its complications are associated with vaccination. In the United States, select military service members still receive routine vaccination against smallpox using vaccinia virus [72]. Serious infections with vaccinia virus have been seen among vaccinees as well as contacts of vaccinees [74, 86, 87]. Vaccination with vaccinia virus is also recommended for laboratory workers who work directly with non-highly attenuated strains of vaccinia virus or other orthopoxviruses that infect humans [88]. Vaccinia virus is commonly used in laboratory research, and multiple exposures and infections have been documented in laboratory workers [89].

In addition to its use in laboratory research, vaccinia viruses can also be genetically altered to produce recombinant vaccines. One such vaccine is a recombinant vaccinia virus containing a rabies virus glycoprotein that is distributed in baits to control rabies in wildlife. Two cases of human vaccinia virus infection have been reported in dog owners following exposures to baits retrieved by their dogs [90, 91]. Surveillance for further human exposure to oral rabies vaccine is ongoing and provides additional data for epidemiologic analysis [92].

Natural infection with vaccinia virus is rare but does occur. Evidence suggests that a vaccinia virus related to a Brazilian smallpox vaccine strain has become established in cattle in Brazil and shows signs of spread within the country [93–95]. Human vaccinia virus infections among farmworkers exposed to cattle in Brazil have been reported [94, 96]. In addition, outbreaks of buffalopox virus, a subspecies of vaccinia virus found in milking buffalo and cattle, have been reported to cause vaccinia-like lesions on animals' teats and milkers' hands in India, Egypt, Bangladesh, and Indonesia [97, 98].

Human cowpox virus infection is classically described as a zoonotic infection associated with occupational exposure to cattle. However, multiple other species have been implicated as sources of human infection including rats, pet cats, and zoo and circus elephants [76]. Two cases of laboratory-acquired human infection with cowpox virus have also been documented [77, 78].

3.4 Mechanisms and Routes of Transmission

Both vaccinia virus and cowpox virus are most commonly transmitted to humans through contact of skin with purified virus, active lesions, or materials from lesion exudates. Intentional infection with vaccinia virus for the purpose of immunization is achieved by inoculating virus through scarification of the skin using a bifurcated needle. Inadvertent inoculation (to others or to a distant site of the same patient) also occurs as vaccinia virus and cowpox virus lesions have the capacity to produce infectious material until a scab has formed and detached to reveal an underlying intact layer of skin.

3.5 Pathogenesis and Immunity

Human infections with vaccinia and cowpox virus produce similar clinical syndromes. Both produce an ulcerative skin lesion that progresses through a well-characterized sequence of events. The site of inoculation develops a papule which becomes vesicular after 3–5 days. Subsequently, the vesicles become pustular and lesions reach their maximum size at day 8–10. The lesions then dry forming a hard black crust which typically separates at day 14–21 leaving a permanent scar. During the vesicular and pustular stages, lesions are often painful with surrounding erythema and edema. Infection is usually also associated with systemic symptoms including fever, lymphadenitis, fatigue, and malaise commonly described as influenza-like. Vaccination with vaccinia virus is typically performed on the upper deltoid; however, secondary autoinoculation or contact transmission can lead to multiple lesions in other anatomical locations. Cowpox typically occurs as a single lesion on the hand, finger, or face but can present with multiple lesions secondary to multiple primary inoculations and autoinoculation and rarely through lymphatic or hematogenous spread of virus [76]. Most vaccinia and cowpox infections are self-limiting and resolve within 6–8 weeks though recovery can take up to 12 weeks in some cases. However, severe systemic illness can be seen in individuals with immunosuppression or immunodeficiency [70, 71, 79, 86].

A number of rare and sometimes fatal complications can result from vaccinia virus infection following vaccination or naturally acquired infections. Progressive vaccinia, also previously referred to as vaccinia necrosum or vaccinia gangrenosum, can occur in persons with severe cell-mediated immunodeficiency [99]. The disease is characterized by uncontrolled spread of infection from the site of inoculation resulting in persistent enlargement of the primary lesion often associated with necrosis (Fig. 21.4).

Fig. 21.5 Eczema vaccinatum in an 8-month-old male infected with vaccinia by a sibling recently vaccinated against smallpox (From the US CDC PHIL Image ID 3311. Credit: CDC/Arthur E. Kaye. This image is in the public domain and thus free of any copyright restrictions)

Subsequent dissemination to other parts of the body can sometimes follow. A vaccination site that continues to show progression without signs of healing 15 days after vaccination should prompt consideration of the diagnosis [100]. Progressive vaccinia is generally lethal in those with a complete lack of cellular immunity (e.g., infants with primary immunodeficiencies), though survival has been documented in adults with acquired immunodeficiencies [86, 99]. The incidence of progressive vaccinia was approximately one case per million recipients of routine smallpox vaccination in the United States during 1968 [70, 71].

Eczema vaccinatum is a potential complication of vaccinia virus infection that can occur in individuals with atopic dermatitis (eczema) regardless of the current status of disease activity. Patients typically present with firm, deep-seated vesicles or pustules 3–14 days following exposure to vaccinia virus [101]. The lesions can be locally or widely distributed, often at the site of a previous eczematous lesions, and generally demonstrate the same stage of development (Fig. 21.5).

Lesions may be accompanied by systemic symptoms including fever, malaise, and lymphadenopathy. Bacterial superinfections and supraglottic edema leading to airway compromise are potentially fatal complications [101]. Underlying defects in the immune system of atopic individual's skin render them particularly vulnerable to infection with vaccinia virus and subsequent local spread or wider dissemination [102, 103]. This susceptibility persists even in the absence of active disease as one case series found that two thirds of eczema vaccinatum patients had no active or obvious eczema at the time of vaccination [104]. Eczema vaccinatum occurred at a rate of 10–39 cases per million primary smallpox vaccinations and 1–3 cases per million smallpox revaccinations in the United States during 1968 [70, 71].

Postvaccinial encephalomyelitis (PVEM) is a rare but important complication that occurs following primary vaccination with vaccinia virus. Symptoms of encephalitis or myelitis including fever, headache, vomiting, and malaise typically develop abruptly 10–13 days following vaccination [2]. Decreased consciousness, seizures, and coma frequently ensue [105]. One case with a similar clinical syndrome has also been reported following infection with cowpox virus [106]. Unlike progressive vaccinia and eczema vaccinatum, no known predisposing factors for PVEM are known [2]. The pathophysiology of PVEM is poorly understood with evidence of direct viral infection in some cases, while others display a demyelinating process more closely resembling an acute disseminated encephalomyelitis (ADEM) [105, 107, 108]. Reported rates of PVEM can vary widely based at least partially on differences between vaccine virus strains. The New York City Board of Health (NYCBOH) strain, a strain with lower incidence of PVEM compared to those used in other countries, produced a rate of 3–12 cases per million primary vaccinees in the United States during 1968 [2, 70, 71]. The fatality rate of PVEM is estimated to be 25 % [109].

A syndrome similar to PVEM is also rarely seen in infants less than 2 years of age. Termed postvaccinial encephalopathy (PVE), cases develop the same symptoms as PVEM but typically present earlier following vaccination (usually within 6–10 days) [110]. The development of hemiplegia and aphasia can also be distinguishing features of PVE [110].

Generalized vaccinia is a vesicular rash that develops after vaccination due to dissemination of virus from the site of inoculation. Lesions typically appear 6–9 days after vaccination and follow a similar progression as the primary lesion only more rapid [2]. The rash can be profuse and cover the entire body but does not follow a centrifugal pattern of distribution as seen with smallpox [2]. Generalized vaccinia is typically self-limiting, and serious cases are only seen when underlying immunodeficiency is present [100]. While generalized vaccinia is thought to result from viremic spread of the virus, isolation of virus from lesions is uncommon [111, 112]. During 1968, generalized vaccinia was reported in 23–242 per million primary smallpox vaccinations performed in the United States [70, 71].

Infections with vaccinia virus can pose a risk to the unborn fetus. Although an analysis of pregnancy outcomes among 376 women vaccinated against smallpox did not reveal higher-than-expected rates of pregnancy loss, preterm birth, or birth defects, approximately 50 cases of fetal vaccinia have been documented previously [113, 114]. This complication often results in death of the fetus or neonate and occurs at an estimated rate of 1/10,000 to 1/100,000 in vaccinated pregnant women [114]. For this reason, vaccination with vaccinia virus is generally avoided in pregnant women.

Cardiac complications have been associated with smallpox vaccination, particularly among civilian and military personnel vaccinated in the United States since 2002 [73, 74]. The observed rate of myopericarditis among this vaccinated population has been higher than the calculated background incidence [75, 115, 116]. Clinical studies suggest that myopericarditis may occur in 1 in 175 adults who receive primary vaccination against smallpox [117]. However, most cases appear to be mild and self-limited with few documented cases of dilated cardiomyopathy [115, 118]. The pathophysiology of myopericarditis associated with smallpox vaccine remains unclear. However, the absence of direct viral invasion seen by histopathologic examination of myocardial tissue from vaccinees with myocarditis suggests this may be an immune-mediated phenomenon [115, 119]. While temporally associated cardiac ischemia and myocardial infarction have been observed among smallpox vaccinees, the incidence of these complications does not exceed the expected background rates, and there is currently no evidence to suggest a causal association with vaccination [115, 119].

4 Monkeypox

4.1 Historical Background

Monkeypox was so named due to its identification in 1958 during an outbreak of a pox-like illness in captive monkeys in Denmark [2, 120]. Initially, this gave rise to concerns that smallpox eradication would not be possible if monkeys served as a reservoir for variola virus. However, subsequent laboratory analyses revealed the monkeypox virus to be a distinct species within the *Orthopoxvirus* genus. The first case of human monkeypox was identified in the Democratic Republic of the Congo (DRC) in 1970 [121, 122]. Further human cases were confirmed when nine samples from Zaire, Nigeria, Cote d'Ivoire, Sierra Leone, and Liberia tested positive for monkeypox virus as part of the efforts of the Commission to Certify Smallpox Eradication in West Africa and the Congo Basin sponsored by the WHO [123]. Since that time, sporadic epizootics continue to occur primarily in Central Africa with evidence suggesting the incidence has increased since the cessation of smallpox vaccination [124]. The emergence of human monkeypox cases in the United States in 2003 and in South Sudan in 2005 further demonstrates the potential for outbreaks in locales discrete and/or distant from the historic geographic range of the virus.

4.2 Methods for Epidemiologic Analysis

In the decade following the discovery of human monkeypox infection, 54 cases were identified and investigated in Central and West Africa providing the first opportunities for epidemiologic analyses [125, 126]. Following the eradication of smallpox, the WHO sponsored enhanced surveillance efforts for monkeypox in the DRC during 1980–1986 which detected 350 cases with the assistance of a monetary reward for reporting [126]. Between 1987 and 1995, surveillance efforts were greatly reduced and few cases were reported. A large outbreak in Zaire in 1996 led to further studies over the ensuing 2 years that were partially hampered by civil unrest [126]. The first appearance of human monkeypox outside of the African continent occurred in the United States in 2003 and provided new insights into the epidemiology of the disease outside of the geographic locations and populations typically affected. Human monkeypox continues to occur in the DRC, and efforts to improve prevention and control through enhanced surveillance remain ongoing.

4.3 Descriptive Epidemiology

With the exception of isolated outbreaks in the United States and Sudan, human monkeypox is limited geographically to Central and West Africa. Males and females are affected equally. Younger age groups are disproportionately affected; 90 % of cases identified in the DRC during 1980–1985 were less than 15 years old [127]. As with smallpox, the vaccination status of an affected population may influence the age distribution of monkeypox cases in an outbreak. However, more recent investigations of outbreaks occurring 20–30 years after the cessation of smallpox vaccination have found that the incidence and attack rates for monkeypox remain highest among those 14 years and younger [124, 128]. Furthermore, recent data suggest that the incidence of monkeypox is increasing in rural Africa due to the growing proportion of unvaccinated individuals in the population, waning immunity in vaccinated individuals, decreasing numbers of smallpox survivors, and human encroachment into areas inhabited by animal reservoirs [124, 128–130]. Most reported deaths occur in unvaccinated children under the age of 14 years. While the overall case fatality rate in Africa is typically ~10 % (range 3.7–11.3 %), rates as high as 14.9 % have been seen among the youngest age groups (0–4 years) [2, 127, 128]. In contrast, no deaths were observed in 37 confirmed monkeypox cases in North America [131, 132]. Differences in the level of medical care administered, route of infection, and underlying host factors are all potential contributors to this disparity in lethality. In addition, genetically distinct isolates of monkeypox virus have been identified from West Africa and the Congo Basin [130, 133–135]. The West African clade has shown decreased virulence compared to the Congo Basin clade in animal models of monkeys, mice, and prairie dogs; the West African monkeypox virus identified in North America may also have contributed to the

absence of fatalities and relatively mild disease observed in the 2003 outbreak [134, 136–138]. Serologic surveys of persons without vaccination scars were performed in the 1980s in Central and Western Africa to estimate the prevalence of monkeypox. These studies found that 1,583/10,300 (15.4 %) sera tested demonstrated orthopoxvirus antibodies by hemagglutination inhibition or immunofluorescence assays [125]. Of these positive sera samples, 420 were tested using a more monkeypox-specific serologic assay (the radioimmunoassay adsorption test), 73 of which gave positive results [125]. Prevalence rates did not vary significantly between the African regions surveyed, providing further epidemiologic evidence for a difference in virulence between West African and Congo Basin monkeypox virus clades when one considers that fewer than 10 % of monkeypox cases and no fatalities occurred outside of the Congo Basin [125, 134]. Initial studies through 1979 evaluating seasonality reported that most cases occurred during the dry season (December, January, and February), whereas surveillance involving the use of monetary incentives to report cases during 1981–1986 showed peak incidence in June, July, and August [125, 139].

The complete host range of monkeypox remains uncertain. Humans and monkeys appear to be incidental hosts, and growing evidence suggests that one or more species of squirrels or rodents serve as the animal reservoir for monkeypox virus [140–142]. However, monkeypox virus has only been isolated from one animal infected in the wild – a squirrel (*Funisciurus anerythrus*) with skin eruptions captured in 1985 near a village where human monkeypox was previously identified [140]. More recently, prairie dogs (*Cynomys* species) housed with rodents from West Africa were implicated as vectors in the North America outbreak in 2003 [132, 143]. This discovery has led to the establishment of prairie dogs as an animal model for monkeypox infection [138].

4.4 Mechanisms and Routes of Transmission

As a primarily zoonotic infection, monkeypox virus is most commonly transmitted to humans through direct contact with the blood, bodily fluids, or lesion exudates of infected animals. The source and types of animal exposures reported by primary contacts prior to rash onset are varied. Case control studies have implicated hunting, skinning, trapping, eating, cooking, or playing with carcasses of nonhuman primates, terrestrial rodents, antelopes, gazelles, and tree squirrels [123, 125]. These studies, however, were confounded by multiple animal exposures in both controls and cases.

Secondary human-to-human transmission occurs though inhalation of virus-containing respiratory droplets or direct contact with lesion exudates from an infected person. Additionally, vertical transmission has been reported in one case of congenital monkeypox [144]. Despite the ability to spread from person to person, monkeypox does not exhibit sustained transmission within human populations. The secondary attack rate of 9.3 % among unvaccinated household contacts documented in African outbreaks is far lower than that observed for smallpox [123, 145]. Moreover, the longest documented chain of uninterrupted human-to-human transmission lasted six generations [146]. Secondary transmission may also be influenced by the clade of virus involved; the longest chain of interhuman transmission occurred in the Congo Basin, whereas no human-to-human transmission of West African monkeypox virus has been documented [139, 147].

4.5 Pathogenesis and Immunity

The pathogenesis and clinical presentation of monkeypox resembles that of ordinary smallpox in many respects. Following exposure, patients enter an asymptomatic incubation period lasting approximately 12 days (range 7–21 days) [2, 123, 125, 128]. The subsequent prodromal phase is usually heralded by fever and often accompanied by headache, prostration, back pain, myalgia, and malaise. In contrast to smallpox, up to 90 % of patients with monkeypox also display prominent lymph node enlargement during this phase [2]. The lymphadenopathy is most often generalized but can sometimes be localized to the cervical or inguinal regions and present as 1–4 cm firm, tender, and occasionally painful lymph nodes [2, 125]. As with smallpox, the rash of monkeypox progresses from macules to papules to vesicles to pustules before umbilicating, crusting, and separating to leave a pitted scar. The rash lesions are typically found in the same stage of development and are distributed peripherally including the palms and soles [2, 125] (Fig. 21.6).

In total, the illness generally lasts 2–4 weeks. Potential complications include secondary bacterial infections of the skin and respiratory tract, severe dehydration secondary to vomiting and diarrhea, and keratitis and corneal lesions which can lead to blindness [123, 125]. The severity of disease is correlated not only with the source of infection (Congo Basin vs. West Africa) but also with the mechanism of transmission. Monkeypox cases reporting a bite or scratch exposure were more likely to experience systemic signs or symptoms of disease and undergo hospitalization than those with only noninvasive exposures [148].

Recent vaccination against smallpox (within 3–19 years) is estimated to provide 85 % protection against monkeypox based on comparisons of attack rates between vaccinated and unvaccinated contacts of index cases in Africa [2, 123, 145]. The monkeypox outbreak in North America in 2003 provided some evidence that vaccine-induced immunity may be maintained for decades and confer a reduced risk of infection [63, 124]. However, remote vaccination (>30 years) did not provide complete protection against monkeypox [131, 143, 149].

Fig. 21.6 Images of the vesiculo pustular rash of monkeypox. A centrifugal distribution, and lesions on the palms and soles, are characteristic of the generalized rash

5 Prevention, Control, and Treatment

The cross-protective immunity provided by smallpox vaccine makes vaccination an effective method of prevention for all orthopoxvirus infections. Vaccine technology has advanced significantly from the first-generation smallpox vaccines used during the eradication campaign such as Dryvax that were typically propagated in the skin of livestock animals. Second-generation smallpox vaccines are manufactured using modern cell culture techniques but are fully replicative live virus vaccines believed to have essentially equivalent efficacy and safety profiles to the first-generation vaccines. ACAM2000®,

a clonal derivative of the NYCBOH/Dryvax smallpox vaccine, is the prototypical second-generation smallpox vaccine that is currently the principal vaccine stockpiled by the United States for use in an emergency [117]. Third-generation smallpox vaccines are live virus vaccines that have been attenuated to improve the safety profile and decrease the risk of adverse events in high-risk populations. IMVAMUNE® is one such vaccine attenuated through multiple passages in chicken embryo fibroblasts such that it is unable to complete a full replication cycle in mammalian cells [150]. Lastly, fourth-generation vaccines remain in development and include protein subunit, DNA, and recombinant vaccines [151].

The global eradication campaign implemented a strategy of ring vaccination in combination with rapid case identification and isolation to successfully achieve its goals. These concepts have been incorporated into modern plans for responding to the use of smallpox as an agent of bioterrorism [152]. A similar approach would be unlikely to succeed in eradicating monkeypox, however, owing to the ability of the virus to propagate within an animal reservoir. Furthermore, implementing a vaccination program to control monkeypox would be challenging due to the relatively low incidence in remote areas that are difficult to access, risks of adverse events, and associated costs [153]. As such, most programs to prevent human infection with monkeypox currently focus on reducing the risk of exposure to animals that can transmit the virus, controlling the trade of animals to prevent the spread of virus outside of Africa, and avoiding close physical contact to limit human-to-human transmission after an outbreak has already occurred. Similarly, vaccinia and cowpox infections can be prevented by avoiding exposures to the animal vectors. Following smallpox vaccination, proper care of the vaccination site is also critical in preventing inadvertent transmission of vaccinia virus.

Limited options are available for treating orthopoxvirus infections after the onset of clinical signs and symptoms. Vaccinia immunoglobulin is the only product currently licensed by the US Food and Drug Administration (FDA) for the treatment of an orthopoxvirus infection (i.e., vaccinia). The licensed indications include eczema vaccinatum, progressive vaccinia, severe generalized vaccinia, vaccinia infections in persons with skin conditions (e.g., eczema, burns, impetigo, varicella zoster, or poison ivy), and aberrant vaccinia infections in areas that would constitute a special hazard such as the eyes or mouth [110].

Though no FDA-approved antivirals are currently licensed for treatment of orthopoxvirus infections, several drugs with antiviral activity against these viruses have been identified and are in clinical development [154, 155]. One such drug is cidofovir, a nucleotide analog with broad antiviral activity against a number of DNA viruses. It is thought to inhibit viral DNA polymerases as well as the proofreading activity of the poxvirus exonuclease [154, 156]. Cidofovir has demonstrated anti-orthopoxvirus activity in vitro and protection against mortality in mouse models of vaccinia and cowpox [154, 156, 157]. However, cidofovir has low oral bioavailability and must be administered intravenously. The development of CMX001, a lipid conjugate of cidofovir, provides several potential advantages over cidofovir including increased oral bioavailability allowing oral administration, decreased toxicity, and enhanced antiviral activity due to greater cellular uptake [158]. Initial safety and pharmacokinetic studies in humans have been successful in achieving predicted therapeutic plasma concentrations with no dose-limiting adverse events reported [158, 159].

ST-246 is another orally bioavailable drug with antiviral activity specific for poxviruses. It was discovered using a high throughput screening approach that assessed compounds for their ability to inhibit virus-induced cytopathic effects [158, 160]. ST-246 acts as an inhibitor of extracellular virus formation through by targeting a major envelope protein critical to this process [160]. Animal studies in mice, rabbits, and nonhuman primates have shown ST-246 to be efficacious in preventing death following challenge with lethal doses of vaccinia virus, rabbitpox virus, monkeypox virus, and variola virus [160–162]. This protective effect was seen even when treatment was begun up to 3 days after the viral challenge was administered in most cases [158]. Clinical evaluation of ST-246 in humans has been limited to safety and pharmacokinetic studies and rare instances of investigational and compassionate use in treating orthopoxvirus infections [86, 87, 90, 163, 164]. Notably, the development of resistance to ST-246 during the course of treatment of one case of progressive vaccinia has been documented [164]. The clinical significance of this finding remains unclear, however, as the patient did ultimately recover. ST-246 has recently entered the US Strategic National Stockpile and is intended to be used in the treatment of smallpox disease in the event of an outbreak. This would likely occur under an investigational new drug and/or emergency use authorization regulatory mechanism given its current status as an unlicensed product.

New options for the treatment of orthopoxvirus infections continue to be sought. For example, a nineteenth-century therapy for smallpox involving a botanical preparation of the carnivorous plant *Sarracenia purpurea* has recently demonstrated antipoxvirus activity against vaccinia virus, monkeypox virus, and variola virus [165]. However, establishing the efficacy of antiviral therapy in treating human orthopoxvirus infections remains difficult due to the low incidence of cases requiring treatment. In particular, evaluation of the potential synergistic effects of combination antiviral therapy suggested by animal studies is not possible with the limited human data available [166]. While the FDA has the ability to approve drugs or license biological products on the basis

of animal studies when human efficacy studies are not ethical or feasible, only two drugs (neither targeting smallpox) have been approved under this so-called animal rule [167]. Further research is needed to help bridge the gap between human and animal efficacy studies and inform the optimal utilization of antivirals for the treatment of orthopoxvirus infections.

6 Unresolved Problems

The orthopoxviruses continue to present many unanswered questions and unresolved problems with direct relevance to human health. As the 2003 monkeypox outbreak in the United States and increasing incidence of monkeypox in Africa demonstrate, the threat of smallpox being used as a weapon of bioterrorism is not the only threat orthopoxviruses pose to human health. Orthopoxviruses circulate widely among various animal species throughout the world. However, neither the prevalence of these viruses in nature nor the risk of zoonotic transmission to humans is well understood [168–170]. Furthermore, there exists the possibility that an orthopoxvirus could mutate into a more highly virulent human pathogen as very likely occurred with smallpox initially many millennia ago [171]. As such, continued efforts to develop antivirals, improved vaccines, and diagnostic assays specific to orthopoxviruses are justified.

The role of research using live variola virus in these efforts and the timing of the destruction of the remaining stores of variola virus are both topics that remain under active debate. Arguments have been made both for and against the immediate destruction of the remaining stockpiles [51, 171]. Most recently, in 2011 the World Health Assembly (WHA) postponed making a decision on setting a date for destruction until 2014. Regardless of the WHA decision, advances in biotechnology and increasing laboratory capabilities and sophistication worldwide may make synthesizing variola virus de novo or engineering more virulent orthopoxviruses more easily achievable [171, 172]. Similar technologies have been applied to the development of vaccinia as a viral vector for recombinant vaccines as well as immunotherapeutic and oncolytic cancer therapies [151]. In fact, over 30 active clinical trials involving vaccinia viruses are currently registered with the US National Institutes of Health at www.clinicaltrials.gov. The widespread implementation of a recombinant vaccinia vector could result in inducing cross-protective immunity against orthopoxviruses in a significant proportion of the population. This would substantially alter the susceptibility of humans to orthopoxvirus infections and directly impact response activities in the event of an outbreak of smallpox. At present, however, continued research and preparedness planning to address the threat of smallpox and other orthopoxviruses remains a prudent investment.

Paramyxoviruses: Henipaviruses

22

Stephen P. Luby and Christopher C. Broder

1 Introduction

The henipaviruses are species of the genus *Henipavirus*, family *Paramyxoviridae,* and subfamily *Paramyxovirnae*. The natural reservoir of the three known henipaviruses, Hendra virus, Nipah virus and Cedar virus, are old world fruit bats of the genus *Pteropus* (order *Chiroptera*, suborder, *Megachiroptera*, family *Pteropodidae*). Human infection with either Hendra or Nipah virus causes a widespread vasculitis that commonly progresses to a fatal encephalitis or pneumonia. People who recover from acute infection with either of these henipaviruses are at risk of recrudescent infection.

2 Historical Background

Hendra virus, previously referred to as equine morbillivirus, was first identified in an outbreak in September 1994 in Hendra, a suburb of Brisbane, Queensland, Australia [1, 2]. Nineteen horses residing in or immediately next to the outbreak stable developed illness; 14 horses died. At autopsy the lungs were heavy and edematous with hemorrhage and frothy secretions in the airways. Histopathological investigations identified interstitial pneumonia with focal necrotizing alveolitis and syncytial giant cells within the vascular endothelium [3].

Two employees at the stable, a 40-year-old male stable hand and a 49-year-old male horse trainer, had particularly close contact with the index mare during the final stages of her fatal illness. The horse trainer, whose hands and arms had abrasions, attempted to force feed the mare by placing his bare hands with food into the sick mare's mouth. Both the stable hand and the horse trainer became ill 5–6 days after the death of the mare with fever, myalgia, headaches, lethargy, and vertigo. The stable hand remained lethargic for several weeks but eventually recovered. The horse trainer developed progressive respiratory failure and died. His autopsy findings were consistent with interstitial pneumonia, with focal alveolitis and syncytial formation [2]. An identical virus, which was ultimately named Hendra virus, was grown from samples from both the affected horses and the affected people [3].

Nipah virus was first recognized in a large human encephalitis outbreak in peninsular Malaysia [4–6]. The initial cases were identified among pig farmers who lived near the city of Ipoh within the state of Perak in late September 1998. Patients presented with fever and headache; many progressed to unconsciousness and death [7]. By December 1998, larger clusters of similar cases were reported within the Port Dickson District of Negeri Sembilan, 300 km south of Ipoh [8]. In March 1999, a novel paramyxovirus was isolated from the cerebrospinal fluid of an affected patient from Sungai Nipah village [9]. Immunostaining demonstrated the virus within the pathological lesions confirming it as the cause of the outbreak [4]. Ultimately, the Malaysian Ministry of Health reported 283 cases with 109 (39 %) fatalities [6]. Cedar virus, is a henipavirus isolated from urine of *Pteropus* bats in Australia and reported in 2012 [10]. Although Cedar virus readily infects guinea pigs and ferrets in the laboratory, unlike Hendra or Nipah virus it does not cause serious illness in these animals [10]. Human infection with Cedar virus has not been described.

RNA consistent with a novel henipavirus was identified from feces of *Eidolon helvum*, the African Straw-colored fruit bat in Ghana in 2008 [11]. Subsequent sampling of 6 bat species across 5 African countries have identified a diversity of henipavirus like RNA sequences, and the full genome of

an apparently novel Henipavirus was characterized [12]. Human infection with African henipaviruses has not been described.

3 Methodology Used in Epidemiologic Analysis

3.1 Wild Animal Studies

The known henipaviruses are not part of the normal human microbiota. Their ecological niche is within old world fruit bats of the family *Pteropodidae* [13, 14]. Closely related henipaviruses have been identified among different *Pteropodidae*. Nipah virus infects *P. vampyrus, P. hypomelanus, P. lylei*, and *P. giganteus* [15–17]. Hendra virus infects all four *Pteropus* species in Australia [18]. RNA fragments suggestive of closely related henipaviruses were collected from feces of *Eidolon helvum*, a fruit bat from family *Pteropodidae* that lives in Africa [19]. These infections of genetically related *Pteropodidae* with genetically related henipaviruses suggests that these viruses coevolved with their *Pteropodidae* hosts [19, 20].

Although not part of the lifecycle of the henipaviruses, humans and many other mammals are susceptible to infection, infections that can have catastrophic consequences. When a human infection with henipavirus is recognized, an underlying question is how this bat virus got into a human.

3.2 Outbreak Investigations

Most of what is known of the epidemiology of human infection with henipaviruses comes from outbreak investigations. Investigators have conducted in-depth case studies to describe unique or illustrative situations. This has been particularly important for Hendra virus, because so few human infections have been recognized. Outbreak investigators have conducted case–control studies and evaluated cohorts of people who were potentially exposed to henipavirus to assess risk factors for transmission.

To complement outbreak investigations, scientists have conducted serological surveys to explore the frequency of unrecognized infection and the risk to groups who were not implicated in outbreak investigations.

3.3 Surveillance

Recurring Nipah virus outbreaks in Bangladesh have characterized the population at risk sufficiently to permit prospective surveillance for the virus in hospitals which have repeatedly identified cases [21]. Nipah virus represents less than 2 % of all cases of encephalitis presenting to these hospitals, so prospective individual level diagnostics are only conducted at the three facilities that have identified the most cases of Nipah virus during the 3 months, January through March, when the most cases have been identified. To efficiently identify outbreaks of Nipah virus in Bangladesh over a broader geographical area and wider seasonality, a complementary surveillance activity focuses on identifying clusters of patients with encephalitis, that is, at least two people who live within a 30-minute walk of each other and who within 2 weeks of each other developed symptoms of meningoencephalitis including fever, new seizures, or mental status changes [22].

3.4 Laboratory Diagnosis

3.4.1 Virus Detection

The most definitive confirmation of henipavirus infection is recovery of the virus from a patient sample. Both Hendra and Nipah virus grow readily on Vero cell culture [3, 4]. Henipavirus has been successfully cultured from human cerebrospinal fluid, respiratory secretions, and urine [9, 23, 24]. Both Nipah and Hendra virus can be identified through polymerase chain reaction (PCR) using either nested or real-time platforms. Different laboratories have used different primers. PCR has been used successfully on respiratory secretions, cerebrospinal fluid, blood, and urine [23, 24–28]. Two research groups have developed a recombinant vesicular stomatitis virus that expresses the F and G protein of Nipah virus (pseudotyped virus) [29–31]. This pseudovirus-based assay can be used safely in a biosafety level II laboratory, has high analytical sensitivity, and provides an alternative more rapid assessment of virus neutralization.

3.4.2 Measurement of Virus-Specific Antibodies

Although there are no commercially available tests for serological diagnosis of henipavirus in humans, several laboratories have developed enzyme-linked immunosorbent assays (ELISA) to detect antibody against Nipah and/or Hendra virus. To secure henipavirus antigen for the ELISA, some laboratories grow henipavirus-infected cells in tissue culture and then use various procedures to purify viral materials that are then used to detect antibody in samples [32–34]. Since most countries consider Nipah and Hendra virus as biosafety level IV pathogens, only laboratories with biosafety level IV facilities can produce reagents, and the disease occurs in places where there are few such laboratories. Alternatively, some laboratories have developed recombinant henipavirus antigens [35–38]. These recombinant-based ELISAs do not require a biosafety level IV laboratory to develop, but their test performance has not been evaluated against a wide diversity of samples. Using either viral culture-derived or recombinant henipavirus antigens, laboratories have developed indirect ELISA assays to detect Henipavirus-specific IgG antibodies and capture ELISA to detect Henipavirus-

specific IgM antibodies [32, 35]. These ELISA assays provide an efficient approach to detect antibody and to screen a high volume of samples, for example, in a surveillance system. However, since the system depends on antibody detection, its diagnostic sensitivity early in illness is suboptimal. Among patients tested within the first 4 days of illness, 30 % of those ultimately confirmed as infected with Nipah virus were anti-Nipah IgM antibody negative by ELISA [33].

3.4.3 Clinical Diagnosis of Henipavirus Infection

During outbreaks in Bangladesh, many people die from apparent Nipah virus infection before samples can be collected or before they develop IgM antibodies [39]. During such outbreaks, clinical assessment is sometimes sufficient for diagnosis. When previously healthy people develop characteristic symptoms of Nipah virus infection – fever with new onset seizures or mental status change – and when they are linked to a laboratory confirmed case, either because they shared a common exposure that was implicated in the transmission of Nipah or because of exposure to the respiratory secretions of a confirmed case, they are generally classified as probable cases [39]. The risk of misclassification is small, because the rapid onset of a fatal illness with symptoms of meningoencephalitis is uncommon. It is unlikely that such an uncommon event would occur from a different etiology during a Nipah outbreak.

4 Biological Characteristics

4.1 Morphology and Morphogenesis

Henipavirus particles are enveloped and pleomorphic, ranging in size from 40 to 1,900 nm and can vary from spherical to filamentous forms when imaged by electron microscopy [3, 40, 41] (Fig. 22.1).

The envelope carries surface projections composed of the viral transmembrane anchored fusion (F) and attachment (G) glycoproteins. Hendra virus possesses a double-fringed appearance of spikes, whereas Nipah virus appears to have a single fringe of projections [41]. Like other paramyxoviruses, the henipavirus genomes are an unsegmented, single-strand, negative-sense RNA [42, 43]. At the time of their discovery, the genomes of Hendra and Nipah virus were the largest among all members of the *Paramyxoviridae* family, one factor that justified their separation into their own genus, *Henipavirus* [44]. Henipavirus genomes conform to the "rule of six," i.e., the total number of nucleotides is evenly divisible by six [45], an important feature in the way the nucleocapsid (N) protein interacts with the viral genomic RNA [43]. The RNA genome in association with the N protein is referred to as the ribonucleoprotein core that has a characteristic herringbone appearance by electron microscopy. The ribonucleoprotein core is contained within a lipid bilayer (envelope) that is derived from the infected host cell during virus assembly and budding.

Scale bar represents 200 nm (Images courtesy of the AAHL Biosecurity Microscopy Facility, Australian Animal Health Laboratory (AAHL) Livestock Industries CSIRO, Australia)

The relative gene order of the henipaviruses is conserved as compared to other paramyxoviruses with the N gene first, followed by P (phosphoprotein), M (matrix), F, G, and L (large/polymerase) genes (in a 3′–5′ order) [42]. The N, P, and L proteins form a complex that replicates the viral RNA; polymerase activity resides within L [43, 45]. The henipavirus P gene is also the largest among the paramyxoviruses and encodes the V and W proteins through a transcriptional editing mechanism that adds untemplated G nucleotides. An alternative start site within the P gene encodes the C protein [42]. The henipavirus M protein, which underlies the viral membrane, organizes viral proteins during virion budding from the host cell; the Nipah virus M protein can independently bud from expressing cells forming virus-like particles (VLPs) [46, 47]. Finally, the G and F envelope glycoproteins project from the surface of the virion as well as on infected cells and are essential for the binding and entry steps of virus infection (reviewed in [48]). The G glycoprotein attaches the virion to host cell via receptors and the F glycoprotein fuses the viral membrane with the host cell membrane (reviewed in [49]). The G and F glycoproteins are also the principal antigens to which virtually all henipavirus-neutralizing antibodies are directed and are the major components or targets of well-advanced vaccine and antiviral strategies (reviewed in [50]).

4.2 Physical Properties

As enveloped paramyxoviruses, Hendra and Nipah virus would be expected to be more labile to environmental factors as compared to non-enveloped virions; however, there is some evidence of persistence. A patient with confirmed Nipah virus infection in Malaysia who neither entered nor went near pig farms prior to his illness worked repairing pig cages [51]. His illness suggests that pig secretions or excretions remain infectious at least for hours and perhaps for days. Nipah virus spillover events in Bangladesh have been attributed to contaminated food [52, 53]. In the laboratory, henipavirus survived greater than 4 days at 22 °C in pH-neutral fruit bat urine and survived in various fruit juices from several hours to 4 days depending on temperature and pH [54].

5 Descriptive Epidemiology

5.1 Hendra

All four *Pteropus* species native to Australia commonly have serum antibody against Hendra virus [18] and three of the four have been confirmed to shed Hendra virus, at least occasionally, in their urine [55]. From 1994 to 2012, only seven human infections with Hendra virus have been recognized; 4 (57 %) died and 1 reportedly has serious, ongoing health problems (www.outbreak.gov.au). All confirmed human Hendra virus infections occurred among people who had close contact with a sick horse in Queensland, Australia. Serological studies among people who cared for ill horses, among healthcare providers who cared for Hendra virus-infected humans [23, 56], and among Australians with close contact with *Pteropus* bats have identified no evidence of asymptomatic infection [57]. Apparently, human infection with Hendra virus occurs rarely.

5.2 Nipah

5.2.1 Malaysia/Singapore

In the large Malaysian Nipah outbreak in 1998, cases occurred almost exclusively among people who worked on pig farms. Males and persons of Chinese ethnicity were more likely to be pig farmers in Malaysia and were more likely to be infected with Nipah virus [58]. Abattoir workers in Singapore who handled pigs imported from Malaysia during the Malaysian Nipah outbreak also became infected [59]. Among asymptomatic persons who lived or worked on pig farms where cases of human Nipah infection were identified, 11 % had antibody to Nipah virus [58]. The human outbreak of Nipah virus infection ceased after widespread deployment of personal protective equipment to people contacting sick pigs, restriction on livestock movements, and culling over 900,000 pigs [60]. Malaysian authorities confirmed 265 cases of human Nipah virus infection and 105 deaths during the outbreak [4]. Authorities in Singapore confirmed 11 cases and 1 death [5]. Since the outbreak ended in 2013, no human or porcine Nipah virus infections have been reported from Malaysia or Singapore.

5.2.2 Nipah Bangladesh/India

The epidemiology of Nipah virus in Bangladesh/India infection has been quite different from Malaysia. In 2001 in Siliguri, India, 47 patients with encephalitis were linked in a web of person-to-person transmission among patients and healthcare workers who had contact with human Nipah cases [26]. Over 70 % of people infected with Nipah virus in Bangladesh and India have died [26, 52]. In Bangladesh, all recognized Nipah outbreaks have occurred in rural communities. Both adults and children have been infected, including many children age 5–15 years [52]. Nipah cases have been remarkably clustered in both space and time [61]. All but one of the recognized human infections with Nipah virus in Bangladesh have occurred in the west, central, and northwest regions. Cases have occurred disproportionately in close proximity to major rivers. The two reported outbreaks from India have occurred within 50 km of the border with Bangladesh [26, 62], adjacent to areas where human cases have been recognized in Bangladesh (Fig. 22.2).

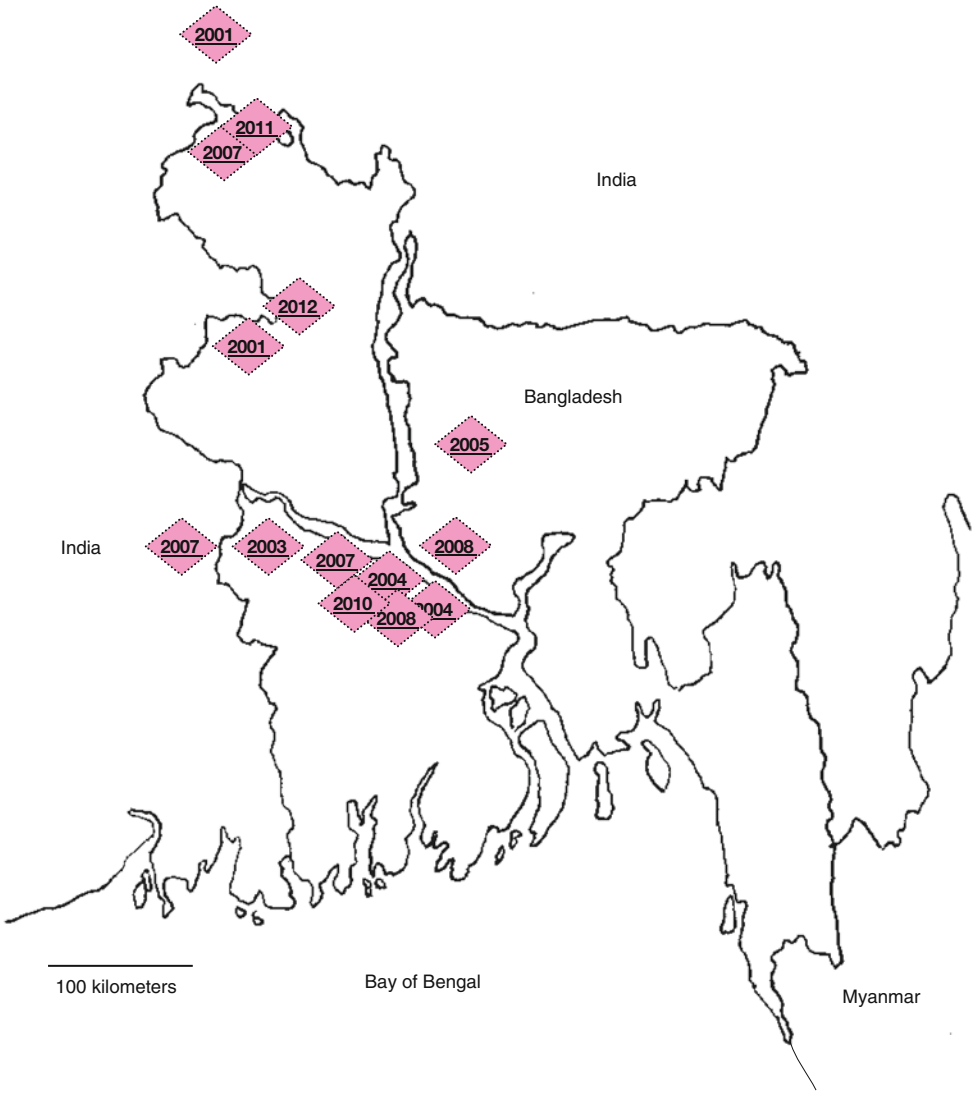

Fig. 22.2 Location of Nipah outbreaks in Bangladesh/India 2001–2012

Surveillance is particularly intense in these areas where outbreaks have repeatedly been identified, but the Government of Bangladesh maintains national surveillance for outbreaks and investigates clusters of various sorts of illness throughout the country. All of the outbreaks which have been confirmed to be Nipah through March 2012 have occurred in this more restricted region. From 2001 to 2014, human Nipah cases were identified every year except in 2002 and 2006. Primary cases of human Nipah infection are those apparently acquired through contact with contaminated non-human secretion/excretions. Among 121 primary cases in Bangladesh, all have been identified between December and April with 79 (65 %) identified in January.

Sero-surveys of communities affected by outbreaks in Bangladesh [63] have identified a much lower proportion of asymptomatic infections than sero-surveys in Malaysia during the outbreak. A study of 104 healthcare workers who cared for Nipah patients identified two nursing students who had IgG antibody against Nipah virus suggesting prior infection [64].

6 Mechanism and Route of Transmission

6.1 Hendra

Four species of *Pteropus* bats, *P. alecto, P. conspicillatus, P. poliocephalus,* and *P. scapulatus*, live in Queensland, Australia [55]. Because of changes in their native habitat, *Pteropus* bats in Queensland now frequently occupy trees in urban communities [65]. Hendra virus has been recovered from urine collected underneath bat roosts of each of these species [55]. Longitudinal collection of bat roost urine specimens suggests that bat colonies shed Hendra virus intermittently without a regular seasonal pattern [55]. Hendra virus

has also been recovered from uterine fluid [13]. Through January 2012, 67 equine infections with Hendra virus have been recognized [66], though the precise pathways that the virus moved from *Pteropus* bats to horses are unknown.

The first recognized Hendra virus infection occurred in a pregnant mare that became ill while staying in an open paddock and was moved to a stable in the Brisbane suburb of Hendra and died 2 days later [2]. Between 8 and 11 days after the mare's death, 18 other horses residing in or near the stable became ill. Among 18 horses with clinical illness, 14 died, 12 horses from the Hendra stable, one horse staying in the paddock adjoining the stable, and one horse living on a neighboring property that had very close contact with horses from the Hendra stable. The index mare was the apparent source of all the subsequently infected horses since they developed illness within one incubation period (8–11 days after the death of the index mare). Whether the virus was transmitted directly from horse to horse or whether transmission was facilitated by the activities of people caring for the horses is unknown. The absence of a successive wave of infection among horses and the rarity of horse-to-horse transmission in subsequent investigations suggest that Hendra virus super spreader horses are exceptional.

In addition to the two employees at the Hendra stable who had particularly close contact with the index mare during the final stages of her fatal illness, other exposures in Queensland that resulted in horse-to-human Hendra virus transmission included a farm worker who cared for two sick horses, one with acute respiratory distress, and the other with a rapid onset of neurological symptoms. After both horses died, the farm worker assisted a veterinary surgeon during the necropsy of the two horses [25]. Throughout caring for the horses and the necropsy, the farm worker never wore gloves, mask, or protective eyewear.

A veterinarian developed Hendra infection after conducting a limited autopsy on a 10-year-old horse that died of a rapidly progressive respiratory illness with large amounts of bloodstained frothy nasal secretions [67]. While not wearing gloves or other personal protective equipment, the veterinarian reached deep into the carcass to examine internal organs and became heavily contaminated with the horse's body fluids. The two autopsy assistants and an adult family member who held the dying animal's head and were exposed to frothy bloody nasal secretions did not become ill and were seronegative for Hendra virus infection [67].

A 33-year-old male veterinarian and a 21-year-old female veterinary nurse became infected with Hendra virus during an outbreak that affected five horses in a veterinary practice in Thornlands, Queensland [23]. Both the veterinarian and the nurse performed nasal cavity lavage on a horse during the 3 days before the horse developed symptoms of what was later confirmed to be Hendra virus infection.

Each of the recognized human cases of Hendra virus had intimate contact with a Hendra virus-infected horse, usually with heavy exposure to respiratory secretions and without wearing personal protective equipment. Other people with close contact with these same horses did not develop Hendra virus infection. These observations suggest that Hendra virus is not easily transmitted from horse to human. It apparently requires a horse that is an unusually efficient transmitter and a person with a high exposure to infectious secretions.

6.2 Nipah

6.2.1 Malaysia

There are two *Pteropus* species native to Malaysia, *Pteropus hypomelanus* which is smaller and prefers island habitats and *Pteropus vampyrus*. Both species commonly have antibodies against Nipah virus [15], and their colonies intermittently shed Nipah virus in their urine [68, 69].

The precise mechanism of transmission of Nipah virus from *Pteropus* bats to pigs in Malaysia is not confirmed, though the index farm was surrounded by native *P. vampyrus* habitat, and both the index farm and other pig producers commonly raised mangoes, a food attractive to *P. vampyrus*, on the same property where they were raising pigs. Mathematical modeling suggests that multiple spillovers from bats into the pig population would be necessary to create a dynamic population with sufficient susceptible pigs to sustain Nipah virus transmission within pigs for months [70].

Unlike the severe illness seen in Hendra virus-infected horses, most pigs infected with Nipah virus had mild illness. Among three pigs infected with Nipah virus through experimental oral inoculation or sharing a cage with an inoculated pig, all developed asymptomatic infections [71]. On farms the case fatality among adult-infected pigs ranged from <1 to 5 % [72]. A minority of Nipah virus-infected pigs developed more severe illness with fever, agitation, trembling, and twitching accompanied by rapid labored respirations, increased drooling, and a nonproductive loud barking cough [72]. Pathological examination of severely affected pigs showed extensive involvement of the lungs with a giant cell pneumonia with multinucleated syncytial cells containing Nipah virus antigen in the lungs and epithelial cells lining the upper airways [4]. Nipah virus was recovered from respiratory secretions of infected pigs, and Nipah virus antigen was detected in renal tubular epithelial cells [4, 71].

Humans infected with Nipah virus in Malaysia were more likely than controls to have direct contact with pigs that appeared sick and to have close contact with pigs through feeding pigs, processing baby pigs, handling dead pigs, and assisting in breeding, birthing, or medicating pigs [58]. Abattoir workers in Singapore who developed Nipah virus infection were more likely than controls to be exposed to pig urine or feces from pigs that had been imported from Malaysia during the Malaysian Nipah virus outbreak [5].

The isolation of Nipah virus from pigs' lungs and respiratory secretions and the observation that human cases of Nipah virus infection had more direct contact with pigs than controls suggests that Nipah virus was transmitted from infected pigs to humans through contaminated saliva and possibly urine.

All human Nipah virus infections in the outbreak in Malaysia/Singapore in 1998–1999 may have been linked to a single event of Nipah virus transmission from an infected bat to an immunologically primed pig population, leading to a sustained porcine epidemic which in turn led to a human epidemic. The genomic sequences from Malaysian Nipah virus isolates from pigs and people were nearly identical [4, 73].

There was little evidence of person-to-person transmission of Nipah virus in Malaysia. Although asymptomatic infections were identified among members of the households of cases [58], these infections may have resulted from shared exposures to infected pig secretions or excretions. A cohort study enrolled 363 healthcare workers from three hospitals that cared for Nipah patients [74]. Healthcare workers reported skin ($n=89$) or mucus membrane ($n=39$) exposure to body fluids of Nipah virus-infected patients and needlestick injuries ($n=12$). None reported any serious illness, encephalitis, or hospital admission. None of the initial 363 serum samples had detectable Nipah virus IgG or IgM antibody by ELISA. Among 293 serum samples collected 30 days later, three (1 %) were positive for Nipah virus IgG antibody, though none had detectable IgM and all three were negative for anti-Nipah virus-neutralizing antibodies.

6.2.2 Bangladesh/India

Pteropus giganteus is the single *Pteropus* species currently living in Bangladesh. These bats commonly have antibody to Nipah virus [17, 75] and urine collected from *P. giganteus* occasionally contains detectable Nipah virus RNA [76].

Drinking raw date palm sap is the most common pathway of Nipah virus transmission from *Pteropus* bats to people identified in outbreak investigations in Bangladesh [21, 53, 77, 78]. Human Nipah virus outbreaks in Bangladesh and India coincide with the cool dry date palm sap harvesting season [52]. At the beginning of the season, the bark is shaved off of one side of the tree (*Phoenix sylvestris*) and a small hollow bamboo tap is placed at the base [79]. In the late afternoon, the date palm sap harvester scrapes the area where the bark was removed so the sap can flow freely and ties a 2–4 l clay pot underneath the tap. During the night, the sap rises to the top of the tree, and some sap oozes out from where the bark is denuded, flows through the tap, and drips into the clay pot. At daybreak, sap collectors gather the clay pots and often sell some of their sap to village residents who drink it fresh in the morning.

Pteropus bats occasionally shed Nipah virus in their saliva [80–82]. Infrared photography confirms that *P. giganteus* bats commonly visit date palm trees during collection and lick the sap stream [83] (Fig. 22.3). Infrared cameras placed in the seven trees that were the source of fresh date palm sap drunk by the human Nipah virus cases in the Manikganj/Rajbari outbreak in 2008 identified an average of four *P. giganteus* bat visits where the bat licked the sap stream per tree per night [21].

Fig. 22.3 Infrared photograph showing a *Pteropus* bat licking date palm sap from the shaved part of the tree

Nipah virus has not been isolated from a domestic animal in Bangladesh, but outbreak investigations have linked human Nipah virus cases to apparent domestic animal infections. The index case in the 2001 outbreak in Meherpur District developed illness on April 20, the latest post-winter onset of any confirmed Nipah virus outbreak in Bangladesh, past the end of the date palm sap season in most communities. Nipah virus cases in Meherpur were eight times more likely to report contact with a sick cow than controls [17]. In the Naogaon outbreak in 2003, Nipah virus cases were six times more likely than controls to report contact with a pig herd that visited the community 2 weeks before the human outbreak [84]. In 2004, a child developed Nipah virus infection 2 weeks after playing with two goats that developed an illness that began with fever and progressed to difficulty walking, frothing at the mouth, and death [61].

Person-to-person transmission of Nipah virus has been frequently recognized in Bangladesh/India. The two largest recognized outbreaks caused by person-to-person transmission include 47 linked cases in the Siliguri, India, 2001 outbreak mentioned above [26] and a person-to-person chain of transmission that infected 33 persons with Nipah virus in Faridpur, Bangladesh, in 2004 [27]. Nipah virus RNA has been frequently identified in the saliva of Nipah virus patients [24, 85]. In Faridpur, Nipah virus cases were more likely than controls to report touching a Nipah virus-infected patient who later died [27]. Similarly, Nipah virus-infected cases in Thakurgaon in 2007 were more likely than uninfected controls to have been in the same room when the index case was

coughing [75]. Across all recognized outbreaks in Bangladesh from 2001 to 2007, Nipah virus patients who had difficulty breathing during their illness were more likely to transmit Nipah virus than Nipah virus patients who did not have difficulty breathing (12 vs. 0 %, $p=0.03$) [52].

7 Pathogenesis and Immunity

7.1 Cellular Tropism and Host Range

A remarkable feature of the henipaviruses that separate them from all other paramyxoviruses is their exceptionally broad species tropism and ability to cause fatal disease in multiple vertebrate hosts including humans, monkeys, pigs, horses, cats, dogs, ferrets, hamsters, and guinea pigs, which, in addition to their bat reservoir hosts, spans 6 mammalian orders [81, 86–98]. The henipaviruses use host cell membrane proteins as entry receptors and bind to ephrin-B2 and ephrin-B3 using their G glycoproteins [99–102]. Human ephrin-B2 and ephrin-B3 are members of a large family of surface expressed glycoprotein ligands that bind to Eph receptor tyrosine kinases and both the ephrins and Eph receptors mediate bidirectional cell-cell signaling within the nervous, skeletal, and vascular systems [103, 104]. The ephrin-B2 and ephrin-B3 molecules are highly sequence-conserved proteins including among those hosts susceptible to henipavirus infection; the human, horse, pig, cat, dog, and flying fox have amino acid identities of 95–96 % for ephrin-B2 and 95–98 % for ephrin-B3 [105]. Ephrin-B2 expression is prominent in arteries, arterioles, and capillaries in multiple organs and tissues including arterial smooth muscle and human bronchiolar epithelial cells [106], while ephrin-B3 is found predominantly in the nervous system and the vasculature (reviewed in [107, 108]). The identification of ephrin-B2 and ephrin-B3 as entry receptors for Hendra virus and Nipah virus helps explain both the broad species tropism that the henipaviruses possess and the observed distribution of viral antigen within infected animals and people (reviewed in [89, 109]).

7.2 Immune Response

Henipavirus infection in people and other susceptible animals induces strong humoral responses. In humans with clinical Nipah virus encephalitis, anti-Nipah virus antibodies were detected in sera (71 %) and cerebral spinal fluid (CSF) (31 %) [7]; levels of virus-specific IgM antibodies were higher than IgG antibodies in CSF and serum [5, 9, 110]. Seroconversion of IgG against Hendra virus was observed in two human cases of Hendra virus infection in 2008 following an influenza-like illness that progressed to encephalitis [23].

Less is known about the memory responses or cell-mediated immune response to henipavirus infection though both are likely present. In Nipah virus challenge studies in African green monkeys when animals survive a severe infection and are rechallenged with very high doses of virus, they remain completely protected from subsequent infection and disease (TW Geisbert and CC Broder 2008, unpublished).

There are a few published reports on cytokine responses to henipavirus infection. In vitro infection of endothelial cells with Nipah virus induced increases in the secreted inflammatory chemokines, monocyte chemotactic protein-1 (MCP-1), interleukin-8 (IL-8), and interferon-inducible protein 10 (IP-10) or C-X-C motif chemokine 10 (CXCL10), and infected cell culture supernatants could induce monocyte and T-lymphocyte chemotaxis [111]. These pro-inflammatory chemokines produced by Nipah virus-infected endothelial cells in vitro are consistent with the prominent vasculitis observed in infections in vivo. In the hamster model of henipavirus infection, the development of neurological disease was correlated with disruption of the blood–brain barrier (BBB) and upregulation of tumor necrosis alpha (TNF-á) and interleukin 1 â (IL-1â) and IP-10 (CXCL10), and these inflammatory mediators are likely important in henipavirus pathogenesis [112]. Nipah virus-infected hamsters expressed IP-10 (CXCL10) mRNA in various organs with kinetics that followed the replication of virus. Elevated levels of CXCL10 were also identified in brain tissue of patients with fatal Nipah virus infection from the Malaysian outbreak [113].

7.3 Antagonism of the Host Interferon Response

Products of the P gene inhibit both double-stranded RNA signaling and interferon signaling and the P, V, W, and C proteins can all antagonize the host interferon response, features that are thought to contribute to viral pathogenicity. The details of these mechanisms have been reviewed elsewhere [114–116]. The W protein is the most potent interferon antagonist and P protein is the least [117]. However, a recent study conducted using live virus infection indicated that interferon signaling remains functional during henipavirus infection of human cell lines while interferon production was inhibited [118]. Further, henipavirus infection of bat cells does not induce interferon expression and interferon signaling is inhibited; these observations suggest that the control of virus infection and lack of disease in these natural hosts is mediated by mechanisms other than the interferon response [119]. In addition, recombinant Nipah virus individually lacking either the V, C, or W proteins antagonized the interferon response, and wild-type virus and in vivo Nipah virus lacking either the V or C protein were

significantly less pathogenic. The roles of these proteins in pathogenicity thus appear to be independent of their interferon-antagonist activity [120].

8 Patterns of Host Response

8.1 Henipavirus Infection in People

The initial site of henipavirus replication is ill-defined but is likely within the respiratory system followed by apparent hematogenous systemic spread [110]. Established infection is characterized by a widespread vasculitis and endothelial cell tropism resulting in multinucleated syncytial cells. There is prominent parenchymal cell infection and pathogenesis of many, if not most, major organs with the brain, lung, heart, kidney, and spleen significantly involved [9, 110, 121]. Clinically, severe infection in humans presents as a severe respiratory disease, encephalitis, or a combination of both [2, 7, 39]. The widespread endothelial cell infection and resulting vasculitis, thrombosis, and parenchymal cell infection in many organ systems, particularly in the CNS and respiratory system, contribute to fatal human henipavirus infection [42, 89, 110].

Human henipavirus infection can also result in a clinically quiescent period following a recovery from an acute infection, which can later recrudesce as encephalitis. For example, the second recognized fatal case of human Hendra virus infection occurred in an individual who experienced relapsed encephalitis 13 months after infection [25]. Similarly, among cases of human Nipah virus infection in the Malaysian outbreak, neurological disease frequently presented >10 weeks following recovery from acute encephalitis [122] and relapsed encephalitis has presented from several months to 11 years following infection [123–125]. An examination of the first two fatal human cases of Hendra virus infection, one from an acute respiratory disease and another from relapsed encephalitis, demonstrated that Hendra virus can cause both acute encephalitis without clinical signs or relapsed encephalitis similar to Nipah virus [121]. Relapsed encephalitis is presumably caused by the recrudescence of virus replication that is restricted to the central nervous system (CNS) [121, 123].

8.2 Natural and Experimental Henipavirus Infections of Animals

8.2.1 Infection in *Pteropus* Bats

No clinical disease caused by Hendra virus [13, 126] or Nipah virus [69, 127] infection has been reported in naturally infected fruit bats. Experimental infections with Hendra virus in *P. poliocephalus* and *P. alecto* [14, 128, 129] and with Nipah virus in *P. poliocephalus* and *P. vampyrus* [14, 81] also produced no clinical disease or gross pathological findings even with high doses (50,000 $TCID_{50}$) of virus inoculation; however, bats do seroconvert [81, 128, 129]. Transplacental transmission of Hendra virus in bats can also occur [129] but fetal tissues show no pathology. Virus shedding from experimentally infected bats also occurs but is rare and has only been observed from urine [14, 81].

8.2.2 Infection in Spillover Hosts

Evaluating henipavirus pathogenesis among various animal species has been critical for understanding their biology, for modeling human disease, and as platforms for testing vaccines and therapeutics. A major limitation to in vivo henipavirus infection studies is the requirement for BSL-4 containment which impacts the size and scope of animal challenge studies. These difficulties were compounded by the early observation that henipaviruses did not cause a pathogenic infection in mice, rats, and rabbits [95, 96]. Several animal modeling platforms of henipavirus infection accurately reflect the pathogenic processes seen in either naturally infected humans or in economically important livestock (horses and pigs).

All cases of natural Hendra virus spillover infections in Australia have been in horses, while Nipah virus infection had first occurred in pigs in Malaysia, although dogs, cats, and horses were also infected (reviewed in [130]). Hendra or Nipah virus infection in horses results in more severe disease than either virus causes in pigs (reviewed in [131]). Natural Hendra virus infection in horses is often severe and experimental infections are essentially uniformly fatal. The incubation period is 8–11 days and the animals initially become anorexic, depressed, with general uneasiness and ataxia, and become febrile with sweating. A severe and fatal respiratory disease will often rapidly progress. Neurological disease can also present but is less frequent [128, 132]. Infection is widespread with an endothelial cell tropism with syncytia [89], and virus can be recovered from a number of internal organs, including lung, and from saliva and urine [128, 133–135]. Experimental Nipah virus infection of horses has not been reported but a naturally infected horse had viral antigen and nonsuppurative meningitis [89].

In natural and experimental Nipah virus infection of pigs, the respiratory system is a primary target organ of virus replication and pathology, with viral antigen present in the respiratory epithelium and syncytia in small blood and lymphatic vessels [71, 89]. The involvement of the CNS appears less common, with meningitis or meningoencephalitis more common than encephalitis [71]. Nipah virus infection of Landrace piglets resulted in a mild clinical disease with fever and respiratory signs, but neurological disease could also appear [93]. Virus replication is seen in the respiratory system, the lymphoid tissues, and the CNS and was greatest in the respiratory system but syncytia were less frequent. Virus was recovered

from the respiratory, lymphatic, and nervous systems, and virus shedding was observed in nasal, pharyngeal, and ocular fluids. Experimental Hendra virus infection of pigs also resulted in a respiratory disease with possible CNS involvement. Hendra virus appeared to cause a more severe disease in pigs in comparison to Nipah virus, and Hendra virus shedding was noted in nasal, oral, rectal, and ocular fluids [97].

Cats were discovered to be susceptible to natural Nipah virus infection and disease in the Malaysian outbreak [89], and cats were later shown to be highly susceptible to infection and disease by both Hendra and Nipah virus. Hendra virus disease in cats is similar to that seen in horses, revealing widespread vasculitis and parenchymal lesions in the lungs and other tissues and organs [89, 133]. Experimental Nipah virus infection in the cat is similar to Hendra virus infection but with more extensive inflammation of the respiratory epithelium [71, 89, 91]. The systemic vasculitis seen in the cat model is consistent with the resulting pathology of Nipah virus infection in humans. In utero transmission of Nipah virus in cats has also been demonstrated with evidence of extensive viral replication in many tissues of a pregnant adult cat and in fetal tissues [136].

8.2.3 Hamsters and Ferrets

The golden hamster is the only small animal model of henipavirus infection that accurately reflects human pathology and was first described with Nipah virus challenge experiments [96] and later with Hendra virus [88]. Intranasally infected hamsters die 9–15 days later, displaying progressive signs of neurologic disease and breathing difficulties; viral genome is detectable in multiple organ systems and severe pathology is most evident in the brain [96]. Hendra virus infection of hamsters also yields pathology that resembles acute human Nipah virus cases [88], including widespread endothelial infection and vasculitis and parenchymal lesions, especially in the CNS. Henipavirus infection in hamsters with higher doses of either virus manifests greater respiratory disease, while lower doses yield greater neurological disease [112].

Ferrets are also an excellent model of henipavirus infection and disease [86, 137, 138]. Six to ten days after low dose oral-nasal challenge with Nipah virus, ferrets develop severe respiratory and neurological disease with widespread vasculitis and parenchymal lesions including the CNS neurons [86, 137]. Hendra virus-infected ferrets, with doses as low as 50 $TCID_{50}$, rapidly progressed with severe disease between 6 and 9 days following infection [138]. Clinical signs and Hendra virus-mediated disease were essentially identical to those observed with Nipah virus infection. Overall, the ferret model reproduces all the hallmarks seen in henipavirus-infected people.

8.2.4 Nonhuman Primates

The African green monkey accurately reproduces human Hendra virus and Nipah virus-mediated disease [87, 92]. Henipavirus infection of African green monkeys results in a uniformly lethal disease with low dose challenge by intratracheal inoculation within 7–10 days. Virus infection yields widespread vasculitis and endothelial and arterial smooth muscle cell syncytia formation in virtually all organs and tissues [87, 92]. Subjects develop severe respiratory disease; lungs show significant congestion, hemorrhage, polymerized fibrin, and viral antigen [87]. Monkeys infected with either Nipah or Hendra virus also exhibit neurological disease, along with vascular and parenchymal lesions in the brain including infection of neurons and significant involvement of the brainstem.

9 Control and Prevention

9.1 Preventing Henipavirus Outbreaks

Preventing henipavirus transmission from bats to domestic animals or humans depends on adopting regular practices that reduce transmission risk. A high index of suspicion for infection in intermediate hosts including horses in Queensland and pigs in Southeast Asia can identify potentially high-risk situations when increased attention to infection control can be lifesaving. Regular surveillance for henipavirus infection among domestic animals can better characterize the magnitude of risk and help to focus preventive efforts.

Healthcare providers should maintain a high index of suspicion for human infection with henipavirus among people who are at high risk for infection including veterinary healthcare providers in Queensland, people who raise pigs in Southeast Asia, and people in South Asia who either drink raw date palm sap or who recently provided care for persons with fever and mental status changes. Early recognition of human cases can identify high-risk situations and help to prevent additional infections.

9.1.1 Preventing Hendra Virus Spillover

The first step to prevent human infection with Hendra virus is to prevent Hendra virus infection in horses. Although the precise pathway the virus moves from *Pteropus* bats to horses is not defined, through 2009 all infected horses were stabled in open paddocks [139]. Prudent steps to minimize horse exposure to *Pteropus* saliva, urine, and birth products include placing horse feed and water containers under shelter and removing horses from open paddocks when nearby flowering and fruiting trees are attracting flying foxes [140]. Sick horses should be isolated from other horses [140].

Next, all persons who work with sick horses in Queensland and the surrounding area should recognize that a sick horse may be shedding Hendra virus. The very high levels of exposure to respiratory secretions and other body fluids among

human cases of Hendra virus infection, while most attendants were uninfected, suggest that modest steps to improve infection control, if consistently applied, could prevent transmission. People who have contact with horses in areas where Hendra virus infections have been recognized should minimize their contact with equine blood and body fluids especially when a horse develops a rapidly progressive febrile illness characterized by respiratory distress and frothy nasal discharge. Horse handlers should regularly wash their hands with soap and isolate sick horses from other horses and people [141]. If Hendra virus infection is suspected, horse handlers and veterinary personnel should wear personal protective equipment to protect their clothing, skin, and face from contact with horse blood or body fluids.

9.1.2 Preventing Nipah Virus Transmission

People who raise pigs in areas where *Pteropus* bats live should remove trees that are attractive to *Pteropus* bats from the immediate area where pigs are being raised.

In Bangladesh, the government is encouraging people to avoid drink fresh date palm sap, because of the risk of Nipah virus. Researchers have been exploring deploying barrier skirts around date palm sap trees during collection to prevent physical access of bats to the sap [79, 83]. These have been quite effective in excluding the bats, but only a small minority of date palm sap collectors are using barrier skirts. Combined efforts to discourage fresh sap consumption, or, if people insist on drinking fresh sap, to ensure that such sap was collected from a tree protected by a date palm skirt, are currently being evaluated.

Preventing person-to-person henipavirus transmission is part of a broader effort to reduce transmission of dangerous saliva-transmitted pathogens in low-income countries. In high-income countries, healthcare providers are professionals, trained on procedures to reduce risk of infection, and provided with disposable personal protective equipment to reduce their risk. In low-income countries, where families are the primary care providers [142, 143], they have no training in infection control, and they neither have the access to nor can afford infection control supplies. An active area of research is to identify practical strategies for low-resource settings that can reduce the risk of saliva-transmitted infections.

9.2 Limiting Human Disease

9.2.1 Antiviral Strategies

Ribavirin, a ribonucleoside analog with broad antiviral activity, was used in the Nipah virus outbreak in Malaysia. The morbidity and mortality among treated patients were significantly lower than was observed among untreated patients earlier in the outbreak [144], though it is unclear how much of this improved survival can be attributed to ribavirin. Chloroquine, an antimalarial drug first demonstrated to block the proteolytic processing of Hendra virus-F [145], was later shown to inhibit henipavirus infection in vitro [146]. Both ribavirin and chloroquine have been evaluated in vivo in animal challenge models. Ribavirin only delayed Nipah virus disease and death and had no benefit against Hendra virus infection in hamsters [147, 148]. Ribavirin therapy also only delayed Hendra virus disease and pathogenesis by 1 or 2 days in African green monkeys [92]. Chloroquine treatment, alone or in combination with ribavirin, had no therapeutic benefit in ferrets challenged with Nipah virus or in hamsters challenged with either Nipah virus or Hendra virus [137, 147, 148]. Ribavirin is still considered a possible treatment for henipavirus infection, though there is little additional evidence of benefit. In 2008, two Hendra virus-infected patients showed no discernible benefit after treatment with ribavirin [23], and combined treatment with chloroquine and ribavirin was unsuccessful in one Hendra virus-infected person in 2009 [149].

PolyIC$_{12}$U, a strong inducer of interferon-α and interferon-β production and a specific activator of the toll-like receptor 3 pathway (reviewed in [150]), blocked Nipah virus replication in cell culture and was tested in vivo against Nipah virus infection in the hamster model [148]. Continuous administration of polyIC$_{12}$U for 10 days beginning at the time of Nipah virus challenge prevented lethal disease in five of six animals. Further studies using TLR3 agonists such as PolyIC$_{12}$U as immunotherapeutic agents appear warranted.

Heptad peptide-based membrane fusion inhibitors corresponding to either of the heptad repeat (HR) domains of a paramyxovirus F glycoprotein can potently block virus infection in vitro (reviewed in [151]). HR-2 peptides have been used more often and act by blocking the formation of the 6-helix bundle structure in F which is required for virus and host cell membrane merger. A 36 amino acid HR-2-based F glycoprotein sequence (Nipah virus-FC2) [152] was the first one tested and it is analogous to the approved HIV-1-specific drug enfuvirtide (Fuzeon™). An HR-2 peptide derived from the human parainfluenza virus type-3 (hPIV3) F glycoprotein has also proved to be a potent Hendra virus fusion inhibitor [153]. A sequence-optimized and cholesterol-tagged hPIV3-based HR-2-derived peptide was tested in the Nipah virus hamster model [154] and showed it could penetrate the CNS and exhibit some effective therapeutic activity against Nipah virus. Peptide fusion inhibitors as henipavirus therapeutics are actively being investigated.

9.2.2 Passive Immunization Strategies

The henipavirus envelope glycoproteins are the major targets of virus-neutralizing antibodies (reviewed in [155]). Challenge studies carried out in hamsters demonstrated that protective passive immunotherapy with either Nipah virus G- or F-specific polyclonal antiserums or mouse monoclonal anti-

bodies (mAbs) was possible [88, 156, 157]. Using recombinant antibody techniques, henipavirus-neutralizing human mAbs specific for the G glycoprotein were isolated from a naïve human phage-displayed antibody library [158]. One mAb, m102, exhibited strong cross-reactive neutralization activity against both Hendra virus and Nipah virus and was affinity maturated yielding mAb m102.4 and converted to IgG1 format for production in a CHO-K1 cell line. The m102.4 mAb has exceptionally potent neutralizing activity and with 50 % inhibitory concentrations below 0.04 against Nipah virus and 0.6 μg/ml against Hendra virus [159]. The epitope recognized by m102.4 maps to the ephrin receptor binding site [160], and it neutralizes all known isolates of Hendra virus and Nipah virus [86].

The efficacy of m102.4 treatment in vivo has been examined in both the ferret and African green monkey models of Hendra virus and Nipah virus infection. In a pre- and postexposure Nipah virus challenge study in the ferret, animals were given a single 50 mg dose (~25 mg/kg) at 24 h before (pre-) or 10 h following (post-) challenge by intravenous infusion. Virus was administered oronasally as a 5,000 $TCID_{50}$ dose of Nipah virus (tenfold the minimal infectious dose – 50 %). Control ferrets became febrile with severe clinical illness and were euthanized by day 8, while one subject in the pre-group and all in the post-group were febrile with depression, but by day 10 fevers began to abate. At 13 days postinfection, 2/3 animals in the pre-group progressed with disease and were euthanized, whereas all other ferrets (3/3 in the post-group and 1/3 pre-group) were free of any disease signs and remained well until study end point. Control subjects revealed severe systemic pathology, and the two pre-group-treated animals which experienced a delayed disease course had markedly reduced pathology, but there was no pathology seen in any of the surviving ferrets [86]. Similar findings have been obtained in a Hendra virus challenge study in ferrets followed by m102.4 postexposure therapy (J Pallister and CC Broder 2012, unpublished).

The m102.4 human mAb has also recently been examined in the African green monkey henipavirus challenge model [161] as postexposure passive immunotherapy. Fourteen monkeys were challenged intratracheally with Hendra virus, and 12 animals were infused twice with a 100 mg dose (~20 mg/kg) of m102.4 beginning at 10, 24, or 72 h postexposure with the second infusion ~48 h later. All 12 animals that received m102.4 survived infection, whereas the untreated control subjects succumbed to severe systemic disease by day 8. Animals in a 72 h treatment group, where mAb therapy began 3 days after lethal challenge, exhibited neurological signs but recovered by day 16. At study end, there was no evidence of Hendra virus-specific pathology in any of the m102.4-treated animals. Further, no infectious Hendra virus could be recovered from any of the m102.4-treated animals. Essentially identical findings have been noted in a Nipah virus challenge and m102.4 postexposure therapy study conducted in African green monkeys (TW Geisbert and CC Broder 2014, submitted).

During the 2010 Hendra virus spillover occurrence in Queensland, Australia, two individuals considered to be at high risk of Hendra virus infection were offered m102.4 therapy on a compassionate use basis even though no human safety testing had been carried out and it was not recommended for use in humans. There were no adverse reactions resulting from infusion of the mAb and both individuals remain well. In July 2012, a third asymptomatic individual in Australia also received a 20 mg/kg dose of m102.4 following high-risk Hendra virus exposure, also with no adverse reaction [162].

9.2.3 Active Immunization Strategies

Active immunization strategies against Nipah virus infection was first examined in hamsters with an attenuated vaccinia virus strain (NYVAC) using recombinants prepared with either the Nipah virus F and G glycoprotein genes [156]. The vaccine demonstrated complete protection from Nipah virus-mediated disease but with evidence of Nipah virus replication and an anamnestic antibody response in challenged animals. Recombinant canarypox-based vaccine (ALVAC) candidates, encoding Nipah virus F and G glycoprotein genes, for use in pigs were tested by immunization of 4-week-old pigs twice within 2 weeks [163]. Each ALVAC vector was tested alone and in combination, and piglets were challenged intranasally with Nipah virus. All pigs were protected from Nipah virus-mediated disease by either vector alone or in combination. The individual ALVAC-F- and ALVAC-G-vaccinated animals had only low levels of detectable virus shedding by nucleic acid analysis but no infectious virus could be recovered, while the combined vaccination with ALVAC-F/G appeared superior with neither infectious virus nor Nipah virus RNA being detected. These data suggest that an ALVAC-G or combination vector formulation could serve as a protective vaccine against Nipah virus disease in pigs but the combination of vectors would be needed to assure the prevention of virus shedding [163].

A subunit vaccine strategy for henipaviruses has been extensively explored using a soluble oligomeric form of the G glycoprotein (sG) [164] and Hendra virus-sG is now commercially deployed as a livestock vaccine [165]. Hendra virus-sG, produced by recombinant expression in mammalian cell culture and properly N-linked glycosylated [166], retains its oligomeric form and ability to bind ephrin receptors [99]. Hendra virus-sG elicits potent cross-reactive neutralizing antibody responses in a variety of animals and presents more cross-reactive epitopes (anti-Nipah virus G antibodies) as compared to sG from Nipah virus [167]. Henipavirus sG vaccination was first tested in the Nipah virus cat model with both Hendra virus-sG and Nipah virus-

sG administered as three 100 μg doses 3 weeks apart. Both immunogens induced a completely protective humoral immune response against lethal subcutaneous Nipah virus challenge [91]. A follow-up study examined lower levels of pre-challenge neutralizing antibody titers together with a high-dose oronasal challenge of Nipah virus [168]. Two doses of either 50, 25, or 5 μg of Hendra virus-sG formulated spaced by 3 weeks were tested. All vaccinated animals were completely protected from a high-dose oronasal challenge of Nipah virus (50,000 $TCID_{50}$). Hendra virus-sG immunization has also been tested in the ferret model [138]. Ferrets were immunized twice with a 20-day interval with either a 100, 20, or 4 μg dose of Hendra virus-sG. Animals were challenged oronasally with a 5,000 $TCID_{50}$ dose (tenfold the minimal infectious dose 50 %), and all vaccinated ferrets remained free of any signs of fever or clinical disease. Postmortem examination of vaccinated animals showed all subjects completely normal except one of four animals in the lowest dose group. There was no evidence of virus or viral genome in any tissues or samples from animals in the 100 and 20 μg vaccine groups. Only a very low level of genome was detected in the nasal washes in one animal in the 4 μg group. No virus was recovered from any vaccinated animal.

Recently, Hendra virus-sG vaccination of African green monkeys followed by intratracheal Nipah virus challenge [169] or Hendra virus challenge (Geisbert and Broder, unpublished) has demonstrated complete protection from henipavirus infection and disease with no recoverable virus or evidence of virus shedding. The application of Hendra virus-sG as an equine vaccine against Hendra virus infection has been tested as a strategy to prevent both infection and virus shedding [170]. Several vaccination and Hendra virus challenge studies have been carried out in Australia; at the high-containment biological safety level 4 (BSL-4) facilities of the Animal Health Laboratories (AAHL), Commonwealth Scientific and Industrial Research Organisation (CSIRO), in Geelong. The Hendra virus-sG was used to immunize horses (2 doses) and both a high and a low dose of Hendra virus-sG antigen were examined. Horses were challenged with a high oronasal dose of Hendra virus (2×10^6 $TCID_{50}$), and to date, all vaccinated horses have remained clinically disease-free with no evidence of virus replication or virus shedding following virus challenge [165]. Development of the equine vaccine against Hendra virus was a collaborative effort among investigators of the US and Australian Government laboratories and private industry. On November 1, 2012, the Hendra virus horse vaccine called Equivac HeV® was released for use in Australia, and it is the first vaccine licensed and commercially deployed for public use against a BSL-4 agent. Preclinical development of Hendra virus-sG in vaccine formulations that could potentially be suitable for use in humans is in progress.

10 Unresolved Problems

The contribution of strain differences within henipaviruses to observed epidemiological differences is an open question. Are some strains of henipavirus more likely to infect humans, more likely to cause a primary respiratory disease and more likely to cause person-to-person transmission than other strains? If strain differences confer different infectious competencies, what are the genetic characteristics that underlie these competencies? We do not yet have enough strains of henipavirus, paired with detailed epidemiological information to resolve these questions, but continued careful outbreak investigation and collection of additional isolates may provide additional insight. Collecting additional strains may also clarify how much genetic variation occurs within the henipavirus genome. Ultimately, a better understanding of genetic diversity and the relationship between genomic differences and epidemiology would permit a sound assessment of the risk of spillover of a henipavirus strain capable of sustained person-to-person transmission.

Studies in non-*Pteropus* bats from China and Ghana [171, 172], pigs in Ghana [173], and cattle and goats in Bangladesh [174] have identified antibodies against henipavirus, but the serum neutralizes neither Nipah nor Hendra virus-infected cells. These serological results as well as the PCR fragments of henipavirus identified in feces of *E. helvum* suggest the existence of other henipaviruses. Isolating the specific viruses and exploring their ecology and the impact of such infections on animals including humans would broaden our understanding of the diversity and risk of henipaviruses.

While human infections with Hendra and Nipah virus have a remarkably high case fatality rate, human infection is rare. Australian animal handlers regularly care for sick horses without complications. Bangladeshi villagers have been enjoying raw date palm sap for generations with only a very small proportion of people enjoying this local delicacy suffering any adverse effect. This rarity of adverse outcomes means that most persons at risk for henipavirus infections never observe a connection between their own behavior and a health outcome. This represents a substantial barrier to adopting and maintaining behaviors to reduce their risk.

This small number of human infections also means that with limited budgets and competing priorities, prevention efforts have to be extremely low cost in order to be cost-effective. Although the m102.4 mAb has been remarkably effective in animal studies and is presently in preclinical development stages in both the United States and Australia, there have been insufficient financial commitments from either government or private industry to support further developmental costs including human safety testing trials.

Because of the high economic value of competition horses, the high mortality associated with Hendra virus infection, and the subsequent risk to people living in a high-income country,

there is a potential private market among horse owners for an effective livestock vaccine against Hendra virus. Indeed, Hendra virus-sG subunit vaccine is now sold as an equine vaccine. If henipavirus infections are recurrently recognized to infect domestic pigs, it's possible that pig producers will adopt vaccination, but the lower economic value of pigs and the lower severity of henipavirus infection in pigs means that many pig owners will be reluctant to invest in vaccine to protect their pigs. The rapid reproductive rate of pigs also makes routine immunization logistically demanding and so more expensive.

The Hendra virus-sG subunit immunogen has shown remarkable cross-protective efficacy in four mammalian species, and recent preliminary data suggests that the Hendra virus-sG subunit vaccine could be developed for human use. Because of concerns that henipaviruses may be adapted as a bioterror agent [175], there is some potential market for such a vaccine. A human vaccine would also be useful to protect the small number of laboratory workers engaged in studies with henipaviruses, biologists working with bats, and veterinarians and staff working with sick horses in Australia, but developing such a vaccine would require substantial additional investment. A human henipavirus virus vaccine is unlikely to be developed by private industry unless a clear and substantial demand from governments concerned with the threat of bioterrorism or deploying a vaccine strategy to reduce pandmic risk ensures a market. The incidence of Nipah virus in Bangladesh is too low for a vaccination program to be cost-effective in the foreseeable future if the sole objective is preventing an average of 20 human cases per year. However, if the risk of emergence of a strain of Nipah virus capable of efficient person to person transmission is high enough, then vaccination may represent a cost effective investment in pandemic prevention.

Paramyxoviruses: Measles

23

William J. Moss and Diane E. Griffin

1 Introduction

Measles is one of the most important infectious diseases of humans and has caused millions of deaths since its emergence as a zoonotic disease thousands of years ago. For infectious disease epidemiologists, measles has served as an exemplary model of an acute infectious disease conferring lifelong immunity to reinfection. Kenneth Maxcy, the second chair of the Department of Epidemiology at the Johns Hopkins University School of Public Health, wrote in 1948, "The simplest of all infectious diseases is measles" [1]. Despite the apparent simplicity, much has been learned about measles in the 60 years since Maxcy's chapter on the epidemiology of infectious diseases. Detailed investigations of the virology, immunology, epidemiology, and transmission dynamics have shown measles to be a much more complex disease than Maxcy's statement suggests. This ignorance, however, has not impeded global measles control. Remarkable progress has been made in reducing measles morbidity and mortality through measles vaccination programs. This achievement attests to the enormous public health significance of measles vaccines. However, this progress is threatened by failures to maintain high levels of measles vaccine coverage and population immunity. Strategies for the global eradication of measles are currently being considered.

2 Historical Background

Measles virus is closely related to rinderpest virus, a recently eradicated Morbillivirus pathogen of cattle, and measles likely evolved as a zoonotic infection in communities where cattle and humans lived in close proximity. Measles virus is believed to have become established as a human pathogen approximately 5,000–10,000 years ago when communities achieved sufficient population size in Middle Eastern river valley civilizations to maintain virus transmission [2]. The earliest extant descriptions of measles are those of Abu Becr, also known as Rhazes, who wrote a treatise on measles and smallpox in the tenth century. Interestingly, he considered measles to be the more severe of the two diseases. Linguistic evidence suggests that measles was recognized as a distinct disease between 450 and 650 AD. In the mid-eighteenth century, Francis Home attempted to prevent measles through inoculation of blood obtained from the skin of an afflicted individual, analogous to Jenner's approach to preventing smallpox.

The first to explicitly document the contagious nature of measles was the Danish physician Peter Panum during an outbreak of measles on the sparsely populated Faroe Islands in 1846. Through careful documentation of clinical cases, Panum provided accurate measurement of the incubation period for measles and evidence of the long-term protective immunity conferred by measles [3]. Specifically, Panum observed that adults who acquired measles during the prior outbreak six decades earlier were protected from disease, despite absence of exposure to measles between epidemics.

Attenuated and killed measles vaccines were introduced in the 1960s after successful isolation and growth of measles virus in tissue culture by John Enders [4] and further attenuation of measles vaccine virus by Maurice Hilleman. As a consequence of high levels of measles vaccine coverage, the WHO Region of the Americas interrupted indigenous transmission of measles virus in 2002. The Measles Initiative (now the Measles and Rubella Initiative) was founded in

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_23,

2001 as a partnership committed to reducing global measles mortality and has been instrumental in providing technical and financial support for measles control activities.

3 Methods for Epidemiologic Analysis

3.1 Clinical and Laboratory Diagnosis of Measles

Epidemiologic studies of measles require accurate diagnosis and valid case series. The characteristic clinical features of measles are of sufficient sensitivity and specificity to have high predictive value in regions where measles is endemic and allow for epidemiologic analyses of measles case series over many decades. However, laboratory confirmation is necessary, particularly where measles virus transmission rates are low or in immunocompromised persons who may not develop the characteristic clinical manifestations. Infection with rubella virus, parvovirus B19, human herpes virus 6, and dengue viruses may mimic measles. Detection of IgM antibodies to measles virus by enzyme immunoassay (EIA) is the most commonly used method to diagnose measles [5]. Alternatively, seroconversion using IgG-specific EIA or virus neutralization assays can be used to diagnose measles based on testing serum or plasma obtained during acute and convalescent phases. Serologic surveys to detect measles virus-specific IgG antibodies using blood or oral fluid samples provide age-specific data on population immunity and the average age of infection, from which the force of infection can be derived [6].

Measles virus can be isolated in tissue culture from white blood cells, respiratory tract secretions, and urine, although the ability to isolate measles virus diminishes quickly after rash onset. Amplification and detection of measles virus RNA by reverse transcription polymerase chain reaction (RT-PCR) from blood, urine, and nasal discharge is highly sensitive in detecting measles virus RNA and allows sequencing of the measles virus genome for molecular epidemiologic studies.

3.2 Molecular Epidemiology

Although measles virus is considered to be monotypic, variability within the genome is sufficient to allow for molecular epidemiologic investigations. Genetic characterization of wild-type measles viruses is typically based on sequence analysis of the genes coding for the nucleocapsid (N), hemagglutinin (H), and phospho (P) proteins [7, 8]. One of the most variable regions of the measles virus genome is the 450-nucleotide sequence at the carboxy-terminal of the N protein, with up to 12 % variability between wild-type viruses. The World Health Organization recognizes eight clades of measles virus (designated A through H) and 24 subclades or genotypes (Fig. 23.1) [9]. New genotypes may be identified with enhanced surveillance and molecular characterization. As measles control efforts intensify, molecular surveillance of circulating measles virus strains can be used to document interruption of measles virus transmission and identify the source and transmission pathways of measles virus outbreaks [10, 11]. Six genotypes have not been reported since at least 2000, and an additional five genotypes have not been reported since 2006, despite enhanced surveillance efforts [9], and may be inactive. A global database for measles virus genotypes was developed by the World Health Organization LabNet to collate information generated from enhanced measles virus surveillance activities (http://www.who-measles.org/Public/Web_Front/main.php).

3.3 Modeling Measles Virus Transmission Dynamics

Because of characteristic epidemic cycles and historical case series, measles has served as a model for understanding the transmission dynamics of an acute infectious disease and the impact of vaccination strategies. Mathematic modeling of measles dynamics was first attempted 100 years ago by Sir William Hamer [12]. The basic principle underlying early models was the law of mass action, in which the periodicity of measles incidence was described as a function of the changing number of infectious and susceptible persons as they contact one another. The number of susceptible persons, in turn, was determined by the introduction of new susceptibles through birth and the removal of susceptibles through the acquisition of protective immunity following infection. However, the epidemic cycles generated by these simple deterministic models approached a steady state, losing their periodicity. The introduction of stochastic (chance) and seasonal processes resulted in models of measles epidemics that closely resembled observed data. Further development of these models allowed for predictions of the impact of vaccination strategies on various epidemiologic characteristics of measles virus transmission, including the increase in the average age of infection and the interepidemic period [13]. More sophisticated models of measles virus transmission dynamics have investigated the role of nonlinear dynamics in temporal and spatial patterns of measles incidence [14], traveling waves of infection originating in large cities and spreading to small towns [15], seasonality [16], and the loss of spatial synchrony in measles epidemics following the introduction of measles vaccination [17].

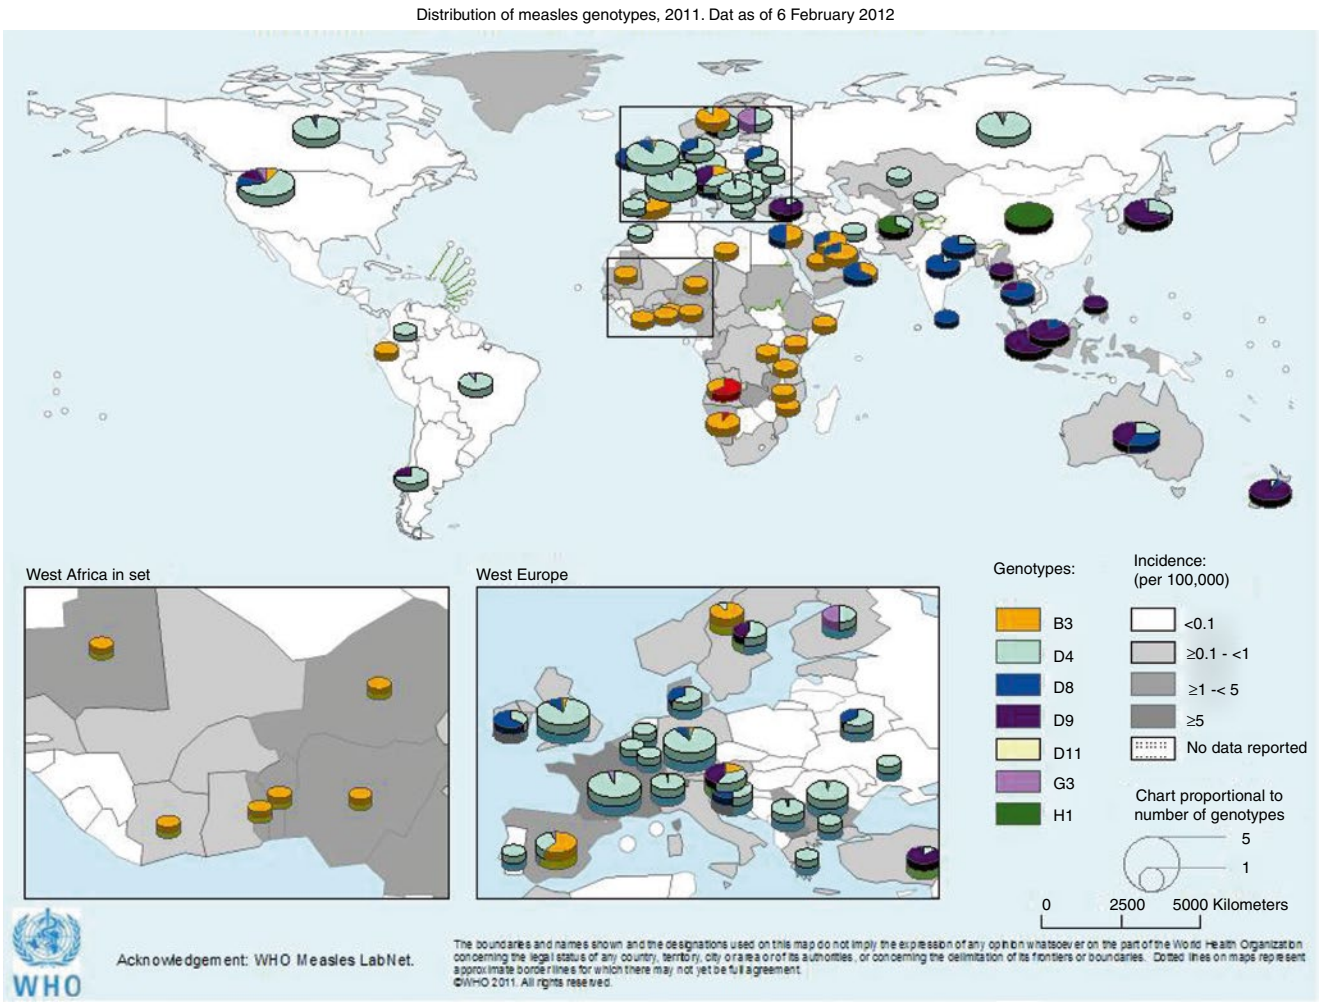

Fig. 23.1 Distribution of measles virus genotypes, 2011 (Source: World Health Organization http://www.who.int/immunization_monitoring/diseases/measles_monthlydata/en/index1.html)

4 Biologic Characteristics

Measles virus is a spherical, nonsegmented, single-stranded, negative-sense RNA virus and a member of the *Morbillivirus* genus in the family of Paramyxoviridae. Although RNA viruses have high mutation rates, measles virus is considered to be an antigenically monotypic virus, meaning that the surface proteins responsible for inducing protective immunity have retained their antigenic structure across time and space. The public health significance is that measles vaccines developed decades ago from a single measles virus strain remain protective worldwide. Measles virus is killed by ultraviolet light and heat, and attenuated measles vaccine viruses retain these characteristics, necessitating a cold chain for transporting and storing measles vaccines.

The measles virus RNA genome consists of approximately 16,000 nucleotides and is encapsalated and enclosed in a lipid-containing envelope derived from the host cell. The genome encodes eight proteins, two of which (V and C) are nonstructural proteins expressed from the P gene. Of the six structural proteins, P, large protein (L), and N form the nucleocapsid housing the viral RNA. The H, F, and matrix (M) proteins, together with lipids from the host cell membrane, form the viral envelope. This relatively simple combination of proteins and ribonucleic acid has evolved to be one of the most highly infectious, directly transmitted agents known and the cause of millions of human deaths.

In terms of understanding the epidemiology and control of measles, the two surface proteins F and H are most important. The H protein interacts with F to mediate fusion of the viral envelope with the host cell membrane [18]. The primary function of the H protein is to bind to the host cellular receptors for measles virus. The H protein elicits strong immune responses, and the lifelong immunity that follows infection is due primarily to neutralizing antibodies against H.

Three cellular receptors have been identified: CD46, CD150 (SLAMF1), and nectin-4. CD46 is a complement regulatory molecule expressed on all nucleated cells in humans. SLAMF1, an acronym for signaling lymphocyte activation molecule family member 1, is expressed on activated T and B lymphocytes and antigen-presenting cells. Nectin-4, the most recently identified receptor, is an adherens junction protein found on epithelial cells [19, 20]. The distribution of these host proteins determines the tissue tropism and cell types infected by measles virus. Wild-type measles virus enters cells primarily through the cellular receptor SLAMF1, and most vaccine strains can use CD46 as a receptor, although wild-type measles virus may use both CD46 and SLAMF1 as receptors during acute infection [21]. Nectin-4 permits measles virus to enter the basolateral surface of respiratory epithelial cells.

5 Descriptive Epidemiology

5.1 Disease Burden

The disease burden due to measles has decreased as a result of several factors. Measles mortality declined in developed countries in association with economic development, improved nutritional status, and supportive care, particularly antibiotic therapy for secondary bacterial pneumonia. Remarkable progress in reducing measles incidence and mortality has been, and continues to be, made in resource-poor countries as a consequence of increasing measles vaccine coverage, provision of a second dose of measles vaccine through supplementary immunization activities (SIA), and efforts by the World Health Organization, the United Nations Children's Fund (UNICEF), and their partners to target endemic countries for accelerated and sustained measles mortality reduction. Specifically, this targeted strategy aimed to achieve greater than 90 % measles vaccination coverage in every district and ensure that all children received a second dose of measles vaccine. Provision of vitamin A as a part of polio and measles SIAs has probably contributed further to the reduction in measles mortality.

In 2003, the World Health Assembly endorsed a resolution that urged member countries to reduce the number of deaths attributed to measles by 50 % compared with 1999 estimates by the end of 2005. This global public health target was met, with estimated measles mortality reduced by 60 % from an estimated 873,000 deaths in 1999 (uncertainty bounds 634,000–1,140,000) to 345,000 deaths in 2005 (uncertainty bounds 247,000–458,000) [22]. Further reductions in global measles mortality were achieved by 2008, during which there were an estimated 164,000 deaths due to measles (uncertainty bounds 115,000 and 222,000 deaths) (Fig. 23.2) [23]. Using a refined model to estimate measles mortality, the number of deaths attributed to measles declined 74 % from an estimated

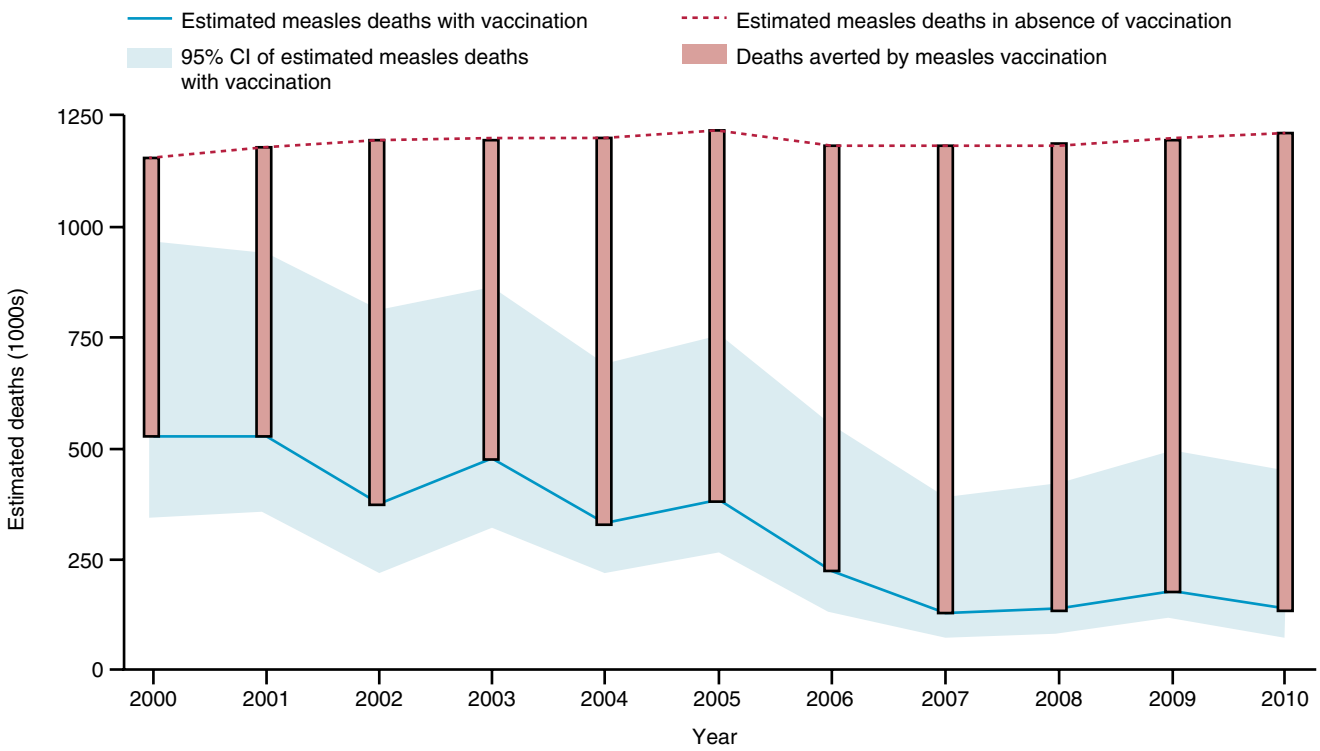

Fig. 23.2 Global estimated measles nortality and measles deaths averted (Source: World Health Organization [23])

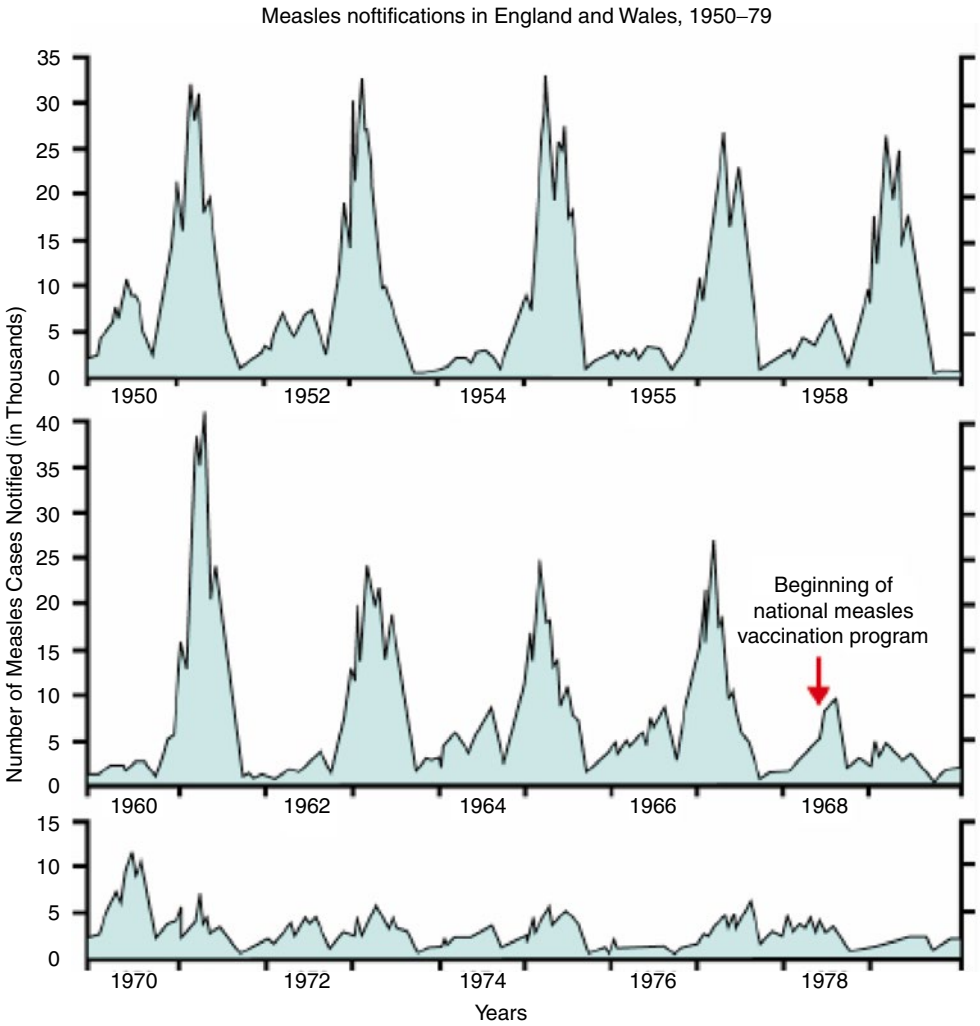

Fig. 23.3 Epidemic cycles of measles cases in England and Wales by week, 1950–1979. The *arrow* indicates the beginning of the national measles vaccination program in 1968 (Source: Fine and Clarkson [26])

535,000 in 2000 (95 % confidence intervals 347,200–976,400) to an estimated 139,000 deaths in 2010 (71,200–447,800) [24]. Prior to this effort, an estimated 30 million cases of measles occurred each year, with more than one million deaths.

5.2 Geographic Distribution

Measles is a global disease but was absent from the Americas prior to contact with Europeans. Measles, in combination with smallpox, likely was responsible for large numbers of deaths of Native Americans, facilitating European conquest [25]. Progress in measles elimination efforts has resulted in the interruption of measles virus transmission in large geographic regions, including the Americas. Because of its mode of transmission and high infectivity, measles virus is most readily maintained in densely populated urban settings. Migration of infected persons to rural areas results in outbreaks in susceptible rural populations too small to sustain measles virus transmission. An extreme example occurs in isolated island populations where periodic introduction of measles virus results in widespread but self-limited outbreaks.

5.3 Temporal Patterns and Seasonality

Measles incidence has a typical temporal pattern characterized by yearly seasonal epidemics superimposed upon longer epidemic cycles of 2–5 years or more (Fig. 23.3). These epidemic cycles have been well documented over many decades in different geographic locations and have been characterized analytically in both simple and sophisticated mathematic models. In temperate climates, annual measles outbreaks typically occur in the late winter and early spring. These annual outbreaks are likely the result of social networks facilitating transmission (e.g., congregation of children at school) and environmental factors favoring the viability and transmission of measles virus [26]. In the tropics, measles outbreaks have variable relationships with rainy seasons, which combined with high birth rates result in highly irregular, large measles outbreaks [16].

Measles cases continue to occur during the interepidemic period in large populations but at low incidence. The longer cycles occurring every several years result from the accumulation of susceptible persons over successive birth cohorts and the subsequent decline in the number of susceptibles following an outbreak. In the absence of a vaccination program, these longer epidemic cycles tend to occur every 2–4 years. Measles vaccination programs that achieve coverage rates in excess of 80 % extend the interepidemic period to 4–8 years by reducing the number of susceptibles.

5.4 Reservoir

Humans are the only reservoir for measles virus, a fact important for the potential eradication of measles. Nonhuman primates may be infected with measles virus and develop an illness similar to measles in humans, with rash, coryza, and conjunctivitis. However, populations of wild monkeys are not of sufficient size to maintain measles virus transmission [2, 27].

5.5 Incubation Period

The incubation period for measles, the time from infection to clinical disease, is approximately 10 days to the onset of fever and 14 days to the onset of rash, with a median of 12.5 days (95 % confidence intervals 11.8–13.3 days) [28]. The incubation period may be shorter in infants or following exposure to a large inoculum of virus, and it may be longer in adults. During this seemingly quiescent period, the virus is replicating and infecting target tissues. The incubation period is best measured during outbreaks in which the time of exposure to the index case can be precisely determined.

5.6 Infectious Period

The infectious period is more difficult to measure than the incubation period as it requires careful observation of the contacts of exposed persons prior to the onset of rash. Generally, persons with measles are infectious for several days before and after the onset of rash, when titers of measles virus in the blood and body fluids are highest. The fact that measles virus is contagious prior to the onset of recognizable disease hinders the effectiveness of quarantine measures. Detection of measles virus in body fluids by a variety of means, including identification of multinucleated giant cells in nasal secretions or the use of RT-PCR, suggests the potential for prolonged infectious periods in persons immunocompromised by severe malnutrition or human immunodeficiency virus (HIV) infection [29, 30]. However, whether detection of measles virus by these methods indicates prolonged contagiousness is unclear.

5.7 Average Age of Infection

The average age of measles virus infection depends upon the rate of contact with infected persons, the rate of decline of protective maternal antibodies, and the vaccine coverage rate. Young infants in the first months of life are protected against measles by maternally acquired IgG antibodies. An active transport mechanism in the placenta is responsible for the transfer of IgG antibodies from the maternal circulation to the fetus starting at about 28 weeks' gestation and continuing until birth [31]. Three factors determine the degree and duration of protection in the newborn: (1) the level of maternal anti-measles virus antibodies, (2) the efficiency of placental transfer, and (3) the rate of catabolism in the child. Although providing passive immunity to young infants, maternally acquired antibodies can interfere with the immune responses to the attenuated measles vaccine by inhibiting replication of vaccine virus. In general, maternally acquired antibodies are no longer present in the majority of children by 9 months of age, the time of routine measles vaccination in many countries [32]. The half-life of anti-measles antibodies was estimated to be 48 days in the United States and Finland, but it is shorter in developing countries. Women with vaccine-induced immunity tend to have lower anti-measles virus antibody concentrations than women with naturally acquired immunity, and their children may be susceptible to measles at an earlier age [33]. Infants born to HIV-infected women may have lower levels of protective maternal antibodies independent of their HIV infection status and also may be susceptible to measles at a younger age [34].

In densely populated urban settings with low vaccination coverage rates, measles is a disease of young children. The cumulative distribution can reach 50 % by 1 year of age, with a significant proportion of children acquiring measles virus infection before 9 months, the age of routine vaccination. As measles vaccine coverage increases, or population density decreases, the age distribution shifts toward older children. In such situations, measles cases predominate in school-age children. Infants and younger children, although susceptible if not protected by immunization, are not exposed to measles virus at a rate sufficient to cause a large disease burden in this age group. As vaccination coverage increases further, the age distribution of cases may be shifted into adolescence and young adults, necessitating targeted measles vaccination programs for these older age groups.

5.8 Infectivity

Measles virus is one of the most highly contagious, directly transmitted infectious agents, and outbreaks can occur in populations in which fewer than 10 % of persons are susceptible. Chains of transmission commonly occur among household contacts, school-age children, and healthcare workers.

The contagiousness of measles virus is best expressed by the basic reproductive number R_o, which represents the mean number of secondary cases that arise if an infectious case is introduced into a completely susceptible population [35]. R_o can be empirically measured, although the introduction of measles virus into a completely susceptible population is rare. In the 1951 measles epidemic in Greenland, the index case attended a community dance during the infectious period resulting in a R_o of 2000 [36]. R_o also may be estimated from the average age of infection (A), the life expectancy (L), and the duration of protection from maternally acquired antibodies (M) using the following equation:

$$R_o = \frac{L\text{-}M}{A\text{-}M}$$

The average age of infection can be inferred from age-specific seroprevalence data in the absence of vaccination. The estimated R_o for measles virus is 12–18 [13], in contrast to only 5–7 for smallpox virus and polioviruses. The high infectivity of measles virus implies that a high level of population immunity is required to interrupt measles virus transmission.

5.9 Herd Immunity Threshold

Interruption of measles virus transmission does not require that all persons be immunized and protected. If a sufficient proportion of the population is immune, the probability that an unprotected person will encounter an infectious individual is reduced to almost zero. Protection of unvaccinated persons by a reduction in the risk of exposure is referred to as herd immunity [37, 38], and the level of population immunity necessary to interrupt transmission is known as the herd immunity threshold (H). The herd immunity threshold can be derived using analytical models of infectious disease dynamics from the equation

$$H = 1\text{-}1/R_o$$

where R_o is the basic reproductive number [13]. A number of assumptions are made in deriving this formula, including the unrealistic assumption of homogenous mixing of the population (i.e., an individual has an equal chance of coming into contact with any other individual). Nevertheless, this simple equation provides a means of assessing the level of population immunity required to interrupt transmission based upon a measure of infectivity (R_o). For measles, with a R_o of 12–18, the herd immunity threshold is 93–95 %. This does not represent the level of vaccine coverage but the proportion of the population protected against measles. This level of population immunity cannot be achieved with a single dose of measles vaccine, for which the primary vaccine failure rate is about 15 % when administered at 9 months of age.

5.10 Critical Community Size

To provide a sufficient number of new susceptibles through births to maintain measles virus transmission, a population size of several hundred thousand persons with 5,000–10,000 births per year is required [2]. Measles virus is believed to have become established in human populations about 5,000–10,000 years ago when human populations achieved sufficient size in the Middle Eastern river valley civilizations to maintain virus transmission. The critical community size is a key parameter for the persistence of measles virus transmission in insular populations [2, 39].

6 Mechanisms and Routes of Transmission

Measles virus is transmitted primarily by respiratory droplets small enough to traverse several feet but too large to remain suspended in the air for long periods of time. The symptoms induced during the prodrome, particularly sneezing and coughing, enhance transmission. Measles virus also may be transmitted by the airborne route, suspended on small particles for a prolonged time [40]. Direct contact with infected secretions can transmit measles virus, but the virus does not survive long on fomites as it is quickly killed by heat and ultraviolet radiation.

7 Pathogenesis and Immunity

7.1 Pathogenesis of Measles Virus Infection

Respiratory droplets from infected persons serve as vehicles of transmission by delivering infectious virus to respiratory tract mucosa of susceptible hosts. During the incubation period, measles virus replicates and spreads within the infected host. In the standard model of measles virus pathogenesis, viral replication occurs initially in epithelial cells in the upper respiratory tract and the virus spreads to local lymphatic tissue (Fig. 23.4). Replication in local lymph nodes is followed by viremia and the dissemination of measles virus to many organs, including lymph nodes, skin, kidney, gastrointestinal tract, and liver, where the virus replicates in epithelial and endothelial cells as well as in lymphocytes, monocytes, and macrophages. In a rhesus macaque model, the predominant cell types infected by measles virus were $CD150^+$ cells and dendritic cells [41]. Recently, an additional model of measles virus pathogenesis was proposed in which measles virus enters respiratory epithelial cells from infected lymphocytes and monocytes through the basolateral surface [42, 43]. Virus then buds from the apical surface, allowing for respiratory transmission.

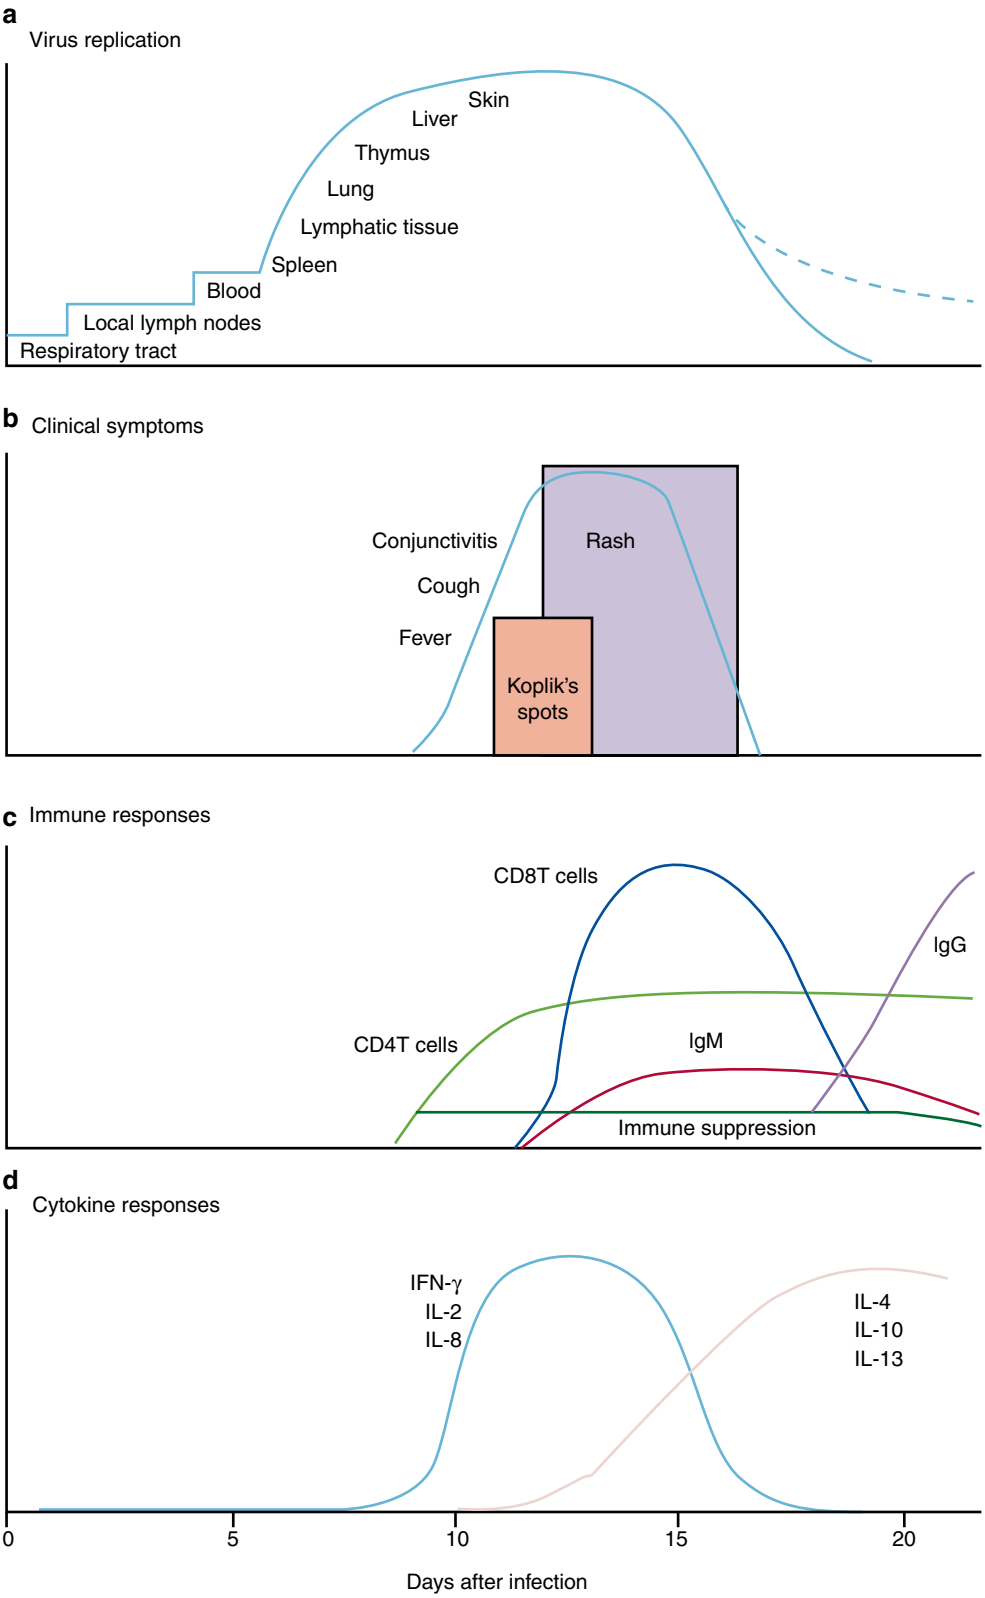

Fig. 23.4 Basic pathogenesis of measles virus infection. (**a**) Virus infection starts in the respiratory tract and then spreads to infect multiple organs including lymphoid tissue, liver, lungs, and skin. Virus clearance begins with the onset of rash. Clearance of infectious virus is complete 20 days after infection but viral RNA persists at multiple sites. (**b**) Clinical signs and symptoms begin about 10 days after infection with prodromal symptoms of fever, conjunctivitis and appearance of Koplik's spots followed by the maculopapular rash that lasts 3–5 days. (**c**) The rash is a manifestation of the adaptive immune response with infiltration of CD4+ and CD8+ T cells into sites of virus replication and initiation of virus clearance. There is a rapid activation, expansion, and then contraction of virus-specific CD8+ T cells. The CD4+ T cell response appears at the same time, but activation is prolonged. Measles-virus specific IgM appears with the rash and is commonly used to confirm the diagnosis of measles. This is followed by the sustained synthesis of measles-virus-specific IgG. Immune suppression is evident during acute disease and for many weeks after recovery. (d) Cytokines and chemokines that are produced during infection in sufficient quantities to be found in increased concentrations in plasma are of several distinct types. Shortly after infection, the chemokine IL-8 is increased. During rash, IFN-γ and IL-2 are produced by activated type 1 CD4+ T cells and by CD8+ T cells. After resolution of the rash, type 2 and regulatory CD4+ T cells produce IL-4, IL-10, and IL-13. *Dashed line* viral RNA, *IFN* interferon, *IL* interleukin.

Although measles virus infection is clinically inapparent during the incubation period, the virus is actively replicating and the host immune responses are developing. Evidence of these processes can be detected. During the incubation period, the number of circulating lymphocytes is reduced (lymphopenia). Measles virus can be isolated from the nasopharynx and

blood during the later part of the incubation period and in the several-day prodromal period prior to the onset of rash when levels of viremia are highest. The prodrome ends with the appearance of the measles rash. The rash results from measles virus-specific cellular immune responses and marks the beginning of viral clearance from blood and tissue. Clearance of infectious virus from the blood and other tissues occurs within the first week after the appearance of the rash, although measles virus RNA can be detected in body fluids of some children for at least 3 months using a PCR-based assay [29, 44].

7.2 Immune Responses to Measles Virus

Host immune responses to measles virus are essential for viral clearance, clinical recovery, and the establishment of long-term immunity. Early nonspecific (innate) immune responses occur during the prodromal phase of the illness. These innate immune responses contribute to the control of measles virus replication before the onset of more specific (adaptive) immune responses [45]. The adaptive immune responses consist of measles virus-specific humoral (antibody) and cellular responses. The protective efficacy of antibodies to measles virus is illustrated by the immunity conferred to infants from passively acquired maternal antibodies and the protection of exposed, susceptible individuals following administration of anti-measles virus immune globulin [46]. The first measles virus-specific antibodies produced after infection are of the IgM subtype (Fig. 23.4). The IgM antibody response is typically absent following re-exposure or revaccination and serves as a marker of primary infection. IgA antibodies to measles virus are found in mucosal secretions. The most abundant and most rapidly produced antibodies are against the N protein, and the absence of antibodies to N protein is the most accurate indicator of seronegativity to measles virus. Although not as abundant, antibodies to H and F proteins are responsible for virus neutralization and are sufficient to provide protection against measles.

Evidence for the importance of cellular immunity to measles virus clearance is demonstrated by the ability of children with agammaglobulinemia (congenital inability to produce antibodies) to fully recover from measles, whereas children with severe defects in T-lymphocyte function often develop severe or fatal progressive disease [47]. $CD4^+$ and $CD8^+$ T lymphocytes are activated in response to measles virus infection (Fig. 23.4) [48]. $CD4^+$ T cells secrete cytokines capable of modulating the humoral and cellular immune responses (Fig. 23.4) [49]. The initial predominant Th1 response (characterized by IFN-γ) is essential for viral clearance, and the later Th2 response (characterized by IL-4) promotes the development of measles virus-specific antibodies. $CD8^+$ T cells are cytotoxic and important for control and clearance of infectious virus [50, 51].

The duration of protective immunity following wild-type measles virus infection is generally thought to be life long [52]. The immunologic mechanisms involved in sustaining high levels of neutralizing antibody to measles virus are not completely understood, although general principles of immunologic memory probably govern this process. Immunologic memory to measles virus includes both continued production of measles virus-specific antibodies by long-lived plasma cells in the bone marrow and the circulation of measles virus-specific $CD4^+$ and $CD8^+$ T lymphocytes [53]. Although immune protection is best correlated with the levels of anti-measles virus antibodies, long-lasting cellular immunity almost certainly plays an important role in protection from infection and disease.

Measles vaccines also induce both humoral and cellular immune responses. Antibodies first appear between 12 and 15 days after vaccination and peak at 21–28 days. IgM antibodies appear transiently in blood, IgA antibodies are predominant in mucosal secretions, and IgG antibodies persist in blood for years. Vaccination also induces measles virus-specific T lymphocytes. Although both humoral and cellular responses can be induced by measles vaccine, they are of lower magnitude and shorter duration compared to those following wild-type measles virus infection.

7.3 Immune Suppression

The intense immune responses induced by measles virus infection are paradoxically associated with depressed responses to unrelated (non-measles virus) antigens, lasting for several weeks to months beyond resolution of the acute illness [54]. This state of immune suppression enhances susceptibility to secondary bacterial and viral infections causing pneumonia and diarrhea and is responsible for much of the morbidity and mortality attributed to measles. Delayed-type hypersensitivity (DTH) responses to recall antigens, such as tuberculin, are suppressed [55], and cellular and humoral responses to new antigens are impaired following measles virus infection [56]. Reactivation of tuberculosis and remission of autoimmune diseases have been described after measles and are attributed to this state of immune suppression.

Abnormalities of both the innate and adaptive immune responses have been described following measles virus infection. Transient lymphopenia with a reduction in $CD4^+$ and $CD8^+$ T lymphocytes occurs in children following measles virus infection. Functional abnormalities of immune cells have also been detected, including decreased lymphocyte proliferative responses [57]. Dendritic cells, major antigen-presenting cells, mature poorly, lose the ability to stimulate proliferative responses in lymphocytes, and undergo cell death when infected with measles virus in vitro [58]. The dominant Th2 response in children recover-

ing from measles can inhibit Th1 responses and increase susceptibility to intracellular pathogens [54]. Engagement of CD46 on monocytes suppresses IL-12 production, a cytokine important for Th1 responses [59]. Engagement of CD46 and CD3 on $CD4^+$ T cells induces production of high levels of IL-10 and transforming growth factor (TGF)-β, an immunomodulatory and immunosuppressive cytokine profile characteristic of regulatory T cells [60]. The role of these cytokines in the immune suppression following measles is supported by in vivo evidence of elevated levels of IL-10 in the plasma of children after measles virus infection [61].

8 Patterns of Host Response

8.1 Clinical Disease and Complications

Clinically apparent measles begins with a prodrome characterized by fever, cough, coryza (runny nose), and conjunctivitis (Fig. 23.4). Koplik's spots, small white lesions on the buccal mucosa inside the mouth, may be visible during the prodrome and allow the astute clinician to diagnose measles prior to the onset of rash. The prodromal symptoms intensify several days before the onset of rash. The characteristic erythematous and maculopapular rash appears first on the face and behind the ears and then spreads in a centrifugal fashion to the trunk and extremities (Fig. 23.5). The rash lasts for 3–4 days and fades in the same manner as it appeared. Malnourished children may develop a deeply pigmented rash that desquamates or peels during recovery [62].

In uncomplicated measles, clinical recovery begins soon after appearance of the rash. Unfortunately, complications occur in up to 40 % of measles cases, and the risk of complication is increased by extremes of age and malnutrition [62]. Complications of measles have been described in almost every organ system. The respiratory tract is a frequent site of complication, with pneumonia accounting for most measles-associated deaths [63]. Pneumonia is caused by secondary viral or bacterial infections or by measles virus itself. Pathologically, measles virus infection of the lung is characterized by multinucleated giant cells that form when measles virus proteins on the surface of infected cells facilitate cell fusion. Other respiratory complications include laryngotracheobronchitis (croup) and otitis media (ear infection). Mouth ulcers, or stomatitis, may hinder children from eating or drinking. Many children with measles develop diarrhea, which further contributes to malnutrition. Eye disease (keratoconjunctivitis) is common after measles, particularly in children with vitamin A deficiency, and was a frequent cause of blindness.

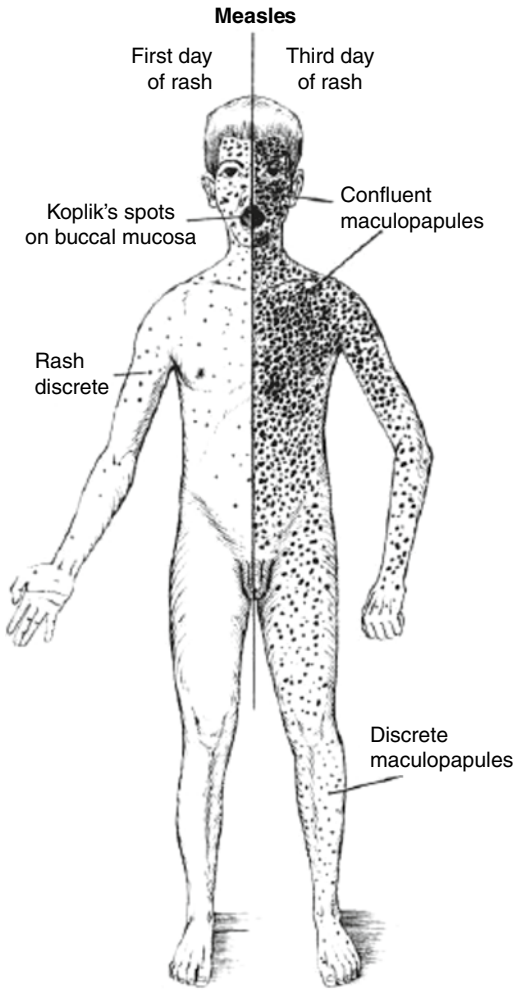

Fig. 23.5 Development and distribution of measles rash (Source: Perry and Halsey [69]. Krugman S. St. Louis: Mosby, 1958; Infectious Diseases of Children)

Because the rash of measles is a consequence of the cellular immune response, persons with impaired cellular immunity, such as those with the acquired immunodeficiency syndrome (AIDS), may not develop the characteristic measles rash. These persons have a high case fatality and may develop a giant cell pneumonitis caused by measles virus. T-lymphocyte defects due to causes other than HIV infection, such as cancer chemotherapy, also are associated with increased severity of measles.

Rare but serious complications of measles involve the central nervous system. Post-measles encephalomyelitis complicates approximately 1 in 1,000 cases, mainly older children and adults. Encephalomyelitis occurs within 2 weeks of the onset of rash and is characterized by fever, seizures, and a variety of neurologic abnormalities. The finding of perivenular

demyelination, the induction of immune responses to myelin basic protein, and the absence of measles virus in the brain suggest that post-measles encephalomyelitis is an autoimmune disorder triggered by measles virus infection. Other central nervous system complications that occur months to years after acute infection are measles inclusion body encephalitis (MIBE) and subacute sclerosing panencephalitis (SSPE). In contrast to post-measles encephalomyelitis, MIBE and SSPE are caused by persistent measles virus infection. MIBE is a rare but fatal complication that affects individuals with defective cellular immunity and typically occurs months after infection. SSPE is a slowly progressive disease characterized by seizures, progressive deterioration of cognitive and motor functions, followed by death that occurs 5–15 years after measles virus infection. It most often occurs in persons infected with measles virus before 2 years of age.

8.2 Measles Mortality and Case Fatality

The measles case fatality proportion is highest at extremes of age. Vaccinated children, should they develop disease after exposure, have less severe disease and significantly lower mortality rates. Vaccination programs, by increasing the average age of infection, shift the burden of disease out of the age group with the highest case fatality (infancy), further reducing measles mortality.

Measles case fatality proportions vary widely, depending upon the average age of infection, nutritional status of the population, measles vaccine coverage, and access to health care [64]. In developed countries, such as the United States, fewer than 1 in 1,000 children with measles die. In endemic areas in sub-Saharan Africa, the measles case fatality proportion may be 5 %. Measles is a major cause of child deaths in refugee camps and in internally displaced populations. Measles case fatality proportions in children in complex emergencies have been as high as 20–30 %. During a famine in Ethiopia, measles alone or in combination with wasting accounted for 22 % of 159 deaths among children younger than 5 years of age and 17 % of 72 deaths among children aged 5–14 years [65].

8.3 Nutritional Status

Measles and malnutrition have important bidirectional interactions. Measles is more severe in malnourished children, although separating the independent effects of nutritional and socioeconomic factors is often difficult. Children with severe malnutrition, such as those with marasmus or kwashiorkor, are at particular risk of death following measles. Measles, in turn, can exacerbate malnutrition by decreasing intake (particularly in children with mouth ulcers), increasing metabolic demands, and enhancing gastrointestinal loss of nutrients as a consequence of a protein-losing enteropathy [66]. Measles in persons with vitamin A deficiency leads to severe keratitis, corneal scarring, and blindness [67].

8.4 Sex Differences

Interestingly, some data suggest that measles mortality may be higher in girls. Among persons of different ages and across different regions, measles mortality in girls was estimated to be 5 % higher than in boys [68]. Although older historical data and recent surveillance data from the United States do not support this conclusion [69], if true, the higher mortality in girls is in contrast to most infectious diseases in which disease severity and mortality is highest in males. Supporting the hypothesis of biologic differences in the response to measles virus was the observation that girls were more likely than boys to have delayed mortality following receipt of high-titer measles vaccine [70]. The underlying mechanisms are likely differences in immune responses to measles virus between girls and boys, although no cogent biological theory has been developed [71].

8.5 Host Genetics

All persons without preexisting protective immunity are believed to be susceptible to infection with measles virus, and geographic differences in disease severity and mortality are almost certainly due to environmental and nutritional factors rather than genetic differences. Nevertheless, genetic factors (e.g., genes regulating cytokine production) may explain some of the differences in response to measles virus between individuals. The host genetics underlying immune responses to measles vaccine have been more extensively studied and suggest that polymorphisms in human leukocyte antigen (HLA) genes are associated with differences in antibody responses [72].

9 Control and Prevention

9.1 Measles Vaccines

The best means of preventing measles is active immunization with measles vaccine [73]. The first attenuated measles

vaccine was developed by passage of the Edmonston strain of measles virus, isolated by John Enders, in chick embryo fibroblasts to produce the Edmonston B virus [74]. Licensed in 1963 in the United States, this vaccine was protective but also induced fever and rash in many vaccinated children. Further passage of the Edmonston B virus produced the more attenuated Schwarz vaccine that was licensed in 1965 and currently serves as the standard measles vaccine in much of the world. The Moraten strain (meaning "more attenuated Enders" and licensed in 1968) was developed by Maurice Hilleman and is used in the United States. Attenuated measles vaccine strains have mutations that distinguish them from wild-type viruses [75] and exhibit decreased tropism for lymphocytes [76].

The recommended age of first vaccination varies from 6 to 15 months and is a balance between the optimum age for seroconversion and the probability of acquiring measles before that age [77]. The proportions of children who develop protective levels of antibody after measles vaccination are approximately 85 % at 9 months of age and 95 % at 12 months of age [78]. Two doses of measles vaccine are necessary to achieve sufficiently high levels of population immunity to interrupt transmission [35]. The first dose is typically administered through the primary healthcare system. The World Health Organization recommends that the first dose of measles vaccine be administered at 9 months of age [73], although countries in which the risk of measles is low frequently provide the first dose at 12–15 months of age. Two strategies to administer the second dose of measles vaccine are through the primary healthcare system or mass immunization campaigns called supplementary immunization activities, an approach first developed by the Pan American Health Organization (PAHO) for South and Central America and modeled after polio eradication strategies [79]. These campaigns are used to deliver other health interventions, including insecticide-treated bed nets for prevention of malaria, vitamin A, antihelminthic drugs, and other vaccines, such as rubella vaccine.

The duration of vaccine-induced immunity is at least several decades if not longer [52]. Secondary vaccine failure rates have been estimated to be approximately 5 % at 10–15 years after immunization, but are probably lower when vaccination is given after 12 months of age [80]. Decreasing antibody concentrations do not necessarily imply a complete loss of protective immunity, as a secondary immune response usually develops after re-exposure to measles virus, with a rapid rise in antibody titers without overt clinical disease.

9.2 Measures of Protection

Measles vaccine efficacy under study conditions, or effectiveness under field conditions, is measured as 1 minus a measure of the relative risk in the vaccinated group compared to the unvaccinated group (VE = 1 − RR). A number of field methods and study designs can be used to measure measles vaccine efficacy [81, 82]. For example, measles vaccine efficacy can be estimated by measuring the proportion of measles cases occurring in vaccinated persons and the proportion of the population that is vaccinated. Measles vaccine efficacy (VE) then can be calculated using the following equation:

$$\mathrm{VE} = \frac{\mathrm{PPV} - \mathrm{PCV}}{\mathrm{PPV} - (\mathrm{PCV} \times \mathrm{PPV})}$$

where PPV is the proportion of the population that is vaccinated against measles and PCV is the proportion of measles cases that are vaccinated.

Immunologic markers of protective immunity are commonly used to assess measles vaccines. Measurement of antibodies to measles virus by the plaque reduction neutralization assay is best correlated with protection from infection and remains the gold standard for determination of protective antibody titers. Neutralizing antibody levels of 120 mIU/mL (or 200 mIU/mL depending upon the WHO reference serum used) are considered protective following vaccination [83].

9.3 Optimal Age of Vaccination

The optimal age of measles vaccination is determined by consideration of the age-dependent increase in seroconversion following measles vaccination and the average age of infection. In regions of intense measles virus transmission, the average age of infection is low and the optimal strategy is to vaccinate against measles as young as possible. However, both maternally acquired antibodies and immunologic immaturity reduce the protective efficacy of measles vaccination in early infancy [84]. In many parts of the world, 9 months is considered the optimal age of measles vaccination and is the age recommended by the Expanded Programme on Immunization (EPI). Most countries following the EPI schedule administer measles vaccine alone, although more countries are introducing combined measles and rubella vaccines as rubella control programs expand. In communities with intense measles virus transmission, a significant proportion of children may acquire measles before 9 months of age. Under some circumstances, provision of an early dose of measles vaccine at 6 months of age (e.g., in outbreaks or to HIV-infected children) is appropriate. In contrast, in regions that have achieved measles control or elimination, and where the risk of measles in infants is low, the age of measles vaccination is increased to ensure that a higher proportion of children develop protective immunity. For example, in the United States, the first dose of measles vaccine is administered at 12–15 months of age, as a combined measles, mumps, and rubella (MMR) vaccine.

9.4 Surveillance and Outbreak Investigation

Disease surveillance is an important component of measles control programs, providing estimates of measles incidence and mortality, the effectiveness of the control program, and information to support targeted interventions [85]. Case-based surveillance with laboratory confirmation of suspected cases should be the goal. Not all suspected cases in an outbreak need to be laboratory confirmed if they can be epidemiologically linked to a confirmed case. As the incidence of measles declines, other viral causes of fever and rash may be mistaken for measles. Many surveillance programs test specimens for rubella virus-specific IgM antibodies. Although confirmation typically requires detection of anti-measles virus IgM antibodies in plasma or serum, less invasive specimen collection methods, including oral fluid swabs and dried blood spots collected on filter paper, can also be used [5].

10 Unresolved Problems

10.1 Measles Virus Persistence

Recent observations of measles pathogenesis in a rhesus macaque model, in conjunction with observations of prolonged detection of measles virus RNA in children [29, 44], suggest that measles virus RNA persists in peripheral blood mononuclear cells for up to 4 months after infection and is associated with a biphasic T-cell response with peaks at 7–25 days and 90–110 days [86]. These observations suggest measles may not be as acute a viral infection as once understood. Persistent measles virus replication could explain the prolonged state of immune suppression and the live-long immunity following infection [87].

10.2 Ideal Measles Vaccine

The ideal measles vaccine would be inexpensive, safe, heat-stable, and immunogenic in neonates or very young infants and administered as a single dose without needle or syringe [88]. The age at vaccination would ideally coincide with other vaccines in the EPI schedule to maximize compliance and share resources. Finally, a new vaccine should not prime individuals for atypical measles upon exposure of immunized individuals to wild-type measles virus (a complication of formalin-inactivated measles vaccines) [89] and should not be associated with prolonged immunosuppression, adversely affecting immune responses to subsequent infections (a complication of high-titer measles vaccines) [90].

Several candidate vaccines with some of these characteristics are undergoing development and testing. Naked cDNA vaccines are thermostable and inexpensive and could theoretically elicit antibody responses in the presence of passively acquired maternal antibody. DNA vaccines encoding either or both the measles H and F proteins are safe, immunogenic, and protective against measles challenge in naive, juvenile rhesus macaques [91]. A different construct, containing H, F, and N genes and an IL-2 molecular adjuvant, provided protection to infant macaques in the presence of neutralizing antibody [92, 93]. Alternative techniques for administering measles virus genes, such as alphavirus [86], parainfluenza virus [94], or enteric bacterial [95] vectors, are also under investigation. Oral immunization strategies have been developed using plant-based expression of the measles virus H protein in tobacco [96], and dry powder attenuated measles vaccine delivered by inhalation was shown to induce protective immunity in rhesus macaques [97].

10.3 Measles Eradication

In the WHO Region of the Americas, intensive vaccination and surveillance efforts interrupted endemic measles virus transmission [98], and all five remaining WHO regions set measles elimination targets of or before 2020. Progress in reducing measles incidence and mortality in sub-Saharan Africa [99] led to the proposal to eliminate measles in the WHO African region by 2020 [100].

The elimination of measles in large geographic areas, such as the Americas, suggests that global eradication is feasible with current vaccination strategies. Potential barriers to eradication include the following: (1) lack of political will, (2) difficulties of measles control in densely populated urban environments, (3) the HIV epidemic, (4) waning immunity and the potential transmission from subclinical cases, (5) transmission among susceptible adults, (6) the risk of unsafe injections, and (7) unfounded fears of disease caused by measles vaccine [101, 102]. Whether the threat from bioterrorism precludes stopping measles vaccination after eradication is a topic of debate, but, at the least, a single-dose rather than a two-dose measles vaccination strategy could be adopted.

Paramyxoviruses: Mumps

24

Steven A. Rubin

1 Introduction

Mumps is an acute contagious disease caused by a nonsegmented negative strain RNA virus in the paramyxovirus family. Infection with the mumps virus typically results in unilateral or bilateral parotitis, frequently accompanied by more significant complications, such as meningitis, pancreatitis, or orchitis. Symptoms usually resolve within 2 weeks of onset; serious complications are rare. Approximately one-third of infections are unrecognized or present with nonspecific or primarily respiratory symptoms. Prior to implementation of national mumps immunization programs, more than 90 % of most populations had serologic evidence of exposure to the virus by adolescence. Following widespread use of mumps-containing vaccine, disease incidence declined sharply, particularly in countries with a two-dose vaccine program. However, over the past few years there has been resurgence in mumps cases globally, even in highly vaccinated populations.

2 Historical Background

Mumps was first described by Hippocrates in the fifth century as an illness accompanied by swelling around one or both ears and, in some cases, painful swelling of one or both testes. Central nervous system (CNS) involvement was first described in the literature by Hamilton in 1790 [1]. The etymological origin of the term mumps is unclear but may stem from the English noun, *mump*, meaning lump, in reference to the distinctive facial swelling that accompanies the disease, or, alternatively, the name may derive from the mumbling speech of patients with parotitis.

Although in modern times mumps is generally thought of as a disease of childhood, historically it was considered to be an illness that affected armies during times of mobilization. Mumps was a major cause of morbidity among Confederate soldiers during the American Civil War [2] and was the leading cause of days lost from active duty by US troops in France during World War I [3, 4]. The annual hospital admission rate for mumps among US soldiers at that time was 55.8 per 1,000, exceeded only by influenza and gonorrhea [5]. The highest reported rate of mumps in the US Army (75.5 in 1,000) occurred in 1918 and declined markedly to 6.9 in 1000 in 1943. Although mumps incidence was greatly reduced during World War II relative to preceding wars, it remained a major problem, having a frequency three times higher than that of the next most common condition, measles [4]. Mumps outbreaks continued to occur in military settings until the implementation of routine MMR immunization of military recruits [6].

A viral etiology of the disease was suggested in several experiments conducted in animals in the early part of the 1900s [7–9], but it was not until 1934 that mumps was determined to be caused by a virus present in the saliva of infected patients [10, 11]. In these studies, Johnson and Goodpasture injected filtered, bacteria-free material from the saliva of patients with epidemic parotitis into the Stenson's ducts of rhesus monkeys and produced nonsuppurative parotitis. A diluted emulsion from the parotids of these monkeys caused parotitis in susceptible children but not in immune controls. Ten years following this landmark study, Habel [12] and Enders [13, 14] cultivated the virus in developing chick embryos, leading to the development of an inactivated vaccine that was tested in humans a few years later [15]. The first live attenuated mumps virus vaccines were used in the late 1950s in the Soviet Union [16] and in the early 1960s in the United States (US) [17].

3 The Agent

Mumps virus is a member of the genus *Paramyxovirus* in the family Paramyxoviridae, genus *Rubulavirus*, which includes human parainfluenza viruses 2, 4a, and 4b; parainfluenza virus 5 (formerly simian virus 5); Mapuera virus; porcine rubulavirus (La Piedad Michoacan Mexico virus); simian virus 41; and tentative genus members Menangle virus and Tioman virus. The virus is readily inactivated by heat, formalin, ultraviolet light, and other agents.

The enveloped mumps virion is polymorphic and contains a negative-sense RNA genome of 15,384 nucleotides encoding seven genes that generally parallel those of the other paramyxoviruses. These include the nucleocapsid (N) gene, V gene, matrix (M) gene, fusion (F) gene, small hydrophobic (SH) gene, hemagglutinin-neuraminidase (HN) gene, and the large (L) gene [18]. Each gene encodes a single protein, with the exception of the V gene, a faithful transcript of which produces the nonstructural V protein, whereas cotranscriptional addition of non-templated guanine residues produces the phosphoprotein (P) and I protein [19, 20]. The N protein coats the viral RNA to form the ribonucleocapsid, which complexes with the P and L proteins, which together provide the polymerase activity responsible for transcription, replication, methylation, capping, and polyadenylation [21–24]. The M, F, SH, and HN proteins are all associated with the viral envelope. The M protein is involved in viral assembly, presumably by linking the N proteins of the ribonucleocapsid with the cytoplasmic tails of the HN and the F proteins that span the host cell-derived viral envelope [25]. The HN protein is responsible for cellular attachment during the initial infection process as well as release of nascent virions from the cell surface postinfection [26, 27]. The HN and F proteins work cooperatively to facilitate fusion of the virion membrane with the host cell membrane and introduce the viral nucleocapsid into the host cell. These two viral proteins also induce cell-to-cell fusion following infection [21, 28]. The V and SH proteins are accessory proteins, acting as antagonists of the host antiviral response, with the former interfering with the interferon response [29–31] and the latter interfering with the TNF-α-mediated apoptotic signaling pathway [32]. Studies of the role of the I protein in virus replication and infection are lacking.

The HN and F glycoproteins, being exposed on the virion surface, are the main targets of the humoral immune response. Only antibodies directed to these two proteins have been shown to neutralize virus infectivity and to confer protection [33–36]. Although mumps virus is serologically monotypic [37], antigenic differences among the various strains of mumps virus have been demonstrated in laboratory studies [38–42], and there is some evidence that such differences may allow for breakthrough infections in persons previously immunized, particularly upon waning of antibody levels [40, 41, 43, 44].

4 Methodology Involved in Epidemiologic Analysis

4.1 Sources of Data

The epidemiologic study of mumps is limited by the frequency of asymptomatic infection, the lack of serological testing in cases of parotitis with other etiologies misdiagnosed as mumps, and the failure to report cases. Large outbreaks, as well as specific studies, have provided information on incidence and complications. The experiences during World War I and World War II have contributed greatly to our understanding of the epidemiology of the disease [3, 4, 45, 46]. Mumps was first made a nationally reportable disease in 1922 but was removed from the list of reportable diseases in 1950. Mumps was reinstated as a notifiable disease in 1968 following the licensure of a live attenuated mumps virus vaccine. The number of cases of mumps reported each week is published in the Morbidity and Mortality Weekly Reports by the Centers for Disease Control and Prevention (CDC), and incidence data (derived from the National Notifiable Diseases Surveillance System) are summarized annually [47].

4.2 Serological Surveys

Over the years, the seroprevalence of mumps immunity has been assessed in a number of serological surveys using various methods available at the times the studies were conducted [6, 48–61].

4.3 Laboratory Methods

The diagnosis of mumps can be confirmed by isolation of the virus, by detection of viral RNA, or, with some limitations, by serological testing for virus-specific antibodies. The latter also forms the basis for assessing susceptibility to mumps infection and responses to vaccination.

4.3.1 Virus Isolation and RNA Detection

The virus can be recovered from most body fluids and secretions with variable degrees of success. The highest success rates have been achieved with buccal swabs obtained from the area proximal to the Stensen's duct. The virus can also be readily detected in saliva and, in cases of mumps meningitis, from the cerebrospinal fluid (CSF). Rates of success with other clinical specimens, such as urine and semen, are lower. Regardless of the source material, virus detection rates dramatically decline after the first week of symptoms. Despite the apparent high frequency of viremia during mumps (based on the evidence of wide dissemination of the virus), mumps virus or viral RNA has rarely been identified in blood or serum [62, 63], possibly related to the presence

of anti-mumps virus antibodies, which begin to appear at the time of symptoms [64].

For virus isolation, a number of cell lines can be used, the most permissive of which are Vero and CaCo-2 [65]. Cultures typically display syncytia formation within 5 days of incubation with mumps virus, followed by lysis; however, reliance on cytopathic effects alone is not a reliable means of confirming the presence of mumps virus since some mumps strains are non-cytopathic, and many of the viruses in the differential diagnosis of mumps cause cellular pathology indistinguishable from that induced by mumps virus. Instead, confirmation by PCR amplification of viral RNA is often required. Because of this need, and the ability to directly assay clinical material by PCR without an intervening in vitro culture step, virus isolation by culture is often unnecessary [44, 66–68]. The success of virus isolation or PCR-based detection may be influenced by vaccination status. While mumps virus RNA has been detected in >80 % of clinically diagnosed cases in children with a history of 0 or 1 dose of mumps-containing vaccine [44, 69, 70], only about 30 % of mumps cases involving children with a history of two doses of vaccine may test positive [66, 71]. While the reason for this phenomenon has not been established, it is likely due to an attenuated course of virus growth and spread in fully vaccinated individuals.

Data from PCR-based detection of the viral genome is also used for molecular epidemiological purposes. Such analyses are usually based on the sequence of the 316-nucleotide-long SH gene, the most variable in the genome and therefore the genomic region used for genotype classification. Presently, 12 different mumps virus genotypes have been assigned based on the SH gene sequence, designated A–N (excluding E and M, which have been merged with genotypes C and K, respectively) [72–74].

4.3.2 Serological Tests

The humoral response to mumps infection follows a course typical of that to respiratory viruses. Salivary IgA develops 5–7 days after infection and is followed by virus-specific serum IgA and IgM, detectable within a few days of symptom appearance. Levels of IgA and IgM peak 1–2 weeks later and decline over the next several weeks [43, 64, 75–78]. During this time, low-avidity serum IgG is produced [64, 77, 79]. Upon a second exposure to mumps virus, a high-avidity, virus-neutralizing IgG is produced, whereas IgM and IgA antibodies are often Undetectable [43]. Although virus-specific IgG can persist for many years to a lifetime, it appears that in the absence of periodic natural boosting, antibody levels and antibody effectiveness decline over time [37, 80–85], possible resulting in the susceptibility of persons previously immune.

Historically, serological testing has been the gold standard for a laboratory confirmation of mumps; however, in the present era of high vaccine coverage, unless a significant rise in virus-specific IgG can be demonstrated using paired acute and convalescent serum samples, results of serological testing must be carefully considered. Before the widespread use of vaccine, enzyme immunoassay (EIA) detection of virus-specific antibody was reliable for confirming mumps, but in the present era where nearly everyone has a history of mumps vaccination, both cases and non-cases would be expected to be IgM negative and IgG positive. Thus, a negative IgM result no longer rules out mumps, and a positive IgG result no longer confirms mumps. It should be noted that some EIAs are highly sensitive, and although IgM is not produced in high amounts in the anamnestic immune response, it is nonetheless present. Thus, the detection of IgM in a person with mumps with a history of vaccination is not an evidence of primary vaccine failure [86].

While the EIA remains the most commonly used serology test, it is worth noting that detection of IgG by EIA does not imply the presence of protective antibody in that both virus-neutralizing (protective) and non-neutralizing antibodies are detected by this method. Seroconversion can be demonstrated by EIA even in the absence of demonstrable neutralizing antibody [87]. For the purpose of assessing protective immunity, only assays that measure levels of virus-neutralizing antibody, such as the plaque reduction neutralization assay or the microneutralization assay, are relevant. Other once prevalent techniques such as complement fixation (CF), radioimmunoassay (RIA), hemagglutination inhibition (HI), immunofluorescence assay (IFA), and hemolysis-in-gel (HIG) are no longer used due to their time-intensive nature, relative insensitivity, and/or problems with cross-reactions with other paramyxoviruses [77, 87–92].

Mumps antibody can also be detected in the CSF of patients with mumps meningitis. Antibody in CSF is detectable within a few days of onset of illness and peaks within 2 weeks. Elevated CSF–serum IgG antibody ratios from samples collected on the same day indicate mumps infection because mumps antibodies are uncommon in the CSF in the presence of other infections [93–96].

Skin tests are unreliable and should not be used to assess immunity to mumps [97, 98].

5 Descriptive Epidemiology

5.1 Incidence and Prevalence

Within a decade after the December 1967 licensure of mumps vaccine in the United States, the number of reported cases declined by nearly 90 % from 152,209 in 1968 when mumps was reinstituted as a reportable disease to 16,817 cases in 1978 (Fig. 24.1). Mumps previously had been a reportable disease between 1922 and 1950. Following a period of a record low incidence in the early 1980s, a resurgence

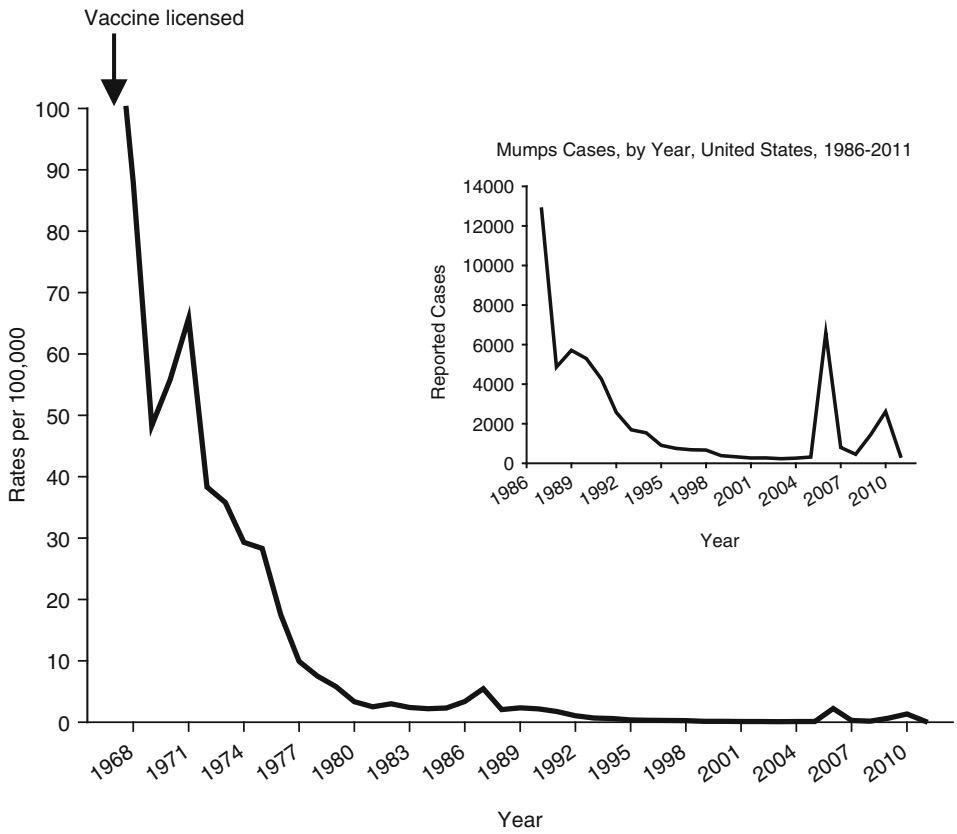

Fig. 24.1 Reported cases per 100,000 population per year. United States, 1968–2011. (Data from Centers for Disease Control and Prevention)

of mumps occurred in the United States between 1986 and 1987, which resulted in an almost fivefold increase in the annual incidence rate per 100,000 population (1985, 1.1; 1987, 5.2) [99]. This resurgence was attributed primarily to the low vaccination coverage of adolescents and young adults who were born between 1967 and 1977 [100, 101]. Although the vaccine was licensed in 1967, its use was limited until 1977 when it was recommended for routine use in young children. By 2003, the number of cases of mumps reported to the CDC reached an all-time low of 231 cases, representing a 99.9 % decrease in the number of cases from the prevaccine era. Mumps incidence remained at historic lows until 2006 when the United States experienced its largest mumps epidemic in 19 years with 6,584 cases reported, mostly in the Midwest (Fig. 24.1, inset) [102–104]. Unlike the 1986–1987 mumps resurgence, the mumps outbreaks in 2006 were not due to unvaccinated cohorts, as nearly all cases occurred in persons with a history of vaccination. The number of reported cases precipitously declined in the 2 years that followed but then spiked again in 2009–2010 with focal outbreaks in New York and New Jersey [105]. Provisional data for 2011 indicates a return to pre-outbreak levels.

The number of cases of mumps reported each year is generally considered to be far less than what actually occurs. Underreporting results in part from the mild nature of the disease and the associated lack of need to seek medical care in many instances. A serological survey conducted in Florida [55] highlighted an infrequent number of physician contacts and the failure of physicians to report cases; only 27 % of the 126 cases identified were seen by a physician and only 6 % were reported. The estimated annual incidence rate based on this study was ten times the rate based on national surveillance figures. Low reporting efficiency was identified in several other studies [3, 106, 107]. In addition, the high rate of subclinical mumps infections, estimated to approach 50 % in several studies [108, 109], contributes to a gross underestimation of the true incidence of infections. On the other hand, cases reported as mumps based on the presence of parotitis without laboratory confirmation may not be mumps, since there are other causes of parotitis. However, this is not a concern for cases of parotitis reported during an outbreak or for cases epidemiologically linked, since only mumps virus causes outbreaks of parotitis.

5.2 Survey Data

Numerous population surveys have been carried out using questionnaires and interviews, skin tests, and serological tests to assess patterns of susceptibility and immunity in communities.

In the 1960s, Harris and coworkers [110, 111] used questionnaires to study the incidence of mumps among health professionals, university faculty members, and households. During this time, which was before the wide use of mumps vaccine, cases were most likely among pediatricians and least likely among the general university faculty. Among households, the peak incidence of mumps was found to occur at 7 years of age, and 74 % of the study population reported mumps before 10 years of age.

An early study by Henle et al. [52] in 1951 showed that 70–80 % of persons with a history of mumps had positive findings on the CF test and skin tests. Although these tests are now known to be insensitive or unreliable, fewer than 2 % of those who tested positive subsequently acquired mumps.

Early serological surveys were conducted in military populations. Serosurveys in the prevaccine era from 1951 to 1962 using the CF or HI tests showed that 46–76 % of army recruits in the United States were immune to mumps [48, 56, 57]. Later serosurveys [49, 58, 59] conducted more than two decades after the licensure of mumps vaccine and using the more sensitive EIA found that 84–88 % of military recruits were immune. In contrast to World War I data that showed increased susceptibility among men from rural areas [112], no significant urban–rural differences were found in the later serosurveys conducted in 1962 and in 1989 [48, 49]. Kelley and coworkers [49] found that black, non-Hispanic recruits were more likely to be seropositive than those from other racial or ethnic groups.

Serosurveys also have been conducted in civilian populations of all ages. Retrospective tests on sera in the World Health Organization (WHO) Serum Bank at Yale University showed a wide variation in the proportion of seropositive findings according to geographic area in the prevaccine era [50]. Among children 5–9 years of age, mumps antibody was not found in any of the children from Alaska and in only 15 % of those from Tahiti. In contrast, antibody was detected in more than half of 5–9-year-olds from New Haven, Connecticut (52 %), the Cape Verde Islands (55 %), the Bahamas (74 %), and Iceland (79 %). Among persons of all ages residing in remote islands off Alaska, only 7 % of residents of St. Paul Island [113] and 12 % of those from St. George Island [114] were seropositive when assessed in the late 1960s. Similarly, mumps antibody was found in an average of only 33 % of members of isolated Indian tribes in South America [115]. In comparison, mumps antibody was found in 90 % of the residents of New Haven and 88 % of medical students tested in another seroprevalence study using the neutralization test [97].

Kenny et al. [116] measured mumps-neutralizing antibody in sera collected between 1970 and 1973 in children 1–15 years old in the Dominican Republic, Honduras, the Republic of Panama, and the United States. The proportion of seropositive 1–3-year-old children in the Middle American countries and in the United States was similar (20–25 %). In the older age groups, significantly higher rates of seropositivity were found among US children compared to children in the Middle American countries. Among children 4–6 years old, 70 % of children in the United States had mumps antibody compared to approximately 55 % of children in the Middle American countries ($p < 0.05$).

Variation in the average age of infection has been found in other serosurveys from other parts of the world. In St. Lucia, 70 % of unvaccinated children were found to be seropositive by 4 years of age [117]. In contrast, a majority of children from the Netherlands [118] and from Scotland [119] remained susceptible at this age. In the Netherlands, most children develop mumps between 4 and 6 years of age, and by 14 years of age, 90 % are seropositive. Before vaccination campaigns were initiated in Spain, 53 % of 3–5-year-old and 61 % of 6–7-year-old children were immune [120]. The lack of immunity was associated with rural residency, low socioeconomic status, and lack of school attendance or siblings. In the United Kingdom, before routine mumps vaccination was initiated in 1988, most cases were in children 6–7 years of age [121]. Subsequent to the routine vaccination program, the average age of infection has decreased, perhaps because of increased contacts among preschool age children [122]. Serological data from England and Wales from 1990 showed that 70 % of 1–2-year-olds and 73 % of 3–4-year-olds were immune [123].

Data from the 1999–2004 US National Health and Nutrition Examination Survey (NHANES) involving participants aged 6–49 years [60] revealed an overall age-adjusted mumps seroprevalence of 90.0 %, with a lower confidence limit of 88.8 %, well below the 92 % level estimated to be required for herd immunity [124, 125]. Seropositivity was higher (93.4 %) among participants in the earliest birth cohort (1949–1956) and lowest (85.7 %) among those born from 1967 through 1976. Seroprevalence among persons born from 1977 to 1986 and from 1987 to 1998 (the youngest cohort in the study) was 90.1 and 90.3 %, respectively. Seroprevalence was higher among US-born non-Hispanic blacks (96.4 %) and non-US-born Mexican Americans (93.7 %). Sex, education, and birthplace were also found to be independent predictors in some cohorts. As discussed in Sect. 9, seroprevalence in young children is likely higher now than indicated by the 1999–2004 NHANES, given that the median coverage with two doses of MMR vaccine among kindergartners during the 2011–2012 school year in the United States was estimated to be approximately 95 % [126].

5.3 Epidemic Behavior and Contagiousness

Mumps outbreaks typically occur wherever children and young adults aggregate, as in schools, military barracks, and other institutions. Mumps is less contagious than measles or

chickenpox. Hope-Simpson [127] demonstrated the infectiousness of mumps by assessing the incidence of cases resulting from every exposure of a susceptible person in the home and concluded that the susceptible–exposure attack rate for mumps was 31.1 % compared to 75.6 % for measles and 61.0 % for chickenpox. The higher rate of subclinical infection with mumps may account for an underestimation of the true infectiousness of the virus; however, the higher average age at infection observed for mumps [128] supports the less efficient transmission of the virus.

Outbreaks in virgin populations have been used to estimate the contagiousness of mumps. In three isolated island groups off Alaska, where no outbreak of mumps had occurred for more than 50 years and approximately 90 % of persons tested were seronegative [113, 114, 129], clinical mumps occurred in 35–65 % of the population and an additional 20–24 % had subclinical infections following the introduction of mumps virus.

5.4 Geographic Distribution

Mumps occurs worldwide with the exception of isolated island groups and remote, sparsely populated areas. In the United States, mumps outbreaks typically occur when a sufficient number of susceptible persons accumulate to support an outbreak. It follows that the incidence is higher in more densely populated areas. Recent data has shown that mumps outbreaks can even occur within highly vaccinated populations, particularly among groups of individuals in close contact, such as university campus environments. Investigations of three different mumps outbreaks in the United States occurring in 2006, all on college/university campuses, revealed that 96–100 % of cases occurred in persons with a history of vaccination during childhood, most with two doses [66, 130, 131]. Mumps outbreaks among high two-dose vaccinated populations were also identified in close-contact environments in other countries [132–134]. There is ample evidence of waning of mumps immunity postvaccination [81, 83–85, 135–140], and this is likely a significant contributory factor in these outbreaks.

Nucleotide sequencing of clinical isolates (see Sect. 4.3.1) indicates that virus genotypes D and G predominately circulate in the Western hemisphere, whereas genotypes F, C, and I predominately circulate in the Asia-Pacific region and genotypes B, H, J, and K in the Southern hemisphere (Fig. 24.2). Co-circulation of multiple genotypes within a region, or even within an outbreak, does occur. Some have suggested that

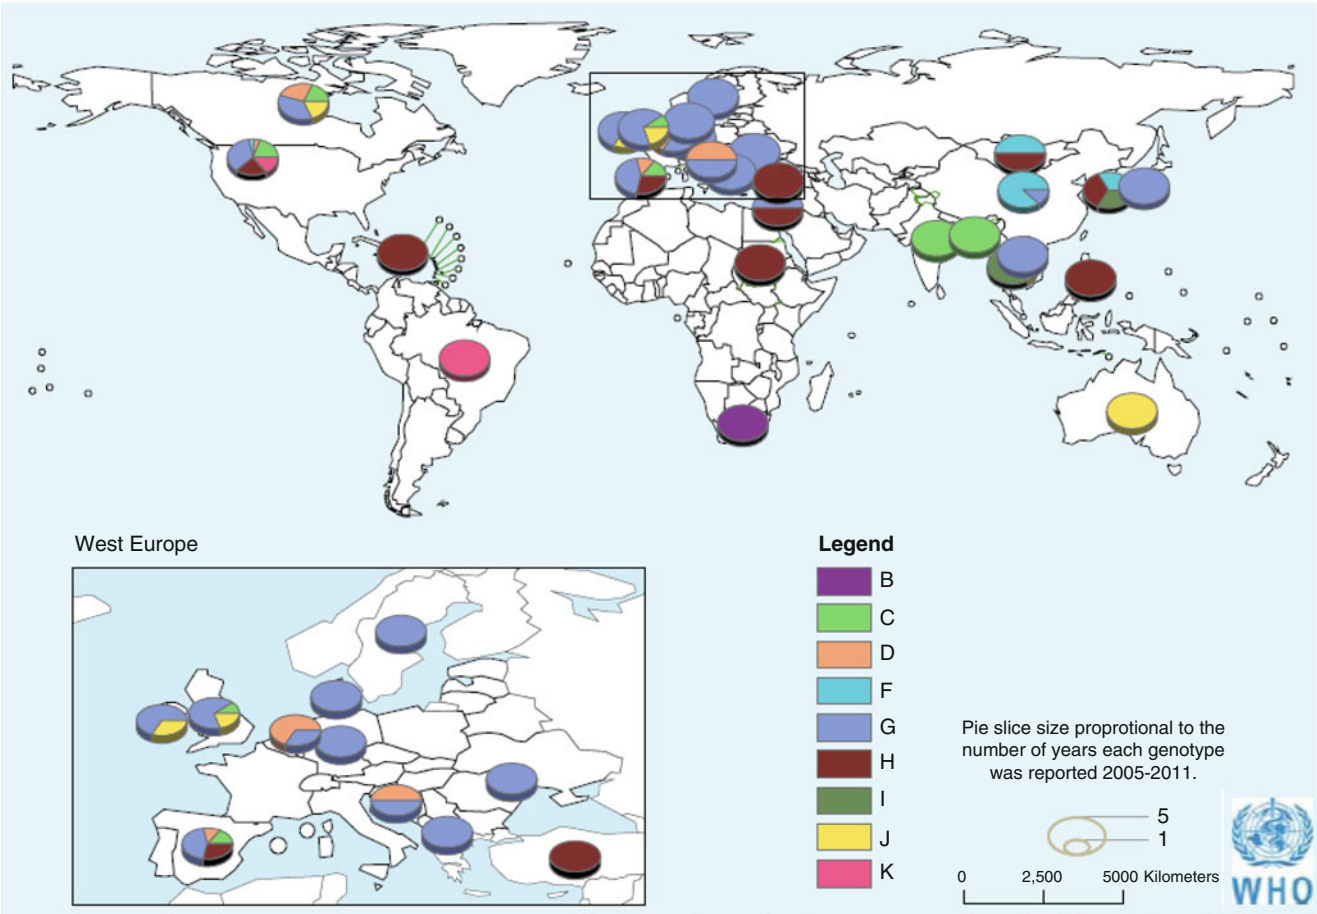

Fig. 24.2 Distribution of reported mumps genotypes, 2005–2011. (Source: courtesy of WHO, with permission http://www.who.int/immunization_monitoring/diseases/mumps/en/index.html, accessed September 11, 2012)

certain virus genotypes are more virulent than others [141–143]; however, this has not been adequately examined and remains to be demonstrated.

5.5 Temporal Distribution

In the North Temperate Zone, mumps occurs more frequently in winter and spring than at other times of the year. This pattern has not changed since the wide use of vaccine and the associated dramatic reduction in incidence. Seasonal differences are not apparent in tropical areas. Epidemiologic reports suggest an interepidemic period for mumps of approximately 3 years [121, 122, 144].

5.6 Age Distribution

In the prevaccine era, the largest proportion of cases occurred in children 5–9 years of age. Although mumps vaccine was licensed in the United States in 1967, it was not until 1977 that the Advisory Committee on Immunization Practices (ACIP) recommended routine vaccination of all children 1 year of age or older [145]. In the years following, the average age of cases began to increase, reflecting protection in younger populations. This shift to older age groups was first observed in 1982 [146]. A more marked shift occurred during a resurgence of mumps in 1986–1987 when a disproportionately high number of cases were reported among older children and adolescents aged 10–19 years and among young adults [147–149]. Between 1988 and 1993, persons 15 years of age and older have accounted for more than one-third of reported cases with known age compared to an estimated 8 % in this age group during the 5 years following licensure [150, 151]. By 1992, the highest age-specific incidence shifted back to the 5–9-years-old age group, remaining in this age group until the multistate mumps outbreak in 2006 when the age-specific incidence shifted again to older age groups [103, 152] before returning to the younger age group after the outbreak [153, 154]. This pattern again repeated itself during the recent mumps outbreaks in New York and New Jersey in 2009–2010 [105]. Mumps incidence by age group since 1990 is presented in Fig. 24.3.

The 1986–1987 resurgence reflected underimmunization of the cohort born between 1967 and 1977, a period of time when mumps vaccine was not administered routinely to children and the risk for exposure to mumps was decreasing [146]. More recent outbreaks, which have occurred in highly vaccinated populations, are thought to be due to waning immunity (see Sect. 5.4).

5.7 Gender Distribution

During non-outbreak years when only sporadic cases are reported, a trend toward higher attack rates is apparent among males than females (Fig. 24.4), likely a consequence

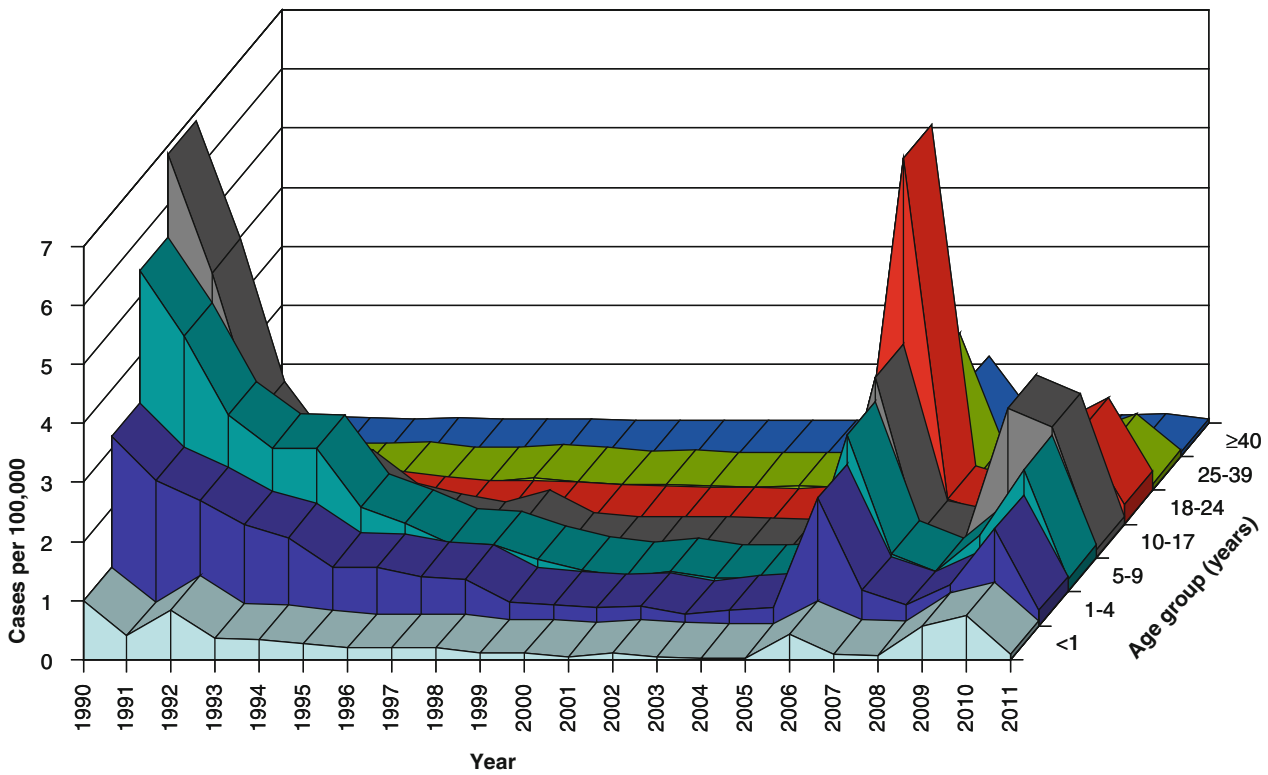

Fig. 24.3 Annual mumps incidence by age group, 1990–2011, as reported to the CDC. Figure courtesy of Albert Barskey, National Center for Immunization and Respiratory Diseases, CDC

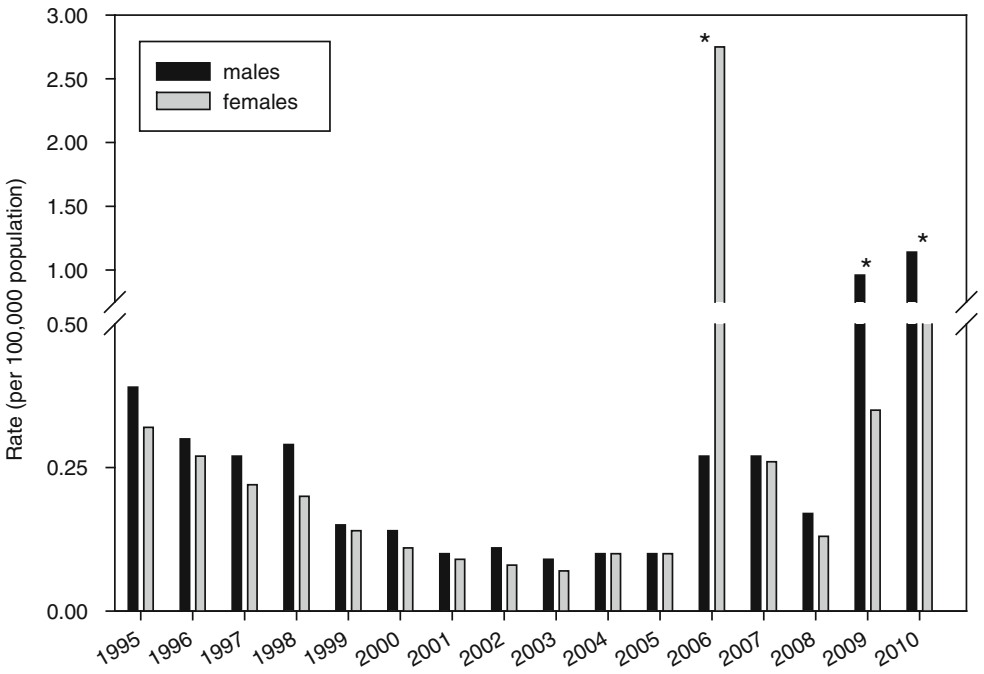

Fig. 24.4 Mumps incidence by gender, as reported to the CDC, 1995–2010, from Summary of Notifiable Diseases (http://www.cdc.gov/mmwr/mmwr_nd/index.html). * Denotes years during which large focal outbreaks significantly contributed to the total number of reported cases

of mumps in postpubertal males being frequently complicated by orchitis, and, thus, cases among males are more likely to be seen by physicians and to be reported. However, during mumps outbreaks, several investigations found higher attack rates in females [131, 139, 155–157]. This was particularly apparent during the multistate outbreak of mumps in the United States in 2006. It has been postulated that higher attack rates among females may be a reflection of gender differences in social behaviors facilitating increased transmission or exposure, but this is not clear [131, 155]. In contrast, during the 2009–2010 mumps outbreaks in the United States, attack rates were much higher among males, but this was a consequence of the outbreak setting, all male schools within orthodox Jewish communities in New York and New Jersey [105]. Fewer than 3 % of cases associated with the 2009–2010 mumps outbreaks occurred among persons outside this community.

Factoring out gender-specific manifestations (e.g., orchitis, oophoritis, mastitis), rates of complications are similar in males and females, with the exception of neurological manifestations, which appear with a 3:1 or greater male–female ratio [117, 158–160].

5.8 Race and Occupation

Historically, incidence rates among the black population tended to be higher than among the white population. This was first shown in the military and has been demonstrated subsequently in studies of civilian outbreaks [161, 162]. Based on data from 28 states in which race and ethnicity were reported for at least one-half of the cases, incidence rates among black persons ranged from 1.2 to 8.2 times those of other racial groups during the 4-year period of 1990–1993 [151]. Since that time, the trend has changed with somewhat higher rates of infection among whites (Fig. 24.5). In non-outbreak years, incidence rates among other racial/ethnic populations have been significantly higher than among blacks and whites. However, caution must be used when drawing conclusions from these data as different racial/ethnic populations might have different patterns of access to health care, regional differences in reporting compliance may exist, and many outbreaks may target racially/ethnically concentrated populations due to circumstances unrelated to race/ethnicity.

Persons engaged in occupations that involve contact with persons in age groups or settings associated with the highest incidence of mumps are likely to have frequent exposures to the mumps virus. A large mail survey conducted in the late 1960s when mumps was primarily a disease of young children showed that the risk for acquiring mumps from an occupational exposure was highest among practicing pediatricians and lowest among university staff [110]. In this study, the risk of mumps among teachers was related inversely to the age of their students. With recent outbreaks mostly occurring on university campuses, it would stand to reason that occupational exposure is now higher among university staff than among practicing pediatricians; however, this has not been examined.

5.9 Occurrence in Different Settings

Any setting in which a pool of susceptible persons are in close contact facilitates the transmission of the mumps virus.

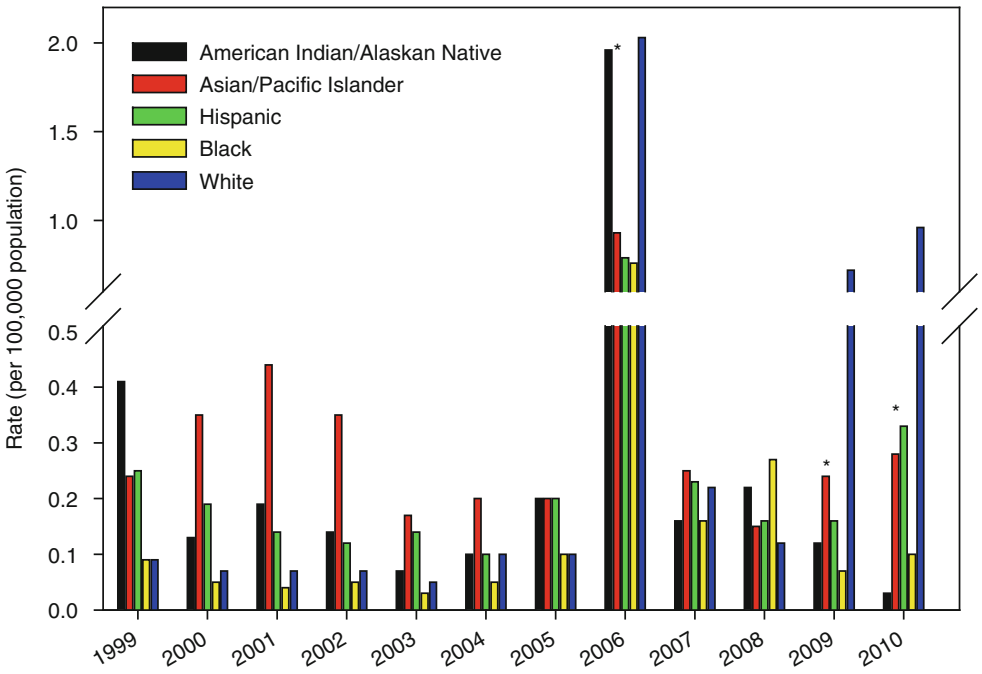

Fig. 24.5 Mumps incidence by race/ethnicity, as reported to the CDC, 1999–2010

5.9.1 Families and Schools

Families and schools have had an important role in the transmission of mumps [106]. Children exposed to mumps at school introduce the virus into the household where it may spread to susceptible family members. Prior to routine vaccination of young children, the younger children in a family usually acquired mumps at an earlier age than their oldest sibling. During that time period, most outbreaks occurred in school settings, with peak incidence in children during the first 5 years of school attendance. In the present era of decades of high vaccine coverage among young children, peak incidence has shifted to older age groups, presumably due to waning immunity in those individuals. Indeed, the time since the last vaccination has been linked to declining levels of mumps virus-specific antibodies [81, 83, 135, 136], decreased vaccine effectiveness [85, 137, 138], and an increased odds of being a case [84, 139, 140].

5.9.2 Military

Historically, epidemiologic data were derived largely from studies of military populations (see Sect. 2). The seasonality of mumps was recognized by the high proportion (70 %) of cases occurring during winter and spring. The incidence was higher among blacks than among whites. Mumps was associated with high rates of hospitalization and days lost from duty. Mortality was low, although deaths resulting from secondary infections such as pneumonia were more common during World War I than in later times when effective treatments for these complications became available. Seroprevalence studies carried out among military recruits in the prevaccine era found larger proportions of susceptible individuals [48, 56, 57] than were found in later serosurveys [49, 58, 59] (see Sect. 5.2). Mumps outbreaks in military settings continued into the postvaccine era [163, 164] but appeared to have tapered off by the mid-1990s, coinciding with the US military's practice of routinely administering MMR vaccine to all recruits without regard to prior vaccination status [6, 165]. The exception to this was the Air Force, which targeted MMR vaccination to recruits lacking serologic evidence of immunity to measles or rubella [49, 166].

5.9.3 Hospitals

Mumps is a relatively uncommon cause of nosocomial disease. Sporadic cases resulting from transmission in hospitals have been documented, including transmission from asymptomatic staff [98, 167–169]. Data from a study in an area with widespread outbreaks of mumps suggested that the introduction of mumps into hospitals by employees or by patients is likely when local incidence is high [170]. In a retrospective cohort study conducted at a hospital in Chicago, in a state reporting 795 cases of mumps during the 2006 multistate mumps outbreak, nine mumps cases were found to have resulted in 339 exposures, 98 % of whom were hospital staff [171]. The cost to the institution, which experienced ongoing transmission for 4 weeks, was calculated at $29,199 per mumps case.

5.10 Other Factors

Socioeconomic status has not been an important risk factor for mumps, except among impoverished populations where overcrowded living conditions facilitate the transmission of mumps virus as well as other infective agents.

6 Mechanisms and Routes of Transmission

Humans remain the only known reservoir of mumps virus. Although a virus with over 90 % similarity to mumps virus at the amino acid level was recently identified in bats [172], the only established route of transmission of mumps is person-to-person. In 1948, Henle and colleagues transmitted mumps to mumps-naïve children by following both oral and nasal routes of inoculation, suggesting that infection is spread through droplets containing mumps virus infecting the upper respiratory tract [109]. The spread of mumps among persons in close contact also suggests this mode of transmission. Mumps virus may be present in the saliva of infected individuals for up to 7 days before onset of clinical illness [173] and 8–9 days following onset; however, it is usually present from 2 to 3 days before and 4–5 days after onset of symptoms [174]. The virus also is present in the saliva of persons with inapparent infections [109]. Outbreak investigations performed during the prevaccine era demonstrate that most transmissions occur before symptom appearance or during the first few days of symptom onset [106]. Transmission of certain vaccine strains of the virus has also been demonstrated, but is an uncommon event [175–181]. In addition to horizontal transmission, data from animal studies and from case reports of humans provide evidence that mumps virus can also be transmitted transplacentally [182–186].

7 Pathogenesis and Immunity

During the incubation period of 16–18 days (range, 12–25 days) following exposure, it is believed by inference from related viruses that the mumps virus multiplies in the upper respiratory mucosa and spreads to the regional lymph nodes, resulting in transient viremia. Despite presumed viremia, the virus has only been infrequently isolated from the blood [63], possibly due to the coincident development of humoral antibody. Both through experimental infection of animals, laboratory studies on human samples, and in vitro studies, viremia appears to be predominately cell associated, with activated T lymphocytes being the most likely infected cell type [63, 187–189]. Cell-free viremia has been suggested by the isolation of virus from clarified human serum on one occasion [63], but this has not been subsequently reported.

The occurrence of viremia during mumps explains the wide dissemination of the virus, as indicated by multiple organ involvement. Parotitis or other salivary gland involvement is evident in nearly all clinical cases, a function of the clinical case definition being based on salivary gland swelling. Viral replication in the parotid gland produces periductal interstitial edema and local inflammation, primarily involving lymphocytes and macrophages [190]. Serum and urine amylase levels may be elevated as a result of inflammation and tissue damage in the parotid gland [191]. Viral excretion in saliva clears with the appearance of mumps-specific secretory IgA antibody about 5 days after onset [109, 173, 174].

Involvement of the CNS is common and may occur whether or not parotitis is present [192]. More than one-half of clinical mumps infections involve the CNS as measured by pleocytosis of the CSF [193, 194], although only a fraction of these cases present with overt CNS symptoms. The virus can be recovered from the CSF early in the course of meningitis [192, 195]. Experimental infection in hamsters suggests that mumps virus enters the CSF through the choroid plexus, permitting distribution of the virus through the ventricular pathways and the subarachnoid space [189]. Based on experimental infection studies, virus-infected choroidal and ependymal epithelia become inflamed and slough off into the CSF, a postulated mechanism for obstructive hydrocephalus and aqueductal stenosis commonly observed in laboratory animals infected intracerebrally [196–198]. Notably, hydrocephalus is a complication of mumps in humans, although relatively uncommon [199, 200]. While encephalitis can also develop, it too is rare, occurring in less than 0.5 % of clinical cases [158, 159, 201]. Encephalitis is probably a result of viral penetration of the brain parenchyma by spread from contiguous ependymal cells that line the ventricular cavities of the brain [18]. Viral entry into neurons allows the virus to spread widely along neuronal pathways. In addition to the evidence for viral persistence from laboratory studies of cell cultures [202–205] and from animal models [189, 206], cellular responses and oligoclonal humoral responses have been shown to persist within the CNS of patients, implying continued antigenic stimulation and suggesting the persistence of the virus [18, 207–209]. The association of such persistence with late-occurring progressive CNS disease has been suggested [210].

Mumps epididymo-orchitis is also common, occurring in up to 30 % of cases in postpubescent males. Epididymo-orchitis is believed to occur by direct invasion of testicular cells by the virus, as evidenced by the recovery of the virus from the semen and testis during orchitis [211, 212], although an indirect immune-mediated mechanism also has been postulated [213]. The pathology in cases of epididymo-orchitis involves both Leydig and germ cells and can lead to altered levels of hormones, including decreased testosterone production [214–216]. Hypofertility can result but is uncommon. Sterility is exceptionally rare.

Renal involvement occurs frequently and is mild. One group of investigators detected viruria in 80 % of specimens collected within the first 5 days [217], and in another study of young servicemen, viruria persisted in some patients for as long as 25 days following onset [218]. All of these men had some abnormal renal function tests; however, none had generalized edema or hypertension, and all had negative cultures and normal renal function at the end of the study.

Involvement of the pancreas is characteristic of experimental mumps, and human pancreatic beta cell cultures are permissive to the virus [219]. Pancreatic involvement in patients with mumps is generally limited to epigastric pain; however, extensive damage can occur, resulting in hemorrhagic pancreatitis, but this has rarely been reported [220].

Although uncommon, transient or permanent deafness is one of the distinctive features in mumps, and mumps virus is the most frequent cause of acquired unilateral sensorineural hearing loss in children. The pathogenesis of deafness in mumps is unclear but likely involves retrograde penetration of the virus from cervical lymph nodes into the perilymphatic fluid, resulting in infection of the cochlea and causing damage to the organ of Corti and the tectorial membrane [221–225]. No pathogenic link has been demonstrated between deafness in mumps and other complications.

Humoral immunity is most likely the primary mode of protection. Studies of infections by related viruses demonstrate cellular responses to also be important, particularly in the recovery and long-term protection from disease; however, the significance of cell-mediated immune responses in mumps infections is unclear. In persons with severely compromised T cell responses, the course of mumps was found to not differ from that seen in healthy individuals [226], suggesting a limited, if any, role of cellular immune responses in mumps symptoms and duration. Similarly, neither severe symptoms of mumps nor a protracted course of illness has been reported in persons with AIDS. Despite this, in vitro lymphocyte proliferative responses to mumps antigen occur in seropositive individuals [227] and are largely dependent on T lymphocytes with IgG receptors [228].

8 Patterns of Host Response

8.1 Common Clinical Features

Mumps virus infections may be asymptomatic or associated only with nonspecific or respiratory symptoms in more than one-half of persons infected [108, 229]. Inapparent infection may be more common in adults than in children, and parotitis may be more common in children. Among persons with clinically apparent disease, host responses vary, depending on which organs may be affected. The major clinical manifestations of mumps and their frequency are presented in Table 24.1, gleaned from a review of data from 47 mumps outbreaks involving at least 20 cases.

Swelling and tenderness of the salivary glands are common, primarily the parotid glands; however, sublingual and submandibular glands also may be involved. Parotitis may be unilateral or, more commonly, bilateral, peaking on about the third day of illness and resolving within 10 days. A prodromal period may precede the parotitis by several days with nonspecific symptoms, including fever, malaise, myalgia, headache, and anorexia. In some patients other glandular tissues may be infected, causing epididymo-orchitis [230], oophoritis, mastitis [231], pancreatitis [220], or thyroiditis [232]. Pleocytosis of the CSF is common [193, 194], but only in a fraction of such cases is aseptic meningitis

Table 24.1 Major clinical manifestations of mumps

	Frequency (%)			
Manifestation	Mean	Range	90 % confidence interval	Number of studies
Glandular				
Parotitis or other salivary gland swelling	98	83–100	96,99	49
Epididymo-orchitis [1]	13	1–39	11,16	46
Oophoritis	4	<1–17	1,7	9
Mastitis [2]	10	<1–31	2,18	6

clinically apparent, much less so for encephalitis. Transient renal abnormalities also are common, but they are seldom accompanied by clinical manifestations and, thus, are rarely reported [218]. Mumps virus can cross the placenta and infect the fetus [185], and mumps has been associated with spontaneous abortions and intrauterine fetal death [233] but not congenital malformations [234].

An investigation of mumps in a seronegative population of Eskimos living on St. Lawrence Island in the Bering Sea in the 1950s provided rates of clinical findings in serologically confirmed cases (Table 24.2) [129]. Mumps infection was confirmed in 82 % of the 561 residents. Orchitis and mastitis were age related with sharp increases in frequency at puberty. Orchitis was bilateral in 37 % of cases. There were a few women who had lower abdominal pain suggesting oophoritis. In a few cases there were symptoms of thyroiditis. Delirium, vomiting, and high fever were associated with stiff neck in some of the patients, but all recovered. One of four deaths reported during the outbreak occurred 2 days following the onset of parotitis in an infant; however, the cause of death was not determined. There were three spontaneous abortions among eight women with clinical mumps in the first trimester of pregnancy and one abortion among 12 women with inapparent infections. No stillbirths or miscarriages occurred among women who acquired infection after the first trimester, and there were no congenital malformations in infants born to mothers with mumps during pregnancy.

8.2 Involvement of the Central Nervous System

Mumps virus is as an important cause of aseptic meningitis and encephalitis [235–241]. The high frequency of involvement of the CNS in mumps infection demonstrated by numerous studies conducted over the past 50 years has led to CNS involvement frequently being considered part of the natural history of the disease.

Many studies of CNS involvement have categorized aseptic meningitis and encephalitis together under the term "meningoencephalitis" rendering it difficult to differentiate between these two CNS complications that have markedly different clinical courses and prognoses. Variability in incidence rates also reflects the case definition used, the skill of the observers, the age distribution of the population, whether cases are hospitalized or are diagnosed as outpatients, and the frequency of the use of lumbar puncture.

CSF pleocytosis most likely occurs in 40–65 % of patients with mumps, but symptoms of meningeal irritation are evident in fewer than 30 % of closely followed cases [193, 242]. Reported rates of meningitis diagnosed during outbreaks range widely from less than 1 % to approximately 20 % (Table 24.1).

The CSF profile consists of normal opening pressure, apredominance of lymphocytes with cell counts commonly between 200 and 600/mm^3, elevated protein in up to 70 % of patients, and moderately low glucose concentrations in up to 30 % of patients [159, 195, 243–247]. Aseptic meningitis associated with mumps is a benign disease that resolves spontaneously and is not associated with long-term morbidity. There is no correlation between the level of CSF pleocytosis and the severity of the illness or outcome [159, 246, 248].

Encephalitis complicating mumps is much less frequent than aseptic meningitis, probably occurring in 0.1 % of cases [159, 201]. Mumps had been considered the most common cause of viral encephalitis until the early 1980s when the incidence of mumps was greatly reduced and other viruses such as herpes simplex, enteroviruses, arboviruses, and varicella-zoster virus became the leading cause of encephalitis. Although mumps encephalitis may be a severe disease, most patients completely recover [195, 243, 249, 250]. Postencephalitis ataxia, behavioral changes, and electroencephalographic abnormalities, should they occur, typically resolve within a few weeks [195]. Rarely, permanent neurological sequelae can result from mumps encephalitis, including behavioral disorders, seizure disorders, cranial nerve palsies, muscle weakness, ataxia, chronic headaches, aqueductal stenosis, and hydrocephalus [159, 192, 196, 200, 244, 245, 248, 251, 252]. Myelitis or polyneuritis also may follow mumps encephalitis [253–256]. Overall, the mortality rate associated with mumps encephalitis is less than 2 % and is higher in adults than in

children. Neuropathologic findings at autopsy are variable, and many reports come from unconfirmed cases. In most carefully examined cases, there is evidence of both cellular destruction, suggesting a direct effect of the virus, and demyelinization, suggesting an autoimmune process [257].

Among children with mumps, CNS disease is three- to fourfold more common in males than in females [159, 195, 242–247].

Sensorineural deafness is an important sequelae of mumps and may occur in the absence of meningitis or encephalitis [258, 259]. Deafness usually has a sudden onset, is unilateral in about 80 % of cases, and is usually thought to be permanent [260–263], although one prospective study of 398 servicemen being treated for mumps at a military hospital found hearing loss due to mumps to be transient in most cases [259]. The incidence of hearing loss associated with mumps has been estimated to range from 0.05 per 1,000 cases [260] to over 40 per 1,000 cases [259], which may be an underestimate since inapparent mumps can cause deafness [264]. The virus may cause direct damage to the cochlea and to cochlear neurons [223, 265, 266]. Mumps virus has been isolated from the perilymph of a patient with mumps and sudden unilateral deafness [221].

8.3 Involvement of the Heart

Acute myocarditis may result from various viral infections, including mumps [267–274]. Among persons hospitalized for mumps, 3 % of children and 7 % of adults show transient electrocardiographic abnormalities involving the ST segment or atrioventricular conduction defects [267, 268]. Electrocardiographic abnormalities suggestive of myocarditis have been detected in 1–15 % of clinical cases, typically between days 5 and 10 of the illness [275], but clinically apparent cardiac complications are rare. When it does occur, myocarditis is usually self-limited; however, it may be catastrophic [267, 268, 271, 276]. Mumps has also been implicated in cases of endocardial fibroelastosis. Some investigators have suggested that maternal intrauterine infection may result in endocardial fibroelastosis based on positive mumps skin test results; however, the data is inconclusive [273, 277–280]. Nonetheless, mumps virus RNA has been detected in endomyocardial biopsies or autopsy samples from children with endocardial fibroelastosis [274, 281].

8.4 Orchitis and Sterility

Mumps may be complicated by orchitis in over one-third of postpubertal males (Table 24.1). In most cases, testicular swelling and pain is unilateral, but bilateral orchitis is common. Follow-up of men who had orchitis during the large outbreaks of mumps that occurred during World War I and World War II did not show an association with impotence or sterility. Although testicular atrophy occurs in approximately one-third of the cases of mumps orchitis [282], an effect on quality or quantity of sperm is infrequent [282, 283], and sterility rarely occurs [211, 215]. A small increased risk of testicular cancer following mumps orchitis has been reported [230, 284, 285], but the significance of this observation is unknown.

8.5 Mumps and Diabetes

Pancreatic involvement in mumps has been linked to diabetes mellitus, but a causal relationship remains to be proved [227, 286, 287]. Notably, pancreatic damage has not been documented in case reports of diabetes in children following mumps infection [288–295]. It has been speculated that mumps and diabetes have a related periodicity based on the occurrence of outbreaks of diabetes months or years following outbreaks of mumps [286]. These studies were uncontrolled and relied on the clinical diagnosis of mumps without supporting laboratory tests. In one study, mumps accounted for 8–22 % of the 30 % of cases of insulin-dependent diabetes mellitus in which a viral infection may have been the precipitating event [296]. Another study found a seasonal relationship of diabetes with coxsackievirus but not with other viruses [297]. In a subsequent study, the association of mumps and coxsackievirus with diabetes could not be confirmed [298]. Less than 1 % of cases of juvenile-onset diabetes followed recent infections with mumps virus in a sample of 1,663 diabetic patients in England [299]. A study in pregnant women found no association between the presence of mumps, coxsackie B or respiratory syncytial virus antibodies, and diabetes [300]. Other investigators also have failed to find a relationship between antibodies to mumps or other viruses and diabetes mellitus [301–303].

8.6 Other Complications

A variety of other acute and delayed complications have been reported following mumps infection. Arthropathy is a rare complication that occurs predominantly in young men. Gordon and Lauter [304] reviewed the literature on mumps arthritis from the first description in 1850 through the early 1980s. They noted that a total of 32 well-documented cases of mumps arthritis had been reported in the literature since 1924 when 6 cases (0.44 %) were reported during an outbreak of 1,334 cases of mumps in Paris. A retrospective survey of 2,482 patients with mumps in England and Wales

failed to identify any cases with arthritis. Arthropathy following mumps may be manifest as arthralgia without signs of inflammation; as polyarticular arthritis, which is often migratory; or as monoarticular arthritis of the knee, hip, or ankle. The arthropathy may last from 2 days to 6 months and is self-limited without sequelae. Mumps virus can replicate in human joint tissue in vitro [305, 306], and one study reported detection of mumps virus RNA in the synovial fluid in 3 of 42 patients with early rheumatoid arthritis [307]; however, there are no reports of isolation of the virus from affected joints of patients.

Viruria is a common finding in patients with mumps [308]. In one study all 20 patients with laboratory-confirmed mumps had abnormal renal function at some time during the acute infection, but all had normal renal function and negative urine cultures within 24 days [218]. Clinically apparent nephritis is uncommon and generally benign [309–312]; however, fatal cases have occurred [309, 313]. Nephritis may result from direct infection of the kidney or immune complex glomerulonephritis [313].

Ocular manifestations of mumps also have been reported, including involvement of the lacrimal gland, which affected 20 % of soldiers in a 1903 epidemic, and optic neuritis, which may be associated with involvement of other sites in the CNS [314]. For unknown reasons, such complications of mumps are now rarely reported. Keratitis, iritis, conjunctivitis, scleritis, endonitis, corneal endotheliitis, and central retinal vein occlusion have been reported rarely.

Although the persistence of mumps virus has been suggested as a factor in neurological and muscular disorders of unknown cause, there is no compelling evidence for a causal association [315–317].

9 Control and Prevention

Given the high rate of asymptomatic infections and that transmissions often occur before symptom appearance or during the first few days of symptom onset [106], case isolation is of limited value in preventing the spread of disease. Where indicated, the recommended period of patient isolation is 5 days following parotitis onset [318], a guideline based on recent data showing that fewer than 15 % of patients continue to shed virus beyond day 4 of symptom onset [319].

Standard immune globulin or gamma globulin preparations have been found to be of little value for postexposure prophylaxis [114, 320], although some success has been achieved with mumps virus-specific immune globulin preparations, but only when administered early after the outbreak [320, 321]. Nonetheless, the value of mumps-specific immune globulin to public health was considered to be not high enough to warrant routine use and the product is no longer available in the United States or most other countries [322, 323]. Thus, vaccination remains the only practical control measure.

The first mumps vaccines were formalin-inactivated virus preparations, produced within a year of the 1945 publications of Habel [12] and Levens and Enders [324] reporting the propagation of mumps virus in embryonated eggs. These products were found to be safe and effective and were widely used [15, 325–329], although the duration of protection was relatively short-lived. In the United States, inactivated mumps vaccine was used from 1950 to 1978.

The observation that vaccines using killed antigens did not produce long-lasting protection led to the development of live attenuated mumps virus vaccines in the 1950s in the Soviet Union [16] and in the 1960s in the United States [17]. This effort was stimulated by the earlier work of Habel [12, 330] and Enders and Levens [14] demonstrating that live virus that had undergone continuous passage in chick embryo produced inapparent infections, but good immune responses in monkeys. At least ten different live attenuated mumps vaccine strains have been used in various countries around the world [331].

A live attenuated mumps virus vaccine using the Jeryl Lynn strain of mumps virus (named after the child from whom the strain was first isolated) was developed in 1965 and licensed in the United States in 1967 [17, 332–334]. This remains the only live mumps virus strain used in the United States and is the most widely distributed vaccine globally. Extensive prelicensure field trials were carried out by Stokes et al. [332] in Philadelphia and by others in several field studies [333–337]. Overall seroconversion rate was 97 % among children and 93 % among adults. Efficacy was approximately 95 % based on a follow-up period of 20 months. Vaccine-induced antibody persists for decades [338–341], although there is ample evidence of declining antibody titers with time postvaccination [81, 82, 135]. Whether such declines in virus-specific antibody levels can lead to breakthrough infections is a matter of controversy [80, 84, 85, 130, 140].

Mumps vaccine administered after exposure does not appear to provide clinical protection or alter the severity of the disease [336]. However, evidence from observational studies suggests that mass vaccination or "ring vaccination" during a mumps outbreak may help contain the disease and terminate the outbreak [161, 342]. This approach, although unlikely to prevent infection in those already exposed, will act to prevent infection in susceptible contacts.

Mumps vaccine is often administered in combination with measles, mumps, and rubella (MMR) vaccine or in combination with measles, mumps, rubella, and varicella (MMRV) vaccine. In the United States, mumps vaccine is no longer available in monovalent formulation. Incorporation of mumps vaccine into multivalent formulations with other viruses was found not to affect mumps vaccine safety or immunogenicity [331, 343–348].

In 1967, when the live attenuated mumps virus vaccine was licensed in the United States, mumps control was not a high priority in the public health community, as the disease was considered primarily a mild inconsequential disease of childhood. At that time, the Advisory Committee on Immunization Practices (ACIP) recommended that the newly licensed mumps vaccine be considered for use in children approaching puberty, for adolescents, and for adults who have not had mumps, but was not recommended for routine use in younger individuals due to uncertainties over the duration of immunity [349]. The specific concern was that protection against mumps in young children might be fleeting, resulting in an increased incidence of postpubertal susceptibility. A series of progressively stronger statements from the ACIP on mumps control followed [350, 351], with routine childhood immunization recommended in 1977. In 1989 the ACIP recommended that all children receive two doses of measles vaccine [352]. Because measles vaccine is generally given to children in the United States as MMR, the effect of implementation of this recommendation has been that most children receive two doses of mumps vaccine.

In general, people who can be considered immune to mumps (1) have documentation of vaccination with live mumps virus vaccine on or after their first birthday, (2) have laboratory evidence of mumps immunity, (3) have documentation of physician-diagnosed mumps, or (4) were born before 1957. During mumps outbreaks, vaccination with mumps-containing vaccine should be considered for people born before 1957.

In 2009 the ACIP revised their recommendations for evidence of mumps immunity for healthcare personnel to include documented administration of two doses of vaccine containing live mumps vaccine or laboratory evidence of immunity or laboratory confirmation of disease. For unvaccinated personnel born before 1957 who lack laboratory evidence of mumps immunity or laboratory confirmation of mumps, healthcare facilities should consider vaccinating with two doses of mumps-containing vaccine at the appropriate interval [353]. There is no increased risk associated with vaccinating immune persons; thus, those who are unsure of their histories of mumps disease or vaccination should be vaccinated.

Adverse effects of vaccination with the Jeryl Lynn vaccine, such as parotitis and low-grade fever, are infrequent and minor. Mild allergic reactions of short duration such as rash, pruritus, and purpura occur infrequently. Postvaccination aseptic meningitis has been reported in association with several mumps vaccine strains used outside the United States, but not for the Jeryl Lynn strain [354].

Mumps vaccine is contraindicated for pregnant women because of a theoretical risk to the fetus. Mumps vaccine virus has been shown to infect the placenta, but there is no evidence that it causes congenital malformations in humans [355]. Inadvertent vaccination during pregnancy should not be considered an indication for termination of pregnancy. Because live mumps vaccine is produced in chick embryo cell culture, persons with a history of anaphylactic reactions to eggs should be vaccinated with caution according to established protocols [356]; however, egg allergy is not a contraindication for vaccination. The vaccine also contains trace amounts of neomycin; thus, persons with anaphylactic reactions to neomycin should not receive the vaccine. Mumps vaccine should not be administered to immunodeficient persons; however, when vaccination against measles is indicated for symptomatic HIV-infected children, MMR vaccine can be used. Children who are infected with HIV but are asymptomatic should be vaccinated.

The benefit-to-cost ratio for mumps vaccination is high, with an estimated savings of $7–$14 per dollar spent on mumps vaccination programs [357, 358]. Zhou and colleagues calculated a savings of over $1.5 billion annually by vaccinating against mumps in the United States, equating to a saving of $3,614 per case prevented per year based on 2001 data [359].

School immunization laws beginning during the late 1970s have had a dramatic effect on outbreaks and the overall incidence of mumps. In 1977 when the ACIP recommended that children routinely be vaccinated against mumps [350], only five states had immunization laws. By 1993, this number steadily increased to 43, including the District of Columbia (DC). Presently, all states but Iowa require vaccination with mumps-containing vaccines for entrance into primary school [360]. The dramatic reduction in reported cases of mumps in the United States since 1991 reflects increasing implementation of school immunization laws requiring two doses of MMR.

In 1985, states without immunization laws had twice the incidence rates as states with comprehensive laws requiring proof of immunity against mumps [100]. During the resurgence of mumps in 1986, the reported incidence of mumps in 15 states without any requirement for mumps vaccination was 12-fold higher than that observed in states that had a comprehensive requirement [100]. An outbreak in New Jersey in 1983, in which students in the sixth grade were nearly seven times more likely to develop mumps than those in lower grades, reflected the partial school law that covered students from kindergarten through grade 5 [361, 362].

Although children can be exempted from immunization laws for various reasons, including religious, personal, or moral beliefs, the end effect of immunization laws is that presently nearly all children entering kindergarten have received at least one dose of mumps-containing vaccine. By 1996, ≥90 % of 19–35-month-old children had received at least one dose of MMR [363–365]. For the 2011–2012 school year in the United States, median coverage with two doses of MMR among kindergartners was 94.8 % based on

47 reporting states and the DC [126]. Among 49 reporting states and the DC, exemption rates ranged from <0.1 to 7.0 %, with a median rate of 1.5 % [126]. Based on the 2011 National Immunization Survey (NIS), among children 19–35 months of age (born January 2008–May 2010), coverage with one or more doses of MMR vaccine was estimated at 91.6 % [366], which is above the national *Healthy People 2020* target of 90 %.

Over 250 million doses of mumps-containing vaccine have been distributed in the United States since licensure in 1967. During this time, the incidence of mumps has been reduced by 99.8 %, with only 363 cases reported in 2011 compared to over 200,000 annually in the prevaccine era.

10 Unresolved Problems

Despite the remarkable success of mumps vaccination programs in reducing disease incidence, sporadic and sometimes large mumps outbreaks continue to occur, even in settings of high two-dose vaccine coverage. In 2006, the United States experienced its largest mumps outbreak in 19 years, with 6,584 cases reported, representing a 20-fold increase in the disease incidence in recent years. Disease incidence returned to the baseline the following year but then spiked again in 2009–2010. Whereas outbreaks in previous decades predominantly affected young, often unvaccinated children in primary and secondary schools, more recent outbreaks involve young adults on college and university campuses, the overwhelming majority of whom have a history of mumps vaccination [66, 132, 138, 367–373]. Thus, rather than a failure to vaccinate, contemporary outbreaks appear to be a consequence of vaccine failure, with the preponderance of evidence pointing toward waning immunity [81, 83–85, 135, 137–140]. Indeed, vaccine effectiveness during recent outbreaks is significantly lower than that reported under controlled clinical trials. In contrast to the prelicensure studies demonstrating a single dose of vaccine to be ≥95 % effective in preventing mumps [333, 334], more recent data from outbreak investigations have estimated vaccine efficacy to be less than 70 %, even for two doses of vaccine [84, 138, 369, 374]. These data support the growing body of evidence of waning immunity, i.e., two doses of MMR do not confer long-term protection against mumps. To some extent, waning immunity may be a consequence of the remarkable success of mumps vaccination programs themselves, i.e., as vaccine coverage increases, opportunities for virus transmission (which in the past served to periodically boost the vaccine-induced immune response) decreases. If indeed immunity is waning in older vaccinated cohorts, then adding a booster vaccination should be considered. The benefits of doing so are highlighted by the experience with military recruits who were spared involvement in the mumps resurgence in the United States in 2006, despite belonging to the same age group and residing in barracks across the United States, paralleling the high density, close-contact environment of university campuses. The likely reason for sparing of the military may lie with the military's practice in 1991 of routine administration of MMR to recruits without regard to prior vaccination status [6, 165]. This was later changed by some branches to targeted MMR vaccination of those lacking documentation of two doses of MMR or lacking serologic evidence of immunity to measles, mumps, or rubella.

While it is clear that the neutralizing antibody is required for protection [327, 375, 376], the amount required is not known. Neutralizing antibody titers in the range of 1:4–1:8 were found to be associated with protection in studies conducted during the prevaccine era [51, 98, 376, 377]; however, it does not appear that vaccine-induced antibody of this concentration is adequate [378]. More work is needed in this area to firmly establish a correlate of protection, if one exists. Particular attention should be given to evaluating the role of cellular immunity in disease prevention. While the presence or absence of mumps virus-specific cell-mediated responses correlates with the presence or absence of virus-specific antibody, the magnitudes of the two types of immune responses do not correlate [379, 380], and, in some instances, cell-mediated immune responses have been detected in seronegative persons [381, 382]. The precise role of cell-mediated immune responses in protection needs to be investigated.

In this era of routine use of more sophisticated epidemiological tools, such as viral gene amplification and nucleotide sequencing, it has been observed that virus isolates invariably cluster into genotype groupings distinct from those of the vaccine strains used, leading to the speculation by some that the recent rash of mumps outbreaks are due to the evolution of virus strains capable of escaping vaccine-induced immunity. While it was demonstrated that serum from recent vaccinees possessed strong neutralizing activity against a wide array of mumps virus strains [37], in light of the evidence of waning immunity, the persistence of such broad virus-neutralizing activity is not known and needs to be established.

Paramyxoviruses: Parainfluenza Viruses

25

Janet A. Englund and Anne Moscona

1 Introduction

Acute respiratory infection is now the leading cause of mortality in young children under 5 years of age, accounting for nearly one-fifth (20 %) of childhood deaths worldwide and killing two to three million children each year [1]. Human parainfluenza viruses (HPIVs) types 1, 2, and 3, human metapneumovirus [2], and respiratory syncytial virus (RSV) cause the majority of childhood lower respiratory tract disease in the United States. The parainfluenza viruses types 1 and 3 belong to the *Respirovirus* genus within the *Paramyxovirinae* subfamily of the *Paramyxoviridae* family of negative-stranded RNA viruses, while parainfluenza virus type 2 belongs to the *Rubulavirus* genus.

Human parainfluenza viruses (HPIVs) cause lower respiratory tract diseases including bronchitis, bronchiolitis, and pneumonia in infants, children, and immunocompromised individuals [3] and are responsible for up to 30–40 % of all acute respiratory tract infections in infants and children. In adults, the impact of these respiratory viruses may be serious as well. For example, in adult hematopoietic stem cell transplant patients, respiratory viruses cause about two-thirds of the respiratory illnesses, with high mortality [4, 5]. HPIV3 accounts for the vast majority of HPIV infections following transplantation, causing pneumonia with a 35 % acute mortality rate and a 75 % mortality rate at 6 months [4, 6]. Parainfluenza virus type 1 (HPIV1) is the principal cause of croup (laryngotracheobronchitis) in children. Parainfluenza virus type 2 (HPIV2) resembles HPIV1 in its clinical manifestations, but serious illnesses occur less frequently. Infections with parainfluenza virus type 4 (HPIV4) are detected less frequently.

With the use of sensitive molecular detection methods, the frequency and importance of HPIV infections in the community and hospital settings are becoming more appreciated. A recent survey study estimated that HPIV accounted for 7 % of all hospitalizations for fever and/or acute respiratory illness in children under 5 years in the United States or 23,000 hospitalizations every year in the United States that can be attributed to HPIV [7]. Half of these result from HPIV3 infection, with most of the remainder caused by HPIV1. The effective use of corticosteroids and nebulized epinephrine for HPIV1-associated croup has decreased the need for hospitalization for croup, and this development helps explain the decreased fraction of severe cases caused by HPIV1 [8].

Despite the impact of these viruses on illness and hospitalization of young infants worldwide, no specific treatment or prevention strategies are yet available, with the exception of the symptomatic benefit derived from corticosteroids for HPIV1-associated croup [9]. Development of antiviral drugs and vaccines for these viruses has been hindered by gaps in fundamental knowledge about the pathogens and about the human immune response to respiratory viruses. Recent discoveries provide a basis for optimism that effective treatments and vaccines may be available in the near future.

2 Historical Background

Chanock [10] first reported the isolation of a virus from human sources in Cincinnati in 1956 from children with croup, a virus originally designated as the "croup-associated" (CA) virus. Two additional strains were identified by their ability to adsorb guinea pig erythrocytes onto infected rhesus monkey kidney cells in culture in 1958 [11]. These two viruses, first designated "HA-1" and "HA-2," for hemadsorption 1 and 2, shared many biological properties with CA virus while being antigenically distinct, and they

were later reclassified as HPIVs: HPIV1 (HA-2), HPIV2 (CA), and HPIV3 (HA-1) [12]. HPIV4 was first isolated in 1960 [13], with two subtypes of this virus now recognized: HPIV4a and HPIV4b. During the same period, these viruses were compared with isolates obtained from animals. The Sendai virus [14] recovered from rodents was found to share antigens with HPIV1 and is classified as a subtype of this strain [15, 16]. In 1959, a hemadsorbing virus [17] antigenically similar to HPIV3 virus [18] was recovered from cattle with "shipping fever." A simian virus, SV5 [19], has been shown to be related to HPIV2 virus [20, 21] and is now called HPIV5.

3 Biological Characteristics

HPIVs are RNA-containing viruses with a spike-covered lipoprotein envelope [22]. Figure 25.1 shows a schematic diagram of a representative virus. The genome consists of single-stranded, non-segmented, negative-sense ribonucleic acid. The spikes are formed by oligomers of two glycoproteins, the hemagglutinin-neuraminidase (HN) and the fusion protein (F). The tetrameric HN is responsible for the receptor-binding (hemagglutinating) and receptor-cleaving (neuraminidase) activities [23], as well as for activating the membrane fusion process during entry. The trimeric glycoprotein (F) directly mediates fusion of virus and cell membranes during viral entry. The mature form of the F glycoprotein is generated by enzyme cleavage, which results in two disulfide-linked subunits, F_1 and F_2 [24], and requires an activation step in order to mediate fusion; activation is provided by the HN upon receptor engagement [25–28]. The viruses are relatively antigenically stable; although subgroups of the specific types may have recognizable antigenic differences at certain epitopes, these differences are stable and nonprogressive. Conserved epitopes—particularly on the fusion proteins—generate antibodies that neutralize across these subgroups [29, 30]. HPIV3 viruses remain infectious in an aerosol for periods greater than 1 h [31]. While there are no reported systematic studies of the stability of other HPIVs in aerosol, HPIV1 has been isolated from air samples collected near infected children [32].

A biological feature characteristic of the HPIVs is their ability to replicate in the respiratory epithelium without deeper invasion or immediate host cell death [26]. In vitro models of HPIV3 infection in the human airway epithelium indicate that infection occurs exclusively in ciliated epithelial cells and utilizes sialic acid residues for initiating infection [33]. The virus buds from the host cell membrane without lysing the cell, permitting continued release of infectious particles from a single cell [22]. HPIV3 virus may infect the mucosa of infants in the presence of maternally derived circulating antibodies [34–37] and also frequently reinfects older children despite circulating antibodies [38]. In fact, multiple reinfection is the hallmark of these viruses. Excretion of virus may be prolonged up to 1 month or longer, even with the second or third infection [39–41]. Immunocompromised patients may shed HPIV for many months, often with no or minimal intermittent symptoms [42]. Epidemiologic evidence suggests that reinfected children are infectious for their contacts [38]. The incubation period is approximately 3–6 days, and the virus spreads rapidly to a high percentage of persons in closed populations, indicating a high degree of infectiousness. In studies carried out in the 1950s, adult volunteers with preexisting antibody were infected with as little as 1,500 median tissue culture infectious doses ($TCID_{50}$) and more than half of the volunteers infected with HPIV developed signs and symptoms of an upper respiratory illness [43].

4 Diagnostic and Laboratory Methods

4.1 Culture

Classical methods of HPIV isolation in tissue culture have been utilized in most epidemiologic studies. However, direct identification of HPIV from cell culture usually requires fur-

ther evaluation because many viruses do not cause a direct cytopathic effect. Infection is therefore detected by a secondary step, for example, HPIV-type-specific labeled monoclonal or polyclonal antibodies [35, 44] or specific molecular detection using amplification strategies. The epidemiology of HPIV4 has been obscured due to difficulties in viral detection; HPIV4 does not cause cytopathic effect in many cell lines and detection of this virus was frequently missed using standard culture techniques.

4.2 Molecular Identification

Molecular methods have been used to detect virus and to examine questions of antigenic diversity among the HPIVs [29, 45–50]. Batteries of monoclonal antibodies directed toward epitopes of the surface glycoproteins were used for antigenic characterization, and gene sequencing later defined these epitopes. Reverse transcriptase-polymerase chain reaction (RT-PCR)-based sequencing assays have been adapted to epidemiologic studies of nosocomial infections [51–58]. The development of more sensitive, specific, and rapid diagnostic assays for respiratory viruses is critical for two major reasons. Diagnosis is becoming increasingly important to clinical management of patients and nosocomial disease in the health-care setting, and there is an urgent need for evaluation of the global distribution of disease.

The significant progress in applying molecular biology advances to respiratory virus diagnosis has led to several new clinically useful strategies [59–67]. For the practitioner, guidelines and clear data about the situations in which specific kinds of assays may be appropriate are needed. In the clinical setting, rapid identification of HPIV has been most frequently performed in clinical specimens using antigen detection with commercially available kits for rapid screening that have sensitivities and specificities of 80–90 %. Antigen detection has been the most widely used type of rapid test for HPIV until the early 2010s. These tests are performed directly in NP secretions, generally using fluorescent-conjugated antibody (DFA) and less frequently employing an enzyme-linked immunosorbent assay [60]. Most recently, molecular detection assays using multiplex quantitative reverse transcription-PCR-enzyme hybridization have been optimized to identify a panel of respiratory viruses and differentiate between HPIV1, HPIV2, and HPIV3 [68–70]. Several FDA-licensed molecular-based diagnostic multiplex RT-PCR assays for the detection of HPIV and other clinically important respiratory viruses are available, and the sensitivity, specificity, and positive and negative predictive values of these methods are excellent. Relatively simple RT-PCR kits such as those produced by Luminex Technology, Idaho Technology, or 3 M are currently being used in many medical center settings; sensitive and specific detection of HPIV and other respiratory viruses can be reliably reported to the clinician within 1 h [71]. Nonetheless, as for all rapid diagnostic assays available at the present time, confirmation by other means may still be important, especially in the face of a negative result in an ill child. Simple, effective assay kits (whether antigen or nucleic acid based) should allow for simple screening of children and are likely to be used more commonly in the future as antiviral therapies become available. Identification of the etiologic agent, even if no specific therapy is available, is key to containing respiratory virus outbreaks and avoiding transmission to vulnerable individuals.

The MassTag polymerase chain reaction method provides a paradigm for new detection strategies for early recognition and containment of a wide range of respiratory pathogens and exemplifies new molecular techniques that are sensitive and specific and potentially adaptable to diverse laboratory settings. Briese et al. have described the development of a MassTag polymerase chain reaction (PCR) for differential diagnosis of respiratory disease [72]. In this multiplex assay, the pathogen gene targets are coded by a library of 64 distinct mass tags. The microbial RNA or DNA is amplified by multiplex RT-PCR using up to 64 primers. Each primer is labeled with a different molecular weight tag, attached to the primer by a photo-cleavable link. After amplification, the mass tags are released from the amplified material by UV irradiation, the identity of the tag determined by mass spectrometry, and the identity of the organism determined by the presence of its two specific tags, one from each primer. The technology has been successfully applied to respiratory disease [72], where multiplex primer sets were designed to identify up to 22 respiratory pathogens in a single reaction. Such technology could be of use in the public health setting for identification of outbreaks and global surveillance.

4.3 Serology

Serological studies have been the main source of data delineating the importance of the parainfluenza viruses as etiologic agents of respiratory disease. Such studies have demonstrated the ubiquity of viral infection with HPIV and the similarity of age at acquisition of antibody throughout the world [73–80]. Many community studies have utilized both serological and viral isolation data but have relied most heavily on serological data to determine the frequency of infection within the population [81–86]. Vaccine studies also rely on serology as indicators of vaccine infectivity [74]. However, the use of newer, more sensitive technologies such as RT-PCR techniques and MassTag polymerase chain reaction method for surveillance in the future will be important.

5 Epidemiology

5.1 Morbidity and Mortality Data

Official morbidity reports do not include acute respiratory infections; furthermore, laboratory diagnosis is required to establish the diagnosis of an HPIV infection. Morbidity data, therefore, are based on prospective research studies of respiratory disease conducted around the world. Standardized techniques have been employed to provide some estimate of the impact of HPIV as causes of acute respiratory disease in diverse populations, with older studies relying on some combination of viral culture and serology and more recent studies mainly relying on molecular detection. Most studies have been cross-sectional studies of the etiology of either illnesses of hospitalized patients or epidemics in closed populations and provide a limited view of the total worldwide morbidity resulting from these viruses. Prospective investigations of the etiology of acute respiratory disease conducted over extended periods of time in large populations merit special mention because of the unique perspective provided. Seven studies carried out in the latter half of the twentieth century in Washington, DC [34, 87]; Chapel Hill, North Carolina [36, 88, 89]; Tecumseh, Michigan [86, 90]; Seattle, Washington [82]; Houston, Texas [39, 91, 92]; Tucson, Arizona [93, 94]; and Great Britain [95, 96] differed in methods of patient selection, types of illnesses surveyed, and ages of subjects, but as a group, they documented respiratory illness over an extended time period in widely diverse geographic environments and socioeconomic groups.

Other studies have focused on the occurrence of respiratory illness in specialized population groups. Children in hospital or outpatient settings have been studied extensively both in North America and Great Britain [7, 35, 97–104]. These patients include those with underlying conditions that put them at high risk for serious consequences of respiratory infections [45, 105–107]. Studies of uncomplicated respiratory disease in institutionalized children [38, 108–110] day-care groups [41, 111] and school children [112] have contributed information about the spectrum of disease caused by these agents. Additional family studies addressing the importance of HPIVs have been described using more classical techniques [113, 114]. The use of PCR detection in children in the family and day-care setting [111, 115] has contributed to the epidemiology by documenting the presence of prolonged shedding, multiple infections and reinfections, and asymptomatic disease. The role of HPIV has also been studied specifically in children with bronchiolitis [116], asthmatic children [117, 118], patients with chronic bronchitis [103], newborn nurseries [119], and children with hematologic malignancies [120]. HPIVs, especially HPIV3, are a serious problem for children with immune system compromise, including stem cell transplant (HSCT) patients. Known risks for increased mortality from HPIV3 after transplantation include graft-versus-host disease, steroid use, the presence of copathogens [121–123], and infection with HPIV3 within the first 100 days after transplant [123]. The lack of any effective therapy is especially troubling in these vulnerable groups (addressed in detail below).

The role of HPIVs as etiologic agents of respiratory illnesses in adults has also been investigated [81, 85, 124–129]. These studies have reported sampling of patients with acute respiratory disease in hospitals, military services, university student health services, and industrial medical facilities, generally relying on culture and serology. More recently, respiratory disease in hospitalized patients with underlying respiratory conditions has been prospectively evaluated utilizing a combination of culture, serology, and RT-PCR techniques [130, 131]. In the past, challenge experiments with HPIV have been conducted in volunteer studies in the United States [132–135] and Great Britain [43, 135, 136].

Evidence of infections with paramyxoviruses has been demonstrated throughout the world [77–79, 137], including tropical climates [80, 138–140] and isolated communities [75, 141], with the notable exception of the absence of HPIV1 and HPIV2 antibody in children in very remote Indian tribes in South America [142]. In developing countries, HPIVs are second only to RSV as the most commonly identified respiratory pathogens in children [138, 140, 143–150]. As in Europe and North America, HPIV3 is the most common HPIV isolated from severely ill infants, but types 1 and 2 have also been found [146, 150, 151].

Limited mortality data are available and consist chiefly of case reports [152–154], fatal pneumonia in severely immunocompromised patients [106, 121, 155–157], and case series in children with hematologic malignancy or HSCT [9]. Most deaths caused by HPIV are likely related to HPIV3 virus infections in young infants, but even in this age group, the etiology of fatal cases is not documented sufficiently to allow a reasonable estimate of the mortality rate in the general population. This problem is magnified in developing countries, where mortality attributed to acute respiratory disease is many times greater than in Europe or North America [1, 158]. Although the exact impact of HPIV in more recent studies in Africa has had varying results [159, 160], available data suggest that HPIV infections contribute to excess mortality [143, 145, 148, 149].

5.2 Incidence and Prevalence Data

5.2.1 Serological Surveys

HPIVs infect most persons during childhood. Serological surveys show that 90–100 % of children have antibodies to HPIV3 by 5 years of age [75, 80, 84]. Antibodies to HPIV1 and HPIV2 are not as universal as antibodies to HPIV3 or RSV, although 74 % of children over 5 years of age have

Table 25.1 Frequency of infection with parainfluenza virus type 3 (para 3) among children studied from birth, Houston Family Study, 1975–1980

Age (months)	Number of child-years	Number with infection with HPIV3			
		Primary	Reinfection	Total (rate)[a]	LRD[b] (rate)
0–12	121	75	6	81 (66.9)	14 (11.6)
13–24	90	30	31	61 (67.8)	9 (10.0)

Totals	337	107	75	182 (54.0)	26 (7.7)

[a]Per 100 child-years
[b]Lower respiratory tract disease

been shown to possess antibody against HPIV1 and 59 % against HPIV2 [161]. Similar data have been obtained in serological surveys in a wide variety of geographic areas [75–77, 80, 84, 140, 141] but not in remote South American tribes [142]. Serological studies of natives of Tristan da Cunha who moved to the United Kingdom demonstrated the rapidity with which an isolated population acquires antibodies to these viruses when they move to a heavily populated area [162].

5.2.2 Association of HPIVs with Illnesses

HPIV viruses were isolated from about 3 % of persons of all ages with acute respiratory disease presenting for medical care in Houston over a 5-year period [92]. During this time, 30 % of infections were type 1 and 10 % were type 2. Over 40 % of persons with HPIV1 and HPIV2 infections occurred among persons over 5 years of age, an older population than in those infected with HPIV3. Studies of lower respiratory disease have shown the highest isolation rates of HPIV1 and HPIV2 viruses to be in children between 4 months and 5 years of age [34, 36]. The rate for lower respiratory disease associated with HPIV1 virus infection in the Chapel Hill pediatric practice was 17 per 1,000 children per year for children under 4 years of age [36, 88, 89]. Infants followed in the Tucson study had lower rates in the first 6 months of life, but thereafter had rates comparable to those reported from Chapel Hill [94]. Lower respiratory disease after 2 years of age was relatively uncommon [37, 128]. Rates of HPIV infection, diagnosed by PCR methods, were demonstrated in 12 % of day-care attendees with respiratory illness, but only a minority (4/37, 11 %) were due to types 1 and 2 [52, 111] (Table 25.1).

Few studies of open populations have had sufficiently sized population denominators to allow calculation of attack rates. In Chapel Hill, studies of children with lower respiratory disease presenting to a pediatric practice from 1964 to 1975 showed that 15 children per 1,000 per year were infected with HPIV3 each year for the first 3 years of life [36, 88, 89]. The rates for lower respiratory disease in Tucson infants were similar in the first 6 months but fell below those in Chapel Hill during the last half of the first year [94].

In Houston, 121 children were followed from birth for infection with HPIV3 [92] (Table 25.1). About two-thirds were infected during each of the first 2 years of life. The risk of illness was at least 30 per 100 children per year. Most lower respiratory tract illnesses accompanied primary infection with a risk of 13 per 100 child-years. Over 90 % were infected at least once by 24 months of age, and almost 40 % had been infected twice. Similarly, 21 of 62 (34 %) infants in Chapel Hill followed longitudinally through the first 2 years of life developed respiratory illnesses associated with HPIV3 virus infection and 6 (9.7 per 100 children) had lower respiratory tract involvement. Four of fifteen were reinfected during the second year, yet 66 % of the total had neutralizing antibodies at the end of 2 years, indicating that mild or inapparent infections occurred at a rate similar to that of children presenting with illness. These two studies with intensive follow-up show that lower respiratory tract involvement due to HPIV3 is common in toddlers.

In contrast, seroepidemiological studies in school-age children [112] and young adults [81, 85, 126] have revealed a relatively low rate of HPIV seroconversions, although infections by these agents are well documented in adults. Prospective studies in long-term care facilities have shown relatively similar rates of HPIV1, HPIV2, and HPIV3 infection determined by prospective serological surveys compared to rates of infection with RSV, HMPV, and influenza [130].

HPIV3 virus infections have been detected in all studies of hospitalized children with acute lower respiratory disease [34, 87, 101, 104, 163], and this virus is now recognized to be second only to RSV as a cause of hospitalization for bronchiolitis and pneumonia in infants [7, 35–37, 89, 95]. Henrickson et al. assessed the disease burden in Wisconsin over 2 years (1996–1998) using multiplex PCR detection. The authors estimated that approximately 545,000 hospitalizations of children under 18 years old for lower respiratory tract disease occurred each year; the most common viruses detected each year in hospitalized children were RSV (A and B, 117,000), HPIVs (HPIV1 and HPIV2, 48, 000; HPIV3, 18,000), and influenza (A and B, 39,000). The HPIVs were detected much more frequently in immunocompromised children than in previously healthy children (33 % vs. 16 %).

A recent New Vaccine Surveillance Network study enrolled children younger than 5 years of age in the United States who were hospitalized with febrile or acute respiratory illnesses in the 2000s and found that HPIV accounted for almost 7 % of hospitalizations for fever and/or acute respiratory illness (ARI) in these young children. The authors estimated that HPIV3 is responsible for half of the 23,000 HPIV hospitalizations yearly [7]. In this study, nasal turbinate/throat swabs were tested for the pediatric respiratory viruses HPIV, RSV, and influenza virus, with culture and reverse transcription-polymerase chain reaction. Over the course of 4 years (2000–2004), 2,798 children were enrolled, and 191 HPIVs were identified from 189 children (6.8 % of enrolled: 73 HPIV type 1, 23 HPIV type 2, and 95 HPIV type 3), compared with 521 RSV and 159 influenza viruses. Mean HPIV hospitalization rates were 3.01, 1.73, 1.53, 0.39, and 1.02 per 1,000 children per year for ages 0–5, 6–11, 12–23, 24–59, and 0–59 months, respectively. The investigators concluded that the pediatric HPIV inpatient burden is substantial [7].

5.2.3 HPIV4 Virus Infections

HPIV4 virus has not been reported as frequently as the other HPIVs, but serological surveys indicate that infection may be common [164–166]. Most of these infections are considered to be asymptomatic, but isolation of the virus has likely been missed in studies relying on culture techniques [164]. More recent studies in hospitalized children [167] or studies of children attending day care [52] have documented variations in infection over time, with rates of symptomatic disease similar to that and sometimes exceeding that of other HPIV types.

5.3 Epidemic Behavior

HPIV can be isolated in any month of the year in both temperate [34, 89] and tropical climates [138–140]. Although HPIV3 circulation peaks generally in the spring, HPIV2 generally peaks in the fall, and HPIV1 seems to peak in the fall of only odd-numbered years [168] (Table 25.2).

5.3.1 HPIV1 and HPIV2

The longest continuous observation of the epidemic behavior of HPIV1 has been carried out at the Children's Hospital, Washington, District of Columbia. From 1957 until 1961, the virus was endemic [34]. Beginning in 1962–1974, sharp epidemics of HPIV1 virus occurred every 2 years in the autumn of even-numbered years [34, 87]. A similar pattern was noted in Great Britain between 1962 and 1977 [95, 96]. Epidemics of HPIV1 virus occurring in the fall of even-numbered years after 1962 have been described in other reports as well [89, 97–99, 101]. After 1970, a 3-year lapse occurred before resumption of biannual epidemics [169]. Since 1973, HPIV1 epidemics have occurred in the autumn of odd-numbered years in Houston, accompanied by HPIV2 [92]. In other longitudinal studies, including those in Tecumseh [86], HPIV1 virus occurred in the endemic pattern until 1971 but thereafter seen in autumn and early winter [90]. The evidence suggests that HPIV1 has varied patterns of occurrence but the predominant pattern in temperate zones is biannual epidemics in the fall [168].

HPIV2 appears to be nearly as ubiquitous as HPIV1 based on serological surveys, but is not associated as frequently with severe clinical disease. Because many laboratories have depended on the detection of viruses from more seriously ill or hospitalized patients with lower respiratory disease to document the presence of the virus in the community, less information on the occurrence of HPIV2 is available; this is changing with the availability of rapid molecular diagnostic methods for respiratory viruses. In the past surveillance studies of young children with minor respiratory illness, HPIV2 has had a distinct epidemic pattern with high attack rates in small, defined populations [41, 109, 110]. HPIV2 appears to occur in a sporadic epidemic pattern, often disappearing from the community for fairly long periods of time. Several studies in the United States have noted HPIV2 epidemics to occur in the fall of the odd-numbered years [87, 89, 90, 92, 170]; however, in Great Britain [95] and in the first Tecumseh study [86], HPIV2 occurred in well-defined but somewhat erratic epidemics, and in the Seattle surveillance studies [82], it was rarely identified.

5.3.2 HPIV3

Infections with HPIV3 virus have usually been described as endemic in nature, occurring throughout the year [87, 89]. Small outbreaks have been noted, but no predictable periodicity in their occurrence was noted until after a sharp outbreak occurred in Houston in 1977 (Fig. 25.2) [92]. Since that time, HPIV3 infections have tended to occur in the

Table 25.2 Clinical and epidemiologic manifestations of various HPIV types

Human serotype	Major clinical syndrome	Peak age (months)	Sex predominance	Periodicity[a]
HPIV1	Croup	6–24	Male	Epidemic (fall)
HPIV2	Croup	6–24	Male	Epidemic (fall)
HPIV3	Pneumonia and bronchiolitis	0–6	None	Endemic
HPIV4	URI	Unknown	Unknown	Endemic

[a]Peak season in parentheses

spring or during the months when HPIV1 and HPIV2 were not prevalent [168]. Although other major respiratory viruses generally cause relatively discrete epidemics, outbreaks of HPIV3 have occurred concurrently with outbreaks of other viruses [89].

5.3.3 HPIV4

HPIV4 has been assumed to cause relatively mild disease and generally has not been included in rapid antigen detection panels or diagnostic tests offered in pediatric centers. The addition of PCR techniques has increased detection rates of this virus. Recently, HPIV4 infection was specifically investigated in 225 young children attending day care in Fort Lewis, WA, using RT-PCR techniques [52]. HPIV was detected in 87/523 (17 %) of illnesses, with HPIV4 present in 10 % of these HPIV illnesses, the second most common type following HPIV3 (85 % of HPIV-positive illnesses). Marked differences in the proportion of HPIV4 infections between the early and later years of the 3-year study period were seen (22 % the first 2 years vs. 2 % the last year). No differences in the demographic profiles of children infected with HPIV4 versus other HPIV types were detected, including age, sex, race, or duration of time spent in day care, and no seasonal pattern was apparent for HPIV4 infection. Only one of 9 HPIV4 infections was associated with croup; the remaining cases all had uncomplicated upper respiratory tract infections. HPIV4 shedding was documented for up to 16 days, with a median of 12 days. In addition, HPIV4 was detected in 4/127 (3 %) asymptomatic enrollment swabs, with no asymptomatic shedding documented for either HPIV1 or HPIV2, and 3/127 (2 %) for HPIV3.

Other recent studies using molecular techniques to detect HPIV4 have been primarily based on hospitalized children, with a potential bias toward children with more severe illness. The proportion of HPIV4 as a cause of HPIV infection in these hospital studies ranges from 1.2 to 9.1 %, with a median of 3.5 % [58, 167, 171, 172], compared to the 10 % rate documented in the day-care study. The relatively higher rate of HPIV4 infection in the outpatient study suggests that HPIV4 may not be as likely to cause severe infection.

5.4 Geographic Distribution

HPIVs are found throughout the world and cause illness in young children wherever they have been identified. There is remarkable similarity of serological and isolation or PCR data obtained from tropical [80, 138, 173], temperate [38, 78, 84], and arctic [141, 174] climates. However, antibody to HPIV1 was found in very few Tiriyo Indians in South America and none under age 20; in the Xikrin tribe, there was no antibody in persons under age 17 years. HPIV2 antibody was present in Xikrin of all ages

but almost entirely absent in other tribes. This suggests that fresh introductions of virus are needed in very remote tribes in which the population base is too small to sustain the infection [142].

5.5 Age Distribution

5.5.1 HPIV1 and HPIV2

Data from studies of lower respiratory disease show few cases of severe disease in infants under 4 months of age [35, 36, 82, 95, 104, 138], with the most severe disease documented in premature infants or in newborn intensive care units [175, 176]. After 4 months of age, the number of cases of croup and other lower respiratory diseases increases dramatically [36], until approximately age 6 years. Lower respiratory illnesses in persons infected by HPIV1 and HPIV2 viruses are unusual in adolescents [89] and adults [81, 128], although they have been reported [129, 177].

Studies of milder illness have shown a similar age distribution. Infection and minor clinical illness occur more frequently in younger children than in adolescents and adults [86, 113, 178]. Infections do occur in older persons [81, 85, 86, 90, 95, 114, 126], most of which presumably represent recurrent infections in persons with antibody. Studies conducted in Tecumseh [86, 90] showed serological evidence of frequent infections in adults in age groups likely to include parents of school children. In family studies, infection in adults occurred concurrently with illness in their children, but attack rates in adults were distinctly lower than those in younger family members [113, 178]. Rates of hospitalization for HPIV1 and HPIV2 in adults with lower respiratory tract disease in the United States appear to represent only 0.2 and 2.5 % of adults hospitalized for lower respiratory tract disease [177].

5.5.2 HPIV3

Initial infections with HPIV3 virus occur early in life. Among children followed from birth in the Houston Family Study, 62 % were infected during the first year of life, and by the end of the second year, 92 % had been infected at least once and 36 % had one or more reinfections [92]. Similar to RSV infections, HPIV3 virus infections often occur in the very first months of life, despite the fact that these infants may still possess circulating antibodies derived from their mothers [34–37, 95]. Infants born with the highest liters of maternal antibody to HPIV3 may be spared during the first months of life. The risk of lower respiratory disease is greater for primary infection during the second year than for primary infection during the first year [92]. In studies of lower respiratory disease in the Chapel Hill pediatric group practice, the age-specific attack rate for HPIV3 disease paralleled that of RSV [36]. The average annual attack rate ranged from almost 15 to 7 per 1,000 children per year for children under 3 years of age [88].

After the first 3 years of life, the incidence of lower respiratory illnesses associated with HPIV3 infections falls off considerably, although studies indicate that reinfections are common in older children and adults. These infections are not generally associated with evidence of lower tract involvement [38, 81, 113, 125, 126]. Studies of HPIV3 infection in adults hospitalized with lower respiratory tract infection indicate an infection rate of approximately 3 % based on serology alone [177]. In a prospective study in adults with underlying respiratory disease, and using diagnostic techniques based on culture, PCR, and serology, HPIV3 was the most common respiratory virus after influenza detected in adults over the age of 45 [83]. HPIV infections are being increasingly recognized, like RSV, as an etiology of serious respiratory disease in elderly adults. Like RSV, HPIV3 causes outbreaks in geriatric facilities and can cause severe disease in older individuals [179–181].

5.6 Gender Differences in Infection

Boys have been long recognized to have a greater frequency of croup [182]. The Chapel Hill pediatric practice studies demonstrated infection rates for HPIV1 virus of 1.8 lower respiratory illnesses per 100 boys compared to 1.1 per 100 girls [36]. This sex difference disappeared after age 6 years. A similar predominance of serious illness in young males has been noted in other studies of lower respiratory disease [183]. Rates of infection in young boys and girls seem to be the same, but clinical manifestations of infection are more severe in boys [89]. Insufficient data are available to analyze HPIV2. HPIV3 caused identical rates of lower respiratory illness in males and females for children observed in Chapel Hill [89] and in the Fort Lewis day-care study [111]; however, in the Houston longitudinal study, boys were more likely to have lower respiratory tract involvement with primary infection [92].

5.7 Special Settings

Nosocomial infections with respiratory viruses occur readily if susceptible individuals are not isolated from those with HPIV shedding or respiratory disease. HPIV infections are detected commonly in studies of hospital-acquired infections in children on pediatric wards [163, 184–186] and neonatal units [119, 175, 176, 187].

Increasing reports of outbreaks and severe disease associated with HPIVs are being reported in immunocompromised hosts [45, 105, 106, 121, 155–157, 188–190].

Hematopoietic stem cell marrow transplant units and hematology/oncology wards are particularly susceptible to nosocomial infections due to cohorts of vulnerable patients who may shed viruses for prolonged periods of time, even asymptomatically [9, 42, 54, 191, 192]. Bronchoalveolar lavage fluid from these patients may contain high viral loads [193], and patients may be hospitalized for prolonged periods with increased exposure to viruses and other pathogens. Lung transplant recipients are also at high risk for serious morbidity and mortality from HPIVs [106], and outbreaks in lung transplant centers have been reported [194]. Symptom-based isolation, institution of good handwashing, and viral surveillance of patients with sensitive and rapid methods of detecting infection are necessary to institute control measures and recognize potential candidates for experimental antiviral therapy.

6 Mechanisms and Route of Transmission

Transmission of HPIV is by direct person-to-person contact or large-droplet spread. These viruses do not persist long in the environment, but HPIV1 has been recovered from air samples collected in the vicinity of infected patients [32]; from 1 to 10 % of HPIV3 virus particles in aerosol may be viable after 1 h [31]. Adult volunteers who have had prior natural infection have been reinfected experimentally by inoculation of the upper airway with a coarse aerosol or nasal drops or both [43, 132]. The high rate of infection early in life coupled with the high frequency of reinfection suggests that the virus spreads readily, that reinfected persons may be infectious, and that a relatively small inoculum may result in infection.

Outbreaks of HPIV1 and HPIV3 in symptomatic and asymptomatic healthy young adults stationed at the Amundsen-Scott South Pole Station in 1978 after 10 and 29 weeks of total isolation present an interesting addition to the story of HPIV shedding and viral transmission [195, 196]. Both HPIV1 and HPIV3 were recovered from frozen throat swabs of personnel overwintering at this station, and serological responses during midwinter outbreaks of HPIV infection when no new personnel had arrived for over 8 weeks suggest that persistent infection accompanied by prolonged shedding of HPIV occurs in healthy persons and may lead to outbreaks of respiratory illness.

There is little evidence of animal reservoirs for human disease and no evidence of vector spread. Sendai virus is a rodent strain of HPIV1 virus, but there is no evidence that it is related to disease in humans [22]. HPIV5 (formerly called SV5), a simian virus related to HPIV2 virus, has been reported to cause human infections but only on very rare occasions [20, 197]. Bovine HPIV3 virus is one of the agents commonly associated with an economically important disease of cattle usually called "shipping fever" [198], but there is no evidence of spread between cattle and man.

7 Pathogenesis and Immunity

7.1 Pathogenesis

The viral surface glycoproteins play a key role in the first steps of infection by HPIV. Infection of host cells is initiated by attachment of the virus to the host cell through interaction of the receptor-binding glycoprotein, hemagglutinin-neuraminidase (HN) with a sialic acid-containing receptor molecule on the host cell surface, as diagrammed in the schematic viral life cycle shown in Fig. 25.2. Upon interaction with receptor, the receptor-binding glycoprotein triggers or activates the viral fusion protein (F) to its fusion-ready state, promoting fusion of the virus into the cell and initiation of infection [25]. The fusion glycoprotein F is synthesized as a single polypeptide chain that forms a trimer before being cleaved by host cell proteases to yield a membrane-distal and membrane-anchored subunit. The new N-terminal region of the membrane-anchored subunit, termed the fusion peptide, contains the hydrophobic residues that insert into target membranes during fusion at neutral pH (reviewed in [199]). Infection also may result in fusion between cells, which involves the interaction of receptor-binding proteins and fusion proteins expressed on the surface of an infected cell with the membrane of an adjacent uninfected cell. The role of the HPIV HN molecule in promotion of fusion during viral entry has been elucidated in recent years [25, 27, 200–202]. Unlike influenza viruses, in which separate surface glycoproteins are responsible for the neuraminidase (NA) and receptor-binding (HA) activities, the HPIV HN is a dual-function molecule, carrying out both receptor binding during entry and receptor cleavage during budding and release of virus. The third function of HN, once receptor engaged, is to trigger or activate F to undergo its final conformational alteration that permits fusion [25]. One bifunctional active site on HN possesses both binding and neuraminidase activities, while a recently identified second site on HN possesses binding and F-protein-triggering activities [27, 203]. Finally, recent evidence suggests that HN interacts with F prior to engaging receptor and exerts a stabilizing effect on F that prevents F from being activated before it is in a suitable position with respect to the target cell [204].

After fusion of the viral envelope with the plasma membrane of the cell, the viral genetic material is released into the cytoplasm, as shown in Fig. 25.2. The nucleocapsid contains the genome RNA in tight association with the viral NP protein, and this RNA/protein complex is the template for both transcription and genome RNA replication. The

first step in the viral growth process, termed primary transcription to denote transcription directly from the infecting nucleocapsid template, initiates at the 3' end of the genome. Each of the mRNAs is transcribed and present in infected cells, at a level correlated to its relative location on the negative-sense viral genome. For five of the six genes of the HPIVs, transcription generally leads to generation of a single mRNA species that encodes a single protein molecule. However, the P gene of HPIVs encodes a number of proteins, and in several members of the family, more than one mRNA is synthesized and the mRNA also encodes a number of smaller protein products in an alternate reading frame from the P protein. These "C" proteins, as they are commonly called, are a nested set of carboxy-coterminal proteins, with each protein encoded in the same reading frame but differing by its start site on the mRNA. The functions of the C proteins are known to include key roles in evasion of the host immune response [205].

Unlike transcription, replication of the viral RNA genome depends on ongoing protein synthesis and therefore is linked to prior transcription of the viral genome. The second stage of genome RNA replication occurs when the newly replicated and encapsidated full-length plus-stranded RNA (antigenome)-containing nucleocapsids are copied into negative-stranded RNA-containing progeny nucleocapsids identical to the nucleocapsid that is packaged into progeny viral particles. These progeny viral nucleocapsids are templates for transcription.

After replication, as shown in Fig. 25.2, new viruses are formed by budding of newly replicated and assembled nucleocapsids containing the viral RNA genome along with the P and L proteins through areas of the plasma membrane that contain the viral surface glycoproteins and the M (matrix) protein. In polarized epithelial cells, the viruses bud from the apical surface of the cell. It is thought that the non-glycosylated M protein binds to the nucleocapsid, and also likely interacts with the cytoplasmic tails of the transmembrane glycoproteins, and thereby mediates the alignment of the nucleocapsid and the areas of the plasma membrane containing viral glycoproteins in preparation for budding [206–211]. It is likely that entry, fusion, and budding involve the participation of the cellular actin cytoskeleton as well as microtubule function [212–217]. Host cellular proteins that are involved in cell mobility may be important for these steps; one possible component of the entry/fusion mechanisms involves interaction between paramyxovirus F proteins and Rho A [215, 216].

Host cells have developed a variety of defense mechanisms in the face of viral infection. In some of these, an interferon (IFN)-induced antiviral state is created; some cell types undergo apoptosis, which limits viral replication. Many viruses have been found to possess strategies for evading these host immune responses, particularly the innate immune response that plays a key role in controlling virus infection [218]. For the paramyxoviruses including the HPIVs, evasion of this response is mediated by the C and V proteins. The V proteins are involved in a wide range of mechanisms for evading the immune response, including prevention of apoptosis [219, 220], cell cycle alterations [221], inhibition of double-stranded RNA signaling [219, 222], and prevention of IFN biosynthesis [219, 220, 222]. The strategies whereby different V proteins inhibit STAT proteins have been found to be highly diverse. For example, HPIV type 2 V protein targets STAT2 for degradation [223, 224], while mumps virus V protein can target both STAT1 [225] and STAT3 [226] and can also interact with cellular RACK1, potentially modifying IFN receptor activity [227].

7.2 Immunity

HPIVs replicate in the epithelium of the upper respiratory tract and spread to the lower respiratory tract within 3 days. The disease manifestations result from inflammatory obstruction of the airway. Epithelial cells of the small airways may become infected with resultant necrosis and inflammatory infiltrates. The interplay between virus-induced cell damage, beneficial immune responses, and inflammatory responses that contribute to disease for HPIV has not been well studied as it has for RSV; however, it is likely that in many cases, disease severity is increased and the pathology of clinical disease is actually caused by the inflammatory response rather than by the cytopathic effects of the virus. This concept is highlighted by the fact that virus titers in the infected host are generally waning by the time disease symptoms become apparent [228] and that virus titer does not correlate with the severity of lower respiratory disease. The pathologic changes that are present in children that have died with parainfluenza infection suggest exaggerated inflammation [152, 229] rather than simply tissue destruction by virus.

HPIV infections can induce both humoral and cellular immune responses in infected humans, including innate responses, local and systemic IgG and IgG responses, and T-cell responses. HPIV primary infection does not confer permanent immunity; however, although reinfection occurs, immunity is usually sufficient to restrict virus replication from the lower respiratory tract and prevent severe disease. Mucosal IgA levels correlate with protection from replication of HPIVs in humans [134, 135] and seem to provide the best correlate for protection, at least in adults. Cell-mediated immunity figures importantly in prevention of disease: for example, HPIV3 infection of T-cell-deficient infants can cause a fatal giant-cell pneumonia [134, 135], and in bone marrow transplant recipients, HPIV pneumonia has a 30 % mortality [106]. However, neutralizing antibodies against the HN and F proteins of HPIV are critical for long-term protection [230].

8 Patterns of Host Response

8.1 Clinical Manifestations

Primary infections with HPIVs are usually symptomatic, with clinical manifestations ranging from an afebrile upper respiratory illness to severe, life-threatening lower respiratory disease. The most characteristic and clinically important syndrome associated with infections with HPIV1 and HPIV2 is croup or laryngotracheobronchitis. HPIV1 was isolated from 20 % of patients with croup in studies in the Chapel Hill pediatric practice [36, 169], but HPIV2 virus is much less frequently associated with croup than is HPIV1 [34, 89, 169]. Studies in ambulatory populations suggest that most initial infections with HPIV1 virus result in febrile upper respiratory illness, whereas initial infections with HPIV2 virus result in less severe upper respiratory illness with many illnesses presenting without fever [41, 109]. Reinfection with HPIV results in similar respiratory symptoms from those caused by other viruses [92, 113]. The clinical manifestations of infections with HPIV viruses may differ in developing countries [147], with more cases of lower respiratory disease noted, although differences in surveillance methods could account for some of these features. The association of HPIV with croup, well described in developed countries, does not appear to be as common in developing countries [138, 146, 151, 231], where HPIV1 and HPIV2 infections are typically associated with pneumonia and tracheobronchitis [138, 146, 151, 231] (Table 25.2).

The clinical manifestations of infections with HPIV3 are varied. In the Chapel Hill studies, the clinical diagnosis varied with age [89]. Infants under 1 year of age were likely to present with bronchiolitis or pneumonia, whereas children from 6 to 18 months might often have croup. Older children were usually diagnosed as having tracheobronchitis. In general, no consistent clinical presentation of HPIV3 virus infection was found. The severe manifestations of HPIV3 infection, usually pneumonia, in developing countries are similar to those in developed countries. Figure 25.3 shows representative radiographic evidence of the pulmonary disease associated with HPIV3 in an immunocompromised child.

Prospective studies of children indicate that primary infection with HPIV3 is usually symptomatic but often mild [41, 92]. In children followed for the first 2 years of life, about one-third of primary infections involved the lower respiratory tract, but only 5 % of primary infections resulted in lower respiratory illnesses for which families sought medical. Frequency of reinfection—both symptomatic and asymptomatic—decreased with age. Reinfection was symptomatic among young children at the Washington, DC, children's home, Junior Village, only 20 % of the time [38], but this is likely higher than that in the family setting.

Evidence that HPIV infections may predispose to bacterial infections is accumulating [232–235]. Both otitis media and bacterial tracheitis in children have been associated with these infections [236], with otitis media documented in about 1/3 of children diagnosed with acute onset of HPIV infection [237], rates similar to that of otitis media following influenza or rhinovirus infection. An outbreak of invasive pneumococcal disease in a chimpanzee colony followed infections with HPIV3 [238]. Animals with HPIV3 upper respiratory illness were 5.7 times more likely to develop invasive pneumococcal infection despite the fact that most of the animals had received pneumococcal vaccine.

8.2 Clinical Syndromes

8.2.1 Pediatric Disease

Clinical diagnosis of the etiology of sporadic episodes of acute respiratory disease is difficult because many viral respiratory diseases have similar signs and symptoms. Infections with HPIV may be suspected when characteristic clinical manifestations occur in known epidemiologic patterns. The determination of HPIV outbreaks in the community is best ascertained using sensitive laboratory methods such as RT-PCR (see Sect. 4.2).

In developing countries, HPIV1 and HPIV2 infections appear to be less consistently associated with croup. In an HPIV1 epidemic in Trinidad, pneumonia was the most common lower respiratory tract diagnosis [138]. In such a setting, the clinical disease pattern will be less useful in identifying the occurrence of an HPIV1 epidemic. HPIV3 virus infections are much less predictable, but this etiology should be considered for infants less than 6 months of age with bronchiolitis or pneumonia occurring at times other than during RSV epidemics. Although medically attended lower respiratory illnesses associated with HPIV3 virus have had an even sex distribution [36], longitudinal studies have found the incidence of both croup and lower tract involvement more common in boys [92].

8.2.2 Disease in the Immunocompromised Host

The severe impact of HPIV infection in immunocompromised patients was first recognized in children with underlying immunodeficiencies, in whom giant-cell pneumonia has been documented at autopsy [156, 239]. Persistent respiratory tract disease and shedding have been observed in these children (Fig. 25.3) as well as HIV-infected patients [240]. In adult hematopoietic stem cell transplant patients, respiratory viruses cause about two-thirds of the respiratory illnesses, with high mortality [5]. HPIV3 accounts for up to

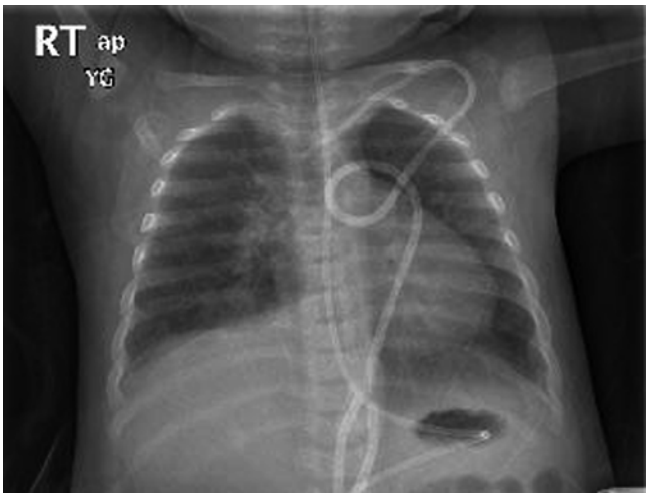

Fig. 25.3 Chest radiograph of an 8-month-old child with severe combined immunodeficiency infected with HPIV2 obtained 3 weeks following a hematopoietic stem cell transplant. The child was infected with HPIV2 pretransplant but unable to clear the virus due to the immunodeficiency and did well clinically until 3 weeks posttransplant, when he had respiratory distress requiring oxygen support. Chest radiograph is remarkable for right perihilar opacities associated with mild perihilar peribronchial cuffing, suggestive of viral lower tract infection. The child was treated with the experimental drug DAS181 (Ansun Biopharma, San Diego, CA), under an emergency IND, cleared the HPIV, and was discharged home

90 % of these cases [121], causing pneumonia (Fig. 25.4) with a 35 % acute mortality rate and a 75 % mortality rate at 6 months posttransplant [121]. High rates of pneumonia have been described in patients undergoing stem cell transplantation [106]; solid organ transplantation with kidney, heart, or lung [194, 241, 242]; and patients with hematologic malignancies undergoing chemotherapy, particularly induction chemotherapy [243]. The largest reports of HPIV infection have been reported in hematologic stem cell transplant recipients [121], where HPIV infection was diagnosed in 253/3,577 transplant recipients (7.1 %), with 78 % of the infections community acquired. In this study based on patients hospitalized in the 1990s, diagnosis was confirmed mainly using direct immunofluorescence testing and culture; rates of HPIV infection using more sensitive methods at the same institution in the early 2000s were noted to be higher—up to 13 % during the first year posttransplant [42]. Most infections in the transplant patients begin with typical symptoms of an upper respiratory tract infection with a low-grade fever, although asymptomatic infections or intermittent asymptomatic shedding have been noted [42]. Sinusitis may be present in up to 40 % of patients [243]. Progression from upper to respiratory tract disease is variable but common, ranging in various reports from 18 to 77 %. Risk of progression in stem cell transplant recipients is associated with steroid use and lymphopenia and may be less with nonmyeloablative conditioning [9, 121, 243]. Radiographic findings can vary from mild focal infiltrates to diffuse interstitial and alveolar interstitial infiltrates (Figs. 25.3 and 25.4) [106]. Risk of death following the development of lower tract disease can range up to 45 % [244]. Dissemination of disease to the pancreas, brain, pericardium, and myocardium has been reported [156, 245], but the most common serious adverse sequelae associated with HPIV infection in stem cell transplant patients and lung transplant recipients are significant declines in pulmonary function posttransplant [194, 246], even in stem cell transplant recipients who had only upper respiratory tract HPIV infection.

9 Control and Prevention Based on Epidemiologic Data

9.1 Vaccines

The development of a vaccine for the HPIVs, as for RSV, has been difficult because of the need to induce an immune response in young infants, who have both an immature immune system and maternal antibodies that may interfere with the development of an adequate immune response. An inactivated HPIV1, HPIV2, and HPIV3 vaccine used in infants in the late 1960s was immunogenic but did not offer protection from infection [247, 248]. Since that time, it has been challenging to identify vaccine viruses that are adequately attenuated for the vulnerable seronegative infant, yet also immunogenic. The development of reverse genetic systems has allowed for specific engineering of attenuated yet immunogenic vaccine viruses. Experimental vaccines are now under evaluation, with a reasonable expectation that a vaccine for HPIV3, and perhaps also HPIV1, will be feasible [230].

Two different strategies of interest are currently under active development by NIAID and industrial partners for HPIV3 vaccines: candidates based on live-attenuated bovine parainfluenza type 3 (BPIV3) strains and those based on a cold-adapted live-attenuated strain. Studies of both bovine-derived vaccines and live-attenuated human HPIV3 vaccines derived from well-characterized passages of human-derived vaccine strains have shown good evidence of safety, infectivity, and immunogenicity in children and infants [249–257]. In addition, new live chimeric candidate vaccines based on a chimeric construct expressing the HPIV3 F (fusion) and HN (hemagglutinin-neuraminidase) proteins and the RSV F proteins from the bovine HPIV3 viral genome have been utilized in human trials in seropositive and seronegative children and young infants [258, 259], suggesting that a combined HPIV3/RSV vaccine could be feasible [252, 260]. Recombinant HPIV3 vaccines have now passed phase

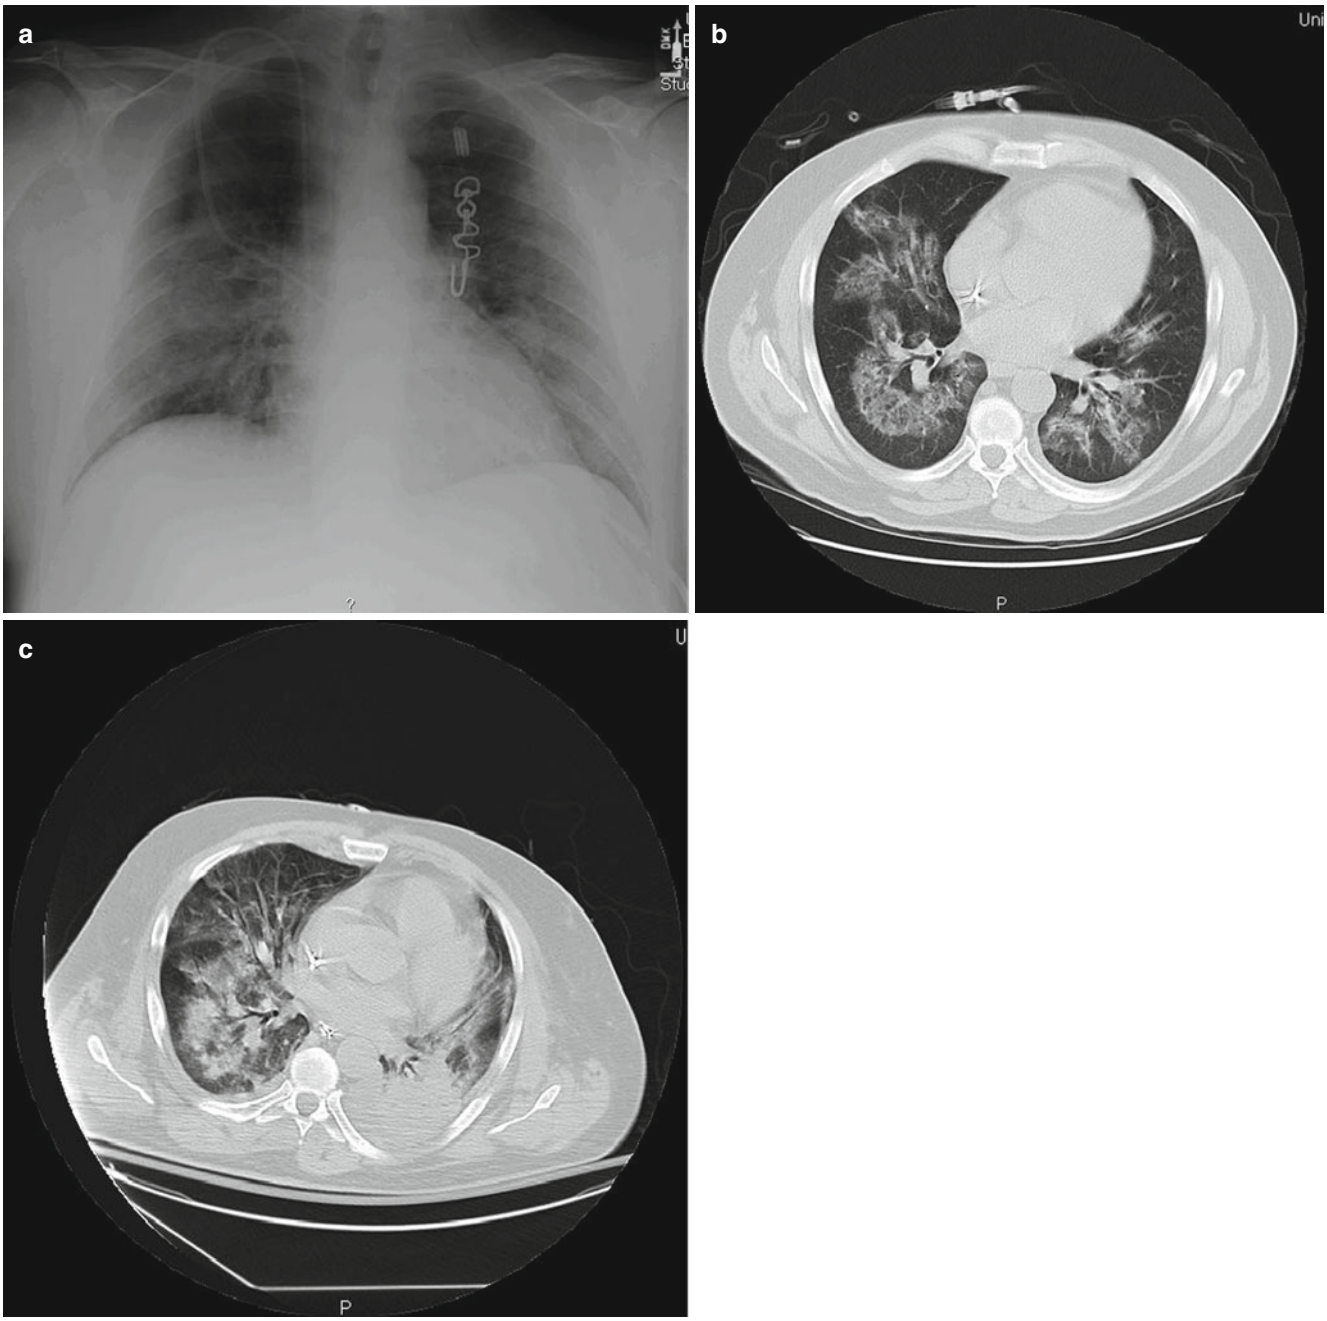

Fig. 25.4 Chest radiographic (**a**) and computed tomography findings (**b**, **c**) of a neutropenic adult male hematopoietic stem cell transplant recipient with HPIV3 infection diagnosed on day 11 posttransplant. No other pathogens other than HPIV3 were identified despite two bronchoalveolar lavage procedures and PCR testing for multiple bacterial, fungal, and viral pathogens. His history was significant for sinusitis pretransplant, with fever and upper respiratory tract symptoms documented beginning on day 7 posttransplant. He required intubation on day 18 posttransplant and, despite treatment with ribavirin, IVIG, and steroids, died soon afterward. (**a**) Chest radiograph, day 11 posttransplant. (**b**) Computed tomography of chest, day 11 post stem cell transplant. (**c**) Pulmonary consolidations and pleural effusions shortly before death, day 18 posttransplant

I evaluation and are undergoing testing in proof-of-concept trials [230].

The approach farthest along for HPIV1 vaccines is an engineered live-attenuated virus, with a series of attenuating mutations in several genes. In addition, a murine HPIV1 (Sendai virus) is being evaluated in a similar strategy to the bovine virus strategy for HPIV3. Approaches to HPIV2 also include specifically attenuated engineered viruses. Attenuated HPIV1 and HPIV2 vaccines are both at the pediatric phase I stage of clinical trials [230].

9.2 Antivirals

Therapy for the treatment of HPIV infections has relied on nonspecific symptomatic or anti-inflammatory treatments. For example, symptomatic benefit for the treatment of moderate to severe HPIV1-associated croup has been demonstrated with short courses of glucocorticoids, such as dexamethasone, shown to provide clinical and economical benefits, although ineffective for HPIV2- or HPIV3-associated respiratory disease [261, 262]. There is no specific antiviral therapy available for the treatment of HPIV infections. While ribavirin has been discussed as a potential HPIV antiviral based on in vitro data, it has no proven benefit, although there are anecdotal reports of benefit and lack of benefit in nonrandomized case series [121, 263–265]. Ribavirin therapy is not recommended [266] as published reports do not suggest a link between ribavirin use in cases of HPIV infection and improved outcome.

The potential benefit of antiviral treatment, especially for very young infants and immunocompromised hosts, is increasingly recognized [26, 244]. Several features of the viral life cycle make HPIV vulnerable to attack. HPIVs enter their target cell by binding to a receptor molecule and then fusing their viral envelope with the cell membrane to enter the cytoplasm. Binding, fusion, and each step in cell entry are critical stages which could be targeted to prevent HPIV infection and disease [26, 267, 268]. One potential strategy for HPIV and other sialic-binding viruses targets the removal of lung epithelial sialic acid receptor for HPIV, thereby preventing viral entry. A new recombinant sialidase, first developed as an antiviral agent for influenza, functions by cleaving sialic acids from the host cell surface, thereby inactivating the host cell receptor recognized by HPIV [269]. Reports of successful use of this agent in several adult and pediatric transplant recipients under compassionate use have been reported [270, 271, 272]. The molecule is an engineered neuraminidase molecule (DAS 181; Fludase) [268] and has not entered clinical trials at this time for HPIV but shows promise in proof-of-concept treatment of immunocompromised humans [273], and trials in specific populations are underway.

The HN molecule, in addition to binding to receptors, contains neuraminidase (receptor-cleaving) activity and cleaves the sialic acid moieties of cellular receptors, allowing new virions to be released from the host cell surface and infection to spread. While neuraminidase inhibition is unlikely to be as effective for parainfluenza viruses as it has been for influenza virus as an antiviral strategy [26, 274, 275], specific inhibition of this activity could prevent virion entry into additional uninfected cells [276].

The fusion protein undergoes a series of structural transitions as it mediates viral entry, and each of these steps is a potential target for antiviral development. F must form a transient intermediate to draw the viral and cell membranes together, and a conserved coiled-coil motif required for this step can be specifically targeted by fusion-inhibitory peptides that bind to specific sequences on the F protein. Such peptides inhibit viral fusion and entry in a dominant-negative manner by binding to F's transient intermediate, preventing F from advancing to the next step in fusion. Recently, it has been shown that membrane targeting of fusion-inhibitory peptides by use of a lipid tag allows efficient inhibition of the transient intermediate of fusion and also increases serum half-life and tissue biodistribution of the peptides, making them promising candidates for development as HPIV antivirals [277–279].

Finally, it is possible to subvert the normal process whereby HN activates F and cause HN to activate the F protein's fusion mechanism before it reaches the target host cell, thus incapacitating F before it can mediate viral entry; compounds are under development that will act by this mechanism [280]. As with other rapidly evolving RNA viruses (influenza, HIV, etc.), it may be important to use several antiviral agents simultaneously to attack different viral targets, to avoid the inevitable development of resistance to single antivirals. It will therefore be critical to develop several antiviral strategies in parallel.

10 Unresolved Problems

The clinical spectrum of illness at a young age, the failure of serum antibody to adequately protect against disease, and the ubiquity of infections make the HPIVs serious and challenging foes. Better understanding of the pathogenesis of disease and of the protective immune response will facilitate the development of effective antivirals and vaccines. The determinants of protective immunity need to be defined for natural infection, so that the natural response can be duplicated by active immunization. The use of attenuated live virus vaccines and particularly live virus vaccines built on the backbone of HPIV requires further investigation as a potentially beneficial and economical approach to immunization of young children. In addition, immunization of women of childbearing age should be considered as a means of protecting infants by passively acquired antibody during the first months of life.

As the number of immunocompromised patients increases due to advances in transplantation and antiviral HIV therapy and new methods of monoclonal antibody immunosuppression and treatment for a wide variety of diseases, the impact of respiratory viruses in general and HPIV in particular is becoming more well known. The need for safe and effective antivirals for the prophylaxis and treatment of HPIV infections in immunocompromised patients should be a high priority, and the need to avoid resistance by potentially using

several simultaneous antiviral strategies is important to any antiviral approach designed to combat RNA viruses.

A major unsolved problem is the substantial excess mortality from acute respiratory disease in developing countries. Acute respiratory disease remains one of the leading causes of death in children under 5 years of age in the developing world; available information suggests that HPIVs contribute significantly to this problem. As conjugate vaccines are becoming more widespread in developing countries to protect against pneumococcal and *Haemophilus influenzae* type B disease and measles vaccine uptake increases, the rates and causes of morbidity and mortality due to respiratory diseases in these young children require further investigation. Studies of the factors contributing to the excess mortality are urgently needed, and methods need to be explored that are adaptable to delivery in developing nations for preventing serious respiratory disease.

Acknowledgment The authors would like to acknowledge and thank Dr. W.P. Glezen for his contributions to previous versions of this chapter.

Paramyxoviruses: Respiratory Syncytial Virus and Human Metapneumovirus

26

James E. Crowe Jr. and John V. Williams

1 Human Respiratory Syncytial Virus

1.1 Introduction

Human respiratory syncytial virus (RSV) and human metapneumovirus (MPV) are members of the family *Paramyxoviridae* of the *Mononegavirales* order, comprising the nonsegmented negative-strand RNA viruses. *Paramyxoviridae* has two subfamilies: *Paramyxovirinae*, which includes the parainfluenza viruses 1–4 and measles and mumps viruses, and *Pneumovirinae*, which includes RSV and MPV. *Pneumovirinae* has two genera: *Pneumovirus*, which includes human RSV, bovine respiratory syncytial virus, and pneumonia virus of mice, and *Metapneumovirus*, which includes human MPV and avian metapneumovirus, sometimes called avian pneumovirus.

1.2 Historical Background

RSV was isolated first in 1956 from an ill chimpanzee in a laboratory setting that had an illness similar to the common cold. A virus causing a similar cytopathic effect in cultured cells was recovered from infants with respiratory illness shortly after, and studies of human antibodies in the serum of infants and children indicated that infection was common early in life [1, 2]. Now it is known that RSV is the most common viral agent of serious pediatric respiratory tract disease worldwide. In most areas of the world, RSV is the most common cause of pneumonia and bronchiolitis in infants less than 1 year of age. RSV causes severe disease in young infants, but disease is not restricted to the early life period. The virus can cause severe lower respiratory tract illness in large numbers of elderly subjects and also in subjects who are severely immunocompromised such as hematopoietic stem cell transplant recipients [3–7].

1.3 Epidemiologic Analysis

1.3.1 Mortality Data

Mortality in infants and children caused by RSV is uncommon in developed countries with modern critical care units. Estimates of the mortality rate are about 0.3 % of hospitalized children or less. Mortality has been dropping over the last several decades, and by the late 1990s the estimated number of deaths in the USA was several hundred children a year or less [8, 9]. Large epidemiologic studies report that the US mortality in children may be only about 100 cases a year. Interestingly, while many providers think of RSV infection as principally a pediatric illness, there are over 17,000 deaths per year in the elderly, making them the highest risk population for death [9]. In less developed countries, however, infant deaths due to RSV infection may be more common.

Infants with underlying illness are at highest risk among young children for morbidity and mortality from RSV infection. Infants with chronic lung disease requiring supplemental oxygen following treatment for prematurity, due to bronchopulmonary dysplasia, are perhaps at the highest risk for prolonged, severe, or fatal illness due to RSV [10]. Infants with severe congenital pulmonary or cardiac disease have been reported to be at risk of death in 3–4 % of cases when hospitalized, although this rate is likely decreasing in the USA [11]. Both children and adults with primary immunodeficiency or medically induced immunosuppression are at

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_26,

high risk of mortality due to RSV infection. The most severely immunocompromised, and thus those at highest risk of mortality, are hematopoietic stem cell transplant patients of any age [12]. In some settings, the mortality rate of RSV infection in hematopoietic stem cell transplant patients with severe immunosuppression verges on 100 % [12].

1.3.2 Morbidity Data

Hospitalization rates of infants for RSV disease vary with the setting, probably due to variations in exposure, genetics, socioeconomic, and other risk factors and due to the local practice style of medical providers. Many developed countries report hospitalization rates of about 1 in 100–200 infected infants during the first year of life [13, 14]. Studies of RSV disease in developed countries suggest that of those infants hospitalized, about 9 % require mechanical ventilation [15, 16]. There are certain populations at extraordinarily high risk of hospitalization with RSV, for example, Alaskan native infants younger than 1 year have been reported to have a hospitalization rate of 53–249 per 1,000 infants [16]. Low socioeconomic status is a risk factor for higher rate of hospitalization in most areas.

RSV also is one of the most common viral causes of serious lower respiratory tract illness in the elderly, especially in institutionalized subjects [17]. Exacerbations of chronic obstructive pulmonary disease (COPD) are frequently associated with RSV infection [18, 19]. The elderly do not exhibit a remarkably diminished level of antibodies to RSV [20]. Decreased levels of T cell memory in the elderly and specifically in patients with (COPD) may contribute to the increased susceptibility to RSV infection in these populations [21]. Many think of influenza virus as the principal viral respiratory pathogen in this population, but in a hospitalized cohort, influenza A virus and RSV infection resulted in similar mortality, lengths of stay, and rates of use of intensive care [17]. RSV infection accounted for over 10 % of hospitalizations for pneumonia.

1.3.3 Serological Surveys

Seroepidemiology studies suggest that virtually all children are infected in the first 2 years of life, and early infection is especially common in infants attending group day care. Serological methods are helpful in epidemiology and vaccine studies, but serologies are not often used for diagnosis in clinical settings. Because of the transfer of maternal RSV-specific antibodies across the placenta, and the high prevalence of early infection, it is unusual to find infants who are RSV seronegative. In older children and adults, a fourfold rise in serum antibodies is often used as evidence of RSV infection, but asymptomatic infections in which viral shedding is low in titer often are not accompanied by serum antibody rises. Serological tests in infants are even less sensitive, because young infants may not exhibit a large or durable rise in antibodies. Neutralizing antibody tests are considered the best functional marker of infection, but sensitivity is much higher in antigen binding assays using individually purified RSV F or G proteins [22].

1.3.4 Laboratory Methods

Isolation of the virus in cell culture provides a definitive test for diagnosis of active infection. Various methods of obtaining respiratory virus secretions for testing have been compared. Most studies suggested that aspiration or gentle flushing of nasal secretions using a solution like saline is best, though some types of nasal swab have given reasonable results. The virus is more thermolabile than most, and thus samples should be transported on wet ice to the diagnostic laboratory and processed rapidly. Prolonged times of transport to remote reference laboratories reduce the effectiveness of isolation. After inoculation onto susceptible cell culture substrates, highly trained staff can recognize cytopathology in the cell monolayers by visual inspection and conventional bright-field microscopy after about 3–7 days of incubation. Detection may be more efficient when using shell vial cultures and immunofluorescence [23]. Various cell lines have been used for RSV detection, such as HEp-2 epithelial cells, MRC-5 fibroblasts, and rhesus monkey kidney cells, but the R-Mix commercial mix of human and mink lung cells may perform better for detection of RSV [24].

Culture is expensive and requires highly trained staff and therefore is not usually available at the point of care, which is often an outpatient clinic or emergency department. Therefore, rapid diagnostic methods were developed for the detection of viral proteins or RNA in respiratory secretions. RSV antigen tests mostly rely on direct immunofluorescent assays (DFA) on exfoliated cells in secretions or enzyme immunoassay (EIA). Nucleic acid detection assays based on RT-PCR are now widely available for RSV, often in a multiplexed panel for detection of multiple respiratory virus pathogens. These tests are typically more sensitive than any of the virus isolation or protein-based detection assays discussed above. Enhanced sensitivity is especially helpful when testing adults, who often shed virus in very low titers. Positive RT-PCR tests need to be interpreted in the context of the clinical scenario, since the tests can remain positive for prolonged periods of time after infection, well beyond the period during which infectious virus can be isolated. Since children may experience symptomatic respiratory infections every few weeks during the winter, caution must be used in interpretation of positive PCR tests, especially when multiple viruses are detected simultaneously in a sample. Some instances of multiple PCR test positivity likely represent residual RNA from a previous virus infection and a second RNA type representing live virus from the active current infection.

RSV typically is propagated in monolayer cell cultures of continuous cell lines of human epithelial cell origin, such as HEp-2 cells. Monkey kidney cells of various types are also

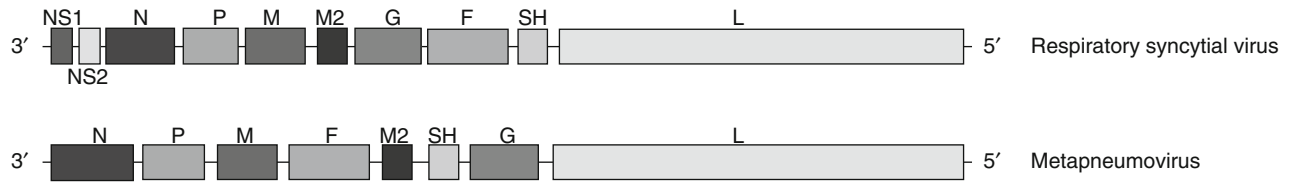

Fig. 26.1 Schematic of the genomic organization of respiratory syncytial virus and human metapneumovirus. Gene segments drawn roughly to scale

used commonly for propagation in the laboratory. In fact, the virus replicates to some extent in most cell lines of mammalian origin. In non-polarized epithelial cells, the virus often causes a typical cytopathic effect in which multinucleated giant cells form due to cell-cell fusion, termed cell syncytia. This in vitro effect is the origin of the virus name, although it is not clear that RSV causes syncytia in vivo. In polarized epithelial cells in culture, the virus assembles and buds from the apical surface of cells, mimicking to some extent the budding of virus into the lumen of the airway.

1.4 Biological Characteristics

The virus has a negative-sense single-stranded RNA genome with 10 genes encoding 11 proteins. Figure 26.1 compares the genomes of RSV and MPV, which are similar in many respects.

The replication proteins are common to both of the viruses, as are the matrix (M) protein and the surface fusion (F) and glycosylated attachment (G) glycoproteins. The gene order differs slightly, and RSV possesses two nonstructural (NS) genes NS1 and NS2 that are not present in MPV. The functions of these genes are not fully defined, but involve interactions with the host response machinery, especially interferons. The presence of these host response-modifying genes may explain in part why RSV appears to cause severe disease more commonly than MPV. Many of the gene sequences exhibit some clear global sequence relatedness; however, the extent of the relatedness of many of the sequences of corresponding proteins is relatively low. Based on sequence homology, it is not expected that there is a significant amount of immunologic cross-reactivity in responses to the two viruses.

The RSV virion buds from airway epithelial cells, incorporating host cell membrane as the lipid bilayer that forms the envelope of the particle. Since the virus is enveloped, chemicals that disrupt lipid bilayers (detergents) inactivate the virus, leading to the strong recommendations for healthcare provider hand washing following patient contact. The genome is a single strand of RNA, which forms a helical complex with the nucleoprotein (N). The final nucleocapsid structure likely is formed by the complete set of replication proteins, which also include the phosphoprotein (P) and the large RNA-dependent RNA polymerase (L). It is suspected that the M protein helps the particle to form by bridging the nucleocapsid and the lipid envelope with its incorporated surface proteins. The surface of the particle incorporates three integral membrane surface glycoproteins, the highly glycosylated RSV G protein suspected to be the attachment protein, the fusion protein F, and the small hydrophobic protein (SH). RSV F (a Type I integral membrane protein) and RSV G (a Type II integral membrane protein) form oligomers on the surface of the particles, which appear like small spikes with globular heads when seen in electron microscopic (EM) images by negative stain. The morphology of particles in EM images or in fluorescent microscopy images labeled by conjugated antibodies suggests that the virion particles are filamentous. However, spherical particles, filaments, and more pleomorphic forms have been observed; therefore, it is uncertain what the morphology of infectious particles in vivo during natural infection is.

The F protein is critical for entry into cells, by breaching the barrier of the cell lipid bilayer. It is thought that binding of virion particles to susceptible cells at physiologic pH triggers a conformational change of the F protein from a metastable pre-fusion state [25] to an altered post-fusion conformation [26, 27] in which the hydrophobic fusion peptide in the protein is exposed and extended to insert into the host cell membrane. This membrane insertion event accomplishes a fusion of the viral and host membranes, allowing delivery of the nucleocapsid to the cytoplasm where viral replication occurs. This event is termed "fusion from without" when the particle enters a cell. An alternative fusion event ("fusion from within") occurs when newly expressed F protein on the surface of infected cells causes fusion of an infected cell to an adjacent cell in culture causing "syncytia." It is not certain whether this latter form of fusion (cell-cell fusion) occurs during natural infection and contributes to pathogenesis or if the formation of syncytia is a tissue culture phenomenon only.

1.5 Descriptive Epidemiology

Although there are many animal forms of RSV, there is no known animal reservoir of human RSV; close contact with infected humans is the only source of RSV infection.

1.5.1 Incidence and Prevalence Data

Early prospective studies showed that approximately half of infants in the USA are infected during their first year of life; most were infected after two winter epidemics [28]. About a quarter of infants exhibit signs and symptoms of lower respiratory tract disease (wheezing and/or pneumonia) during a primary RSV infection [14, 28–31]. RSV is the most common virus associated with hospitalization for respiratory illness and in fact is one of the most common of all causes of infant hospitalization. For example, RSV caused 13 hospitalizations per 1,000 US children younger than 1 year in one large study [32]. During winter RSV epidemics, over 75 % of the children hospitalized for acute lower respiratory tract infection are infected with RSV [33, 34]. The rate of very severe disease in hospitalized infants is high, with about 2–5 % of hospitalized infants requiring mechanical ventilation for respiratory failure [35].

1.5.2 Risk of Infection and Reinfection

Although primary infection of infants is probably most efficient, RSV can infect subjects of any age [28, 36, 37]. Some adult infections are asymptomatic, and most are limited symptoms related to infection of the upper respiratory tract, such as the common cold [28, 36, 38]. Since otherwise healthy adults all possess measurable RSV serum antibodies and RSV-specific T cells, it is clear that prior exposure and induction of immune responses may not prevent infection. However, disease severity is usually reduced after one or several infections early in life, thus immune effectors such as serum neutralizing antibodies do prevent severe disease during reinfections. Unlike influenza virus, RSV does not exhibit a progressive antigenic drift. Although RSV antigenic diversity is observed in field strains, diversity of the antigenic proteins is not required for RSV to cause reinfection [39–41]. Most experts believe that serum neutralizing antibodies protect against severe lower respiratory tract disease but do not result in sterilizing immunity against infection at the respiratory mucosa. Thus, healthy adults show signs and symptoms of the common cold in about half of cases of natural or experimental infections, even though they have experienced numerous previous RSV infections [39].

There is a single serotype of RSV, but two antigenic subgroups of RSV, with about 25 % antigenic relatedness, have been defined using immune sera; the subgroups are designated A and B. Antigenic dimorphism for RSV had been noted in an early study [42] and subsequently was delineated using MAbs, which identified extensive differences in the G protein and less extensive differences in F and other proteins [43]. The two subgroups exhibit a three- to fourfold reciprocal difference in neutralization by polyclonal convalescent serum. Analysis of glycoprotein-specific responses in experimental rodent models or human infants by enzyme-linked immunosorbent assay (ELISA) with purified F and G glycoproteins showed that the F proteins are 50 % related antigenically and the G proteins are 1–7 % related [44]. Consistent with this level of antigenic relatedness, F protein expressed by a vector immunization was equally protective in small animals against challenge with the homologous or heterologous subgroup virus, whereas the G protein was 13-fold less effective against the heterologous subgroup virus [45]. Thus, the F protein is responsible for most of the observed cross-subgroup neutralization and protection. In some communities a pattern of infection with viruses of alternating subgroups has been described, but this is not a universal phenomenon. RSV subgroup B virus is more difficult to isolate and propagate in culture, so subgroup B viruses are less commonly associated with severe disease in some studies. However, clearly viruses of both subgroups can cause severe disease leading to hospitalization [46–50].

1.5.3 Risk of Serious Lower Respiratory Infection (LRI) During Infancy

Infants exhibit the highest risk of severe lower respiratory tract disease. This elevated risk is explained by a myriad of physiologic, immunologic, and other factors. First, the highest point of resistance in the airways is the bronchioles, and the resistance of airways is inversely proportional to the airway radius to the fourth power (resistance ~ $1/\text{radius}^4$, from Poiseuille's law). The bronchioles of infants are narrow, and inflammation and secretion in the bronchioles leads to turbulent airflow, and further reduction of the airway lumen size. These physical factors lead to the clinical signs of wheezing (a sign of outflow obstruction) and air retention. Increased respiratory rate can compensate to some extent for respiratory compromise, but prolonged tachypnea can lead to fatigue and eventual respiratory failure. Also, during primary infection infants do not possess active immunity to infection, which allow this efficient virus to replicate in the airway to titers as high as 10^7 infectious particles per mL of secretion. Mothers pass RSV antibodies to infants across the placenta during the third trimester, but premature infants do not obtain maternal antibodies prior to 32 weeks' gestation. Also, the airways of premature infants are smaller than those of term infants. Another factor leading to respiratory difficulty is dehydration. Obstruction of the nasal passages with thick secretions can impede the feeding of infants, who are obligate nose breathers.

1.5.4 Role of RSV Infections in Adults

RSV also is an important cause of serious infection in elderly adults; in fact RSV appears to cause substantially more fatalities in elderly adults than in children [17, 51]. As above, a large study of the US population showed that RSV was associated with approximately 17,000 all-cause deaths per year among persons of all ages in the USA [9], with most of those deaths in the elderly.

1.5.5 Role of RSV in Infections with Underlying Cardiopulmonary and Other Medical Diseases

Virtually any serious medical or genetic condition is associated with some increased risk of severe diseases [32]. Certain particular categories of subjects are at highest risk for severe RSV disease, including infants with congenital heart or chronic lung disease, immunodeficient subjects of any age and the elderly [9, 10, 17, 33, 52–57]. These latter subjects are thought to have reduced competency of RSV-specific T cells. Prematurity increases risk to a small extent, but more importantly chronic lung diseases are important factors [10, 33, 56, 58–62]. Infants who are born prematurely and then suffer persistent chronic lung disease, especially those needing oxygen supplementation, are at very high risk of hospitalization with RSV. Children with cystic fibrosis are at high risk of severe disease [63, 64]. In children younger than 2 years with cystic fibrosis, the consequence of RSV infection may be prolonged respiratory morbidity [65]. Children with congenital heart disease also are at increased risk [33, 56, 58, 62, 66, 67].

1.5.6 Role of RSV Infections in Patients with Immunodeficiency

RSV is a common cause of severe respiratory disease in immunocompromised patients, including lower respiratory disease [68]. Mortality rates in some populations of immunocompromised patients verges on 50 % [7, 69]. Infants with congenital severe combined immunodeficiency are at special risk [57, 70], but any acquired immunosuppressive condition such as cancer or transplantation puts patients at risk, especially when T cell function is compromised [68, 71, 72]. RSV infection can cause severe lung disease in recipients of lung transplants, sometimes with a long-term outcome of obliterative bronchiolitis [73–75]. Children with HIV infection shed RSV for extended periods, but disease is not especially severe in HIV-infected children prior to onset of AIDS [76–78]. Interestingly, although most immunocompromised subjects appear to be at risk because of T cell problems, infants with phagocytic cell defects including those with interferon-γ receptor deficiency or chronic granulomatous disease also are at risk of severe RSV disease.

1.5.7 Role of RSV in Nosocomial Infection

Transmission of RSV in the hospital setting can lead to serious disease, especially in critical care units with neonates or other high-risk infants [79–86]. Nosocomial outbreaks in inpatient transplantation facilities are sometimes severe and unit outbreaks can be difficult to terminate because transplant patients can shed RSV for many months [57, 58, 69, 84, 87, 88]. Theoretically, transmission in inpatient healthcare settings should be preventable through strict compliance with infection control practices, especially hand washing and contact precautions, which are universally recommended for RSV patients. A high level of compliance with precautions is difficult to achieve in busy care settings but is needed to prevent transmission by healthcare providers. The use of the prophylactic monoclonal antibody palivizumab has been studied to interrupt an outbreak in a neonatal intensive care unit setting [89], but currently palivizumab use is not recommended for this purpose.

1.5.8 Role of RSV in Otitis Media

Bacterial otitis media is a common complication of RSV upper respiratory tract infection. In fact, RSV infection is probably the most common precipitating factor associated with otitis media. RSV antigens and nucleic acids have been reported in middle ear fluids [90, 91]. The disease is predominantly due, however, to Eustachian tube dysfunction, resulting in bacterial stasis in the middle ear and subsequent otitis media.

1.5.9 Epidemic Behavior

RSV regularly occurs in annual epidemics. The US National Respiratory and Enteric Virus Surveillance System (NREVSS) considers that the RSV season starts when the first of two consecutive weeks during which the mean percentage of specimens testing positive for RSV antigen is ≥10 %. The RSV season is considered to have ended in a community when the mean percentage of positive specimens is ≤10 % in reference laboratories for two consecutive weeks.

1.5.10 Geographic Distribution

RSV infection occurs in infants and adults worldwide, in yearly epidemics. The virus has been isolated in every area of the world in which surveillance studies have been conducted. The principal season varies depending on the climate and region, but infection is ubiquitous. Virtually all children in the world are infected within the first few years of life.

1.5.11 Temporal Distribution

Epidemics occur in the winter and early spring in the USA. Onset of the annual epidemic varies by region of the country and by year but typically begins in the USA in October or November and lasts through late spring. Within a region, the timing of RSV season changes slightly each year. Florida often has the earliest onset of RSV epidemic and the longest lasting season in the USA. Near the equator, infections may be more common during rainy season.

1.5.12 Occurrence in Different Settings

During community outbreaks of RSV, the venues with the highest level of young infants and children exhibit the highest rates of transmission of virus, especially large families and day-care settings with large numbers of children per

room. Hospital infection control practices must be used to prevent RSV spread, using measures including careful hand hygiene, contact precautions for patient isolation, gowns and gloves [92, 93], and, when direct coughing occurs, facemasks and goggles [94, 95]. RSV rapid diagnostic testing can be used in hospital infection control practice to identify RSV-infected patients during the admission process [96, 97]. RSV is shed for prolonged periods. It has been reported that 92–100 % of hospitalized children are still shedding infectious virus after 7 days [98, 99].

1.5.13 Environmental Risk Factors

Exposure to tobacco smoke and poor nutrition increase the incidence of disease [100–102]. Low socioeconomic status increases the risk of severe disease for uncertain reasons. Lower income populations exhibit a five- to tenfold increased risk of hospitalization in many studies [14, 32, 103].

1.5.14 Other Factors

Breast-feeding may confer some protective benefit against RSV disease, but the extent of the benefit of breast-feeding has been controversial. The results of epidemiologic studies on benefit have been conflicting, although recent studies suggest that breast-feeding may have a strong protective effect only in girls [104]. The sex of the infant modulates the severity of RSV infection for additional reasons that are not fully understood. Even though the same high proportion of both male and female infants become infected, males have a higher incidence of RSV lower respiratory tract disease than girls [30, 32, 105–108]. Ethnic and genetic factors appear to play a role. Alaska and other Native American children are at increased risk of severe respiratory disease during RSV infection [109].

1.6 Mechanisms and Routes of Transmission

Direct contact with secretions from an infected human, usually by fomites (contaminated objects, including hands), allows transmission of virus. In some cases, infected subjects may inoculate contacts at short distance by coughing via large-particle droplets. However, the virus is not spread efficiently by small-particle aerosols [110, 111]. The nasal and conjunctival mucus membranes are probably the most common portals of entry [112]. RSV is one of the most infectious viruses spread by contact, and transmission is very efficient even among subjects who possess partial immunity due to prior infection. Spread among family members and day-care contacts is especially common. The infectious doses for humans are probably only a few infectious particles per mL of respiratory secretions, but infants routinely shed at least a millionfold higher concentration of virus during the peak of illness. The incubation period is not known definitely but is about 3–6 days and likely varies according to the intensity of exposure and the amount of virus in the inoculum. The period of viral shedding is many days; infants can shed infectious virus for weeks [98, 99]. RSV can survive on hard surfaces for greater than 24 h.

1.7 Pathogenesis and Immunity

Infection occurs by inoculation of the nasal or conjunctival mucosa, often by self-inoculation with infected secretions from a close contact. Adult volunteers were infected experimentally if virus was inoculated onto the conjunctival sac or into the nose, but not following introduction into the mouth [112]. The incubation period from time of inoculation to onset of illness for RSV is likely about 4–5 days [113]. Virus replication initiates in the nasopharynx and rapidly can reach concentrations of over a million particles per mL in the upper airway in children. Adults, who are partially immune, typically shed much lower amounts of virus. Virus spreads quickly to the lower respiratory tract, often causing symptoms within days of onset of upper respiratory symptoms. Virus may spread from cell to cell, but also it is likely that small aspirations of upper respiratory secretions with virus inoculate the lower tract.

Higher titers of virus in respiratory secretions usually are associated with increased severity of disease, in prospective studies of natural infection [114] or of clinical vaccine trials [115]. RSV infection is an acute infection and virus shedding usually resolves within days to weeks. RT-PCR tests for virus nucleic acid may remain positive for prolonged periods. Some animal studies suggest that a negligible amount of infectious virus may persist in airways far after apparent resolution of shedding, as evidenced by the recovery of low amounts of infectious virus during immunosuppression several months after infection [116].

The virus infects respiratory epithelial cells in the lung and airway. It is not clear whether RSV also replicates productively in macrophages and dendritic cells in the airway or not. RSV protein antigens have been detected in circulating mononuclear cells [117], and viral genomic RNA and mRNA have been detected by RT-PCR in blood cells [118], but this probably represents cells from the airway recirculating, as infectious virus in the blood (viremia) is not detected. RSV replicates in the cells at the luminal surface of the respiratory epithelium and virus both enters and is shed from the apical surface of infected epithelial cells [119, 120]. Studies of polarized, differentiated respiratory epithelial cells in vitro show that RSV infection preferentially infects ciliated cells at the luminal face [121], but it is not clear if infection is restricted to such cells in humans. Histopathology studies of infected humans are very limited, but show RSV antigens in

the superficial cells of the airway in a patchy distribution, with antigen-positive cells and debris in the airway lumen.

Pathology caused by RSV infection during infant bronchiolitis includes necrosis and proliferation of the bronchiolar epithelium and destruction of ciliated epithelial cells [120, 122]. There is an influx of a large variety of immune cell types including neutrophils, lymphocytes, and macrophages. The respiratory tissues become edematous. Mucous secretion, sloughing of dead cell debris, and the influx of apparent inflammatory cells obstruct the lumen of the narrow bronchioles and alveoli. The small diameter of infant bronchioles is easily obstructed in the presence of dead cells and edema of the airway tissues [123]. Virus-infected cells can be identified in the epithelium of the bronchi, bronchioles, and alveoli [120]. It is surprising, given the extent of disease, that RSV antigen staining is usually patchy or focal, and even in some cases of fatal RSV bronchiolitis, antigen is present only in small amounts [119, 120]. The number of cases that have been collected is limited, however, and there is virtually no histopathology from milder cases.

RSV upper respiratory infection is complicated frequently by otitis media caused by bacteria. It is unusual to observe frank bacterial pneumonia or sepsis as a complication of RSV infection, in contrast to some other respiratory viruses like influenza. Although some clinicians may empirically use antibiotics during infant pneumonia, there is no evidence that antibiotic therapy alters the course of RSV bronchiolitis or pneumonia. Antimicrobial therapy should not be used in most cases of RSV bronchiolitis or pneumonia because of the lack of benefit and risk of selection of antibiotic-resistant colonizing organisms. Nevertheless, there is some suggestion that bacterial-viral interactions may affect the overall rate of disease in the population. It is interesting that annual RSV and influenza virus epidemics correlate directly with the time of peak incidence of invasive pneumococcal disease in many population studies [124]. A double-blind, randomized, placebo-controlled trial of pneumococcal conjugate vaccine showed a vaccine-attributable reduction in rates of childhood viral pneumonia requiring hospitalization, caused by any of seven respiratory viruses, including RSV [125].

The immune mechanisms responsible for resolution of infection and protection against reinfection by RSV are not fully defined.

Antibodies. Most experts agree that high levels of serum neutralizing antibodies are associated with relative protection against severe lower respiratory tract disease in otherwise healthy subjects. This idea is supported strongly by the observation that prophylaxis of high-risk infants with a neutralizing monoclonal antibody prevents about half of hospitalizations in that group of patients. Many population studies suggest that infants born with high levels of transplacental RSV-neutralizing maternal antibodies develop milder illness or illness at an older age than infants with low maternal antibody levels [15]. Most infants and children in whom maternal antibodies have declined to a low level make their own serum and secretory antibodies to both the F and G surface glycoproteins in response to RSV infection [126]. Antibody responses in neonates are particularly low in quality and magnitude due to immunologic immaturity and the suppressive effect of passively acquired maternal antibodies [126, 127]. Antibody-mediated immune suppression by passive antibodies primarily affects humoral rather than cell-mediated immunity [128, 129]. High levels of serum antibodies do not appear to provide solid immunity against disease in the upper respiratory tract. Mucosal secretory IgA appears to contribute to local protection against reinfection in the airway, although potent protective IgA responses are likely relatively short lived. In human infants, the decrease in virus shedding in nasal secretions was associated with the appearance of RSV-specific IgA antibodies [130].

T Cells. T cells clearly play a major role in resolution of active infection. RSV-specific T cells with cytolytic activity, thought to be CD8+ T cells, have been detected in peripheral blood mononuclear cells from infants with RSV disease [131]. Immunodeficient children, especially those with T cell defects, often fail to clear RSV infection and can shed virus for many months [57]. Adults with leukemia or hematopoietic stem cell transplant also have a very high incidence of prolonged RSV infection leading to severe disease and sometimes death.

1.8 Patterns of Host Response

1.8.1 Symptoms

RSV infection usually causes upper respiratory tract symptoms during primary infection in otherwise healthy term infants; asymptomatic primary infection is not common. There is often profuse rhinorrhea, and the upper tract disease is very often complicated by otitis media. Symptoms of lower respiratory tract involvement occur in about a third of primary cases [28]. The principal diagnoses are bronchiolitis (manifested by tachypnea and wheezing) and pneumonia. These entities are probably not discrete processes but more likely represent a continuum of disease involving increasing tissue distribution. The typical illness starts with nasal congestion, followed in a few days by cough. The infection is sometimes associated with fever, which is usually low grade. After several days of upper tract symptoms, infants may wheeze. Many infants suffer mild wheezing that resolves, but some cases progress with tachypnea, diffuse inspiratory crackles, and expiratory wheezes. Most children recover in 1–2 weeks with supportive care and observation. If expiratory obstruction becomes severe, however, hyper-expansion of the chest occurs due to air retention, and the compliant nature of the infant chest wall leads to intercostal and

subcostal retractions during tachypnea. With prolonged tachypnea, fatigue may occur with poor oxygenation and CO_2 retention (measured by pulse oximeter or arterial blood gas measurement), markers of respiratory failure. Intubation and mechanical ventilation is used in this setting to manage the respiratory failure.

Infection during the first day or weeks of life may just be characterized by temperature instability or fever, irritability, and lethargy even in the absence of overt respiratory signs or symptoms. In very young infants, especially those born prematurely, apneic spells may occur in response to RSV infection. Apnea may be the first reported evidence of infection in some cases, and apneic spells may recur during the acute infection. These events thankfully are usually self-limited and rarely cause neurologic damage. Apneic events are an indication for hospitalization and careful medical supervision with respiratory monitoring. Because of the association with apnea, some have considered whether RSV is associated with sudden infant death syndrome (SIDS). Although RSV has been detected in the lung tissues of some cases of SIDS, there is no statistically significant association between RSV and SIDS. The reported cases likely reflect a temporal association caused by the high prevalence of RSV in this age group, the prolonged pattern of shedding, and the simultaneous peak incidence of both RSV infection and SIDS in winter months [132].

It is not clear whether infection with RSV causes prolonged abnormal pulmonary function during childhood or whether children with underlying predisposition to lower respiratory tract disease of all causes manifest their susceptibility first to RSV because of the young age of RSV infection. Certainly measureable pulmonary function abnormalities are common after RSV lower respiratory tract disease, and these findings may persist for a decade or more [133]. Recurrent wheezing is common during subsequent viral infections after severe RSV bronchiolitis or pneumonia, with an incidence of 10–50 % [134]. A large case-control study of 200 children hospitalized for bronchiolitis or pneumonia in which RSV was the most common cause found that 7 years later there was a strong predisposition in these subjects toward decreased pulmonary function, recurrent cough, wheezing, and bronchitis [135]. Seminal prospective studies by Martinez et al. involved measurement of pulmonary function in infants at birth and then found a strong correlation between prior lower pulmonary function and the development of wheezing during RSV infection [136]. This correlation persisted in children during the first 3 years of life [136]. Even some individuals who do not typically exhibit recurrent wheezing have postexercise or pharmacologically induced bronchial reactivity [137], which may be responsive in part to bronchodilators [134].

Symptomatic upper respiratory tract RSV infections manifested by common cold symptoms are common in otherwise healthy adults, especially in those with frequent exposure to small children [80]. In the elderly, particularly those with underlying medical diseases, severe pneumonia may occur, leading to hospitalization or even death.

1.8.2 Diagnosis

Astute clinicians can often make a presumptive diagnosis of infection based on the clinical signs of wheezing or pneumonia in an infant during a local epidemic. Laboratory testing of nasal or lower airway secretions by antigen test (ELISA) or nucleic acid detection (by RT-PCR) provides rapid diagnosis of the presence of virus in many cases. The gold standard for diagnosis is isolation of the virus in cell culture, but this test is typically only available in referral laboratories because of the need for extensive equipment and a high level of technical expertise.

1.9 Control and Prevention

1.9.1 Treatment

Medical Treatment

Primary treatment is supportive care, which includes oral or intravenous hydration; monitoring of respiratory status, especially of oxygen saturation during tachypnea; use of supplemental oxygen; removal of secretions from the upper airway; and, in the case of respiratory failure, intubation and mechanical ventilation. Advances in support care in pediatric critical care units have caused a major decrease in morbidity and mortality from RSV in the developed world. Infants hospitalized for RSV disease should be monitored for apnea. Investigators have studied nitric oxide [138, 139] mixtures of helium and oxygen [140, 141] and surfactant treatment [142] in clinical experimental studies in the support of infants with severe RSV disease. Nitric oxide treatment does not appear to mediate a bronchodilator effect during RSV infection [139].

Antivirals

Therapy of RSV disease by any antiviral agent is challenging because it is a rapid acute infection, and by the time the onset of disease is recognized, it may be too late to alter the course of disease by reducing viral load. The guanosine (ribonucleic acid) analog ribavirin is a nucleoside inhibitor that inhibits viral RNA synthesis and viral mRNA capping. The drug has in vitro antiviral activity against RSV, and aerosolized ribavirin therapy has been associated with a small but statistically significant increase in oxygen saturation during the acute infection in several small studies. Decreases in mechanical ventilation and duration of RSV-associated hospitalization have not been proven (reviewed in [143]). Ribavirin was approved in 1986 in the USA for treatment of RSV infection [144]. Clinically, the drug usually is administered as a

small-particle aerosol using a tent, mask, or mechanical ventilator, delivered for 6–18 h daily for a period of 3–7 days. The drug now is not recommended for routine use because follow-up studies have not shown a major benefit. The drug may be considered for use in select patients with documented, potentially life-threatening RSV infection. Over a dozen other experimental small molecule inhibitors of RSV fusion to cells have been described and tested in preclinical studies for inhibition of RSV, but none have progressed in development to date. A third approach employs short interfering RNAs (siRNAs), taking advantage of an ancient host cell regulatory system. Single-stranded and double-stranded RNA molecules that exhibit RSV-specific small interfering RNAs have been developed for treatment, which cause RNA interference activity against RSV, destroying the corresponding RSV RNA. These novel compounds have shown promising results in preclinical studies [145] and have been tested in small clinical trials. Human immune globulin with a high titer of RSV antibodies and the RSV monoclonal antibody palivizumab have been tested as therapy of acute RSV disease, but they were not effective for treatment of established disease.

Anti-inflammatories

Anti-inflammatory strategies have been investigated. No benefit of corticosteroid therapy on disease severity or length of hospital stay has been demonstrated, despite studies in over a dozen randomized clinical trials of outpatients or hospitalized infants with RSV bronchiolitis. Since the drug is of no benefit on its own [146] and may prolong virus shedding, it is not recommended. In the future, a possibility might be to combine an effective antiviral treatment with an anti-inflammatory agent [147].

Antibiotics

Intravenous antimicrobial therapy is not appropriate in hospitalized infants with RSV bronchiolitis or pneumonia unless there is clear evidence of secondary bacterial infection. Otitis media occurs very often in infants with RSV bronchiolitis; oral antimicrobial agents can be used for therapy of otitis media if necessary.

Bronchodilators

It is intuitive to think of using beta-adrenergic agents, commonly used for the treatment of asthma, to treat the wheezing associated with RSV infection. These agents are not usually recommended for routine care of first-time wheezing associated with RSV bronchiolitis. Short-term improvements in oxygenation and clinical scores can be achieved by these therapies, but it has not been established that their use results in improvements in duration or severity of illness or disease outcomes. Studies in this area have been conflicting, but systematic reviews of randomized clinical trials of nebulized beta-agonist therapy for treatment of bronchiolitis suggest that they offer little benefit [148, 149]. Alpha-adrenergic receptor stimulation results may decrease interstitial and mucosal edema [150], and use of nebulized epinephrine (with combined alpha- and beta-adrenergic activity) has been studied with conflicting results [151, 152]. Alpha-agonist stimulation of the sympathetic nervous system is expected to reduce capillary leakage by constricting precapillary arterioles, reducing hydrostatic pressure and consequently bronchial mucosal edema [150]. Racemic epinephrine treatment relieves some respiratory distress but does not affect length of stay [153]. The usefulness of such agents in the management of RSV bronchiolitis is not clear.

1.9.2 Prevention and Immunoprophylaxis

The most effective mode of prevention is to avoid contact with infected subjects. In the hospital setting, careful adherence to infection control practices is important for the protection of high-risk patients from RSV infection. Careful hand washing may reduce transmission in family and day-care settings. Pharmacologic intervention is indicated to prevent hospitalization for the highest risk infants, however. Passive RSV immunoprophylaxis with antibodies has proven a costly but relatively effective intervention. Parenteral infusion of RSV-neutralizing antibodies into experimental animals was shown early on to confer substantial resistance in the respiratory tract to a subsequent RSV virus challenge [154]. Significant reductions in RSV-associated hospitalizations and disease severity in high-risk human infants were first accomplished with prophylactic administration of human immunoglobulin with high RSV-neutralizing activity given by the intravenous route (RSV-IVIG; FDA licensed in 1996) [155, 156]. Monthly intravenous infusions during the RSV season reduced the frequency of pediatric hospitalization and duration of stay by approximately 55 % and decreased the number of days spent in intensive care by 97 %. The use of RSV-IVIG was superseded by the use of a monoclonal antibody (MAb) that was developed subsequently that could be given by intramuscular route, and production of the former has been discontinued. Several MAbs were developed for immunoprophylaxis against RSV. The most successful of these was based on murine MAb 1129 [157], which is specific to the F protein and efficiently neutralizes viruses of both RSV subgroups A and B. This MAb was humanized by recombinant methods by transferring its variable regions onto a human IgG1 backbone, resulting in a recombinant antibody now named palivizumab [158]. This MAb is 50–100-fold more effective for in vitro neutralization on a per weight basis than was RSV-IVIG, and thus the total amount of immunoglobulin administered could be reduced to an amount that could be given IM. Palivizumab (trade name Synagis) was licensed in 1998 for RSV prophylaxis of high-risk infants, following studies demonstrating its

safety and efficacy [159–162]. Palivizumab is administered monthly through the RSV season and has been widely used in high-risk patients with prematurity, chronic lung disease, and hemodynamically significant heart disease [163]. More potent derivatives of this recombinant antibody have now been developed [164]; however, the lead candidate from these affinity maturation efforts exhibited increased side effects in a large efficacy study.

1.9.3 Vaccines

Prevention of severe disease probably will best be accomplished by development and use of an effective vaccine. Vaccine development for RSV has proven exceptionally difficult, however. First, young infants are a difficult population to immunize. Obstacles to immunization at this early age include immunologic immaturity and immunosuppression by maternal antibodies, as already noted [165]. Also, severe adverse events occurred in early RSV vaccine trials. A formalin-inactivated RSV vaccine candidate (FI-RSV) was developed and evaluated in infants and children in the 1960s [166, 167]. This vaccine suspension was made by mixing concentrated, inactivated virus with alum adjuvant and was delivered by the intramuscular (IM) route. This inoculation did not protect against infection or disease, but rather during subsequent natural infection vaccinees experienced more frequent and severe disease. Most FI-RSV vaccinees (80 %) required hospitalization during subsequent natural infection, compared to 5 % in the control group. Autopsies of two fatalities showed evidence of RSV replication and pulmonary inflammation [167]. This event put a chilling effect on RSV vaccine development efforts. Therefore, RSV protein vaccines have been problematic for use in infants given their possible potential for disease enhancement, together with the poor immunogenicity in this population.

However, an RSV protein vaccine might be useful in boosting immunity in RSV-experienced older children and adults who are at increased risk of severe RSV disease due to underlying disease or advanced age. Protein vaccines for RSV have been evaluated clinically for use in such RSV-experienced individuals, in whom they appear to be safe. One experimental subunit vaccine consisted of purified F protein (PFP) isolated from RSV-infected cell culture. This purified protein vaccine candidate was evaluated in adults, in older children with and without underlying medical diseases, and in the elderly [168]. The PFP vaccine candidate was well tolerated and moderately immunogenic in these settings. A large multicenter study in children 1–12 years of age with cystic fibrosis did not provide evidence of significant protection against RSV infection [169]. PFP also has been evaluated for maternal immunization in the third trimester of pregnancy. In the single study to date, the increase in antibody titers was only minimal [170]. Maternal immunization studies are being pursued currently with newer non-replicating vaccine candidates such as emulsion vaccines [171] and nanoparticle protein preparations [172, 173].

Live-attenuated vaccines represent an attractive strategy for preventing RSV, since live infection induces a balanced immune response that is not associated with enhanced disease on subsequent natural infection. Many live-attenuated RSV vaccine candidates have been developed over several decades. It has proven difficult to identify a candidate that is satisfactorily attenuated while remaining satisfactorily immunogenic in the youngest infants. Clinical trials of a safe, live-attenuated RSV vaccine for intranasal administration have shown restriction of viral replication in infants following administration of a second dose and have been encouraging [174], and additional attenuated vaccine candidates are being developed [175].

1.10 Unresolved Problems

Despite over 50 years of research on RSV, many challenges and questions remain. There are many unanswered fundamental questions about the biology of the organism and the pathogenesis of disease. Why does reinfection occur throughout life? What are the definitive mechanisms of immunity in humans? Is there a genetic basis for susceptibility to severe disease? Does severe RSV disease cause asthma? What drives the seasonality of RSV?

The mortality in infants has been greatly reduced in the USA through advances in critical care, but little RSV-specific intervention is available. Currently, there is little to offer for therapy except for supportive care. Prophylaxis of high-risk infant with a MAb prevents some hospitalizations but is expensive and is not always effective. There are no licensed vaccines. Given the disaster of early FI-RSV trials, it is not clear that a non-replicating vaccine can be proven safe enough in preclinical models to absolutely assure that enhanced disease will not occur. On the other hand, the explosion of new technologies for generation of recombinant RSV strains, the determination of pre- and post-fusion antigen structures, and new tools for the detailed study of the molecular and genetic basis of human immune responses suggest that much progress will be made in the RSV research field in the coming years.

2 Human Metapneumovirus

2.1 Introduction

Human metapneumovirus (HMPV, MPV) is a paramyxovirus isolated in 2001 from Dutch children with acute respiratory infection (ARI). Epidemiologic studies have since confirmed that MPV is a leading cause of upper and lower

respiratory infection in children and adults worldwide. MPV causes many hospitalizations annually in young children and presumably deaths in developing nations. Children with comorbid conditions including prematurity, immune compromise, and chronic cardiopulmonary disease are at higher risk for severe disease. However, the majority of MPV-associated hospitalizations occur in otherwise healthy infants and children. Conversely, while MPV is associated with severe lower respiratory infection in adults at rates similar to those of influenza virus and RSV, almost all of the MPV infections in this population are in patients with comorbidities. MPV causes predictable annual outbreaks with late winter-early spring predominance in temperate regions. Substantial progress has been made in defining the biology, pathogenesis, and immunology of the virus. Small animal and nonhuman primate models of MPV have been developed and used to elucidate mechanisms of immunopathogenesis and test candidate vaccines. A variety of vaccine approaches against MPV are under study, including recombinant subunit, vectored, and live-attenuated vaccines. Human and murine monoclonal antibodies have been generated that exhibit potent in vivo efficacy in rodent models. A subset of integrins with a binding site for a natural ligand that contains an Arg-Gly-Glu (RGD) motif (RGD-binding integrins) has been identified as receptors that mediate MPV attachment and entry via an RGD motif in the MPV fusion protein. Remarkable scientific progress has been made during the decade since the discovery of MPV.

2.2 Historical Background

MPV was discovered by investigators in the Netherlands who cultivated specimens from children with respiratory infection on a variety of cell types [176]. A hitherto unknown virus produced cytopathic effects (CPE) in tertiary monkey kidney cells, but could not be identified by antibody staining or RT-PCR for common viruses. Electron microscopy of infected cells revealed pleomorphic enveloped particles with surface projections suggesting protein spikes, while biochemical experiments showed that the virus contained a lipid envelope and did not hemagglutinate avian or mammalian red blood cells. Elegant randomly primed RT-PCR experiments yielded multiple fragments of genome, which sequence analysis identified as related to avian metapneumovirus (AMPV).

AMPV (formerly turkey rhinotracheitis virus), identified in 1979, is an important global pathogen of poultry including turkeys and chickens [177]. There are four serotypes of AMPV (A–D), and MPV is most closely related genetically to AMPV-C [178]. Phylogenetic analysis shows that MPV likely diverged from AMPV-C ~200 years ago and thus MPV is of zoonotic origin [179, 180]. However, MPV exhibits extremely restricted or no replication during experimental infection of chickens or turkeys and thus is a true human pathogen [176]. Human poultry workers exhibit serological evidence of asymptomatic infection with AMPV, providing evidence for the feasibility of an original trans-species transmission event [181].

While recently identified, MPV is not truly a new virus. Studies using archived sera collected in the 1950s revealed a 100 % seroprevalence in humans greater than 5 years old [176]. Nasal washes collected prospectively during the 1970s from children with ARI had detectable MPV RNA upon retrospective testing by RT-PCR 25 years later [182]. The specialized cell culture requirements, slow growth, and limited CPE of MPV likely prevented the earlier discovery of this common respiratory pathogen.

2.3 Methods for Epidemiologic Analysis

2.3.1 Sources of Mortality Data

Limited mortality data are available and consist of sporadic case reports, case series, or the identification of fatal cases of MPV infection in research studies. MPV is not a reportable infection and there is no specific ICD-9 diagnostic code. Thus, an accurate estimate of the mortality associated with MPV is not feasible. However, lower respiratory infections are a leading cause of death in children worldwide, primarily in developing nations. MPV is a common cause of severe lower respiratory infection and thus likely accounts for a substantial number of deaths globally.

2.3.2 Sources of Morbidity Data

A substantial body of literature has accumulated in the last decade describing the epidemiology, disease burden, and clinical features of MPV. Many groups have used standard techniques to provide some estimate of the burden of MPV in diverse populations. Most reports have been cross-sectional studies of selected populations, usually based on convenience samples of patients with acute respiratory illness. These studies are thus limited by potential selection bias, narrow time periods, and incomplete demographic or clinical data and often lack controls. Nonetheless, the broad application of these studies to sizable global populations has illuminated the frequency of MPV infection. Many of these studies have focused on special populations, such as patients with asthma, immune compromise, or chronic obstructive pulmonary disease (COPD), and thus offer valuable information about MPV among these persons.

A number of prospective, well-designed studies in adults and children have been published and offer the best estimates of the population-based incidence of MPV infection. Some of these used preexisting prospective data and samples collected prior to the discovery of MPV for retrospective

analysis. Classical methods including active day care and clinic surveillance, as well as newer approaches such as home surveillance with parent-collected swabs, have been used. These studies have been built upon the foundations of seminal longitudinal studies conducted to investigate other viruses including influenza, parainfluenza viruses, and RSV. Taken together, these reports provide a broad survey of MPV epidemiology across diverse geographic environments, socioeconomic populations, and high-risk groups.

2.3.3 Serological Surveys

Seroprevalence studies using diverse methods have been performed in different populations. Most have used enzyme-linked immunosorbent assay (ELISA) techniques against whole virus or purified proteins to detect IgM or IgG. A few have used immunofluorescent detection of MPV-specific antibodies or measured serum virus-neutralizing antibodies. These data have mainly been useful in determining the ubiquity of infection with MPV. Some studies have measured acute and convalescent sera to diagnose MPV infection, while others have attempted to establish a serum neutralizing titer that correlates with susceptibility to infection. Inherent limitations of serological surveys include the potential for cross-reactive antibodies and the lack of standardized reagents for MPV.

2.3.4 Laboratory Methods

Most studies have used RT-PCR to detect MPV due to the difficulty in cultivating the virus. The original isolation of MPV in tertiary monkey kidney cells was possible because the investigator had access to a monkey kidney cell source that was free of the endogenous simian foamy virus (A.D.M.E. Osterhaus, personal communication). Primary monkey kidney cells commercially available in the USA all contain SFV, and even the addition of anti-SFV antisera cannot prevent the growth of this endogenous virus prior to the slow emergence of MPV. Further, the fusion protein of MPV requires cleavage by exogenous trypsin for robust in vitro growth. Trypsin is added by most clinical virology laboratories only to cultures of Madin-Darby canine kidney (MDCK) cells for the isolation of influenza virus; however, MDCK cells are very poorly permissive for MPV even in the presence of trypsin. Finally, primary isolation of MPV often requires one or more passages prior to visible CPE and few laboratories routinely follow this procedure. Unlike RSV, MPV is not particularly labile to freeze-thaw cycles [183] and thus can be retrospectively isolated from PCR-positive specimens. Fluorescent antibody staining of patient specimens or shell vial cultures can facilitate more rapid identification [184–187].

Thus, molecular diagnostic techniques have been used for virtually all studies of MPV epidemiology. A number of sensitive and specific real-time RT-PCR assays have been described [188–195]. Many early assays were based on limited sequence data and subsequently were found to be suboptimal for detecting multiple diverse strains [195]. Both individual and multiplexed RT-PCR assays offer more sensitive detection of MPV than culture; however, multiplex assays sometimes balance decreased sensitivity for a single agent with the convenience of detecting multiple viruses simultaneously [196]. Another limitation of molecular detection for all viruses is the ability to detect low levels of viral nucleic acid in the absence of infectious virus. It has become common to detect more than one virus in a single specimen, and the interpretation of these data is far from clear. Community respiratory viral infections are frequent in childhood, and the likelihood of detecting viral genome prior to the onset of illness or for prolonged periods after illness resolution complicates the assignment of causation to one of several co-detected viruses.

2.4 Biological Characteristics

MPV is an enveloped pleomorphic virus ranging in size from 150 to 600 nm, containing a single-stranded negative-sense RNA genome [178]. Complete genomic sequences of numerous MPV strains have been published [178, 180, 197]. The genome comprises eight separate open reading frames encoding nine distinct proteins (Fig. 26.1). MPV genes are analogous to those of RSV (though NS1 and NS2 are absent in MPV), but the organization of genes differs. AMPV and MPV have been taxonomically classified in the separate *Metapneumovirus* genus based on the gene order. Phylogenetic analysis of MPV genes consistently identifies four genetic clades, two major groups designated A and B, each with two minor groups designated A1, A2, B1, and B2 [180, 198–203]. One group has suggested further sublineages based on partial F sequence diversity [204], but there is no evidence that this further genetic distinction is of any antigenic or immunologic importance.

The two major surface proteins are the fusion (F) and attachment (G), with a third integral membrane short hydrophobic (SH) protein. F is the target of neutralizing antibodies in animal models, F-only vaccines induce protection in animals, and F-specific monoclonal antibodies provide passive protection [205–213]. In contrast, G-specific antibodies do not neutralize virus and G-only vaccines induce neither neutralizing antibodies nor protection [206, 209, 214]. Thus, it appears that MPV is unique among human paramyxoviruses in that the attachment protein does not contribute to protective antibodies. Further, the G protein exhibits a high degree of genetic variability between subgroups, with as low as 29 % amino acid identity between the major A and B subgroups and a minimum 60 % identity within subgroups [202, 215–218]. The selective pressure for this diversity is unclear.

In contrast to G, the F protein is conserved, with a minimum 94 % amino acid identity between A and B subgroups and a minimum 98 % identity within subgroups [179, 202, 203]. Presumably there are functional constraints on the diversity of F, since the mutation rate of MPV is high, similar to other RNA viruses. The major question regarding the diversity between major or minor subgroups is whether it contributes to antigenic variation or escape in human populations.

Cross-neutralization against heterologous virus from the A and B lineages was tested using experimental infection of ferrets [202]. This study found relative neutralization of homologous to heterologous virus ranging from 12 to 96-fold difference, thus providing some evidence for antigenic serotypes. However, subsequent experiments using hamsters, African green monkeys, chimpanzees, and rhesus macaques found that the A and B groups were 64–99 % related antigenically [219]. Infected animals developed neutralizing antibodies that were highly effective against heterologous virus, and previously infected primates were protected against challenge with heterologous virus. Cynomolgus macaques infected with A or B subgroup viruses or with candidate vaccines exhibited only a 6–16-fold difference in neutralizing titer against homologous and heterologous viruses [220, 221]. Taken together, these data show that while MPV F exhibits some antigenic diversity, the virus does not have truly distinct serotypes. The potential implications for human epidemiology are discussed further below.

2.5 Descriptive Epidemiology

2.5.1 Incidence and Prevalence Data

Numerous studies document the fact that MPV infection is ubiquitous and that reinfection is common. Serosurveys testing large sample collections in Canada, China, Croatia, Germany, Israel, Japan, the Netherlands, Taiwan, Thailand, the USA, and Uruguay show that 95–100 % of children have antibodies against MPV by the age of 5 years [222–231]. In many of these studies, 50–75 % of children are seropositive by age 2 years, suggesting that most acquire primary MPV infection early. Most identify a decrease in serum MPV antibody titer from birth to 6–12 months, presumably due to the expected decline of maternally derived antibodies. Studies in Japan and India that compared MPV and RSV titers in the same cohort found that after the expected nadir during early infancy, RSV titers began increasing at an earlier age than MPV [232, 233]. This finding is interesting in light of epidemiologic data suggesting that primary MPV infection peaks between 6 and 12 months of life compared with the peak of RSV at 2–3 months (discussed below). Longitudinal studies in adults and children have documented reinfection by a fourfold rise in serum antibody titer [222, 230, 231, 234–237].

2.5.2 Risk of Infection and Reinfection

The serological data show that MPV infection is nearly ubiquitous during the first years of life. Further, reinfection occurs throughout life. In children, primary MPV infection is associated commonly with lower respiratory illness, while reinfection is associated with upper tract disease [182, 238].

2.5.3 Risk of Serious Lower Respiratory Infection (LRI) During Infancy

Most epidemiologic studies of MPV in children show that the virus is the second leading cause of lower respiratory infection after RSV. The prevalence of MPV in studies of children with LRI is 5–25 %. A 25-year prospective study of otherwise healthy children <5 years old detected MPV in 12 % of children with LRI; several children experienced recurrent infection [182]. A 2-years multicenter study of inpatient and outpatient Japanese children with ARI identified MPV in 57/637 (8.9 %) [239]. A 5-years observational study of otherwise healthy Korean children <5 years old found MPV in 24/515 (4.7 %), similar to the rates for influenza and parainfluenza virus type 3 (PIV-3) [240]. A very large observational study in Queensland, Australia, tested specimens obtained from patients of all ages with LRI from 2001 to 2004; MPV was detected in 707/10,025 (7.1 %). Ninety-two percent of patients with MPV were <5 years old, and MPV was the second most common virus after RSV in these children [241]. A South African group tested specimens from children hospitalized with ARI who were subjects in a prospective pneumococcal vaccine trial; MPV was present in 126/1,409 (8.9 %) and was the most common virus after RSV. The estimated incidence of MPV-associated hospitalization in HIV-negative children was 29/1,000; a number of children had repeat infections [242]. A prospective study of hospitalized children in Hong Kong over a 13-month period found MPV in 32/587 (5.5 %); the estimated incidence of MPV-associated hospitalization was 4.4 per 1,000 children <6 years old [243]. A Chinese group conducted a prospective 2-years study of children hospitalized with ARI and identified MPV in 227/878 (25.9 %), with most <6 years old [244]. A large, population-based, prospective surveillance study conducted in three US cities over 6 years found that the incidence of hospitalization for MPV in children <5 years old was 1 per 1,000, lower than the rate of RSV-associated hospitalization in the same cohort (3/1,000) but similar to the rates for influenza (0.9/1,000) and PIV-3 (0.5/1,000) [245].

2.5.4 Role of MPV Infections in Adults

Respiratory disease is among the leading causes for hospitalization of adults in the USA, and "influenza and pneumonia" ranks among the top 10 causes of deaths annually. Although the data are limited, MPV appears to be associated with a substantial burden of ARI in adults, primarily those with comorbidities. A prospective study in Rochester, NY,

enrolled four cohorts during four winters: healthy adults >65, high-risk adults >65 with comorbidities, healthy adults 19–40 years old, and adults hospitalized for acute cardiopulmonary illness [246, 247]. Overall, MPV infection was detected in 8.5 % of ARI in the cohort. The rate of MPV infection was highest in young adults at 13 %, though many of these were asymptomatic and detected only serologically. Of note, this group had a mean age of 33, was predominantly female, and had daily exposure to children. Of the hospitalized patients, the incidence of MPV annually ranged from 4.4 to 13.2 %. More than 85 % of the hospitalized MPV-infected subjects had underlying conditions, chiefly cardiopulmonary disease or diabetes mellitus. There were six deaths in this study, all with comorbidities; one had concomitant bacteremia with *Streptococcus pneumoniae*. Interestingly, the incidence of MPV infection was similar to the annual average infection rate for RSV (5.5 %) and influenza A (2.4 %) in these cohorts during the same study period.

A prospective, population-based study in Nashville, TN, recruited adults hospitalized for ARI at several county hospitals over three winters [248]. Of 508 subjects, 23 (4.5 %) had MPV, 33 (6.5 %) influenza, and 31 (6.1 %) RSV. Notably, MPV-infected subjects were significantly older than influenza-infected subjects (mean 76 vs. 60 years) and had higher rates of chronic cardiopulmonary disease (78 % vs. 52 %). The overall population-based rates of hospitalization for the three viruses were similar, at 1/1,000 for MPV, 1.5/1,000 RSV, and 1.2/1,000 for influenza. However, for subjects ≥65 years, hospitalization rates were much higher for MPV and RSV at 2.2/1,000 for MPV and 2.5/1,000 for RSV compared to 1.2/1,000 for influenza, likely reflecting the use of influenza vaccine for older adults. A prospective study of community-acquired pneumonia in Canada found MPV in 4 % of hospitalized cases during an 18-month period, all with underlying conditions [249]. A Dutch group detected MPV in 2 % of bronchoalveolar lavage specimens from intensive care unit patients. All were >50 years old with comorbid conditions and 83 % died [250]. Similarly, a retrospective study in North Ireland found MPV in only 0.8 % of residual respiratory specimens from adults, but 33 % of these died [251]. Together, these data show that MPV is an important cause of acute respiratory disease in adults, primarily older adults or those with underlying comorbid conditions.

2.5.5 Role of MPV Infections in Patients with Asthma

MPV is associated with acute asthma exacerbations [252–254]. MPV was detected in 10 of 132 hospitalized Finnish children with acute wheezing [255]. Similarly, MPV was isolated from 7 % of adults hospitalized for acute asthma exacerbation, only one of whom tested positive 3 months later [256]. Premature infants who developed MPV bronchiolitis within the first year of life had decreased lung function at 1 year of age [257]. A prospective, case-control study of children with MPV bronchiolitis during infancy compared to infants with acute gastroenteritis found that MPV infection early in life was significantly associated with a later diagnosis of asthma and recurrent wheezing at 5 years of age [258].

2.5.6 Role of MPV in Infections with Underlying Cardiopulmonary Disease

MPV causes severe disease in children with comorbid conditions such as cardiac and pulmonary disease or prematurity [259–263]. A prospective 1-year study of hospitalized children found that 34 % of patients with MPV had a history of prematurity, chronic lung disease, complex congenital heart disease, or immunodeficiency [264]. Vicente et al. detected MPV by RT-PCR in 6 % of adults >64 years old with acute exacerbations of COPD; none had other pathogens identified by culture or PCR [265]. A Canadian study found that 4 % of hospitalized adults with community-acquired pneumonia or COPD exacerbations tested positive for MPV, all with comorbid conditions; one also had influenza A and *S. pneumoniae* [266]. RSV was present in 9 % and influenza A in 6 % of the cohort. MPV was detected in 12 % of adults hospitalized for COPD exacerbation during one winter in Connecticut, none with other viruses co-detected; RSV was present in 8 % and influenza A in 4 % of the entire cohort [267].

2.5.7 Role of MPV Infections in Patients with Immunodeficiency

Severe and fatal MPV disease can occur among immunocompromised individuals, including solid organ and stem cell transplant recipients, HIV-infected persons, and chemotherapy patients [268–275]. MPV is associated with morbidity and mortality in adults with hematologic malignancies and stem cell transplant; [270, 276] MPV was detected in bronchoalveolar lavage specimens from 5/163 (3 %) episodes of acute respiratory infection in stem cell transplant recipients, and four died [270]. HIV-positive South African children with MPV were significantly more likely to receive a diagnosis of pneumonia and experience longer hospitalization, lower mean oxygen saturation, and bacteremia; further, HIV-positive children were fivefold more likely to be infected with MPV than HIV-negative children [242].

2.5.8 Role of MPV in Nosocomial Infection

MPV has been implicated in several hospital and institutional outbreaks leading to mortality [277, 278]. Kim and colleagues [279] report the transmission of MPV to pediatric hematology-oncology patients during a nosocomial outbreak. The incubation period was between 7 and 9 days. Standard, but not droplet, precautions were used. In laboratory studies, infectious virus persists on metal and nonporous surfaces for up to 8 h [183]. Due to the significant morbidity and mortality of MPV in high-risk children, isolation precautions are important.

2.5.9 Role of MPV in Different Clinical Syndromes

MPV is associated with both upper and lower respiratory tract disease [182, 280–282]. Rhinorrhea and cough are the most frequent symptoms, while hoarseness, laryngitis, sore throat, and croup are less common [238–241, 243, 282]. A large prospective study of children with URI detected MPV in 5 % of patients, similar to RSV, influenza, and PIV but less frequent than adenovirus and rhinovirus. In these children with URI associated with MPV, fever was present in 54 %, coryza in 82 %, cough in 66 %, pharyngitis in 44 %, hoarseness in 8 %, and conjunctivitis in 3 % [280]. MPV is associated with acute otitis media and has been detected in nasal secretions and middle ear fluid [182, 280, 283–285].

Signs and symptoms of LRI with MPV include cough, wheezing, and rhonchi. A large Chinese study of children with acute respiratory infections found that wheezing was more common in children with MPV than with RSV [282]. In that study, children with MPV were diagnosed with pneumonia significantly more than children with RSV, 47 % versus 31 % ($p=0.002$). Conversely, a larger percentage of children with RSV were diagnosed with bronchiolitis compared to MPV, 62 % versus 42 %, respectively ($p<0.001$). Other studies also note the trend toward a higher percentage of children with MPV and pneumonia compared to RSV [182, 238, 245] although this is not always statistically significant [243].

MPV has been associated rarely with neurologic complications, including febrile seizures and altered mental status, but there is no conclusive evidence for direct neural infection. One case report describes a patient who died and had MPV isolated by RT-PCR from brain and lung tissues [286]. MPV was detected by RT-PCR in nasal specimens from 4 of 1,570 persons with encephalitis of unknown etiology [287]. Several other reports describe the detection of MPV in a respiratory specimen from patients with encephalitis [286, 288–290]. Only one case reports detection of MPV in cerebrospinal fluid [291].

2.5.10 Epidemic Behavior

The incidence of viral infection varies between countries and years, but MPV circulates in every year [176, 182, 239–241, 243, 282, 292–296].

2.5.11 Geographic Distribution

Epidemiologic studies have verified the presence of MPV worldwide.

2.5.12 Temporal Distribution

MPV is present during all months in temperate regions, although predominant in late winter-early spring, often following the peak of RSV (Fig. 26.2) [176, 182, 191, 239, 241, 246, 264, 280, 282, 294, 297].

In subtropical climates such as Hong Kong, a spring-summer season similar to RSV occurs [243]. Biannual peaks of seasonality have been described in some European studies [298, 299]. Annual rates of MPV-associated ARI are lower than RSV and comparable to parainfluenza virus types 1–3 combined and influenza [240, 241, 243, 282, 294, 300] although MPV does on occasion surpass RSV in incidence [293].

2.5.13 Occurrence in Different Settings

Multiple outbreaks have been reported in nursing homes and other long-term care facilities (LTCF). MPV was the only pathogen identified in an outbreak of ARI that occurred over a 6-weeks period at a Quebec LTCF, with 6 PCR-confirmed and 96 epidemiologically linked probable cases. There were three deaths among the confirmed and nine deaths among the probable cases [278]. A California study described an outbreak of ARI in 26/148 (18 %) residents and, importantly, 13 staff of a LTCF; MPV was confirmed in 5 residents, 2 of whom were hospitalized, and no other viruses were detected in any case [301].

2.5.14 Environmental Risk Factors

Attendance in out-of-home day care, breast-feeding, and passive smoke exposure are not significantly associated with MPV infection [245]. MPV infection is not associated with lower socioeconomic status.

2.5.15 Other Factors

Viral coinfection has been suggested with MPV; dual infection with RSV and MPV increased the risk of PICU admission compared to RSV alone in one small study [302]. However, this finding was refuted by subsequent larger reports [303–305]. Other studies demonstrate no significant difference in children with coinfections, including adenovirus, bocavirus, coronavirus, influenza virus, parainfluenza viruses, or RSV [240, 241, 282, 293, 306, 307].

MPV has four distinct genetic lineages or subgroups: A1, A2, B2, and B2 [202, 203, 218]. The predominant subtype varies by year and location [241, 280, 293, 297, 308]. In Italy, over a 3-years period, all four subtypes were identified each season but the predominant subtype changed. In 2001–2002, A1 accounted for 59 % of all strains, the following year B1 and B2 were present equally, and in 2003–2004, 72 % of strains were A2 [308]. Similar variation was observed over 20 years in a US study, with multiple subgroups present in most seasons (Fig. 26.3) [280].

It is unclear whether viruses from different subgroups differ in virulence. A study in Spain reported that children with group A infection more frequently had pneumonia and higher disease severity [309], while in Canada, group B was associated with more severe disease in hospitalized patients [261]. Patients with group B strains in a French study were more likely to have abnormal chest radiographs but did not have significant differences in oxygen saturation, hospitalizations, or clinical severity scores [310]. Other studies have found no major distinctions in disease severity [239, 241,

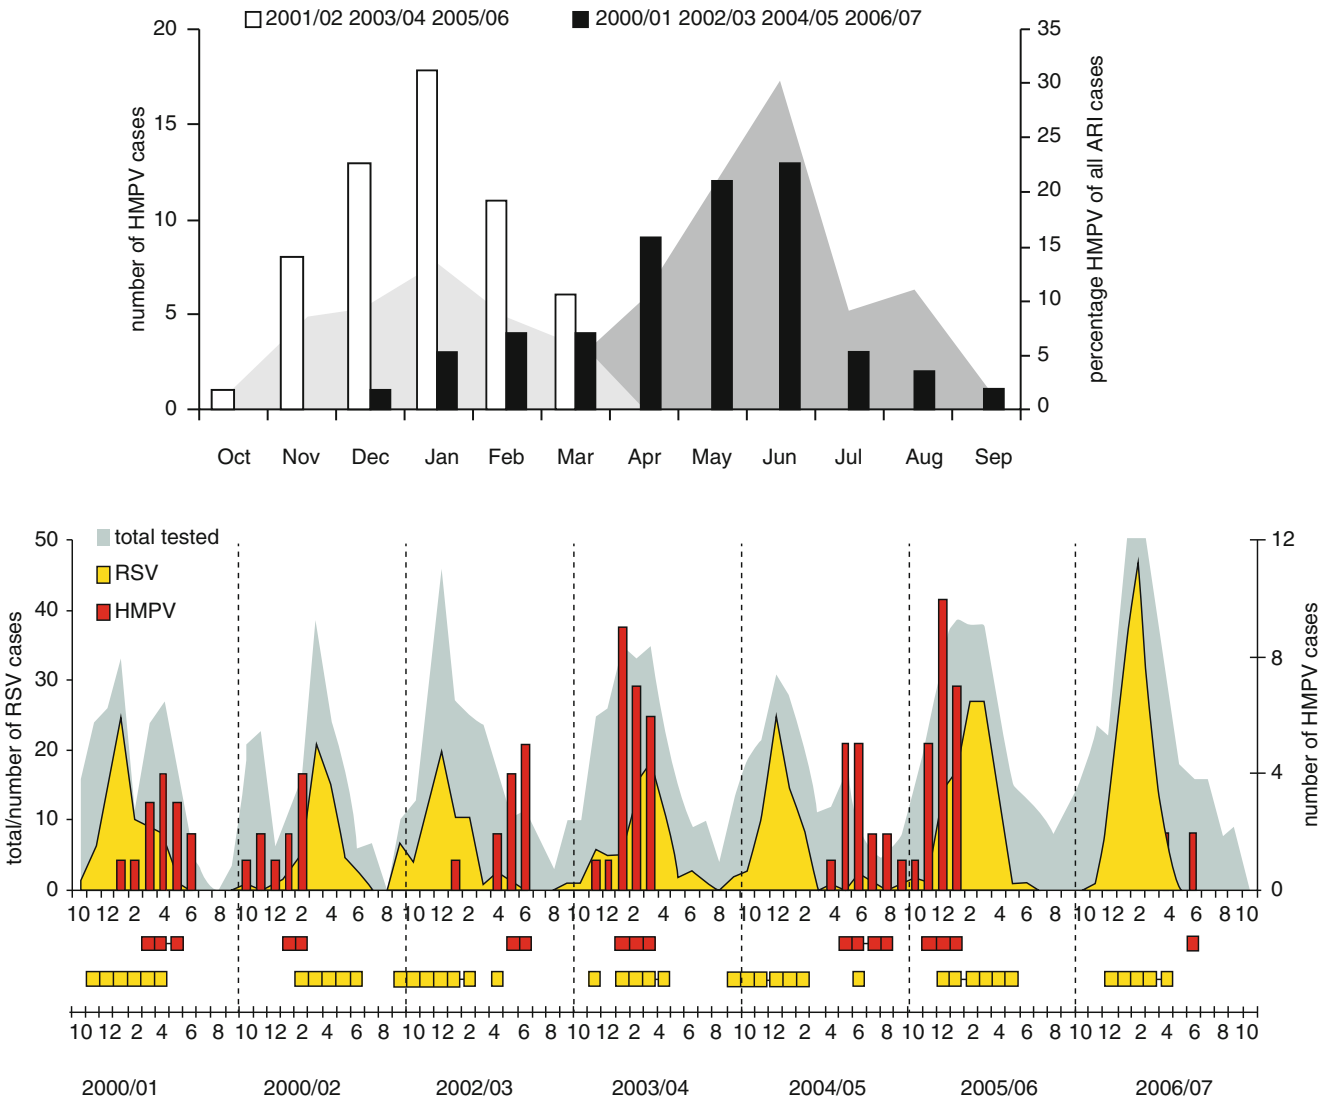

Fig. 26.2 Number of infants admitted to hospital with acute respiratory illness and the seasonality of RSV and MPV in Austria from 2000 to 2007 (*top panel*). The weeks of onset and end of RSV and MPV activity (*bottom panel*) are defined as the first of 2 consecutive weeks where >10 % of specimens test positive by PCR and the last week of >10 % positive preceding 2 consecutive weeks of <10 % positive. Gray indicates total tested; yellow, RSV; red, HMPV (Used with permission from Aberle et al. [298])

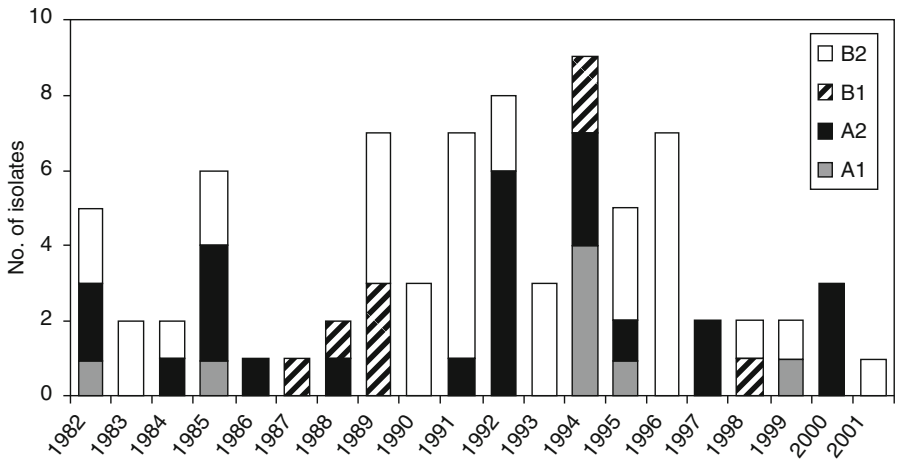

Fig. 26.3 Rates, by year, of each genetic lineage of human metapneumovirus. Data are from specimens collected from children with acute respiratory infection between 1982 and 2001 in the Vanderbilt Vaccine Clinic (Used with permission from Williams et al. [280])

311], laboratory abnormalities [228], or symptoms [240] between subgroups. Group A viruses replicate more efficiently in animal models, suggesting some meaningful biological differences between groups [219, 220].

2.6 Mechanisms and Routes of Transmission

MPV is an enveloped virus and thus inactivated by soap, disinfectants, or alcohols. Spread is thought to occur by direct or close contact with contaminated secretions. Infectious virus can persist at room temperature, especially nonporous surfaces, for up to 8 h [183]. Contact precautions are recommended as for RSV with meticulous hand hygiene. Cohorting of patients and caregivers should be considered during outbreaks in care facilities.

2.7 Pathogenesis and Immunity

Human data are limited; studies in rodents and nonhuman primates reveal mild erosive and inflammatory changes in the mucosa and submucosa of the airways, with viral replication observed in ciliated epithelial cells in the respiratory tract [312–314]. Inflammatory infiltrates with a lymphocytic and monocytic predominance are present in perivascular and peribronchial areas. Sumino and colleagues [315] reviewed the lung pathology of five adults with MPV infection. Histopathology in three patients demonstrated acute, organizing lung injury with diffuse alveolar membrane formation and the presence of smudge cells. The fourth patient had no evidence of lower respiratory tract infection, and the fifth patient had nonspecific acute and chronic inflammation. A similar study in children revealed chronic inflammatory changes of the airways with intra-alveolar macrophages [316]. A major limitation of reports of human pathology is that patients had been mechanically ventilated prior to death, making it difficult to distinguish virus-induced pathology from barotrauma and nonspecific inflammation.

MPV lacks genes present in other paramyxoviruses that inhibit interferon responses; nevertheless, MPV is capable of blocking type I interferon responses by an unknown mechanism [317, 318]. MPV and other respiratory viruses induce pulmonary CD8+ T cells that fail to secrete IFNγ or exhibit cytotoxic degranulation in response to viral peptides; these impaired CD8 T cells resemble exhausted CD8 T cells induced by chronic infections such as HIV and hepatitis C virus [319].

Humans develop neutralizing antibodies to MPV, and passive antibodies alone can protect in animal models. However, immunity wanes over time and likely provides limited cross-protection between subgroups, since reinfections occur in children and adults [246, 248] with genetically different strains [182, 239, 240, 268, 320] as well as strains from the same subgroup [280]. Early protection against reinfection following primary infection was confirmed in macaques; however, when challenged 12 weeks later, virus replication was detectable despite the presence of serum antibodies [220]. Eleven months later, antibody levels had waned still further, and all macaques challenged with heterologous virus and two of three animals reinfected with homologous virus had no evidence of protection [220]. A prospective study in humans noted that baseline MPV antibodies were lower in patients who subsequently became infected versus those who did not become infected [321]. Thus, cross-protection and duration of antibody responses are important issues for vaccine development.

2.8 Patterns of Host Response

2.8.1 Symptoms

MPV causes both upper and lower respiratory tract signs and symptoms clinically indistinguishable from disease associated with RSV and other respiratory viruses [182, 239, 300, 322, 323]. Fever is present in most cases, especially children [239–241, 243, 264, 280, 293]. Transient maculopapular rash has been described in a minority of patients [241, 243, 293], and vomiting or diarrhea are described with low frequency [182, 239, 243]. Laboratory abnormalities are uncommon, although one study identified 27 % of patients with elevated ALT and AST values [293]. White blood cell count and C-reactive protein were not significantly different between RSV and MPV [238, 282].

MPV is rarely detected in asymptomatic persons [182, 191, 324–326], though in otherwise healthy young adults, MPV infection can be subclinical [246]. The duration of shedding in healthy individuals is approximately 7–14 days [239, 327].

2.8.2 Diagnosis

Detection in cell culture requires prolonged incubation and is both insensitive and often impractical. Shell vial culture offers increased sensitivity over traditional culture [184, 328]. IFA has demonstrated a sensitivity of 73 % and specificity of 97 % with RT-PCR as the gold standard [329]. DFA has shown similar results [330]. Commercial antibody kits for immunofluorescent detection of MPV are available. RT-PCR is most commonly used for detection of the virus in epidemiologic studies and is becoming more common in clinical laboratories [176, 320, 331, 332]. Real-time RT-PCR targeting the conserved N gene has high sensitivity for detection of all four subgroups [189, 195].

2.9 Control and Prevention

2.9.1 Treatment

The primary therapy for MPV infections is supportive care, including oral or intravenous hydration, monitoring of respiratory status and oxygen saturation, supplemental oxygen, and mechanical ventilation for frank respiratory failure. There are no licensed antivirals for MPV. Reports of pharmacologic treatment of MPV are limited to severely ill or immunocompromised patients. Ribavirin, an antiviral agent used in severe RSV infection, reduced inflammation and viral replication in mice with MPV infection [333]. Commercial intravenous immunoglobulin (IVIG), ribavirin, and NMSO3 (a sulfated sialyl lipid) effectively inhibited MPV in vitro [334, 335]. Ribavirin, with and without IVIG, has been used in immunocompromised adults [336]. Bonney and colleagues [337] reported successful treatment of an immunocompromised child with MPV using IV ribavirin and IVIG. Subsequently, oral ribavirin and inhaled ribavirin with IVIG have been used [275, 338]. However, no randomized, controlled trials have been conducted, and these data should be regarded as purely anecdotal.

2.9.2 Immunoprophylaxis

Human and murine monoclonal antibodies exhibit therapeutic efficacy in rodent models and thus offer potential for immunoprophylaxis [210, 211, 213].

2.9.3 Vaccines

A number of vaccine approaches for MPV have been investigated. The F protein is conserved between subgroups, immunogenic, and the only target of neutralizing antibodies; in contrast to RSV, the MPV G protein does not induce neutralizing antibodies and is not a protective antigen [206, 209, 214]. A recombinant parainfluenza virus encoding the MPV F protein demonstrated protection against MPV [339], and soluble F protein vaccines reduced viral titers in cotton rats and hamsters [207, 208]. Reverse genetics technology has been developed for MPV and has been used to produce recombinant strains for vaccine development [197, 340]. Viruses lacking the G, M2-1, M2-2, or SH proteins or with point mutations are attenuated and immunogenic in rodent and primate models [197, 221, 341–344].

2.10 Unresolved Problems

The major unresolved problems in MPV epidemiology and research involve understanding mechanisms of disease and developing therapeutic or preventive strategies. Abundant evidence shows that MPV is a significant cause of acute respiratory disease, especially in the very young, older adults, and persons with underlying conditions. As with all mucosal viruses, the short incubation period of MPV combined with the transient nature of mucosal IgA means that reinfection is possible throughout life. However, serum IgG appears to offer protection against severe lower respiratory involvement, and thus a vaccine would likely ameliorate the most severe cases. The best candidate vaccine is not yet clear. Further, MPV has as yet unidentified mechanisms to subvert host immunity. Elucidation of these pathways might help guide vaccine development and uncover novel host targets for immunomodulation.

Parvoviruses

27

Kevin E. Brown

1 General Introduction

Parvum is Latin for small, and *Parvoviridae* are among the smallest known DNA-containing viruses that infect mammalian cells. The virions are nonenveloped particles about 22 nm in diameter with icosahedral symmetry. The *Parvoviridae* are divided into two subfamilies, *Parvovirinae* and *Densovirinae*, on the basis of their ability to infect vertebrate or invertebrate cells, respectively. The *Parvovirinae* are currently further subdivided into eight genera on the basis of their transcription map, their ability to replicate efficiently either autonomously or with helper virus, and their sequence homology. The five genera are *Protoparvovirus* (formerly *Parvovirus*), *Dependoparvovirus*, *Erythroparvovirus, Bocaparvovirus, Amdoparvovirus, Aveparvovirus, Copiparvovirus and Tetraparvovirus* [1].

At least four different parvoviruses are known to infect humans. Parvovirus B19 (B19V) is the best characterized and is classified as the type member of the *Erythroparvovirus* genus. The other human viruses are the human adeno-associated viruses (*Dependoparvoviruses*), human bocaparvoviruses (*Bocaparvovirus),* and human Parv4, a member of the newly recognised *Tetreparvovirus* genus [2–4].

The human dependoparvoviruses are nonpathogenic and as such are being utilized as vectors for gene therapy [5]. They will not be discussed further in this chapter.

2 Parvovirus B19 (B19V)

Parvovirus B19 (B19V) was discovered in 1975 [6] and, until the discovery of the human bocaviruses, was the only human pathogenic parvovirus. Unlike many virus infections, the clinical manifestations of infection with parvovirus B19 vary widely with the immunologic and hematologic status of the host. In individuals with underlying hemolytic disorders, B19V is the primary cause of aplastic crisis. In immunocompromised patients, persistent parvovirus B19 viremia may manifest as pure red cell aplasia and chronic anemia, and in the fetus, where the immune response is immature infection, it may lead to fetal death in utero or hydrops fetalis. The major disease manifestation in normal immunocompetent individuals is erythema infectiosum (EI), also called fifth disease or "slapped-cheek" disease. Generally, this is an innocuous rash disease of childhood, but in adults, it may also be associated with an acute symmetrical polyarthropathy, which can mimic acute rheumatoid arthritis.

2.1 Historical Background

2.1.1 The Virus

Parvovirus B19 was discovered by Yvonne Cossart and coworkers [6] in England. They were evaluating tests for hepatitis B surface antigen (HBsAg) using panels of serum samples. One serum (coded 19 in panel B) gave anomalous results, positive in counterimmune electrophoresis (CIE) with human antisera but negative in the more specific radioimmunoassay (RIA) and reverse passive hemagglutination (RPHA) tests that used hyperimmune animal sera. When the precipitin line from the CIE was excised, electron microscopy (EM) showed the presence of 23-nm particles resembling parvovirus. There was no reactivity with antisera to adeno-associated viruses or to rat parvovirus, and the virus was originally labeled "serum parvovirus-like particle" (SPLV). Approximately 30 % of adults had antibody to the new virus detectable by CIE.

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_27,

The first clinically significant illness associated with B19V infection was hypoplastic crisis in patients with sickle-cell anemia [7]. Sera from such patients contained B19V antigen, detectable by CIE or EM at the time of crisis, and convalescent sera lacked virus but showed evidence of antibody seroconversion.

In 1985, the virus was officially recognized as a member of the *Parvoviridae*, and the International Committee on Taxonomy of Viruses (ICTV) recommended the name B19V to prevent confusion with other viruses (i.e., human papillomavirus). It is classified as a member of the *Erythrovirus* genus with the name parvovirus B19 (official abbreviation, B19V) [1].

2.1.2 Transient Aplastic Crisis

Transient aplastic crisis (TAC) was the first clinical illness associated with B19V infection. The term "aplastic crisis" was coined by Owren [8] to describe the abrupt onset of severe anemia with absent reticulocytes in patients with hereditary spherocytosis. (Hemolytic crises in hereditary spherocytosis patients are associated with increased bone marrow turnover and reticulocyte production.) Also, in contrast to hemolytic crises, aplastic crisis occurred as a single episode in the patient's life. In TAC cases, there was a common history of a preceding prodromal illness and the occurrence of epidemics in large kindreds of hereditary spherocytosis suggested an infectious etiology.

When stored sera from (over 800) children admitted to a London hospital were examined for B19V antigen by CIE, a precipitin line was found in a child with sickle-cell disease suffering a hypoplastic crisis. Five other patients presenting with similar symptoms were also investigated, and all had evidence of recent infection with B19V (either antigenemia or seroconversion). All were Jamaican immigrants with sickle-cell disease presenting with aplastic crisis. There was a reduced hematocrit and deficient red cell production in their bone marrow [7]. Retrospective studies of sera from Jamaican sickle-cell patients showed that 86 % of TACs were associated with recent parvovirus infection [9].

2.1.3 Erythema Infectiosum

This exanthematous rash illness of childhood was probably first described by Robert Willan in 1799 and subsequently illustrated in his 1808 textbook [10]. The disease was rediscovered in Germany, and in 1899, Sticker gave it the name erythema infectiosum. Six years later, Cheinisse classified it as the "fifth rash disease" of the six classical exanthemata of childhood [11]. Subsequently, many outbreaks of fifth disease were documented in the medical literature but the cause remained a mystery. Often the epidemiologic data suggested "a common source exposure to a highly effective transmitter," and an atypical rubella virus or echovirus was thought to be responsible [12]. However, neither virus could be reproducibly isolated from fifth disease patients.

In 1983, following an outbreak of fifth disease in London, England, 31 of 31 children or adolescents who had been affected had anti-B19V-specific immunoglobulin M (IgM) antibody in their serum detectable by RIA [13]. Similar results were obtained in other epidemics of fifth disease worldwide, and parvovirus B19 is now known to be the etiologic agent for EI [14–16].

2.2 Methodology Involved in Epidemiologic Analysis

2.2.1 Sources of Mortality Data

Parvovirus B19 is a common infection and death due to B19V must be rare. However, life-threatening B19V infection can occur in patients with underlying hemolytic disease. In one study in Jamaica, of 308 children with homozygous sickle-cell disease followed from birth to 15 years of age, 114 (37 %) became infected with B19V and four deaths were attributable to the infection [17]. The prevalence of B19V as a cause of chronic anemia and its contribution to excess mortality in immunocompromised patients is still unknown, although deaths have been reported [18–21]. Case reports of myocarditis following parvovirus B19 infection have also been described [22–24]. Finally, it has also been suggested that B19V infection contributes to the mortality of malaria in tropical countries [25–28].

2.2.2 Sources of Morbidity Data

Parvovirus B19 infection is not a notifiable disease in any country, and official morbidity reports in the United States do not include EI or parvovirus B19 infection. Morbidity data are therefore based on studies of outbreaks of EI (with and without serological confirmation) or on case reports of confirmed infections. In England, laboratory-confirmed parvovirus B19 infections are reported to the Public Health England. The majority of B19V infections are not reported since laboratory investigation is rarely performed for fifth disease. Similarly, there are no formal reporting systems or for documenting the incidence of parvovirus B19 infections in pregnancy.

2.2.3 Serological Surveys

Serological surveys were originally performed using the relatively insensitive CIE [6, 29, 30], now superseded by more sensitive enzyme immunoassays (ELISA). Due to the inability to grow B19V in standard cell culture systems, early serology assays were based on the use of synthetic peptides [29] or fusion proteins in *Escherichia coli* [31] as antigen. However, the epitopes presented by these products do not accurately reproduce the epitopes of the native capsids, and the sensitivity and specificity were disappointing. The expression of B19V capsid proteins as virion-like particles

using transfected B19V genome into CHO cells [32], COS-7 cells [33], or the use of yeast [34] or baculovirus [35, 36] expression systems appears to have overcome these problems, with results based on these antigens showing good correlation with assays based on native virus. The antigens are not only relatively easy to mass produce; they are also noninfectious and therefore without hazard to laboratory workers. They are widely used in seroprevalence studies.

2.2.4 Laboratory Methods

Virus Isolation and Detection

In the absence of suitable methods for isolating virus from clinical specimens, documenting the presence of virus relies on the detection of viral DNA by molecular biology techniques. B19V DNA can be detected in serum at the time of transient aplastic crisis by hybridization or more commonly by quantitative polymerase chain reaction (PCR). Due to the exquisite sensitivity of PCR, B19V DNA can then remain detectable for months or even years at low levels even following complete recovery, and thus quantitative PCR is required to distinguish recent infection from previous infection with the virus.

In situ hybridization can be used to identify B19V DNA within specific cells. Assays for B19V antigen based on monoclonal antibodies are relatively insensitive ($<10^6$ virus particles/ml). Electron microscopy (EM) can be used to detect B19V in serum with the same sensitivity as antigen assays. Within cells, EM cannot always distinguish intracellular virus from ribosomes.

Serological Assays for B19V-Specific Seroprevalence

ELISA-based assays using virus-like particles are both sensitive and specific. Although parvovirus B19V IgG can be detected by both capture assay and indirect assay, an indirect format is generally used for seroprevalence studies. Antibody to virus is usually present by the seventh day of illness (aplastic crisis) or day after the onset of rash, and probably is lifelong thereafter, although some waning of antibody has been suggested [37].

2.3 Biological Characteristics of B19V

2.3.1 Physical Properties

Parvovirus B19 has the typical features of a member of the *Parvoviridae*. On EM, the particles are nonenveloped, 15–28 nm in diameter, and show icosahedral symmetry. Often both "empty" and "full" capsids are visible. Mature infectious parvovirus particles have a molecular weight of 5.6×10^6, a buoyant density in cesium chloride gradients of 1.41 g/ml, and a sedimentation coefficient of 110S.

The DNA in infectious particles made up 19–37 % of the total mass of the capsid. The genome size is extremely limited, consisting of a single strand of DNA of 5,596 nucleotides. The genome has two large open reading frames (ORF) with the left ORF encoding the nonstructural protein and the right ORF encoding the two capsid proteins, VP1 and VP2, by alternative splicing. Parvovirus B19 particles do not appear to contain lipids or carbohydrates. The virion itself has phospholipase activity [38, 39], which is probably critical for viral entry into cells.

As a consequence of their lack of an envelope and limited DNA content, parvoviruses are extremely stable to physical inactivation. Depending on the environment, heat treatment at 60 °C does not inactivate the virus [40, 41], and in clinical studies heat-treated clotting factors (56 °C for 60 min or even, 80 °C for 72 h) did not prevent transmission [42]. B19V is resistant to lipid solvent treatment (ether, chloroform) but can be inactivated by formalin, β-propiolactone, and oxidizing agents. Gamma irradiation will also inactivate B19V, with 1.4 mR producing a 10 $\log_{10}$ reduction in infectivity [43].

2.3.2 Morphology

The parvovirus B19 virion is an icosahedron consisting of 60 copies of the capsid proteins. Most of the capsid protein is VP2, with 5 % or less of the larger VP1 protein [32]. VP2 capsid proteins self-assemble in the absence of B19V DNA, and in these systems, protein expression leads to formation of recombinant virus-like particles. VP1 is not required for capsid formation [35, 44].

The atomic structure of both infectious B19V and B19V VP2 empty capsids has now been resolved to <0.75 nm [45–47]. The virion surface has a major depression encompassing the fivefold axis, similar to the canyon structure found in RNA-containing icosahedral viruses. In B19V capsids, there is also a hollow cylindrical structure about the fivefold axes that appears to penetrate to the inside of the virion. The structural distribution of VP1 in the B19V capsid structure is still unknown. VP1 capsomers alone will not self-assemble to form icosahedral capsids; rather, they form smaller and irregular structures. In native virions, the VP1 unique region appears to be on the outside of the capsid, and it has been proposed that it may extend through the fivefold axis cylinder to the outside of the virion [48].

2.3.3 B19V Strain Variation

Parvovirus B19 is now recognized to have three different genotypes, with ~10 % variability at the DNA level between genotypes [49–51]. Most of the B19V identified is genotype 1 [49], the original B19V genotype, which is distributed worldwide. Genotype 3 seems to be the predominant B19V genotype in Ghana, representing more than 90 % of the sequences identified [52]. Genotype 2 has been primarily identified in tissues of older patients (born before 1973), suggesting that it may have circulated more frequently prior to the 1970s [53]. However, blood samples or donations

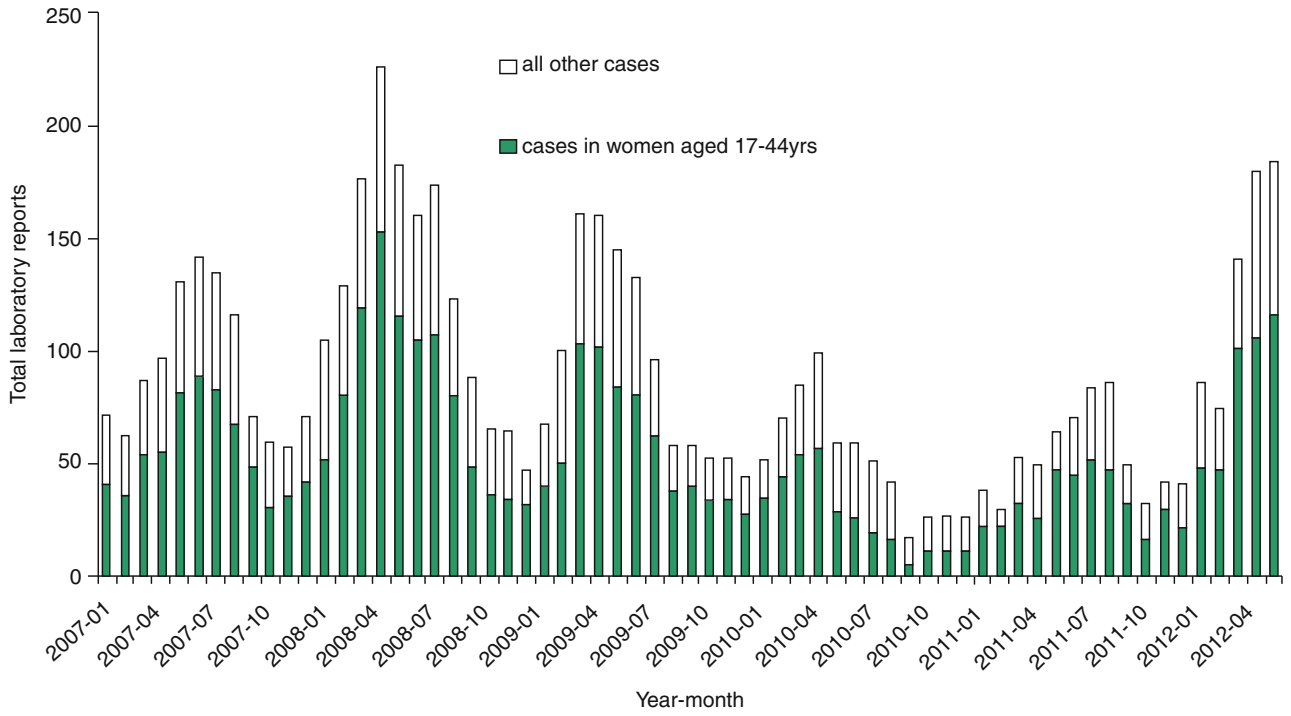

Fig. 27.1 Laboratory-confirmed cases of parvovirus B19 infection 2007–2012 in England and Wales, showing the seasonal variability (© Crown copyright. Reproduced with permission of Public Health England [83])

containing high titer genotype 2 are occasionally identified [54, 55]. The observation of both genotype 2 and 3 sequences in blood and tissues from many different parts of the world [56–58] indicates a more widespread distribution than originally assumed.

Despite the differences in the DNA sequences, the capsid protein sequence is conserved between the different genotypes, and there is evidence for both serological and cross-neutralization [59]. There is no evidence that the different genotypes show any differences in virological or disease characteristics [60, 61].

2.4 Descriptive Epidemiology

2.4.1 Prevalence and Incidence

Parvovirus B19 is a common infection in humans, and although there is some variation in different countries [62], by age 15, approximately 50 % of children have detectable IgG [63]. Infection also occurs in adult life, and more than 80 % of the elderly have detectable antibody [64]. Significantly higher seroprevalence is found in some parts of Africa [65] and Papua New Guinea [66], with >80 % of 10-year-olds having detectable antibody. In contrast, some parts of Asia [67–69] and some isolated communities in other parts of the world have a much lower seroprevalence [70, 71].

The prevalence of parvovirus B19 DNA in blood samples depends on the sensitivity of the assay used. When a relatively insensitive assay that would detect high titer viremia (indicating acute infection) was used between 1:20,000 and 1:40,000 units of blood during epidemic seasons were positive [72]. With more sensitive PCR assays then ~1 % of all donations have low-level parvovirus B19 DNA detectable [73].

Due to the risk of adverse outcome in pregnancy, a number of studies have attempted to calculate the incidence of infection in women of childbearing age [74–77]. This varies between countries but is estimated for women with no known exposure to be between 0.6 % [63] and 2.4 % [78], with most estimates around 1 % [63, 79, 80].

2.4.2 Epidemic Behavior and Contagiousness

Infections in temperate climates are more common in late winter, spring, and early summer months [81–83]. Rates of infection may also increase every 3–5 years (Fig. 27.1), and this is reflected by corresponding increases in the major clinical manifestations of B19V infection, TACs, and EI [84].

The virus can be readily transmitted by close contact. In studies in Europe, the highest force of infection (FOI) is in children aged 7–9, with an overall R_0 (basic reproduction number) of between 1.5 and 3 [85]. The secondary attack (seroconversion) rate has been calculated in various settings. In one study the secondary attack rate from symptomatic TAC or EI patients to susceptible (IgG negative) household contacts was approximately 50 % [84]. In school outbreaks, serological studies are generally not available, but 10–60 % of students may develop a rash disease consistent with B19V

infection [75–77]. The highest secondary attack rates and also seroprevalence and annual seroconversion rates even in the absence of known outbreaks of infection are observed among workers such as day-care providers and school personnel who have close contact with affected children [64, 86]. In one modeling study using seroprevalence data from five European countries, the highest risks of transmission were within households and schools, and where there was close physical contact on a daily basis and for at least 1 h [85].

Although nosocomial transmission in hospital situations has been described [87–89], especially in patients with persistent disease, this is unusual, and health-care workers do not have a significantly higher seroprevalence than age-matched controls [64]. However, patients with TAC or persistent infection should be considered infectious and appropriate precautions taken to limit transmission.

2.5 Mechanism and Routes of Transmission

Parvovirus B19 DNA has been found in the respiratory secretions of patients at the time of viremia [16, 84] suggesting that B19V infection is generally spread by a respiratory route of transmission. In contrast to other respiratory viruses, however, no site of replication for B19V has been found in the nasopharynx. There is little evidence of virus excretion in feces or urine [90].

The virus can be found in serum, and infection also can be transmitted by blood and blood products. Although ~1 % of blood donations have low-level B19V DNA detectable [73], reports of transmission of B19V infection by individual units of blood or platelets are rare. In a linked donor-recipient study, transmission of infection only occurred with components that contained B19V DNA at concentrations greater than 10^6 IU/mL (estimated to occur in 1:6,000 donations) [91].

Without prior screening for parvovirus B19, pooled products could contain high concentrations of parvovirus B19. Parvoviruses, including B19V, are very heat resistant and at high virus concentration can withstand the usual heat treatment (80 °C for 72 h) used to destroy infectivity. In addition, solvent–detergent methods, which only inactivate lipid-enveloped viruses, are ineffective. Parvovirus B19 infection has been transmitted by steam- or dry-heated factor VIII or IX [42, 92] and by solvent–detergent-treated factor VIII [92]. Hemophiliacs who received heat-treated factor VIII alone had lower prevalence of B19V antibody and lower rates of seroconversion compared to those receiving nonheat-treated factor [93].

Recommendations in Europe and America now require all plasma pools for fractionation to be screened for high levels of parvovirus DNA to try to minimize the transmission of parvovirus B19 by blood products.

2.6 Pathogenesis and Immunity

2.6.1 Pathogenesis

Parvovirus B19, like all autonomous parvoviruses, is dependent on mitotically active cells for its own replication. Parvovirus B19 also has a very narrow target cell range and can only be efficiently propagated in human erythroid progenitor cells. For erythroid progenitors from bone marrow, susceptibility to parvovirus B19 increases with differentiation; the pluripotent stem cell appears to be spared and the main target cells are CD36 positive erythroid colony-forming cells (CFU-E) and erythroblasts [94, 95]. In erythroid progenitors, the virus is cytotoxic, producing a cytopathic effect with characteristic light [96] and electron microscopic [97, 98] changes. Infected cultures are characterized by the presence of giant pronormoblasts or "lantern cells," which are early erythroid cells, 25–32 μm in diameter, with cytoplasmic vacuolization, immature chromatin, and large eosinophilic nuclear inclusion bodies. On EM, virus particles are seen in the nucleus and lining cytoplasmic membranes of infected erythroid progenitors, and infected cells show marginated chromatin, pseudopod formation, and cytoplasmic vacuolation, typical of cells undergoing apoptosis [99]. The light microscopic findings are also seen in the bone marrow of infected patients [100].

The basis of the erythroid specificity of parvovirus B19 may be explained by the tissue distribution of the virus cellular receptor, globoside, also known as blood group P antigen [101]. P antigen is found on erythroblasts and megakaryocytes. (It is also present on endothelial cells, which may be targets of viral infection involved in the pathogenesis of transplacental transmission, possibly vasculitis and the rash of fifth disease, and on fetal myocardial cells [102].) Rare individuals who do not have P antigen on their cells are resistant to B19V infection, and their bone marrow cannot be infected with B19V in vitro [103].However, erythroid specificity may also be modulated by specific erythroid transcription factors [104], and other cofactors including a hypoxic environment [105, 106].

Studies in normal volunteers have shown that B19V infection leads to an acute but self-limited (4–8 days) cessation of red cell production and a corresponding decline in hemoglobin level [90, 107]. In patients with normal erythroid turnover, this short interruption of red cell production does not lead to anemia; but in patients with high red cell turnover, due to hemolysis, blood loss, and so forth, the interruption can precipitate an "aplastic crisis." The crisis resolves as virus is "cleared" from the bone marrow by the immune response. In patients who are immunocompromised, the infection may persist and produce chronic pure red cell aplasia.

The infected fetus may suffer severe effects because red blood cell turnover is high and the immune response deficient. During the second trimester, there is a great increase in red cell

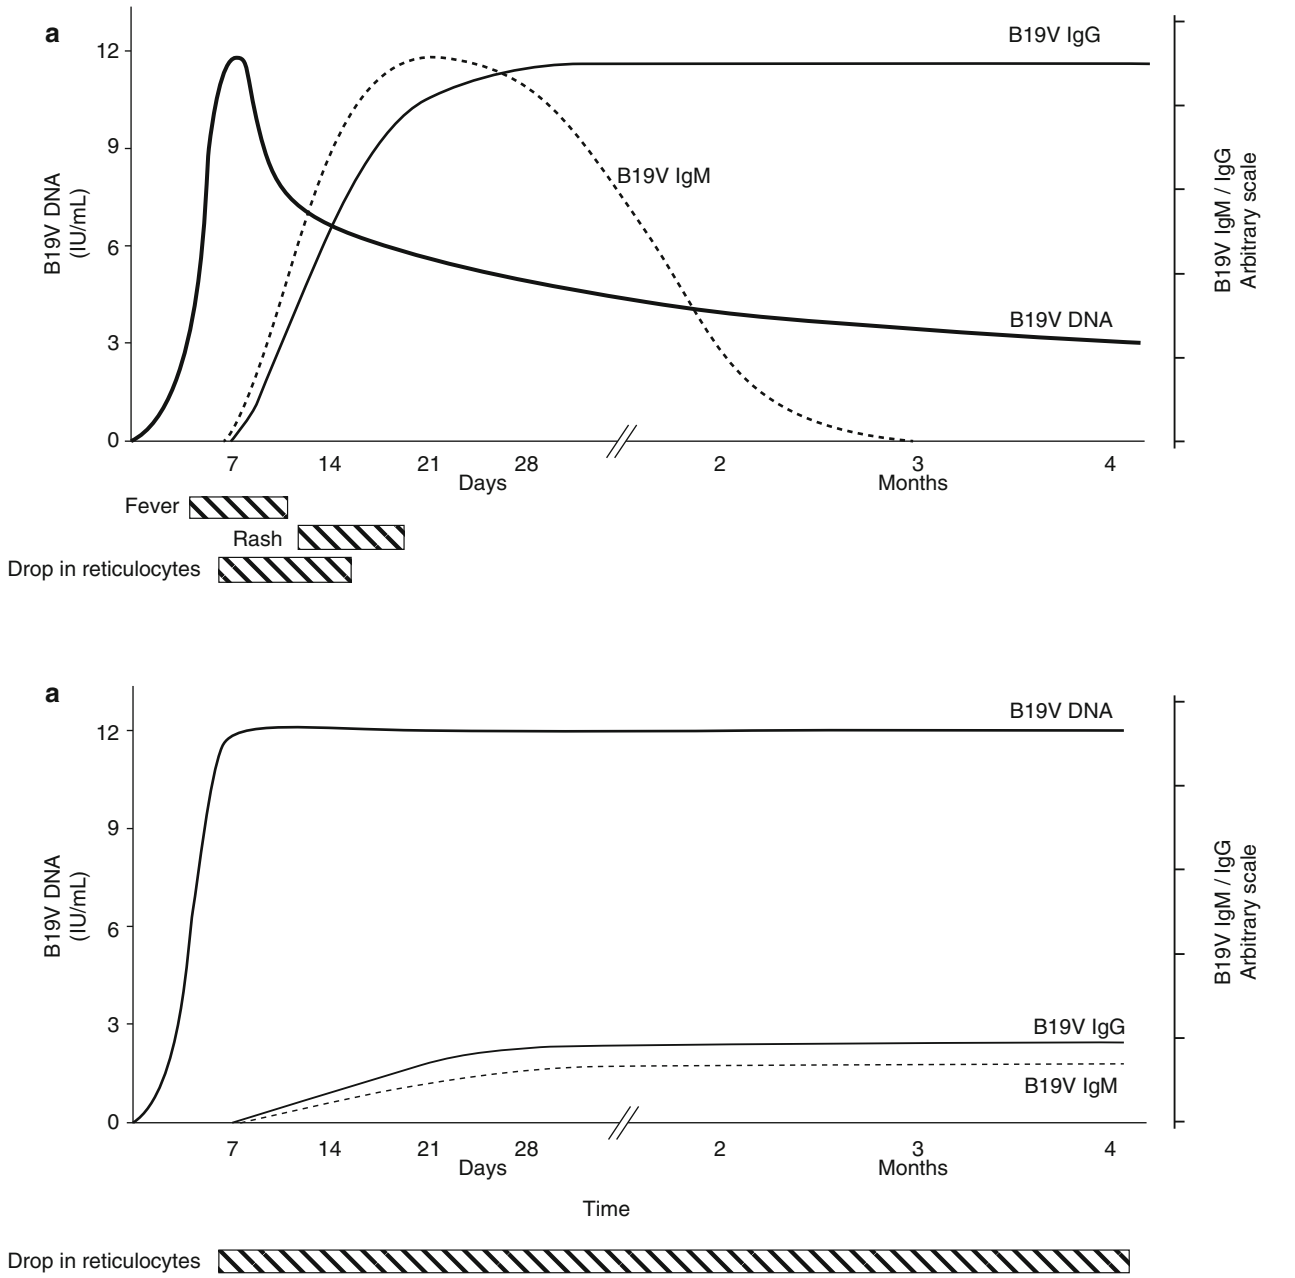

Fig. 27.2 Schematic diagram of the clinical and virological events following B19 parvovirus infection. (**a**) Virology and immune response in immunocompetent individual. (**b**) Virology and immune response in immunosuppressed patient prior to treatment with intravenous immunoglobulin (Data from Anderson et al. [90], Potter et al. [107] and the case presented by Kurtman et al. [18])

mass. Parvovirus particles can be detected by EM within the hematopoietic tissues of liver and thymus [108], and B19V DNA and capsid antigen have been detected in the myocardium of infected fetuses [109]. In addition, there is evidence that the fetus may develop myocarditis [110, 111], compounding the severe anemia and secondary cardiac failure. By the third trimester, a more effective fetal immune response to the virus may account for the decrease in fetal loss.

The pathogenesis of the rash in EI and polyarthropathy is almost certainly immune complex mediated. In volunteer studies, the rash and joint symptoms appeared when viremia was no longer detectable and at the time of development of a detectable immune response [90]. Similar findings have been reported in chronically infected individuals treated with immunoglobulin therapy [112].

2.6.2 Immune Response to B19V Infection

Both virus-specific IgM and IgG antibodies are made following experimental [90] and natural [113] B19V infection (Fig. 27.2). Following intranasal inoculation of volunteers,

virus can first be detected at days 5–6 and levels peak at days 8–9. IgM antibody to virus appears about 10–12 days after experimental inoculation; IgG antibody appears in normal volunteers about 2 weeks after inoculation.

There is a similar time course in natural infections. In patients with TAC, 10^8–10^{14} genome copies/ml of virus DNA may circulate [114, 115]. IgM antibody may be present in patients with TAC at the time of reticulocyte nadir and during the subsequent 10 days; IgG may not be present at the time of reticulocyte depression but appears rapidly with recovery. High levels of B19V DNA are not detectable in patients with clinical fifth disease (the manifestations are secondary to immune complex formation), although B19V DNA can still be detected by PCR [116].

IgM antibody may be found in serum samples for several months after exposure [117]. IgG persists for life and levels rise with reexposure [90]. Transient aplastic crisis due to parvovirus B19 infection does not occur more than once in the life of a sickle-cell patient [17]. Measurable IgA antibodies specific to B19V may play a role in protection against infection by the nasopharyngeal route [118].

In immunocompetent individuals, the early antibody response is to the major capsid protein VP2, but as the immune response matures, reactivity to the minor capsid protein, VP1, dominates [119, 120]. Sera from patients with persistent B19V infection typically have antibody to VP2 but not to VP1 [121]. Recovery from infection correlates with the appearance of circulating specific antivirus antibody.

The importance of the anti-VP1 response in developing neutralizing antibody has been confirmed in animal experiments using recombinant capsid. Rabbits immunized with capsids containing only VP2 produced a strong antibody response, but the sera had low neutralization titers. In contrast, rabbits immunized with capsids containing VP1 produced antibody with neutralizing titers comparable to those produced in humans following acute B19V infection [122, 123].

Persistent B19V infection is the result of failure to produce effective neutralizing antibodies by the immunosuppressed host. Perhaps because of the limited number of epitopes presented to the immune system by parvovirus B19, the congenital immunodeficiency states associated with persistent infection may be clinically subtle, with susceptibility largely restricted to parvovirus, although multiple immune system defects are apparent once directed testing of T- and B-cell function is performed. Administration of commercial immunoglobulins can cure or ameliorate persistent parvovirus infection in immunodeficient patients [112].

The role of the cellular immune response in limiting parvovirus B19 infection has been studied less intensively. Using a combination of recombinant capsids and peptides from the nonstructural and capsid proteins, it is now clear that B19V infection induces both a profound CD8 [124, 125] and CD4 [126, 127] response, both of which are required for viral control. Perhaps surprisingly, prolonged activation of the CD8 response is seen even after apparent acute infection and resolution of symptoms [124], presumably in keeping with the low levels of B19V DNA that are detectable in serum and tissues for months or even years following infection [128, 129].

2.7 Patterns of Host Response

2.7.1 Asymptomatic Infection

Most people with B19V specific antibody have no recollection of any specific symptoms. In one epidemiologic study of a school outbreak, B19V caused asymptomatic infection in approximately 25 % of adults [77]. In household contacts of patients with aplastic crises or EI due to B19V, 32 % (17/52) reported no symptoms [84]. There were more asymptomatic infections in those with darker skin (69 %) compared to whites (17 %), but the numbers studied were small and the clinical presentation of the index infection was different in the two groups (TAC for the black contacts and EI for the white contacts). Parvovirus B19 may go unrecognized in those with darker skin color who do not have an underlying hemolytic anemia, since the rash is particularly difficult to see in these circumstances.

2.7.2 Erythema Infectiosum

As indicated earlier, EI, otherwise known as fifth disease or slapped-cheek disease, is the major manifestation of B19V infection and was well characterized clinically before the discovery of B19V [130, 131]. The nonspecific prodromal illness often goes unrecognized and may be associated with symptoms of fever, coryza, headache, and mild gastrointestinal symptoms, such as nausea and diarrhea. Two to five days later, the classic slapped-cheek rash appears a fiery red eruption on the cheek, accompanied by relative circumoral pallor. One to four days after the slapped-cheek rash, the second-stage rash may appear—an erythematous maculopapular exanthem on the trunk and limbs. As this eruption fades, it takes on a typical lacy appearance. There may be great variation in the dermatological appearance, and rarely it may present as papulo-purpuric glove and sock syndrome (PPGSS) [132–136]. The classic slapped-cheek rash is more common in children than adults, and the second-stage eruption may vary from a very faint erythema that is easily missed to a florid exanthema and may be transient or recurrent over 1–3 weeks. The rash may be accompanied by pruritus, which can be the dominant symptom and may be especially prominent on the soles of the feet [77, 137].

2.7.3 Polyarthropathy Syndrome

In children, B19V infection is usually mild and of short duration. However, in adults and especially in women, there may be arthropathy in approximately 50 % of patients [77]. The

joints can be painful, often with accompanying swelling and stiffness. The distribution is usually symmetrical; mainly the small joints of hands and feet are involved. Joint symptoms last 1–3 weeks, although in 20 % of affected women, arthralgia or frank arthritis may persist or recur for more than 2 months, even to 2 years. In the absence of a history of rash, the symptoms may be mistaken for acute rheumatoid arthritis, especially as B19V infection can be associated with transient rheumatoid factor production [138–140]. In one study of patients attending an "early synovitis" clinic in England, 19 of 153 (12 %) had evidence of recent infection with B19V [140]. Parvovirus B19 infection should be considered as part of the differential diagnosis in any patient presenting with acute arthritis.

It has been postulated that B19V is involved in the initiation and perpetuation of rheumatoid arthritis leading to joint lesions [141], but these results have not been reproducible by other groups. In contrast, parvoviral B19V DNA is frequently found in synovial tissue of patients with rheumatoid arthritis, chronic arthropathy, and control subjects. In one carefully performed controlled study, although B19V DNA was detected in synovial tissue of 28 % of individuals with chronic arthritis, it was also found in 48 % of nonarthropathy controls [142], indicating that PCR-detectable DNA may persist in synovial tissues for months or years. In addition, in one study with long-term follow-up, none of the 54 patients with B19V-associated arthralgia reported persistence of joint swelling or restricted motion, and no evidence of inflammatory joint disease was found [143]. Therefore, it seems unlikely that B19V plays a role in classic erosive rheumatoid arthritis. The association of B19V and juvenile rheumatic disease is more convincing [144], but whether it is the cause of the disease or one of many potential triggers is less clear.

2.7.4 Aplastic Crisis

Transient aplastic crisis is the abrupt cessation of erythropoiesis characterized by reticulocytopenia, absent erythroid precursors in the bone marrow, and precipitous worsening of anemia. TAC was the first clinical illness associated with B19V infection [7]. TAC due to B19V has been described in a wide range of patients with underlying hemolytic disorders, such as hereditary spherocytosis, thalassemia, and red cell enzymopathies such as pyruvate kinase deficiency and autoimmune hemolytic anemia [145]. TAC can also occur under conditions of erythroid "stress," such as hemorrhage, iron deficiency anemia, and following kidney, bone marrow, or liver transplantation [146–149]. Acute anemia has been described in hematologically normal persons [150], and a drop in red cell count (and reticulocytes) was seen in healthy volunteers [90].

Although suffering from an ultimately self-limiting disease, patients with aplastic crisis can be severely ill. Symptoms may include dyspnea, lassitude, and even confusion due to the worsening anemia. Congestive heart failure and severe bone marrow necrosis may develop [151, 152] and the illness can be fatal [17]. Aplastic crisis can be the first presentation of an underlying hemolytic disease in a well-compensated patient [153].

TAC and B19V infection in hematologically normal patients are often associated with changes in the other blood lineages. There may be varying degrees of neutropenia, thrombocytopenia, and transient pancytopenia [145]. Some cases of idiopathic thrombocytopenia purpura [154] and Henoch–Schönlein purpura [155, 156] have been linked to parvovirus B19 infection. Less often, agranulocytosis has been described following B19V infection [157, 158].

Community-acquired aplastic crisis is almost always due to parvovirus B19 [159] and should be the presumptive diagnosis in any patient with anemia due to abrupt cessation of erythropoiesis as documented by reduced reticulocytes and bone marrow appearance. In contrast to patients with EI, TAC patients are often viremic at the time of presentation, with concentrations of virus as high as 10^{14} genome copies/ml, and the diagnosis is readily made by detection of B19V DNA in the serum. As B19V DNA levels fall in serum, B19V-specific IgM becomes detectable.

TAC is readily treated by blood transfusion. It is a unique event in the patient's life, and following the acute infection immunity is lifelong.

2.7.5 Infection During Pregnancy and Congenital Infection

B19V infection in pregnancy may be associated with miscarriage or nonimmune hydrops fetalis [160]. Although nonimmune hydrops fetalis (NIHF) is rare (1 per 3,000 births) and in approximately 18 % of cases the etiology is unknown, 7 % can be ascribed to an infectious cause, generally parvovirus B19 [161]. In one study of 63 fetal deaths due to NIHF, 8 were due to parvovirus B19 infection [162]. In cases where pathological studies were undertaken, the fetuses showed evidence of leukoerythroblastic reaction in the liver and large, pale cells with eosinophilic inclusion bodies and peripheral condensation or margination of the nuclear chromatin. Parvovirus B19 DNA could be detected by DNA hybridization [163] and in situ hybridization [164], and parvovirus particles could be seen by electron microscopy [108].

Even in the absence of treatment, an adverse fetal outcome is not typical after maternal B19V infection. In a prospective British study of more than 400 women with serologically confirmed B19V during pregnancy, the excess rate of fetal loss was confined to the first 20 weeks of pregnancy and averaged only 9 % [165]. No abnormalities were found at birth in the surviving infants, even when there was evidence of intrauterine infection by the presence of B19V IgM in the umbilical cord blood, and there were no long-term sequelae attributable to B19 infection in the 129

children observed for more than 7 years. The findings in studies in other countries were similar [166–170].

Many cases of parvovirus B19-induced hydrops fetalis are now treated with intrauterine blood transfusion. In one study of follow-up of 20 children, no long-term sequelae were observed [171]. However, in a second study of 24 transfused infants, 5/16 infants that were followed had delayed psychomotor development [172]. Neither study included controls, and it is not clear whether the developmental abnormalities were a direct effect of the virus or due to the treatment intervention. Even in the absence of intrauterine transfusion rare case reports of congenital ocular and neurological abnormalities after maternal B19V infection have been reported.

Rare cases of congenital anemia after a history of maternal B19V exposure have been reported [173]. In these cases, the virus load is generally low and the anemia does not respond to immunoglobulin therapy. The B19V infection may mimic Diamond–Blackfan anemia [174, 175], and the role of in utero B19V infection in inducing constitutional bone marrow failure such as that in Diamond–Blackfan anemia is still not clear.

2.7.6 Chronic Bone Marrow Failure

Persistent B19 infection resulting in pure red cell aplasia has been reported in patients with a wide variety of immunosuppressive conditions, ranging from congenital immunodeficiency, acquired immunodeficiency syndrome (AIDS), and lymphoproliferative disorders to transplantation [176]. The stereotypical presentation is with persistent anemia rather than the immune-mediated symptoms of rash or arthropathy. The patients have absent or low levels of B19V-specific antibody and persistent or recurrent parvoviremia as detected by high levels (>10^9 IU/mL) of B19V DNA in the serum. Bone marrow examination often shows the presence of scattered giant pronormoblasts. Often there is a pure red cell aplasia, but other lineages may also be affected.

The prevalence of B19-induced anemia in human immunodeficiency virus (HIV)-seropositive patients is probably higher than recognized. In one early study of 50 patients with AIDS, no patients with B19V viremia were identified. In a larger cohort study, B19V DNA was found in only 1 of 191 (0.5 %) HIV-seropositive men who have sex with men. However, B19V DNA was found in 5 of 30 (17 %) of the transfusion-dependent HIV seropositives, and when a hematocrit of less than 20 was used as a criterion, 4 of 13 (31 %) had detectable B19V DNA [177]. In contrast to the earlier studies, the marrow morphology need not be suggestive of pure red cell aplasia, and giant pronormoblasts may not be present.

Administration of immunoglobulin can be beneficial and ameliorative even if not curative [178]. Temporary cessation of maintenance chemotherapy also led to resolution of the anemia, and in two cases, reinstitution did not lead to recurrence [179, 180] suggesting that decreasing the level of immunosuppression may allow the host to produce antibody and resolve the virus infection.

Virus-associated hemophagocytic syndrome (VAHS) is characterized by histiocytic hyperplasia, marked hemophagocytosis, and cytopenia in association with a systemic viral illness [181]. In contrast to malignant histiocytosis, VAHS is usually a benign, self-limiting illness in which histiocytic proliferation is reversible. Hemophagocytosis is not uncommon and occurs in the setting of a wide range of infections, not only viral but also bacterial, rickettsial, fungal, and parasitic [182]. However, in many patients, there is underlying immunosuppression, usually iatrogenic, so that the role of the incriminated pathogen as an etiologic agent or coincidental opportunistic infection remains unclear.

Parvovirus B19 infection has been detected in 15 cases of hemophagocytosis syndrome among children and adults [183]. The majority of patients were previously healthy, but four patients were immunosuppressed by drug therapies. In all but one case, there was a favorable outcome (one immunosuppressed patient died of fulminant aspergillosis). Further studies are required to determine whether parvovirus B19 is a major cause of VAHS as well as the rate of VAHS in otherwise uncomplicated parvovirus B19 infection.

2.7.7 Vasculitis

The role of parvovirus B19 in vasculitis remains unclear. Several case reports have described positive B19V serology in patients with vasculitis and/or polyarteritis nodosum [184–187]; however, in each individual report, it was uncertain as to whether the association was coincidental or causative. More recently, parvovirus B19 infection has been associated with acute systemic necrotizing vasculitis [188]. Recent infection with parvovirus B19 was indicated in three patients by the presence of both B19V IgM in the serum and B19V DNA in serum and tissues. Treatment with intravenous immunoglobulin led to clearing of the virus and resolution of the patients' symptoms.

A similar report linked parvovirus B19 to Kawasaki disease, a multisystem vasculitis of early childhood. In a study from Italy, parvoviral B19 DNA and/or IgM antibodies were found in 10 of 15 patients with Kawasaki disease compared to 0 of 36 control children [189, 190]. The authors do not report on treatment of their cases, but immunoglobulin therapy is known to be beneficial in Kawasaki disease. However, other studies have not shown a relationship between Kawasaki disease and parvoviral infection [189, 191, 192].

2.7.8 Myocarditis

There have been several case reports of myocarditis associated with B19V infection in both children and adults [193, 194]. Many of the case reports attributed the syndrome to B19V as the cause based simply on the detection of B19V DNA genome; but given the known persistence of B19V

DNA in tissues, this may be erroneous. The putative role of B19V in the pathogenesis of myocarditis nevertheless warrants further investigation, particularly because P antigen is found on fetal myocardial cells and B19V appears to cause myocarditis in the fetus [110, 111].

Less convincing is the evidence for parvovirus B19 as a cause of cardiomyopathy [195]. Many parvovirus-associated cases are based simply on the detection of B19V DNA in cardiac tissue. However, when control studies have been performed, B19V DNA is also found in control cardiac tissue [196–198].

2.8 Diagnosis of B19V Infections

The detection of B19V viremia is based on quantitative PCR. High titer parvovirus B19 DNA (>10^9 IU/ml) can be detected in serum at the time of TAC (Fig. 27.2). In immunocompetent individuals, high titer B19V DNA is only detectable for 2–4 days and then drops to between 10^4 and 10^6 IU/mL as the immune response develops.

Within 1 day of onset of the rash of EI, parvovirus B19 IgM and IgG are detectable by ELISA in serum samples, and diagnosis of EI is therefore based on IgM assays, ideally performed by the capture technique [199, 200]. (Indirect assays to detect B19V IgM often give false positives due to cross-reacting antibodies or rheumatoid factor.) IgM antibody remains detectable for 2–3 months following infection.

Parvovirus B19 IgG can also be detected by ELISA. With current IgG assays, IgG is also detectable within 1 day of onset of rash and is probably present for life thereafter. As more than 50 % of the population have IgG antibody to B19V infection, detection of B19V IgG is not helpful for the diagnosis of acute infection.

Immunocompromised or immunodeficient patients with chronic infection may not mount an immune response to B19V, and therefore, quantitative PCR is required for diagnosis. As with TAC, patients generally have high titer B19V DNA (>10^9 IU/mL) detected.

The sensitivity level of detection of B19V has greatly increased by the use of PCR, but at the risk of possible contamination and false-positive results confusing interpretation. Even in immunocompetent persons whose recovery from acute infection is uncomplicated, a sensitive assay can probably detect B19V DNA for the rest of their lives [53, 129]. Thus, simple detection of B19V DNA in serum or tissues does not indicate active infection.

2.9 Control and Prevention

The humoral immune response plays a dominant role in the normal immune response to parvovirus, and antibodies are protective in both passive and active immunizations. Human convalescent-phase antisera [121] and commercial immunoglobulin preparations [201, 202] contain neutralizing antibodies to parvovirus, as assessed in vitro using erythroid colony systems or tissue culture. In addition, commercial immunoglobulin from normal donors can cure or ameliorate persistent B19V infection in immunosuppressed human patients [18, 112].

Prospects for a B19V vaccine should be good, as baculovirus-produced B19V capsids induce neutralizing antibodies in experimental animals [203], even without adjuvant. The presence of VP1 protein in the capsid immunogen appears critical for the production of antibodies that neutralize virus activity in vitro, and capsids with supranormal VP1 content are even more efficient in inducing neutralizing activity in immunized animals [123]. Candidate vaccines have been produced, but the most recent study was halted due to unexplained cutaneous reactions in 3 of the 43 patients enrolled [204]. All patients had produced neutralizing antibodies to parvovirus B19. Whether the cutaneous reactions were due to the presence of insect cell proteins in the preparation of the phospholipase activity of the VP1 was not resolved. Further efforts to develop a safe and effective parvovirus B19 vaccine are currently on hold, but given the possible severe consequences of parvovirus B19 infection, production of such a vaccine continues to be an important goal.

2.10 Unresolved Problems

2.10.1 Full Spectrum of Disease

Although B19V is associated with a wide variety of diseases, almost certainly the list is not complete. In addition, the discovery of P antigen as the receptor for B19V suggests a possible role for the virus in diseases previously unsuspected as related to parvoviral infection. P antigen is found on thyroid tissue [102], and B19V has been found in patients with Hashimoto's disease and thyroid malignancy [205–207]. Whether it triggers disease or is a bystander remains unclear [208].

Neurological disease has also been associated with parvovirus infection. Pruritus is not uncommon in fifth disease, and in one study, 50 % of patients with serologically confirmed fifth disease experienced neurological symptoms, especially neurasthenia in fingers or toes [209]. One patient developed more significant disease with progressive weakness of one arm. Brachial plexus neuropathy has been described in other patients with B19V infection [210–212].

In those illnesses where B19V is known to be involved, the full spectrum of disease is still uncertain. Parvovirus B19 is recognized as the cause of acute polyarthropathy, but its role in chronic arthropathy and as a possible trigger for rheumatoid arthritis is still undetermined. Similarly, the role for B19V as a cause of autoimmune disease, kidney disease, vasculitis, and in utero B19V infection inducing constitutional

bone marrow failure such as Diamond–Blackfan anemia is still under investigation.

2.10.2 B19V Vaccine Policy

Apart from the problems in developing a vaccine without the cutaneous side effects, the target populations for such a vaccine also remain to be determined. Should only patients at high risk of severe or life-threatening disease, such as sickle-cell patients, be protected? Or, in view of the wide variety of disease manifestations affecting all strata of the population, should a universal vaccine policy be pursued? A universal vaccination policy would have the added advantage of possible eradication of B19V from a community but would have the disadvantages of high cost–benefit ratio.

3 Human Bocaviruses (HBoV)

3.1 Historical Background

Human bocavirus was discovered in 2005 as part of a virus discovery program to identify the causes of lower respiratory tract infections in children [213]. Human bocavirus sequence was first identified in two large pools of nasopharyngeal aspirates submitted for diagnosis of respiratory tract infections in young Swedish children. After sequence-independent specific primed amplification (SISPA) two libraries of DNA were obtained, and 62 of the >800 clones analyzed contained bocavirus sequences. A specific human bocavirus PCR was developed, and testing confirmed the presence of the novel bocavirus in 17 of 540 (3.3 %) of clinical samples. This respiratory human bocavirus is now classified as human bocavirus 1 (HBoV1). Subsequently related viruses, human bocaviruses 2–4, have been detected in fecal samples [214–216].

3.2 Methods Involved in Epidemiological Analysis

3.2.1 Sources of Mortality Data

There have been no reported cases of fatal infection due to any of the human bocaviruses to date, although there is a single case of fatal type 7 adenovirus reported in a patient who also had bocavirus detected on a throat swab [217]. However, no viral titer or serology results were provided, and the significance of the detection of the bocavirus is unknown. There has also been an additional case of life-threatening infection with bocavirus in a 4-year-old, with no other pathogen identified [218].

3.2.2 Sources of Morbidity Data

Most studies of human bocavirus infection are performed based on the detection of viral DNA in respiratory (HBoV1) or fecal samples (HBoV2–4). However, the bocavirus DNA is also commonly found in asymptomatic individuals, raising concerns that they may simply be "passenger" viruses, acquired early in life and not necessarily pathogenic [219–223].

3.2.3 Serological Surveys

As with Parv4, several groups investigating human bocavirus have expressed viral capsids in insect cells [224–229] and developed serological assays to detect both IgM and IgG. However, most assays probably measure cross-reacting antibodies to any of the four different human bocaviruses, and few studies have tried to distinguish between the antibody responses [230, 231].

3.2.4 Laboratory Methods

Although HBov1 can be grown in vitro in well-differentiated airway epithelial cells [232], replication is inefficient, and for most cases, viral DNA is detected by PCR. HBoV1 DNA is commonly found in between 2 and 33 % of hospitalized children with respiratory symptoms (see Jartti et al. [233] for a review of published work), making it the fourth most common infection identified. However, in many of the cases (13–19 %) [233], the virus is found with other pathogens, raising questions as to whether it is the main cause of symptoms. Patients with active or symptomatic bocavirus infections have higher concentrations of virus; therefore, in order to identify primary infection, it is important to perform quantitative PCR to determine the viral loads in respiratory secretions and in serum or plasma samples, in combination with detection of bocavirus-specific IgM or IgG seroconversion.

3.3 Biological Characteristics of Human Bocaviruses

HBoV1 has the typical structure of a member of the *Parvoviridae*, with nonenveloped icosahedral particles of ~25 nm on diameter [234]. The full-length genome, including the inverted terminal repeat sequences, has been cloned into a plasmid and, when transfected into cells, leads to the production of infectious virions with typical features [235]. Similar culture or reverse genetics have not been described for the other human bocaviruses.

The full-length genome of HBoV1 is 5,543 nucleotides, with dissimilar hairpin sequences at the 5′ and 3′ ends. The genome has three large open reading frames (as seen in other members of the bocavirus genus) encoding the nonstructural protein (NS1), the capsid proteins (VP1 and VP2), and a second nonstructural protein, NP1 [236].

The capsid protein, VP2, has been expressed in insect cells and self-assembles to form virus-like particles that are the basis of most serology assays. The three-dimensional structure of these virus-like particles has been solved to

<0.79 nm. Although it shares the β-barrel structural core, a depression at the twofold axis, a protrusion at the threefold axis, and a channel at the fivefold axis common to parvoviruses, the surface morphology is different and appears much "flatter" than other members of the group [237].

The coding sequences for the other human bocaviruses (HBoV2 [214], HBoV3 [238], and HBoV4 [216]) is known, but apart from HBoV3, the terminal sequences have not been elucidated. The different human bocavirus species show between 10 and 30 % divergence, with increased genetic variation and evidence for recombination between HBoV2 and HBoV4 [216].

3.4 Descriptive Epidemiology

Human bocaviruses have a worldwide distribution and have been identified in every country where a search has been undertaken. HBoV1 is predominantly found in respiratory secretions and has been observed in 2–20 % of samples from children with upper or lower respiratory tract disease [233]. Although HBoV1 DNA can be detected throughout the year, primary infection occurs predominantly in the winter and spring months [213, 221, 239], as is true of many other respiratory infections. Based on serological studies using HBoV1 as antigen, most, if not all, individuals are infected in early childhood before the age of six [224, 225, 240]. More recent studies have indicated that some of the antibody detected will be cross-reacting to the other human bocaviruses [226, 230], but even so, HBoV1 infections appear to be almost universal in childhood.

HBov2–4 are predominantly identified in fecal samples, both in patients (children and adults) with gastroenteritis and in healthy control subjects [216, 233]. HBoV2 appears to be the most commonly identified species, followed by HBoV3 and then HBoV4 [226, 233]. This is also reflected in the seroepidemiology, with seroprevalence showing species-specific frequencies as follows: HBoV1 > HboV2 > HBoV3 > HBoV4. Adult sera from individuals in China, Pakistan, and Finland showed similar seroprevalences: HboV2, 30–50 %; HBoV3, 8–38 % (8 % in Finland); and HBoV4, 1–4 %.

3.5 Mechanism and Routes of Transmission

HBoV1 appears to be transmitted predominantly by the respiratory route, although detection of HBoV1 DNA in urine [241, 242] and fecal samples [243, 244] suggests that it may also be spread by fecal–oral route.

HBoV2–4 are found mainly in fecal samples and appear to be spread by the fecal route. Studies of sewage confirm that HBoV2 at least is commonly found there [245].

Although low levels of human bocavirus DNA have been detected in serum from blood donors [246], it is not known if this nucleic acid represents infectious virus, and there is no evidence of transfusion-transmitted infection.

3.6 Pathogenesis and Immunity

HBoV1 can be grown in human airway epithelia [235], and cells in the respiratory tract are presumed to be the main site of replication during infection. Virus can also be detected in serum during primary infection [226, 247], and this finding almost certainly reflects high-level virus replication in the target tissues.

Following primary infection and local replication, there is a serological response with IgG seroconversion and production of a short-lived bocavirus-specific IgM [226, 242, 248, 249].

Little is known about the pathogenesis of the fecal human bocaviruses.

3.7 Patterns of Host Response

Many of the published associations of bocavirus and disease associations are difficult to interpret because it is now clear that there can be prolonged persistence of bocavirus DNA in respiratory tract (or fecal) samples. Thus, early studies often did not find a clear association with clinical presentation. However, now that the criteria for diagnosing HBoV1 are defined (high viral load in respiratory secretions, DNA in serum, and a serological response), many groups have shown that acute primary infection is associated with both upper and lower respiratory tract infection, and specifically with wheezing [247, 250, 251].

In a study of 109 Finnish children followed up at 3–6 monthly intervals, primary HBoV1 infection diagnosed on virological and serological grounds was associated with symptoms of respiratory tract infection in 61 % of children [249]. Upper respiratory tract infection was the most common (60 %), with lower respiratory tract infection only being seen in 5 % of children. Acute otitis media was reported in 46 % of children, and further studies are needed to see if this is a true clinical association.

Similar criteria for the diagnosis of infection due to the fecal bocaviruses have not been identified, and although HBoV2–4 can be found in patients with acute gastroenteritis, in controlled studies, they are found in healthy controls at similar rates [222, 252].

3.8 Diagnosis

It is now recognized that diagnosis of active human bocavirus infection should not be based on the detection of bocavirus DNA in respiratory or fecal samples alone, because of

the persistence of DNA at these sites. For HBoV1, a firm diagnosis should be based on the detection of viral DNA in the serum, along with a serological antibody profile of recent infection. This diagnostic profile generally includes evidence of IgG seroconversion, or detection of IgM, or low avidity IgG antibody. If serum is not available for serology and PCR, then high titer (>10^4 genome copies/mL) HBoV1 DNA in respiratory secretions should be used [233].

Similar criteria have not been developed for HBoV2–4 infections.

3.9 Unresolved Problems

There is still much to be learned about human bocavirus infections, not least their pathogenesis and role in human disease. With the recently developed criteria for HBoV1 diagnosis, the true role of HboV1 as a human respiratory pathogen can be determined. The significance of finding human bocaviruses in the elderly or immunosuppressed is still unknown.

4 Parv 4

4.1 Historical Background

Human parvovirus 4 (Parv4) was also discovered in 2005 as part of a virus discovery program looking for new viruses in plasma samples using sequence-independent single primer amplification. The positive sample was from a daily injection drug user (IDU) with signs of acute viral infection who was HIV-RNA negative.

Testing of pooled plasma products from Europe and North America readily detected this virus in 4–5 % of pools, with viral loads varying from <100 copies/mL to 4×10^6 copies/mL. The prevalence may be significantly higher in other parts of the world.

4.2 Methodology Involved in Epidemiologic Analysis

4.2.1 Sources of Mortality Data

Parv4 infection is not known to be a fatal disease, although the virus has been found in two patients with encephalitis of unknown etiology [253]. However, Parv4 infection is rarely looked for.

4.2.2 Sources of Morbidity Data

Very little information is available on the clinical features of acute infection with Parv4 because cohorts of recipients of blood products and IDUs, who are at high risk of acquiring infection have received only limited attention.

4.2.3 Serological Surveys

Several groups have expressed the Parv4 capsid protein in insect [254, 255] or bacterial cells [256] and used these to develop assays to detect antibodies for Parv4. However, these assays have generally only been used to test for antibody levels in high-risk populations and not to look at seroprevalence in the general population.

4.2.4 Laboratory Methods

Parv4 has not been grown in culture, and thus, diagnosis of Parv4 infection is by the detection of Parv4 DNA by molecular techniques, usually PCR. As with parvovirus B19, low levels of Parv4 DNA in serum or tissues likely represent previous infection and are part of the "bioportfolio" as described for erythroviruses [53].

Acute infection can also be established by detection of Parv4-specific IgM by ELISA [254, 257].

4.3 Biological Characteristics of Parv4

Although the virus has not been grown in culture, and the full-length sequence is not known, it appears to have the typical features of a member of the *Parvoviridae*. On EM the particles are nonenveloped 20–22 nm icosahedral particles [258].

So far 5,268 nucleotides of the sequence have been identified, and although this sequence represents the full-length genome, the inverted terminal repeat sequences are incomplete [259]. The genome has two large open reading frames, similar to B19V, but a very different transcription profile, with a spliced RNA encoding the nonstructural protein, and in the middle of the genome a second promoter from which the RNA for the two capsid proteins (VP1 and VP2) are transcribed [260]. The ability to transmit Parv4 infection with virally inactivated blood products [257] suggests that Parv4 will have a similar inactivation profile to parvovirus B19.

As with B19V, Parv4 does show sequence variation, and virus sequences can be divided into three main groups or genotypes. Genotypes 1 and 2 (previously known as Parv5) have been found in many countries [261–268]; genotype 3 appears to be predominantly found in sub-Saharan Africa [269, 270].

4.4 Descriptive Epidemiology

In Europe and North America, Parv4 appears to be a rare infection outside certain high-risk groups—those who share needles or receive blood products. However, only been limited seroprevalence studies have been conducted in the general population, and the true prevalence is not

known [254, 255]. Within high-risk groups, seroprevalence varies widely with up to 95 % of HCV-HIV coinfected intravenous drug users having detectable antibody in one study [271]. Parv4 DNA has also been detected in a variety of different tissues from patients who fall into these high-risk groups, confirming previous Parv4 infection [255, 272, 273]. Together these results suggest that the main route of acquisition of the virus in these countries is through parenteral transmission.

However, the epidemiology appears to be very different in other parts of the world. In one study, Parv4 DNA was frequently detected in the sera of young children, with approximately 12 % of 2-year-olds having detectable Parv4 DNA [270]. Following this study, further serological assays for Parv4 IgG have been performed, and seropositive rates of 20–37 % have been found in adults in sub-Saharan Africa [274]. Similar high levels of Parv4 antibody have been described in elderly patients from the Cameroon [275]. Parv4 DNA has also been detected in nasal secretions and fecal samples from young children in Ghana [276].

4.5 Mechanism and Routes of Transmission

In Europe and North America, the contrast between high seroprevalence and detection of Parv4 DNA in tissues of individuals at high risk of blood-borne infection compared to a virtual absence of seropositivity in the general population is striking. It suggests that the main route of transmission in these countries is parenteral. However, that seems less likely in other parts of the world, such as in Africa. Although the high seroprevalence and detection of Parv4 viremia in young children do not rule out parenteral transmission, the identification of Parv4 DNA in nasal secretions and fecal samples from young children in Ghana [276], as noted above, does add additional support to the possibility of respiratory or oral–fecal routes of transmission in some countries.

4.6 Pathogenesis and Immunity

Virtually nothing is known of the pathogenesis of Parv4, not even which cells the virus targets and replicates in. Low levels of viral DNA have been found in numerous tissues, including the bone marrow and liver, but as with parvovirus B19, this may not reflect the true site of replication.

Acute infection with Parv4 appears to correlate with high levels of viremia and the development of Parv4 IgM and Parv4 IgG [257]. This pattern resembles that seen with acute B19V infection. As with parvovirus B19, there seems to be a rapid drop in Parv4 DNA titers, but with low levels ($<10^4$ copies/mL) being detectable for many months.

4.7 Patterns of Host Response

In the study of acutely infected hemophiliacs, the only repeatedly observed clinical presentation was a rash in three patients and unexplained hepatitis in two of them [257]. However, no further information on the rash was provided, and no significant increase in liver enzymes was reported. The original index case had symptoms of an acute viral syndrome.

4.8 Diagnosis

Diagnosis is generally by the detection of Parv4 viral DNA by PCR. Patients with acute infection appear to have transient high levels of Parv4 DNA in serum. However, the duration of the high-level viremia before the development of an IgM and IgG response is not known.

4.9 Unresolved Problems

There are still many unsolved questions about Parv4, including its route of transmission and the main clinical presentation of infection. Although this virus appears to be transmitted by the parenteral route, there are very few data on the seropositivity rate among blood donors in most countries.

Rhabdovirus: Rabies

28

Kira A. Christian and Charles E. Rupprecht

1 Introduction

Rabies is an acute, progressive encephalitis of mammals and has the highest case fatality proportion of any conventional infectious disease. This disease is an ancient, reemerging global zoonosis, caused by highly neurotropic viruses in the family *Rhabdoviridae*, genus *Lyssavirus* [1].

Illness develops following a productive infection with bullet-shaped, enveloped virions that contain single-stranded, non-segmented, negative-sense RNA [2]. The usual route of virus transmission is via the bite of a rabid animal. Non-bite exposures, such as direct mucosal contact, inhalation of virus, inoculation with improperly inactivated vaccines, or transplantation of infected corneas, tissues, and organs, have occurred [3]. Historically, in the United States, the primary source of human exposure to rabies virus was the domestic dog, which still predominates as the major reservoir in developing countries. In developed countries, multiple wildlife species are affected. For example, current rabies reservoirs in the United States include raccoons, skunks, coyotes, foxes, and bats [4]. The incubation period usually ranges from 1 to 3 months after exposure, but can range from days to years [5]. Once virus is deposited in peripheral wounds from a bite, centripetal passage occurs toward the central nervous system [6]. The virions may replicate locally or enter unmyelinated nerve terminals and migrate by retrograde axonal transport to the neuronal cell body. After replication in the cell body of a primary neuron, infection proceeds via retrograde axonal transport and transsynaptic spread through several neurons to the central nervous system (CNS), before infecting acinar cells of the salivary glands and excretion by saliva into the oral cavity [7]. Onset of disease is initially nonspecific, consisting in humans of signs and symptoms compatible with a "flu-like illness," such as fever, headache, and general malaise. Following the prodrome, an acute neurologic phase may include intermittent insomnia, anxiety, confusion, paresis, percussion myoedema, excitation, agitation, hallucinations, cranial nerve deficits, chorea, dysphagia, hypersalivation, piloerection, priapism, paralysis, and sometimes maniacal behavior [8]. Clinical presentation may also include paresthesia at the site of the bite exposure, and classically hydrophobia or aerophobia, manifesting as phobic pharyngeal spasms following provocative stimuli [8]. The clinical course is progressive, with death ensuing usually within days. One form of the disease, termed paralytic, or "dumb rabies," may also present as part of the clinical spectrum, with the general sparing of consciousness, together with ascending paralysis, progressive unresponsiveness, coma, and death. Once clinical signs are present, there is no proven cure. Intensive medical support may prolong life, but typically death ensues due to cardiac or respiratory failure. Exceptions to this general scheme are exceedingly rare, with few well-documented cases of human survival from clinical rabies, usually (but not always) with a history of either pre- or postexposure prophylaxis (PEP). Survivors may have significant residual neurologic impairment, but this is not found in all patients. Serological surveys and documented occurrences under laboratory conditions in the animal reservoir species have supported the existence of acquired immunity, which presumably follows subclinical exposure, abortive infection, or survival of overt clinical rabies [9, 10].

2 Historical Background

Rabies is an ancient disease of uncertain origin and one of the oldest recognized infectious diseases [11]. As such, it is difficult to provide more than highlights, given the fascination

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_28,

and dread it evoked in historians of the past. For a more thorough treatise, the interested reader is referred to Steele and Fernandez [12], Baer [13], and Wilkinson [14]. Most global reference languages singularly denote the terms damage, violence, fury, madness, or rage as literally synonymous with this affliction. Many great civilizations refer to a disease akin to rabies, weaving a tapestry of overstated fact, legend, and nightmare, exceedingly out of proportion to its actual pathos. In the not-too-distant past, extreme ostracism, torture, or execution were inflicted on those even suspected of having hydrophobia. Democritus in 500 BC recognized rabies in dogs and other domestic animals, as did many other Greek and Roman scholars. Thus, it can be assumed that this viral disease, or a similar contagion, was well recognized and occurred throughout Asia, Europe, and, perhaps, Africa, during centuries of recorded history.

Early historical accounts focused primarily on individual human or animal case reports. For example, wildlife rabies was recognized throughout the Middle East since biblical times [11]. However, few epizootics were well documented until the Middle Ages. Dramatically, there were multiple accounts of rabid wolf attacks in Franconia during 1271 [12]. Perhaps such incidents were one of the origins of the "big bad wolf" of the fairy tale. Throughout Europe, outbreaks were recorded in wolves, foxes, and dogs, especially during the eighteenth and nineteenth centuries. These episodes continued sporadically until World War II, when another major epizootic in foxes swept Europe, from east to west, at a rate of approximately 30–50 km/year, the epidemiological repercussions of which are still felt.

Quite likely, lyssaviruses evolved in the Old World. In most of the New World, the disease was largely unknown, at least among dogs, until the early eighteenth century; one of the first descriptions dates to 1703, from Mexico. Rabies was subsequently identified in the Caribbean by the mid- and late 1700s. By 1753, dogs in Virginia had been affected, and most of the Mid-Atlantic American and New England colonies shortly afterward. Pioneer expansion in the early 1800s was replete with tales of "madstones" and "phobey cats." In South America, one of the first reports of rabies was in Peruvian dogs during 1803. Besides typical incidents involving carnivores, Baer cites Spanish reports from the 1500s onward that associated bat bites and human mortality in Latin America [13]. Thus, rabies viruses were likely imported repeatedly into the New World, perhaps from the Old World circumpolar invasions predating recorded history, and more extensively during European colonization in the sixteenth through eighteenth centuries, contemporaneous with major domestic animal outbreaks in Europe. Later documentation of antigenic and genetic similarities between both Old and New World rabies viruses [15, 16] supports trans-Atlantic introduction by infected animals, in whom incubation periods could exceed the length of the voyage [17, 18]. Continued isolation of distinct viruses in Africa, serologically and genetically related to rabies virus [19], supported the hypothesis of an African genesis [20], with adaptive radiation of several lyssaviruses throughout the Old World.

Beyond mere geographic documentation, the history of rabies was also marked by a series of observations and speculations regarding its cause, prevention, treatment, and diagnosis. For example, about 100 AD, Celsus treated animal bite wounds by cauterization. In 200 AD, Galen recommended amputation of the bitten limb. Both had limited success (later supported by laboratory animal research) [12]. During 1804, Zinke demonstrated transmission of rabies virus to a normal dog by inoculation of infected saliva, considering it a toxin [12]. These observations helped lead to institution of muzzle laws and stray dog control, which resulted in rabies elimination from several countries such as Denmark, Norway, and Sweden by 1826, before the invention of rabies vaccination.

Animals have been central to progress in applied rabies research since the late nineteenth century. For example, in 1879, Galtier used the domestic rabbit as a suitable laboratory host for rabies [12]. His observations enabled the later classic 1881 experiments in which Pasteur (with important primary contributions by collaborators such as Roux, Chamberland, and Thuillier) reported the characterization of a "microbe of infinite smallness" attenuated for the dog but having a uniform (fixed) incubation period in the rabbit [21]. Pasteur distinguished this adapted laboratory form of disease from that of the agent in nature, or "street virus." He used this laboratory-adapted "fixed" virus (based upon derived characteristics, not to be confused with inactivation), grown in rabbit spinal cords, and dried for varying periods, to give graded doses of noninfectious to fully infectious virus for the immunization of animals. The first successful human rabies vaccination was administered in 1885 to a boy aged nine years, Joseph Meister, severely bitten by a presumably rabid dog, based on the animal's clinical derangement and pica [21]. This single historic event ushered in the era of rabies vaccinology, which was reasonably successful by accepted standards of the day. Occasional failures were attributed to either prolonged delays before vaccine initiation or to the particular severity of an exposure.

Since Pasteur's time, numerous improvements in safety and efficacy of the early nerve tissue origin (NTO) biologics have been attempted. Such gradual attempts were partially frustrated, until the 1940s, by the lack of standardized vaccine potency evaluation [22]. For example, in 1908, Fermi developed the first chemically treated rabies vaccine, unfortunately still with residual live virus. By 1919, Semple showed that phenol might more fully inactivate rabies virus without destroying its antigenicity. Semple's vaccine was used extensively for at least 65 years but was replaced gradually in Latin America and elsewhere by a suckling mouse NTO vaccine, by the efforts of Fuenzalida and Palacios in 1955. By circumventing the sensitization to myelin basic proteins found in

adult animal brains, the suckling mouse NTO vaccine had a lower rate of neuroparalytic reactions. A number of studies in the 1940s suggested that, besides vaccine, rabies immune serum was also effective in preventing disease. The importance of combined therapy consisting of serum plus vaccine, in combination with local wound treatment, had been demonstrated most convincingly in those few cases where human rabies occurred, despite intervention, when one of these facets of an accepted protocol was altered or delayed [23]. Other major vaccine initiatives during the 1950s and 1960s moved away from NTO vaccines, with the development of avian embryo vaccines, initially of dubious potency. Such alternative strategies eventually culminated with the first true cell culture vaccine in the 1970s, the human diploid cell vaccine (HDCV), with improved safety and efficacy [22, 24, 25]. Although the original Pasteurian use of an attenuated virus vaccine in rabbit CNS tissue was discontinued by the 1950s, inactivated NTO vaccines, from small mammals or livestock, were still used in parts of the developing world during the twenty-first century, despite the availability of safer, potent, albeit more costly alternatives. The further development of purified avian embryo vaccines and Vero cell vaccines today should compete economically and displace historical NTO vaccines altogether over the next few years.

Before the development of routine laboratory tests for rabies diagnosis, the clinical presentation of the biting animal provided a primary motivation for human PEP. At the beginning of the twentieth century, scientists such as Babes and Van Gehuchten described lesions in the CNS, presumptively related to rabies [12], but which were actually nonspecific, and applicable for a set of other etiologies as well. However, in 1903, Negri described intracytoplasmic acidophilic inclusion bodies (which he believed to be protozoa) in neurons of rabid humans and other mammals, facilitating the early diagnosis of rabies when brain tissue was collected, fixed, and stained appropriately. Histopathologic identification was a key procedure despite the relatively high rate of false-negative observations until Goldwasser and Kissling introduced the immunofluorescence diagnostic technique in 1958 [26]. This technique is still in routine use today, as the global gold standard for rapid, sensitive, and specific rabies diagnosis.

These historical accomplishments reveal that rabies research efforts focused primarily on the human as victim, rather than on primary prevention in the animal reservoir. While animals did serve as critical experimental subjects, focused human vaccination preceded the serious consideration of dog immunization, which was originally deemed impractical. It was not until 1919 that an attempt at mass vaccination of dogs occurred with the use of Fermi vaccine in Japan, with the focus shifting to the source of exposure, compared with the preceding three decades, during which many thousands of persons were treated with Pasteurian postexposure prophylaxis (PEP). However, problems associated with potency of early inactivated vaccines plagued these first trials. By 1948, a live virus vaccine using an attenuated Flury strain of egg-adapted virus was successfully applied to dogs. A variety of both inactivated and live virus vaccines was shown subsequently to be effective in preventing rabies in most of the major domestic animals. During the 1950s, animal management and mandatory dog vaccination programs resulted in the gradual elimination of canine rabies in the United States and other developed nations [27]. This, coupled with still-ongoing improvements in epidemiologic surveillance, diagnostics, and preexposure immunization and PEP, has markedly decreased the number of human rabies cases in developed countries. Clearly, an extensive public health infrastructure and proper allocation of resources are required to minimize domestic animal rabies and maintain the vigilance necessary to recognize potential human rabies exposure for the prompt initiation of prophylaxis.

3 Methodology Involved in Epidemiologic Analysis

3.1 Sources of Mortality Data

There is no single definitive depository for human rabies data at a global level. Data, if collected, may be available in national summaries, regional reports, or the peer-reviewed literature. Human rabies is a notifiable disease in the United States, as in most other developed countries. Statistics for humans and animals are compiled from local and state health departments by the Centers for Disease Control and Prevention (CDC) and published in the *Morbidity and Mortality Weekly Report*, as well as in an annual summary. In Europe, numbers and distribution of human rabies cases and cases in animals are published in the *Rabies Bulletin of Europe*. The World Health Organization (WHO) in Geneva and the associated Pan American Health Organization (PAHO) in Washington, DC, together with the World Organization for Animal Health (OIE), collect data from countries or political units on deaths attributable to rabies. These data are distributed from national governments as a source of information on global rabies occurrence and the general relative risk of infection, which, provided that proper epidemiologic surveillance is ongoing, should be nil in countries with no reported cases during any one particular year (Table 28.1). Notably, the amount of human PEP administered in some countries, such as the United States, may be lacking in these global summaries, because reporting may not be required by most localities or on a national level. Obviously, the temporal and spatial occurrence of rabies in animals will affect exposure patterns in people. For example, the emergence of a raccoon rabies epizootic in the mid-Atlantic and northeastern United States during the 1970s

Table 28.1 Global disease surveillance: selected countries/political units reporting no cases of rabies during 2012

Region	Places
Africa	Cape Verde, Libya, Mauritius, Réunion, São Tomé and Principe, Seychelles
Americas	
North	Bermuda, St. Pierre and Miquelon
Caribbean	Antigua and Barbuda, Aruba, The Bahamas, Barbados, Cayman Islands, Dominica, Guadeloupe, Jamaica, Martinique, Montserrat, Netherlands Antilles, St. Kitts (St. Christopher) and Nevis, St. Lucia, St. Martin, St. Vincent and Grenadines, Turks and Caicos Islands, Virgin Islands (the United Kingdom and United States)[a]
Asia and Middle East	Hong Kong, Japan, Kuwait, Lebanon, Malaysia (Sabah[a]), Maldives[a], Qatar, Singapore, Taiwan[b], United Arab Emirates
Europe	Austria, Belgium, Cyprus, Czech Republic[a], Denmark[a], Finland, Gibraltar, Greece, Iceland, Ireland, Isle of Man, Luxembourg, Netherlands[a], Norway, Portugal, Spain[a] (except Ceuta/Melilla), Sweden, Switzerland, United Kingdom[a]
Oceania[c]	Australia[a], Cook Islands, Fiji, French Polynesia, Guam, Hawaii, Kiribati, New Caledonia, Northern Mariana Islands, Palau, Papua New Guinea, Samoa, Vanatu

Sources: CDC [154], as well as PAHO/WHO reports
Bat rabies may exist in some areas that are reportedly free of rabies in other mammals
[a]Bat lyssaviruses are known to exist in areas that are reportedly free of rabies in carnivores
[b]Taiwan remained rabies-free during 2012, however, in July 2013 reported its first case of rabies in over 50 years to OIE with the identification of a rabid ferret-badger, *Melogale moschata* (http://www.oie.int/wahis_2/public/wahid.php/Reviewreport/Review?page_refer=MapFullEventReport&reportid=13775, cited 24 July 2013)
[c]Most of Pacific Oceania is reportedly "rabies-free"

significantly affected the epidemiology of human PEP, diverting critical health resources as animal rabies cases increased. Moreover, if predicted effects of climate change models occur, an expansion of vampire bat distribution in the Americas could subsequently result in an increase in the number of human exposures requiring PEP administration [28]. To properly assess global and national needs and implement appropriate use of PEP, efforts toward proposing a nationally notifiable reporting system for PEP should be encouraged.

When rabies surveillance is "adequate," human death rates may begin to approximate incidence rates of human infection. Generally, for statistical purposes the disease can be regarded as 100 % fatal, because the acute clinical course incidence rates are also virtually equivalent to prevalence rates. However, in most developing countries, human rabies is grossly underreported. When it is reported, human cases may outnumber documented cases in animal species. Such limitations are not limited to developing countries, as human rabies is underreported even in the United States, considering that human cases have been diagnosed retrospectively from autopsy material.

Where canine rabies occurs, human exposure and rabies incidence rates appear related to the local epizootiology of the disease. However, the relationships between human rabies mortality, virus exposure, and wildlife rabies cases are less well established. For example, since most animal reservoirs in the United States are free-ranging wildlife species, the number of animal rabies cases is variable and biased by surveillance efforts first developed for canine rabies detection, prevention, and control. Surveillance, typically based on the intensity and occurrence of animals with suspicious clinical presentations and encountering humans or domestic animals, would tend to be more reliable in detecting cases during an outbreak but less so during expected enzootic periods. This bias may be greatest in localities in which the responsibility for suspect animals, such as predominantly sick or nuisance wildlife rather than domestic dogs, does not rest with any one particular agency. Historically, as vestiges from the time of enzootic canine rabies, an animal control officer may respond to domestic animal problems in a community. However, without a mandated and funded local response to suspect wildlife, a "shoot-and-bury" practice may evolve to cope with rabies among wildlife species, with the result that fewer cases are recorded. Disease-specific incidence (or death) rates for animals are generally unavailable, since free-ranging wildlife populations are not well enumerated, and one cannot approximate the true populations at risk. Thus, in the United States, representation of the public health magnitude or burden of the disease, solely by absolute case numbers of animal rabies reported, is inherently biased and should be qualified in view of its obvious historical, scientific, and logistical limitations.

Predictably, predominant animal reservoirs change over time and in geographical distribution. For example, before World War II, dogs were the major rabid animal in the United States. After dog rabies management began, the advantages of surveillance in other species became more apparent, first during the 1960s with foxes and skunks, until the latter 1970s. Thereafter, since the incursion of raccoon rabies into the eastern United States, the annual totals of rabid wild animals have surpassed historical records, demonstrating the magnitude of

the wildlife rabies problem in such particular geographic regions [29]. Thereafter, the total areas affected, and the proportion diagnosed rabid among raccoons tested, appear stable. Based upon such observations, when animal outbreaks occur, administrations of human PEP will increase dramatically.

3.2 Sources of Morbidity Data

Human rabies case morbidity is largely reflected in mortality data. In contrast, only a few documented cases of humans surviving clinical rabies exist, some with serious neurological sequelae. Morbidity that has otherwise been averted could be assessed through numbers of human PEP administered. However, because reporting PEP in countries such as the United States may not be required, information on potential morbidity prevented by PEP is not available readily. Such occurrence may be approximated, as in developing countries, by the number of vaccine doses and human rabies immune globulin (HRIG) sold or used. Based on these imperfect data (because of the vaccine's utilization in both pre- or PEP protocols and administration of HRIG on a per-weight basis), current national estimates range between 10,645 and 35,845 (average = 23,415) human administrations of PEP per year in the United States [30]. In some localities, PEP data are reportable and partially quantifiable, whereas in many other places, vaccine and HRIG are available only through the state or local government, or private providers, from which the number of PEP administrations may be approximated. Representative reporting of human PEP would be advantageous for proper assessment of the epidemiology of rabies, for national and regional PEP needs, and to assess risk factors for exposure, as well as for further definition of the overall economic impact of rabies. These data tend to be more rabies-specific, as opposed to all of the other requisite morbidity factors associated with the trauma of the bite occurring after a rabid animal exposure, and the secondary effects that may result thereafter (such as death, or serious morbidity, associated with the severity of the attack itself, rather than from viral induced mortality or morbidity, per se).

3.3 Serological Surveys

In general, serology may be used to assess natural exposure to viral antigens and evaluate an induced response to immunization. Historically, rabies serological evaluation [31] had been performed by antigen-function assays, such as a mouse neutralization test, by antigen-binding assays, such as an indirect immunofluorescence test, or by antibody-function assays, such as the hemagglutination test. Currently, one of the most widely used serological tests is the rapid fluorescent focus inhibition test (RFFIT). Results are typically reported in relation to a known standard, as international units (IU) per milliliter of sera. The RFFIT requires trained personnel and appropriate laboratory equipment for cell culture and manipulating live rabies virus, in addition to being somewhat complex and time-consuming [32]. Alternatively, commercial enzyme-linked immunosorbent assays (ELISA) have been applied for simple, rapid screening of large numbers of sera. However, specificity may be less reliable, especially at low antibody levels, and utility is determined by the source and quality of crude antigen. The fundamental difference between these tests is that the ELISA is based on primary recognition of antigens, whereas the RFFIT and other neutralization assays (such as the fluorescent antibody virus neutralization test) are functional tests.

The absolute interpretation of such rabies serological survey data is not straightforward. Titers do not directly correlate with protection against disease, because other factors, more difficult to measure and interpret, play a role in prevention of disease [4]. Further, minimal differences in the reported values of rabies antibody results might occur between laboratories that provide antibody determination using variations in tests such as the RFFIT [5]. Obviously, there is no known absolute "protective antibody" level for all humans or other animals [31]. Minimum standards for humans are based empirically on presumed protective activity of rabies-specific antibodies, e.g., virus-neutralizing antibody (VNA), for a given exposure scenario and on repeatable values for paired sera, as could be readily detected by reference laboratories.

With regard to rabies in animal reservoir species, a subset of animals may be exposed to virus, may develop measurable viral antibodies, and are then immune to subsequent challenges. Such data do not support the existence of a "carrier state" in animals. Thus, serological surveys of wildlife in areas with enzootic rabies may reveal a low prevalence of antibodies [33]. These incidents may occur among animals that are infected and will ultimately die of rabies or more likely among individuals that have developed immunity to rabies, presumably following natural sublethal exposures. These naturally occurring antibodies are distinct from those due to purposeful immunization of free-ranging animals via limited trap–vaccinate–release programs, regional oral rabies vaccination programs, or occasional parenteral vaccination of wildlife with domestic animal vaccines by well-intentioned wildlife rehabilitators [34].

Clearly, multiple ecological factors will affect rabies epizootiology, as related to host, agent, and environment. Among carnivores, the small Asian mongoose provides one clear example of outbreaks influenced by host biology and distribution [35]. Mongooses were introduced for rodent control onto most of the larger Caribbean Islands, including Puerto Rico, Dominican Republic, Haiti, Cuba, and Grenada. Though mongooses are wild, their population density is

usually directly proportional to human activities [35]. As such, mongooses proliferated and are now deemed undesirable due in part to predation on native fauna and the risk from rabies in this introduced reservoir species. For example, 56 % of the 73 rabies cases diagnosed in Puerto Rico in animals during 2012 were attributed to mongoose [29]. Although poisoning has been practiced, such control was undesirable and ineffective over time. Many mongooses (as many as 55 % at the end of an epizootic cycle) have evidence of rabies antibodies, possibly as a result of sublethal virus exposure, and such animals may be immune for life [48]. Removal through poisoning or other lethal means appears detrimental, which may simply enhance reproductive turnover, dispersal, and increase the number of naive, susceptible animals. In view of such levels of naturally occurring disease and probable consequent herd immunity, the nearly closed populations of these nonindigenous mammals should be ideal candidates for oral vaccination. This would represent one means of disease management to limit human and domestic animal exposures, especially in a circumscribed island environment [36].

3.4 Laboratory Methods

Several etiologies which cause encephalitis may be confused with rabies. Epidemiologic studies should be based on laboratory confirmation of suspected disease or death from rabies. As summarized in the above historical description, laboratory techniques have evolved gradually over the last century. Although variations are practiced in many laboratories, the standard techniques of the WHO Expert Consultation on Rabies (2005), and the current edition of the WHO *Laboratory Techniques in Rabies*, are recommended and widely used [37]. Included in these texts are methods for the collection, preparation, and shipping of specimens; tissue and organ removal; laboratory animal inoculation; immunofluorescent antibody (FA) procedures for detection of virus antigens; serological determinations; cell culture propagation of virus; electron microscopy; vaccine production; potency and safety determinations; and specific virus identification by antigenic and genetic techniques. For regulations governing specific international or national shipment of potentially infectious specimens, such as rabies, the local or national public health laboratory should be consulted for current updates.

Historically, brain tissue from the rabid subject was examined for Negri bodies, which are specific intracytoplasmic inclusion bodies observed under the light microscope. These inclusions contain viral nucleoproteins, which accumulate in quantities large enough to be detected after staining by the Seller's, Giemsa, Mann, or other methods, and can be visualized microscopically. Within the hippocampus, Ammon's horn is one particular portion of the CNS usually examined for Negri bodies, as are the Purkinje cells of the cerebellum and pyramidal cells of the cerebral cortex. Limitations from this technique include a concern that Negri bodies may be absent in up to one quarter to one third of rabies cases, while artifact and inclusions produced by other agents could be confusing and differentiated only after considerable laboratory experience.

Classically, animal inoculation with suspect diagnostic material was once used widely to support rabies diagnosis, particularly because of the potential dramatic ramifications of false-negative results in human rabies exposure situations. Laboratory rodents were used routinely for viral isolation, as suckling and weanling mice are highly susceptible to infection by intracerebral inoculation. Typically, the time from inoculation to illness varied from 7 days to 4 weeks, but viral antigens in brain may be confirmed as early as 4 days following inoculation. Confirmation in the inoculated animals of rabies, as the source of illness and mortality, should always be performed, because laboratory species may die of comorbid conditions or as a result of infections by other agents in the original clinical specimen.

Besides the use of mice, murine neuroblastoma cell cultures are as sensitive as laboratory animals for isolation of field strains from saliva and brain of rabid animals and are the method of choice in laboratories where cell culture facilities are available [38]. The presence of antigens in infected cells is demonstrated by the FA test.

In brief, the direct FA test uses a fluorescein dye conjugated to rabies immune serum, which in turn is reacted with acetone-fixed impressions from CNS tissue of the presumed rabid subject, including the brainstem and cerebellum or hippocampus [26]. The antigen–antibody reaction is detected by microscopic observation of fluorescence under light of the appropriate wavelength. The direct FA test is very rapid and reliable when used by an experienced laboratorian. The direct FA method is the test of choice for fresh or frozen tissue, because of test sensitivity, specificity, and economy. Immunohistochemical testing, or a modified FA technique, can be applied on formalin-fixed tissues; however, the method is more cumbersome and cannot distinguish between different lyssavirus species. Also, RT-PCR methodologies can be used for diagnostic support but may be unreliable due to RNA degradation in these fixed tissues [39]. Brain tissues from suspect rabid animals continue to be submitted in formalin, and research continues to develop an ideal molecular methodology to confirm rabies and to determine variant characterization [39]. Significantly, in the Old World, other lyssaviruses related to rabies virus will cross-react in the direct FA test, depending on the quality of the particular diagnostic conjugate. Specific monoclonal antibodies (MAbs) can be used to distinguish rabies virus from these related lyssaviruses, but the public health consequences of identification are the same, regardless of exposure to any one

of these etiologic agents, in that appropriate medical care and PEP considerations are necessary.

Rather than reliance upon a history of relevant viral exposure and compatible clinical signs, proper laboratory-based diagnosis is needed for case confirmation. Besides the direct FA test from the 1950s, during the early 2000s, a rapid immunohistochemical test (RIT) to detect lyssavirus antigens was developed. Modifications of a former indirect test led to a direct test, the dRIT, which uses a cocktail of highly concentrated and purified biotinylated anti-nucleocapsid MAbs produced in vitro, in a direct colorimetric staining approach, and allows a diagnosis to be made in <1 h. Currently, the dRIT is an experimental procedure designed for consideration as a potential confirmatory test of the direct FA test. Similar to the direct FA test, the dRIT can be performed on brain touch impressions, and based upon the reagents used, viral antigens may appear as magenta inclusions against a blue neuronal background. The test recognizes all variants of rabies virus and all representative lyssaviruses [40]. One advantage to the dRIT, compared with the direct FA test, is that the dRIT can be conducted by light microscopy, compared with the FA test, which must employ the use of a fluorescence microscope [41]. The dRIT may be used to enhance field surveillance among suspect animals, particularly in support of national, regional, state, or local oral vaccination programs. However, until the concept is validated as sensitive and specific as the direst FA test, the dRIT should not to be used for public health decisions, in those situations in which human or animal exposure has occurred or is suspected, and local public health authority or other officials should be contacted for immediate and appropriate diagnostic testing [41].

While animals are diagnosed postmortem, rabies in humans can be diagnosed while the patient is still alive. Human antemortem diagnosis can be made by virus isolation from saliva, antigen detection in biopsy tissue, or demonstration of virus-specific antibody (without prior vaccination). Selected FA tests are performed on human brain or skin biopsies, the latter usually taken from highly innervated areas, such as the nape of the neck, where piloerector nerve plexi are prominent [42]. Also, in some human rabies cases, corneal cells obtained from touch impressions may be antigen-positive during life, care being taken not to abrade the delicate corneal tissue (a rationale to caution against this method vs. other stated procedures). Antemortem diagnosis may also be made by showing a fourfold or greater rise in serum antibody titer during the illness in the absence of vaccination or administration of rabies immune serum. Demonstration of virus antibody in the cerebrospinal fluid (CSF) is also a reliable indicator of infection, even after vaccination. Vaccination alone does not elicit CSF antibody. During viral infection, other pathophysiologic changes in the CSF, such as an increase in specific proteins, and pleocytosis, particularly a monocytosis which is compatible with a viral encephalitis, may also occur [43]. Repeated samples should be taken for antibody and antigen detection, because negative results in early initial samples do not rule out rabies. Further, because of the risk of false-negative results with a potential human exposure, intravitam testing of the rabies-suspect animal is inappropriate.

In addition to classical laboratory procedures for detection of viral antigens and antibodies, recent progress has been made in the application of molecular techniques, particularly nucleic acid detection and amplification of cDNA by RT-PCR [44–46], with subsequent generation of viral nucleotide sequences, leading to a greater understanding of lyssavirus epizootiology and phylogeny [19, 43, 47]. However, the extreme sensitivity of molecular methods, such as the RT-PCR technique, also greatly increases the probability of a false-positive diagnosis from laboratory contamination. Moreover, because of lyssavirus heterogeneity, false-negative results can occur if primer selection is inadequate to compensate for heterogeneity. To date, universal primers for all known lyssavirus variants have not been clearly defined or standardized. Considering these factors, related costs, and the considerable expertise required for proper analysis and interpretation, such molecular techniques are not recommended for routine primary rabies diagnosis alone when CNS tissue is available, as opposed to laboratory confirmation in concert with other techniques.

The routine sequence characterization of lyssaviruses from formalin-fixed tissues is possible but may be difficult, partially as a function of the fixation time and resultant short fragments of nucleic acid [16]. Optimization of these methods, beyond mere qualitative diagnostic methods for viral antigen analysis preserved in such tissue, may be feasible by the adaptation of techniques that would employ MAbs for retrospective virus identification in archival material [48]. Besides determination of optimal specific reagents, corroborative data would have to be generated on the sensitivity and specificity of such technique in comparison to fresh tissue analysis. Because of increased utilization for other viral diseases, such as HIV, influenza, polio, etc., additional development of appropriate modern molecular methods is anticipated to improve the application to basic rabies diagnosis in developing countries.

4 Biological Characteristics of the Agents That Affect Epidemiologic Patterns

Rabies virus is the type species of the genus *Lyssavirus*; additional and proposed members of the genus *Lyssavirus* include those listed in Table 28.2.

Rabies is essentially a “dead-end” disease in humans and several other species. While possible, human-to-human

Table 28.2 Viruses currently included in the genus Lyssavirus

Recognized and proposed species	Predominant natural hosts	Geographical range
Rabies virus (type species)	Chiroptera, Carnivora	Worldwide
Australian bat lyssavirus	Pteropodid and insectivorous bats	Australia
European bat lyssavirus, type 1	Insectivorous bats	Europe
European bat lyssavirus, type 2	Insectivorous bats	Northwestern Europe
Khujand virus	Insectivorous bat, *Myotis mystacinus*	Central Asia
Aravan virus	Insectivorous bat, *Myotis blythii*	Central Asia
Bokeloh bat lyssavirus	Insectivorous bat, *Myotis nattereri*	Germany
Irkut virus	Insectivorous bat, *Murina leucogaster*	Eastern Asia
Duvenhage virus	Insectivorous bats	Sub-Saharan Africa
Lagos bat virus	Pteropodid bats	Sub-Saharan Africa
Mokola virus	Unknown (shrews, rodents?)	Sub-Saharan Africa
Shimoni bat virus	Insectivorous bat, H. *commersoni*	Kenya
West Caucasian bat virus	Insectivorous bat, *Miniopterus* sp.	Southeastern Europe
Ikoma lyssavirus	Unknown (isolated from civet, *C. civetta*)	Tanzania

Recognized viral species are listed in italics, as adapted from Kuzmin and Tordo [155]

transmission via bite has not been reliably established [49]. However, likely cases of human-to human transmission continue to be reported [50]. A marked exception to the apparent rarity of direct human contagion from exposure to patient secretions, such as saliva, consists of at least eight human rabies cases resulting from the surgical implantation of infected corneas from donors that had succumbed to undiagnosed rabies [51, 52]. In addition, other cases have occurred in Europe and the United States from other organ and tissue transplants. For example, in 2004, four recipients of kidneys, a liver, and an arterial segment from a common organ donor died an average of 13 days after the onset of neurologic symptoms following the development of encephalitis, and antibodies against rabies virus were later found to be present in three of the four recipients and the donor [53].

Biological characteristics of lyssaviruses have a measurable, although incompletely understood, effect on epizootiologic patterns among their animal host species [54]. Initially, through classic serology, and later by MAb and genetic analysis, translational research was possible to differentiate serotypes, variants, and genotypes of rabies virus and related lyssaviruses [2, 15, 16]. All mammals are believed susceptible to lyssaviruses; however, prominent reservoirs among bats and carnivores perpetuate largely independent cycles of infection. Epizootiologically, such variant viruses are maintained by different host species. Complex virus–host interactions lead to the emergence of viral characteristics that are beneficial to self-perpetuation among these particular species that manifest as regional epizootiological "compartments" [55–57]. Thus, in countries with adequate laboratory-based surveillance, such as the United States, there are discrete geographic zones of raccoon rabies, skunk rabies, and so forth. Such viruses are fully transmissible to other mammals within a region but genetically and antigenically distinguishable as a single variant in a particular geographic area, regardless of affected host, be it the reservoir species (e.g., raccoon) or mere "spillover" into an essentially dead end, but susceptible host (e.g., domestic cat). In short, all animal reservoirs are also vectors, but not all potential vectors are reservoirs for rabies.

Not all mammals are equally involved in rabies maintenance from an epizootiological perspective, but for poorly understood reasons. Among the Carnivora, meso-carnivores, ranging in size from the mongoose to the jackal or coyote, are most significant. As one specific example of virus vagility, coyotes possess many host qualities ideal for the initiation of a rabies epizootic. Historically, during 1915–1917, an extensive outbreak of coyote rabies extended over large portions of southeastern Oregon, northeastern California, western Utah, and Nevada [58]. Thereafter, rabies among coyotes was reported only sporadically in the western United States, despite the coyotes' widespread distribution and abundance. Another major focus was detected in Texas during 1988 [59], and the virus spread throughout southern Texas. Antigenic and genetic analysis of isolates obtained from this outbreak suggested the involvement of a rabies virus variant associated with canine rabies along the United States–Mexico border but apparently capable of sustained coyote-to-coyote perpetuation. Intensive oral vaccination progress initiated during 1995 was able to eliminate this virus in the United States [60], which contributed to the United States being declared free of canine rabies virus transmission in 2007 [61].

Another unique characteristic of virus infection is a prolonged incubation period during which the infection is virtually undetectable. In humans, although the incubation period is generally several weeks to months, unusually long incubation periods of 6 or more years have been described [17]. This potential for long incubation periods influences directly the management of exposed domestic animals. An exposed, unvaccinated domestic animal may be euthanized or held in

quarantine for 6 months [4], which extends beyond the majority of documented incubation periods for dogs and cats.

Mechanisms for successful in vivo productive infections are not fully appreciated. Neurotropism appears to be a critical facet of a successful strategy to partially evade immune detection [62, 63] with the ultimate end to ensure future viral progeny. Under the constraints of mammalian anatomy, there are fairly limited routes available to a virus for transit from an initial portal of entry (i.e., a bite in a peripheral muscle) to a primary portal of exit (e.g., saliva). One of the most common mechanisms for other viruses to transit to such distant sites is by viremia or spread via lymphatics. The passage along both of these latter pathways may also initiate a vigorous immune response. An effective blood–brain barrier would limit the utility of viremia in enhancing the spread and perpetuation of a neurotropic virus. In contrast, all known lyssaviruses utilize neurotropism. Direct evasion, and suppression of host immune surveillance, appears to be a critical evolutionary strategy [64]. Long incubation periods may be one consequence of reliance on flow within neural circuitry [65]. Adaptation to the CNS may also be a mechanism to lower the risk of extinction in a host that may pursue a more solitary existence for short periods of its life history. Since the reservoir host must eventually seek a breeding partner, an opportunity for transmission is readily available, considering the common use of teeth and oral mucosal contact preparatory to typical mammalian copulation, especially among carnivores and bats. Following bite inoculation, covert access to the CNS via neuron-to-neuron passage would be one unique mechanism for minimizing immune detection while reaching distant sites important for replication and transmission [62, 66]. Lyssaviruses are rather fragile, maintained by direct transmission, and do not survive readily in the external environment, where inactivation is operative. Dependence on fluid-sucking arthropod vectors is unnecessary, as are additional structural proteins to ensure extra-mammalian environmental survival, because in vivo transmission is largely a direct host-to-host event. For example, virus may perpetuate fox-to-fox, bat-to-bat, and so on, irrespective of firm constraints imposed by either geography or season.

5 Descriptive Epidemiology

Rabies is a zoonosis with diverse natural mammalian reservoirs [54]. Predominant hosts are bats and mammalian carnivores. These mammals include canids, such as the domestic dog (as the principal global reservoir, particularly in equatorial regions of Asia, Africa, and Latin America [27]), foxes (in the circumpolar Arctic, Central and Eastern Europe, the Middle East, and scattered foci throughout the western United States [29, 67]), raccoon dogs (in eastern Europe [68]), jackals (in Africa and Asia), and coyotes (historically in the western United States [29]); skunks (primarily in the central United States and Canada [29]); procyonids, such as the raccoon (in the southeastern, mid-Atlantic, and northeastern United States [29]); and mongoose species (in Asia, Africa, and several Caribbean islands [35]). Other conspicuous carnivores, such as bears, wolves, and all of the felids, can serve as effective short-term viral transmitters intra- and interspecifically, but insufficient documentation is available to suggest that these groups can continue to propagate virus or serve as reservoir hosts for unique viral variants, as opposed to primary infection by the primary host. "Bat" rabies from infection by rabies viruses per se is a New World phenomenon only, described primarily among the insectivorous species of North America and the hematophagous vampires and frugivorous species from Latin America [69, 70]. Ultimate evolutionary and ecological perpetuation of lyssaviruses appear to be driven by bats [71]. Distinct from the type species rabies virus, related lyssaviruses have been diagnosed in Australian, African, and European bat species [72–75]. While the disease is naturally maintained by relatively few taxa, rabies may affect any mammal, such as ungulates, and result in a largely "dead-end" infection. Contrary to popular belief, small mammals, such as rodents (mice, rats, etc.) and lagomorphs (rabbits, hares, etc.), are not important in rabies, and cases are uniformly rare [76]. Further, rodents have not arisen as "missing link" reservoirs in any region in which domestic dog or wildlife rabies has been controlled.

5.1 Incidence

To properly understand the occurrence of human rabies, the context of animal rabies is fundamental. Rather than a global rabies pandemic, single or multispecies animal host groupings are apparent when appropriate disease surveillance is practiced systematically. Combined with historical temporal and geographical data, both antigenic characterization and nucleotide sequence analysis can be used to "compartmentalize" viral isolates with different animal reservoirs responsible for their perpetuation and to estimate relative risks of human disease from differential animal exposures (Table 28.3). For example, during 2012, only one human fatality occurred; however, 6,162 animal rabies cases were reported in the United States (including the District of Columbia and Puerto Rico) [29] (Fig. 28.1). In contrast to fulminant canine rabies pre-World War II, >90 % of current animal rabies cases in the United States are from wildlife (Fig. 28.2, top). Most of this increase resulted from continued spread of a predominant raccoon rabies virus variant, following unrestricted progression of an outbreak initiated by animal translocation during the late 1970s to the Virginias from a nidus in the southeastern United States [77, 78]. Cases rise as infected individuals within raccoon populations encounter naive conspecifics with dramatic results.

Table 28.3 Rabies immunization: preexposure and postexposure

Criteria for preexposure immunization			
Exposure category	Nature of risk	Typical populations	Preexposure regimen
Continuous	Virus present continuously, often in high concentrations. Specific exposures may go unrecognized. Bite, nonbite, or aerosol exposures	Rabies research lab workers.[a] Rabies biologics production workers	Primary course. Serologic testing every 6 months. Booster immunization if antibody titer falls below acceptable level[ab]
Frequent	Exposure usually episodic with source recognized but exposure also might be unrecognized. Bite, nonbite, or aerosol exposures	Rabies diagnostic lab workers,[a] cavers, veterinarians and staff, and animal control and wildlife workers in areas where rabies is enzootic. All persons who frequently handle bats	Primary course. Serologic testing every 2 years. Booster vaccination if antibody titer is below acceptable level
Infrequent (greater than population at large)	Exposure nearly always episodic with source recognized. Bite or nonbite exposures	Veterinarians and animal control staff working with terrestrial animals in areas where rabies is uncommon to rare. Veterinary students. Travelers visiting areas where rabies is enzootic and immediate access to appropriate medical care including biologics is limited	Primary course. No serologic testing or booster vaccination
Rare (population at large)	Exposure always episodic. Bite or nonbite exposure	US population at large, including individuals in rabies-epizootic areas	No vaccination necessary

Adapted from CDC [5]

Preexposure immunization. Preexposure immunization consists of three doses of HDCV or PCEC vaccine, 1.0 ml, IM (i.e., deltoid area), one each on days 0, 7, and 21 or 28. Administration of routine booster doses of vaccine depends on exposure risk category as noted

Postexposure immunization. All PEP should begin with immediate thorough cleansing of all wounds with soap and water. *Persons not previously immunized*: HRIG, 20 IU/kg body weight, as much as possible infiltrated at the bite site (if feasible), with the remainder administered IM; 4 doses of HDCV or PCEC, 1.0 ml IM (i.e., deltoid area), one each on days 0, 3, 7, and 14. *Persons previously immunized*: Two doses of HDCV or PCEC, 1.0 ml, IM (i.e., deltoid area), one each on days 0 and 3. HRIG should not be administered. Preexposure immunization with HDCV or PCEC; prior PEP with HDCV or PCEC; or persons previously immunized with any other type of rabies vaccine and a documented history of an acceptable rabies virus-neutralizing antibody response to the prior vaccination

[a]Assessment of relative risk and extra monitoring of immunization status of laboratory workers are the responsibilities of the laboratory supervisor (see United States Department of Health and Human Services' *Biosafety in Microbiological and Biomedical Laboratories* [137])

[b]Routine Preexposure booster immunization consists of one dose of HDCV or PCEC, 1.0 ml/dose, IM (deltoid area), or HDCV, 0.1 ml ID (deltoid). The acceptable antibody level is a 1:5 titer (complete inhibition in the RFFIT at a 1:5 dilution, approximately equivalent to 0.1 IU/ml). Boost if titer falls below this level, as long as the person remains at risk of viral exposure

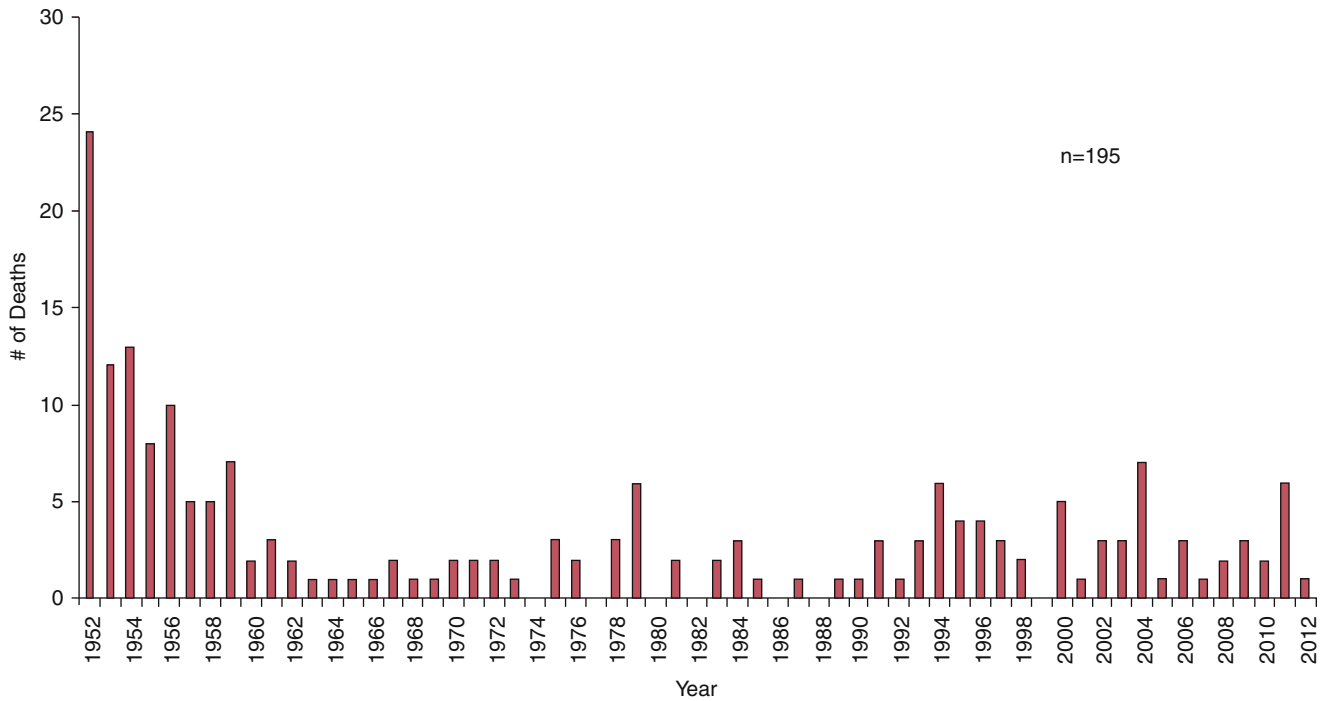

Fig. 28.1 Reported human rabies cases in the United States, 1952–2011 (Sources: Petersen and Rupprecht [81] and Dyer et al. [28])

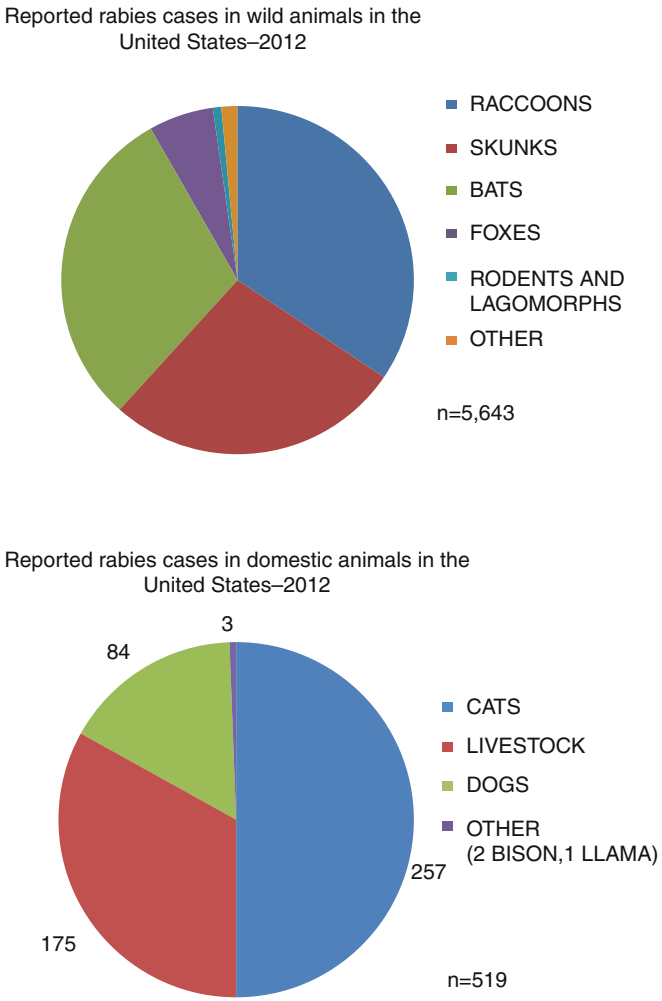

Fig. 28.2 (*Top*) Reported rabies cases in wild animals in the United States, 2012. (*Bottom*) Reported rabies cases in domestic animals in the United States, 2012 (Source: Dyer et al. [28])

During 2012, rabies was also reported in other important wildlife, primarily skunks (1,539 cases) and foxes (340 cases), in the Midwest and Alaska/northeastern United States, respectively, and rabies in bats (1,680 cases) was widely distributed [29]. In the eastern United States, rabies was reported in 1,953 raccoons during 2012 [29]. Historically, Hawaii is unique in the United States as never having reported a case of indigenously acquired rabies, attributable in part to its remote insular geographical isolation in Oceania and 120-day quarantine policy.

Domestic animals most at risk include those with a lower likelihood of parenteral vaccination but higher potential for virus exposure (especially if poorly supervised and free-ranging), such as cats. During 2012, 257 cases of rabies were reported in cats [29], compared with 303 cases during 2011 (Fig. 28.2, bottom) [79]. Cats are significant in part because they have begun to outnumber their canine counterparts, owing to the increased popularity of cats as pets, but also lower likelihood of routine vaccination. Difficulties in clinical recognition also increase the public health significance of rabies in cats, as early nonspecific signs may easily be compatible with unrelated differential diagnoses, and may be compounded by an abscess compatible with a bite wound in an outdoor cat [80]. By temporal comparison, 84 cases of rabies in dogs were reported in the United States during 2012, compared with 303 cases in cats reported during 2011 [79].

In contrast to areas enzootic for dog rabies with a consequent high case load (e.g., estimated at >20,000 annual human fatalities in India alone), human rabies is rare in developed countries. For example, between 1980 and 2011, only 71 human deaths were diagnosed in the United States, 20 of which were imported. Of the 45 cases for which viral variant data were available among those suspected of infection while in the United States during 1980–2011, 40 were attributable to bat rabies virus variants. By contrast during the same time period, of the 20 imported cases for which variant data were available, 18 (90 %) were attributable to dog virus variants [81].

5.2 Epidemic Behavior

Application of MAb and molecular technology to the study of the epizootiology of the *Lyssavirus* genus (previously felt to consist of a relatively homogeneous group of viruses) first provided substantive evidence for considerable variation within the group, based on the nucleoprotein (N) and glycoprotein (G) protein reactivities among both fixed and street rabies viruses and between rabies viruses and related lyssaviruses [15, 82]. The use of MAbs was particularly useful in determination of the extent of natural antigenic variation among lyssaviruses as well as epizootics—such as the raccoon epizootics in the eastern United States described below—either isolated from a variety of wildlife reservoirs within a fairly restricted geographical area or between continents. In particular, through the use of genetic sequence comparisons, distinctions became much more obvious between those viruses isolated from bats and carnivores [82].

5.3 Geographic Distribution

As illustrated in Table 28.2, rabies is distributed on all continents, with the exception of Antarctica, but varies greatly dependent upon the dynamics of certain viruses among particular mammalian hosts and the degree of operational surveillance, prevention, and control methods used in each geographical unit. Currently in the United States, the most prominent wildlife rabies hosts include raccoons, skunks, foxes, and bats [29].

Through MAb and molecular laboratory techniques applied to public health and agricultural surveillance, fox rabies outbreaks in Canada and Alaska appear related, as do the raccoon epizootics in the eastern United States [57, 78]. Skunk isolates group as distinct variants defining separate outbreaks in the north central/south central states and California. Such investigations, when extended over large geographic areas, lead to a better understanding of lyssavirus dynamics and improved animal rabies management programs, to distinguish recent viral introductions, potential vaccine failures, and so on.

Antigenic or molecular characterization can also be employed to investigate unusual or unexpected lyssavirus mortality, especially in domestic animals or humans that lack an obvious exposure history. The antigenic patterns or nucleotide sequences obtained can be compared with variants from known animal reservoirs. For example, analysis of recent human rabies cases from the United States implicates variants of virus associated with insectivorous bats (e.g., *Eptesicus*, *Tadarida*, *Myotis*, *Lasionycteris*, or *Perimyotis* spp.), indirectly or directly, in the etiology of infection. Unfortunately, bat rabies cases are not routinely identified to species. Thus, case surveillance data alone do not provide adequate clues about unique variants affecting different bat species or species groups. More rigorous reporting standards coupled with modern virological analysis will be necessary to provide further detail into epidemiologic facets of bat lyssaviruses.

In contrast to most countries in North America and western Europe, where wildlife rabies predominates, Southeast Asia, Africa, Latin America, and most developing countries, canids continue to be the principal causative vectors of transmission to humans [83]. Additionally, transmission by hematophagous bats, unique to the Americas, is an emerging public health problem, in addition to being a historically important disease of livestock, with widespread economic implications [69, 70].

5.4 Temporal Distribution

Human rabies occurrence is predicated in part by the seasonal patterns of the infected animal species. In the absence of an active or sensitive surveillance system for human PEP, epidemiologically it would be reasonable to investigate a potential association between increased animal movements, seasonality of human outdoor activities (adjusted for age), and exposures resulting in PEP. Due to the exceedingly low occurrence of human rabies mortality in the United States, there is no obvious meaningful historical trend in the temporal distribution of cases, with the exception of cases associated with bats. Most bat rabies cases appear in late summer. Associated human cases occur typically in autumn, after an incubation period of approximately 1–3 months [84]. Clearly, the overt limitations of a passive surveillance system for domestic animal rabies may obscure temporal trends in wildlife reservoir species and consequent risks for humans, as evidenced by the encroachment westward of the raccoon epizootic from the eastern seaboard, described above.

5.5 Age, Sex, Race, and Occupation: Socioeconomic, Nutritional, and Genetic Factors

There do not appear to be reliable trends associated with many risk patterns leading to viral exposures, with few exceptions. Racial, genetic, nutritional, or socioeconomic differences in risk of exposure have not been fully investigated, and there does not appear to be a trend in occurrence or susceptibility with regard to these factors, as well. If an active surveillance system for the reporting of PEP were established, these epidemiologic characteristics would be analyzed to further delineate sources of exposure and target preventive measures. For a variety of reasons, presumably related to exposure, there is a bias in gender (toward males) and in age (toward children) among human rabies cases. For example, in many developing countries children are the primary caretakers of animals and, accordingly, are more at risk for exposure to.

6 Mechanisms and Route of Transmission

Lyssaviruses are transmitted by saliva from the bite of a rabid animal, which may be infectious for days before obvious illness, but not prior to brain involvement [5, 17, 45, 65]. If the converse existed, thousands of human mortalities would be obvious following exposure to animals proven nonrabid by routine postmortem diagnostic examination of brain material. Moreover, if a true "carrier" state readily existed, in which most infected animals remained healthy while excreting large quantities of infectious material, human rabies would not be rare and the current practice of confinement and observation of the rabies-suspect biting dog, cat, or ferret would fail as an effective public health measure. Beyond the domestic dog, cat, and ferret, reliable observation periods have not been established routinely because the shedding period for virus is undetermined for most species [4].

Virus does not penetrate intact skin. Hence, touching a rabid animal does not constitute exposure. Other nonbite routes of natural viral transmission have been documented very rarely and largely remain unimportant epidemiologically [85]. For example, contamination of mucous membranes with infectious material is considered the major nonbite route of

exposure, and as previously discussed, transplant recipients of tissues or solid organs have succumbed, in which the donors had died of undiagnosed rabies [51–53]. In February 2013, a patient in the United States died of rabies 18 months after receiving a deceased-donor kidney transplant. The donor, in retrospect, had displayed signs and symptoms consistent with rabies upon death: vomiting, upper extremity paresthesias, fever, seizures, dysphagia, autonomic dysfunction, and subsequent brain death. At the time of his death, his symptoms were thought to have been caused by ciguatera, a foodborne toxin [86]. The rabies viruses infecting the donor and deceased recipient of the kidney were found to be consistent with the raccoon rabies virus variant and were more than 99.9 % identical across the entire *N* gene (1,349/1,350 nucleotides), thus confirming organ transplantation as the route of transmission [86]. Three additional persons had received organs from the deceased donor: the other kidney, heart, and liver. All three persons remained asymptomatic for the 18-month period between organ receipt and administration of PEP, recommended upon retrospective diagnosis of rabies in the donor, and to date have not shown signs or symptoms of rabies. A comprehensive public health investigation identified a further 38 contacts of the donor and 17 contacts of the recipient who were recommended to receive PEP; the investigation further revealed that the kidney donor was an avid hunter and trapper with frequent wildlife exposures and at least two raccoon bites, for which he did not seek medical care, in February 2010 and in January 2011 [87]. Four cases of apparent aerosol transmission have been implicated: two individuals working with extremely dense populations of bats in the confines of caves (vs. millions of cavers who may do the same) [88] and in two laboratory workers who were exposed to high concentrations of aerosolized rabies virus [89, 90], and in 2002 a bat conservationist in Scotland died of infection with European bat lyssavirus 2. It is posited that the individual acquired the virus via inhalation [91]. These considerations aside, there is a theoretical risk of human-to-human transmission resulting from contact with rabid patients [49, 50]. Although suspected on occasion in both wild and domestic animals, neither the oral route nor other unusual means, such as transplacental transmission, have been implicated definitively as important in human rabies cases to date, partially because of the difficulty in ruling out the traditional bite route as the primary means of exposure, especially in regions with enzootic dog rabies.

7 Pathogenesis and Immunity

The final outcome after viral exposure, leading to either death, or apparent immunity, is complex. Following local introduction at the site of a bite, the virus may remain localized and undergo limited replication at extraneuronal sites, such as in muscle tissue. Currently, it remains unclear if this period during which the virus is virtually undetectable represents a phase of extraneuronal infection [62] or coincides with direct infection of the nervous system [66]. During these early phases of virus infection, the neuronal synaptic transfer may occur in the form of ribonucleoprotein–transcriptase complexes [64], rather than the assembly and passage of complete virions per se, as regularly occurs in later phases of replication. After a relatively quiescent early phase, viral antigens can be found distributed in most parts of the CNS [92]. A temporal relationship between viral RNA synthesis and immediate-early gene mRNA expression suggests an activation and upregulation mechanism may be responsible for the burst of viral activity after a variable incubation period [93].

Rabies is often considered as a disease due to prototype neurotropic viruses. Multiple nonneural sites have also been associated with viral antigens following centrifugal transport from the CNS [62]. Studies suggest that the relative proportions of infectious virions will vary depending on the end organ examined [94]. Typical exit portal tissues important in transmission, such as salivary glands, support high viral titers and contain only a minimal accumulation of matrix and deviant viral production products, while multiplication in other nonneural sites, such as adrenal glands and mucous glands of the nasal mucosa, produce only moderate viral concentrations but large amounts of viral nucleocapsid and anomalous structures [94]. Further, antigens may be found in free sensory nerve endings of tactile hair in a skin biopsy, which is one of the best diagnostic methods of confirming an antemortem diagnosis of rabies in humans [95].

One relatively unique characteristic of lyssavirus infection is consequent behavioral changes that may favor transmission, most notably irritability and the predilection to bite. Other more subtle behavioral changes may occur as well. For example, in the case of raccoon rabies, induction of juvenile vocalizations in an infected adult host has been observed, which may enhance investigation by conspecifics, bringing into close proximity another susceptible host.

Mechanistically, behavioral manifestations of "dumb" or "furious" rabies in a given host may be dependent on the specific accumulation and differential effect of virus in selective brain areas, and these two extreme clinical presentations may likely reflect differences in viral infection within specific areas of the CNS. Further, an individual may alternatively manifest both of these generalized forms [96]. Host incapacitation during clinical disease may be obvious and dramatic. As such, lyssaviruses have been characterized as poorly adapted or imperfect parasites because infection typically results in host death. However, in an ecologic sense, the type of behavioral changes associated with classic rabies may ensure viral perpetuation regardless of ultimate host outcome, provided transmission of progeny virus has occurred before host demise.

While the phenomenon of differential susceptibility of mammalian hosts to various viral variants is clear, the mechanisms underlying such observations are not. For example, free-ranging raccoons may have serum VNA detected even in areas without raccoon rabies [33]. Moreover, while skunks inoculated with a Midwestern skunk isolate succumbed within 4 or 5 weeks, raccoons infected with several greater concentrations of virus did not succumb or shed detectable amounts of rabies virus; 2 of 12 raccoons developed VNA and were the only two that survived subsequent rabies virus challenge [97, 98]. Such observations may help to explain the differential occurrence of rabies in Midwestern skunks, without apparent perpetuation in raccoons. In the eastern United States, raccoons are competent hosts for a different variant, which does not appear to be independently supported by skunks. Additionally, the relative resistance of the only North American marsupial, the opossum (*Didelphis virginianus*), to rabies virus and its paucity of acetylcholine receptors provide experimental data suggesting that host susceptibility may be influenced in part by receptor occurrence and relative abundance, to which virus may bind and be internalized [99].

Rabies VNA, induced solely by the viral glycoprotein, is believed to play a major role in the pre- and PEP protection against rabies [22]. However, comparison of absolute VNA titers and mortality in laboratory rodents immunized with whole virus vaccine or viral glycoprotein did not delineate a clear role for VNA in vaccine-induced resistance to disease [100]. Specific discrepancies between VNA titer and rabies protection were also shown in wild carnivores where no firm correlation existed between any known titer level of VNA resulting from oral vaccination and protection per se [101]. Data from immunization experiments suggest that protective activity may ultimately correlate with a vaccine's ability to induce immunologic memory. Lack of firm correlation between absolute VNA titers and survivorship in immunized animals suggests that, in addition to VNA, other immune effector mechanisms may be involved in the protection against lethal rabies virus infection in either pre- or PEP situations [22, 31].

Studies have demonstrated that in addition to glycoprotein [2], the internal viral ribonucleoprotein (RNP) may also be important to the induction of protective immunity [102, 103]. In related studies following RNP immunizations, primates developed a strong anti-RNP antibody response, were protected against lethal rabies, and were primed for the induction of a VNA response following exposure to antigens [104]. These experiments and others suggest that the RNP plays an important role in inducing both primary protective immunity and cross-protective immunity against infection to heterologous strains. Since RNP is a strong inducer of nonneutralizing antibody, one of the functions of RNP-specific antibodies may be the promotion of viral RNP attachment via Fc receptors to phagocytotic cells, stimulated by virus to produce cytokines such as interferon, which inhibits viral replication.

8 Patterns of Host Response

8.1 Clinical Features

The bite of a rabid animal may often be too superficial to produce a productive infection. Even if exposure is effectively transdermal, the bite must be concomitant with the presence of virus from the infected host, which may be excreted only intermittently. A host is only considered potentially infected once the virus has breached the skin or mucous membrane barriers. This is not synonymous with disease but is partially dependent on viral load and variant characteristics within a host ranging from fully susceptible to immune. Host immune response following viral exposure may or may not result in the production of detectable amounts of VNA. While in theory only a single virion is necessary, a fully productive infection usually requires numbers of fully infectious particles several orders of magnitude greater to produce disease.

"Inapparent" infection of long duration may occur rarely, but has not been demonstrated to be of epidemiologic importance, regardless of widespread speculation to the contrary. Distinct from inapparent or so-called latent infection (which is a misnomer compared to the latency of other truly persistent herpesvirus or retroviral infections), the incubation period associated with overt disease can be highly variable in rabies and prolonged, during which the host is not infectious [85]. Productive infection, during which input virus replicates, may result in viral encephalitis that manifests with neurologic signs and symptoms. Perhaps the only consistent feature of the resulting clinical presentation is that it is rarely typical from one host to another. The prodromal stage is uniformly acute, lasting from 2 to 4 days, including moderate fever, malaise, anorexia, headache, and nausea. Presenting symptoms in humans are often nonspecific. However, paresthesia at the site of the bite and aerophagia or hydrophobia (spasms of pharyngeal or inspirational musculature induced by air currents or anticipation of swallowing) are highly suggestive of rabies. Physical and mental status deteriorates rapidly. Not discounting classical Pasteurian observations of spontaneous recovery in animals or the remarkable contemporary accounts of the few human survivors [81], the case fatality proportion in practice still approaches unity, once clinical signs are present. Death is usually attributable to respiratory or cardiac failure.

8.2 Diagnosis

The incidence of more common infectious agents that result in human encephalitis should be compared to the relative rarity of rabies in the establishment of a diagnosis. Pairing of a known animal exposure followed in several weeks' time with the appearance of classic signs and symptoms should alert the astute infectious disease professional. However,

rabies should also be considered in any suspected viral encephalitis of unknown origin, regardless of a definitive history of animal bite, especially once a compatible clinical syndrome is manifest. An exposure may have been unrecognized, forgotten, or discounted. In humans, differential diagnoses include herpesvirus and arboviral encephalitis and poliomyelitis, among others. Although lyssavirus infection and pathogenesis can be described experimentally, there remains no practical or reliable method for detecting exposure or infection in humans until the CNS has been extensively infected and there has been centrifugal distribution of virus via peripheral nerves. At this point, rabies may be diagnosed in humans through positive FA results on brain biopsy, full-thickness skin biopsy from the nape of the neck or on a corneal impression, virus isolation from saliva, detectable antibody in the CSF or serum (the latter from an unvaccinated individual), or demonstration of viral amplicons in samples of CNS, saliva, skin, or other tissues. Negative results do not rule out rabies. Optimal diagnostic material is fresh brain tissue for detection of viral inclusions in neurons. Use of appropriate laboratory-based techniques is the only method to confirm a suspected rabies case based upon clinical appearance alone and/or a history of likely exposure to infectious material.

9 Prevention and Control

9.1 Basic Epidemiologic Methods

A modern preemptive public health strategy against rabies encompasses prompt and proper PEP of humans bitten by infected animals, prevention of disease among companion animal species by preexposure vaccination, and the ecologically sound management and control of rabies among free-ranging reservoirs. While a focus upon the exposed person is an obvious and primary biomedical responsibility, the ultimate management of the host is the only way to selectively eliminate rabies in animals. Management of animal rabies extends beyond domestic animals. Since the conception of oral rabies vaccination (ORV) of wildlife during the 1960s at the CDC and the initial field experiment during 1978 in Switzerland with modified live rabies virus, the distribution of millions of vaccine doses in Europe and North America attests to the utility of this technique, with local disease elimination as one intended result [67, 105–109]; as evidenced by the elimination of fox rabies in many sites in Europe and southern Canada, and in the United States of a coyote rabies virus variant [61]; the suppression toward elimination of gray fox rabies, as exemplified in west-central Texas [60]; and the containment of raccoon rabies to the eastern states.

With regard to domestic animals, for millennia prior to the modern age and through the first half of the twentieth century in the United States, canine rabies was enzootic throughout the world [110]. In the early 1880s using virus obtained from a rabid dog and serially passed in rabbits by intracerebral inoculation, Pasteur vaccinated a series of dogs and subsequently challenged them with rabies virus resulting in acceptable results; additional challenge studies using monkey intracerebral inoculation allowed Pasteur to demonstrate that dogs became resistant to additional challenge with virulent wild rabies virus [111]. Post-Pasteur, refinement and evolution of vaccine designed to protect dogs against rabies resulted in extensive vaccination campaigns implemented during the 1940s and 1950s and subsequent decline of rabies reported in dogs in the United States [110]. Today in the United States, rabies vaccine is administered paranterally to dogs every 1 or 3 years depending on local or state requirements. However, despite the successes in the United States, canine rabies remains responsible for the most human rabies deaths globally. The domestic dog in developing countries is often unowned, "community" owned, or otherwise neglected by agricultural veterinary services [112]. Canine population mismanagement is one contributor: although vaccination campaigns in the developing world have been found to achieve the WHO recommended vaccination coverage of ≥70 %, high dog turnover rate in the population (i.e., introduction of new susceptible individuals) contributes to enzootic canine rabies [83]. Considering the success of the elimination of canine rabies virus transmission in the United States, the burden of rabies deaths attributable to dogs throughout the developing world, and availability of vaccine, surveillance, and laboratory diagnostics, the need for a global effort to achieve the elimination of canine rabies transmission is increasing. A tool developed in the context of promoting attention to the interdependency of human and wildlife health, i.e., One Health, aims to assist the global public health community in achieving this goal and eliminate the approximate 55,000 deaths per year attributable to rabies through The Blueprint for Rabies Prevention and Control [113].

With a concentration upon wildlife, a vaccinia-rabies glycoprotein (V-RG) recombinant virus vaccine [114–116] was developed that has proved to be an effective oral immunogen in raccoons [101, 117] and a variety of other important species [118–122] and provides long-term protection against rabies [120]. Advantages of this recombinant orthopoxvirus vaccine included greater thermostability than attenuated rabies viruses and the inability to cause rabies, because only the cDNA of the surface glycoprotein of the rabies virus was inserted within the recombinant virus [114]. The period of the 1980s was marked by intensive, collaborative, safety evaluations of the V-RG virus under laboratory conditions in North America and Europe [120, 123] that culminated in the initial limited field experiments by the end of that decade [124, 125].

Despite the successes of V-RG in conferring immunity against rabies among several wildlife species including raccoons, V-RG is not efficacious for control of rabies in several other important reservoirs, such as *Mephitis mephitis*, the striped skunk [121]. Further, less-attenuated, first-generation rabies virus candidates, such as the rabies virus strains SAD/ERA, may be associated with vaccine-induced rabies in these species [126]. For safe, effective, and more comprehensive wildlife rabies control, a human adenovirus type 5 (HAdV-5) vectored rabies virus glycoprotein recombinant vaccine (AdRG1.3; ONRAB®) has been tested for safety and efficacy in the laboratory and used in the field in Canada and is currently being considered for broader use throughout North America. Adenoviruses belonging to the family *Adenoviridae*, subfamily *Mastadenoviridae*, are nonenveloped DNA viruses found ubiquitously among many mammalian species, including humans [127]. The ONRAB® vaccine employs a replication-competent HAdV-5 vector into which a DNA copy of the ERA virus glycoprotein gene has been inserted [128, 129] and, similarly to V-RG, is packaged into sachets for oral administration to wildlife. Results from field trials in Canada have indicated that ONRAB is stable both in vitro and in vivo, with a limited ability to replicate in an established model for human adenovirus infection and is suitable for environmental use as an oral rabies vaccine for wildlife [130].

Some opponents to wildlife ORV espouse depopulation, rather than vaccination, as a control method, citing the effectiveness of dog rabies control via compulsory muzzling, movement restrictions, and stray animal removal in Europe and North America during the early 1900s, before the utilization of efficacious vaccines en masse. Two components of this technique—animal movement restrictions and muzzling—are inapplicable to wildlife, leaving only depopulation. As a sole mechanism of control, depopulation may decrease the local intensity of rabies or postpone the invasion of a new geographic area, but it is unlikely to completely eliminate rabies or permanently protect a region from an impending epizootic.

Several professional groups may view a number of wildlife species, including some rabies vector species, as nuisance or pest species, and hence oppose ORV, citing the undesirable potential for increased numbers following elimination of rabies, inappropriately viewing rabies as a form of wildlife population control. However, proportionate mortality due to rabies among the most prominent wildlife vectors in the United States, such as raccoons, skunks, and so on, has not been investigated. In Europe, collective data suggest that rabies may not be a significant regulator of population size; there has been no substantial increase in red fox numbers following the elimination of rabies over large geographic areas [131].

Addressing bat rabies control, the importance of bat exclusion from human habitations and better public education to facilitate recognition of potential exposures cannot be overemphasized. Overall, bat conservation is very compatible with basic public health tenets.

9.2 Basic Immunization Concepts and Practice

For practical purposes, rabies may be viewed as universally fatal once clinical symptoms manifest. In the same context, extremely effective human PEP consists of vaccine and RIG if administered promptly and properly, after thorough wound cleansing, if a bite is evident. Besides application in humans, the extension of PEP to companion animals and livestock has also been investigated, such as in dogs [132, 133] and sheep [134]. Moreover, further epidemiologic investigations to include the use of PEP for animals should be conducted, from a One Health perspective within the veterinary field, considering the critical role of domestic animals in human society for food, fiber, security, companionship, transportation, etc., among others.

As described earlier, minimum standards as opposed to an absolute "protective antibody" for humans are based empirically on presumed protective activity of rabies-specific antibodies and can be detected by reference laboratories. A RFFIT titer of ≥1:5 (approximately 0.10 international units [IU]/mL) or higher is evidence of adequate immunization in persons at either constant or frequent risk of exposure, at 6-month or 2-year intervals, respectively, as a measure of baseline immunity, as recommended by the United States Advisory Committee on Immunization Practices [85]. A single booster vaccine dose is administered if the level is lower, based on a determination of apparent risk (Table 28.3). Preexposure immunization simplifies human PEP because of priming of the immune response and is thought to provide some degree of protection against unrecognized exposures, which by definition should be negligible if proper protocols are followed. Nevertheless, when pre-immunized persons are knowingly exposed to rabies virus, two booster doses of vaccine, administered on days 0 and 3, are required to induce a sufficient anamnestic response to prevent development of disease. Also, rabies immune globulin (RIG) is contraindicated under such circumstances, because it may interfere with development of an adequate anamnestic response [135]. Pre-immunized individuals should remain vigilant in recognizing potential viral exposures and seek appropriate PEP. If actual viral exposures occur but are unrecognized, the pre-immunized individual may still die of rabies, albeit very rarely, as did one Peace Corps volunteer, who was bitten by her own puppy, that died of a disease compatible with rabies [136] (Table 28.4).

Table 28.4 Rabies postexposure prophylaxis (PEP) guide, United States

Animal type	Evaluation and disposition of animal	Postexposure prophylaxis recommendations
Dogs and cats	Healthy and available for 10 days observation	Should not begin PEP unless animal develops signs of rabies[a]
	Rabid or suspected rabid	Initiate PEP immediately[b]
	Unknown (escaped)	Consult public health officials
Raccoons, skunks, bats, foxes, other carnivores, woodchucks	Regard as rabid unless geographic area is known to be free of rabies or until animal is proven negative by laboratory tests	Initiate PEP[c]. Consider factors such as provocation, suggestive clinical signs, severity of wounds, type of exposure, and timeliness of test results (24–48 h) for decisions regarding immediate initiation or to delay pending test results
Livestock, rodents, and lagomorphs (rabbits and hares)	Consider individually	Consult public health officials; bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other rodents, and lagomorphs almost never require PEP

Adapted from the ACIP

[a]If clinical signs compatible with rabies develop during the 10-day confinement and observation period, the animal should be euthanized and tested. Depending on circumstances, initiation of PEP may be delayed pending a positive report, if results may be obtained in 24–48 h

[b]If the bite was unprovoked or resulted in severe wounds, treatment of the bitten person should begin immediately with human rabies immune globulin (HRIG) and human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCEC). PEP may be discontinued if the test is negative

[c]If available, the animal should be euthanized and tested as soon as possible. Holding for an observation period is not recommended since the potential viral shedding period prior to clinical signs has only been determined for dogs, cats, and ferrets

Newer approaches to immunization from conventionally prepared products may also include subunits such as DNA vaccination. For example, mice immunized intramuscularly with a plasmid vector expressing the rabies virus glycoprotein under a SV40 early promoter developed specific cytotoxic lymphocytes, thymic lymphocytes (subset TH1), and rabies VNA and were protected against rabies virus challenge [138]. Although many questions remain regarding the consequences of persistent "infection" with a plasmid, the effects of long-term stimulation of the immune system, the genetic stability and safety of foreign promoters and nucleic acids, and the potential benefits are clear, which include simplicity and economy. Obviating the need for booster immunizations would be particularly useful for certain applications, such as livestock in extensive range situations, for example, where protection against bovine paralytic rabies via vampire bats in Latin America with current vaccines is prohibitive economically and logistically and could have similar utility for humans in remote locations.

Viral sources as substrates for vaccine development could also be expanded. Compared to the conserved fixed virus strains that form the basis for most rabies virus vaccine production historically, considerable diversity is obvious among lyssavirus antigens by MAb analysis. Nevertheless, even recombinant rabies virus vaccines that only express one viral glycoprotein are able to fully protect animals from severe experimental and field exposure against all of the major rabies variants. Moreover, after considerable investigation, there is no firm evidence to suggest that current human rabies deaths are attributable to antigenic variation of street rabies viruses, but rather they appear due to serious omissions in basic PEP protocols [23].

Besides epidemiologic utility (for which they were originally generated), antirabies MAbs are also useful in the refinement of host immunization and PEP concepts. Rabies VNA are induced solely by the viral glycoprotein and play a major role in the immune protection. Hybridomas that secrete rabies virus antigen-specific MAb have been generated and can effectively neutralize fixed and street lyssavirus isolates. These MAbs were selected on the basis of isotype, antigen and epitope specificity, virus strain specificity, affinity, and neutralizing activity. Administration of such MAbs protected animals when challenged with a lethal dose of rabies virus in experimental PEP models [139]. These data strongly suggest that MAbs, alone or in combination with vaccine, may be an effective method of protection against clinically relevant lyssaviruses [140]. Such an approach has several theoretical advantages over presently used hyperimmune sera: first, in contrast to current products, comparatively small volumes of MAbs would have to be inoculated for equivalent active protein content, because specific neutralizing activity per mass of protein is higher, so MAbs may be optimal for lessening the trauma and pain of local wound infiltration with a source of passive antibodies, and second, safety issues arising from the possibility of adventitious agents associated with human or animal blood products would be alleviated by bulk production under modern GMP conditions in cell culture. Despite the experimental progress shown, the rationale and acceptability of heterogenous murine MAbs for future human rabies PEP have been questioned on the grounds that a human anti-mouse response to the MAbs would present a significant drawback by the consequent effects on kinetics and antigenic targeting. If murine or other heterologous MAbs are used, human anti-species responses might be expected, but these are not necessarily

deleterious, because MAbs would only be used once in rabies PEP. As is the case for HRIG, MAbs would not be readministered should the person be reexposed in the future. In the previously vaccinated subject, rabies PEP in these situations consists of vaccine only on days 0 and 3. Moreover, if such MAbs are recognized as foreign antigens, with an expected shortened serum half-life, this potentiated clearance may be advantageous by minimizing the opportunity for interference with an active immune response on behalf of the vaccinated host, while effectively neutralizing virus, prior to induction of host VNA. This is one of the primary reasons cited for homologous or human MAbs, as opposed to heterologous. As such, several homologous MAbs are under clinical evaluation [141].

Given the above considerations, what is an appropriate gauge for immunoprotection for extension to humans? Mere in vitro neutralizing capacity alone may not be fully indicative of protective efficacy in vivo. Some MAbs that do not neutralize viruses in cell culture are still effective when administered via PEP to animals [141]. Besides extracellular neutralization, other useful capabilities of MAbs may also be operative, such as the inhibition of intracellular viral spread and interference in transcription of rabies viral RNA. Such questions, as well as the ability to consider the conduct of phase III clinical applications, should require introspection as MAbs progress toward regulatory approval for use in human PEP.

10 Unresolved Issues

10.1 Rabies Management in the Free-Ranging Dog: Oral Vaccination (ORV) as a Solution?

Rabies management of animals is linked directly to human rabies prevention. One of the most cost-effective methods to prevent rabies in humans is the mass vaccination of dogs by the parenteral route. Whether oral delivery of vaccination is needed for application to dogs remains uncertain. During the past century, considerable progress has been made in the laboratory development and field testing of ORV for free-ranging wildlife disease prevention and control in Europe and North America. Major species have included the red and gray fox, raccoon, raccoon dog, and coyote. Oral vaccines tested in the field to date have included attenuated rabies (e.g., SAD/ERA/SAG) and recombinant glycoprotein (e.g., orthopox-, adeno-) viruses. Especially with regard to any application for domestic canine vaccination, intended biologics should at minimum be pure, potent, efficacious (against a virulent, epidemiologically relevant rabies virus challenge), and safe to target and nontarget species, especially humans, at risk for exposure to distributed, edible baits, or through direct, intimate contact with a vaccinated host.

Self-replicating attenuated or recombinant vaccines offer the greatest versatility for oral rabies vaccination of animals such as dogs. While a few candidate oral rabies vaccine preparations have demonstrated sound protective immunity in captive dogs, no self-replicating viral system, conventional or otherwise, may be considered completely apathogenic, especially in the context of the immunocompromised host [142]. As an alternative, inactivated oral preparations should maximize safety considerations, yet the significant quantities required for minimal efficacy may be cost-prohibitive unless novel adjuvants, delivery techniques, or production methods are found [143].

Applied research on the oral or enteric administration of affordable inactivated rabies biologics may diminish the public health concerns related to the current products under consideration for application to free-ranging dogs, particularly as they relate to human rabies deaths in developing countries. However, regardless of the approach, limited laboratory trials of oral canine vaccination may not directly equate to rabies control under field conditions, where a combination of ORV and traditional parenteral vaccination may be necessary. This may be especially applicable when considering that the majority of successful canine rabies elimination programs have only involved traditional parental application, and not canine ORV.

10.2 Alternatives to Current Biologics for Human/Animal Disease Prevention?

While current biologics to prevent rabies in humans, domestic animals, and wildlife are extremely effective, progressive development toward new paradigms is necessary. The vigilance necessary to minimize human rabies mortality necessitates an extensive public health infrastructure and requires the annual prophylaxis of tens of millions in the developing world and tens of thousands of potential exposure cases throughout a developed country, such as the United States. Following a bite from an infected mammal, PEP of rabies in humans includes proper wound care and the simultaneous administration of multiple doses of an efficacious rabies vaccine, together with a preformed antibody source, typically HRIG. However, this regimen presents certain obstacles. Modern inactivated cell culture vaccines and HRIG are vastly improved over historical NTO vaccines, but such products are relatively expensive (especially in the developing world where they are most needed), are often in scarce supply, and may carry a perceived theoretical risk of adventitious agent acquisition to the public. Major concerns in rabies prevention have concentrated on the need for potent, inexpensive PEP for humans, especially replacement for more costly HRIG, while retaining activity against a wide variety of diverse lyssaviruses.

In contrast to the relatively impotent equine antirabies serum used in the past that resulted in high adverse reactions, such as serum sickness in up to 40 % of human recipients, modern purified equine rabies immune globulin (ERIG) products are safer, more potent, and more affordable than older cruder products and may be at a fraction of the cost of HRIG [144–146]. The ERIG products have been used effectively in conjunction with vaccine in human rabies PEP, particularly in developing countries under the continued threat of enzootic dog rabies. In surveys, less than 1 % of humans have reported adverse events, coupled with adequate efficacy [147]. By comparison, no ERIG has been available in the United States market for several years, although it was still licensed into the late 1980s. Due to its potency and lack of apparent significant local or systemic effects, purified ERIG products were the only immediate alternative, should the supply of available HRIG be threatened by shortages, contamination, or other limitations. Such use might be considered a temporary antecedent until the availability of more novel replacements, such as MAbs.

To be most effective, conventional PEP should be applied prior to viral invasion of the nervous system. However, PEP may still be effective even after virions access the nervous system. For example, in one experimental animal infection study, analysis by RT-PCR has revealed the presence of rabies virus-specific RNA in the olfactory bulb and cerebral cortex of animals within 6 h of direct intranasal inoculation. Yet, when animals were administered a neutralizing MAb up to 24 h after inoculation, 80 % survived a challenge in which all controls succumbed [139, 140]. Neither virus nor virus-specific RNA was detected when these survivors were euthanized a month later. These data clearly demonstrate that virus "neutralization" and clearance from the CNS are complex processes, less than fully understood [148]. Thus, if produced in a cost-effective manner, antirabies MAbs may be useful in the future PEP of humans, as well as in economically or otherwise important, unimmunized domestic animals. Such biologics that abrogate infection even after virus enters the CNS present exciting new possibilities for intervention with significant advantages over historical polyclonal rabies immune globulin.

10.3 Treatment of Clinical Human Rabies?

While prevention of disease among reservoir hosts and victims alike is still the optimal approach, when this fails, further alternatives regarding treatment of clinical rabies may be warranted. Historically, the individual experimental application of RIG and Ig fragments, cytosine or adenine arabinoside, interferon, acyclovir, antithymocyte globulin, steroids, vidarabine, tribavirin, inosine pranobex, or ribavirin has not demonstrated any substantive utility to date [8]. However, case histories of recovery after clinical signs in animals suggest that host defenses may be exploited to alter the end stage of this otherwise fatal malady, if the pathophysiologic mechanisms of disease can be understood.

As one now classical example, during 2004, a girl aged 15 years in Wisconsin rescued and released a bat, which had bitten her on her left hand. The wound was cleaned with peroxide, but PEP was not administered. Approximately 1 month later, she developed a clinical syndrome consistent with infection with rabies virus, including generalized fatigue and paresthesia of her left hand, which later developed into diplopia, ataxia, nausea, and vomiting. On the fourth day of illness, blurred vision, left leg weakness, and ataxia were present which developed into fever, slurred speech, nystagmus, and tremors of her left arm [149]. She was admitted into a pediatric referral facility in Milwaukee. On the second day of care, CDC confirmed the presence of rabies virus-specific antibody in the patient's CSF and serum. However, attempts to isolate virus, detect viral antigens, and amplify viral nucleic acids from two skin biopsies and nine saliva samples were unsuccessful [149]. An experimental treatment protocol, later termed the "Milwaukee Protocol" that combined anti-excitatory and antiviral drugs, including ketamine, ribavirin, and amantadine, was administered in conjunction with supportive intensive care [149]. Neither rabies vaccine nor HRIG was administered because of the patient's demonstrated immune response and the potential for potential harm from a potentiated or altered immune response [150]. After more than 70 days of hospitalization, the patient recovered, with only minor neurologic sequelae at the time. While promising, this experimental protocol has been attempted in several additional human rabies cases without success. Clearly, prevention of exposure, or prompt appropriate prophylaxis after exposure, but before development of clinical signs, remains a primary focus in public health. While there is no established therapy that is effective for patients who develop rabies, efforts should continue on basic viral pathogenesis research, development of relevant surrogate animal models and protocols that mimic supportive intensive care, and experimental applications in human cases where ethical/legal approvals and modern facilities exist [151].

10.4 Animal Translocation and the Threat of Disease Introduction/Reintroduction?

People who reside in true rabies-free areas enjoy a luxury of not having to be concerned with PEP following an animal bite. However, given the availability and rapidity of modern transportation, alarming trends are evident in animal translocation on local, regional, and intercontinental levels. Such deliberate translocation, but often with unintended results, carries a significant risk of the emergence of infectious agents into new niches previously unavailable

because of zoogeographic barriers. There are limited legitimate reasons for purposeful animal translocation, such as for species reintroduction, research, education, or zoological captive breeding. Unrestricted importation of nonnative species, or translocation of native mammalian species during the incubation stage of the disease, poses the threat of rabies introduction into rabies-free regions. Within rabies enzootic countries, there is also a danger that other variants may be introduced into new areas, such as occurred in the late 1970s with translocation of infected raccoons from the southeastern United States, resulting in the initiation of the mid-Atlantic raccoon rabies epizootic, which perpetuates along the Atlantic seaboard states. The same potential looms over the transportation of infected carnivores to unaffected states for hunting, trapping or other recreational use. Translocation of infected wildlife (i.e., bats and canids), from enzootic rabies areas in one country to another, would hamper public health efforts at wildlife rabies control, if they escape. Little is known about the clinical signs, incubation periods, or potentials for transmission of related agents, such as other Old World lyssaviruses to New World hosts via importation of reservoir species; such establishment would be problematic, owing to the questionable vaccine efficacy against certain nonrabies lyssaviruses. Enlightened and targeted education, enforced legislation, improved regional surveillance, and a rapid, appropriate public health response will minimize the overall dangers associated with animal translocation and will hopefully prevent an infectious nidus from becoming an epizootic, as seen increasingly in island nations, such as Indonesia.

10.5 Reservoir Population Management: Immuno-Contraception of Animals?

As most humans are infected with rabies virus after a bite, new focused animal management strategies appear obvious to minimize the burden of disease in people. Rabies is but one of a multitude of factors that arguably may influence the density of free-ranging carnivores over time [131]. One criticism of wildlife rabies vaccination is a concern that by decreasing or eliminating rabies mortality, a program may increase local carnivore populations over time, which in many instances may be undesirable. Historically, lethal means to control carnivore populations have been employed extensively, primarily to decrease economic loss from predation on livestock. Additionally, limiting or reducing carnivore populations may be beneficial for the protection of other, more "valued" animals, including important game, endangered, and threatened species, and to decrease human nuisance carnivore interactions. Regardless of the potential benefits, sustained reduction of carnivore populations exclusively by lethal means over large regions is unacceptable due to economic factors, questionable efficaciousness, and ethical considerations. Besides the carnivore issue, there has been a significant renewed impetus to enact population management for other species as well, most notably humans. One of the major modern strategies under consideration has been fertility control by immuno-contraception [152, 153]. Contraceptive approaches have pursued several avenues, including (1) eliciting an immune response to ova, sperm, or zona pellucida antigens; (2) disrupting spermatogenesis; or (3) interfering with reproductive hormones. The ideal technique would entail a targeted approach, involving either a species-specific antigen or vector, although none has yet been identified. Application to dogs and wild carnivores may be an important adjunct to current management techniques. Although the need appears obvious and preliminary efforts are promising, considerations that must be addressed include (1) the levels of herd immunity needed to preclude the persistence of either a subpopulation that evades exposure to these agents (e.g., bait avoidance) and prevent "nonresponders" from gaining a significant reproductive advantage; (2) the nontarget species issue, because of bait competition; and (3) the escape of a transmissible agent and propagated spread beyond an intended "pest" target population (i.e., introduced red foxes in Australia) to other distant geographic regions (i.e., red foxes in North America) by deliberate or unintentional animal or agent translocation. If such concerns could be minimized, a recombinant vaccine could, in theory, not only immunize against an infectious agent of choice, but also simultaneously decrease host abundance as well. For these reasons, more limited, targeted parenteral application to animals may be more relevant than generalized bait distribution in the environment.

Acknowledgments The authors would like to thank Jesse D. Blanton and Jessie L. Dyer for their assistance in the preparation of this manuscript.

Rhinoviruses

29

Ian M. Mackay and Katherine E. Arden

1 Introduction

Picornaviruses, which include the human rhinoviruses (HRVs) and enteroviruses (EVs), are the most frequent cause of acute human illness worldwide [1]. HRVs are the most prevalent cause of acute respiratory tract illnesses (ARIs) which usually commence in the upper respiratory tract (URT). ARIs are the leading cause of morbidity in children under 5 years and occur in all seasons [2, 3]. ARIs linked to HRV infections are associated with excessive and perhaps inappropriate antibiotic prescribing [4] and with significant direct and indirect healthcare expenditure [5, 6]. ARI incidence is highest in the first 2 years of life, with up to 13 episodes per year including up to six positive for an HRV, and it is not uncommon to average one infection per child-month [3, 7–9]. In preschool-aged children, nearly 50 % of general practitioner visits are for ARI [10], many of which are self-limiting. ARIs can often be managed in the community with supportive care from parents, but complications can arise that require a medical visit for management of asthma, otitis media, or sinusitis [11]. HRVs replicate in nasal cells, sinus cells, bronchial epithelial cells (BECs) [12, 13], and smooth muscle cells [14] but not in monocytes [15] or dendritic cells (DCs) [16]. The inflammatory immune response they trigger very soon after infection has its greatest impact in the young, the elderly, those with asthma or chronic obstructive pulmonary disease (COPD), and in the immunocompromised. First infections usually elicit a stronger response. Antiviral interventions have been under development for decades; to date most have met with varying degrees of failure or unacceptability. Vaccines have been considered unachievable because of the large number of diverse and distinct viral types.

There are 100 classically defined and recognized HRV serotypes grouped into two species, HRV-A and HRV-B, and a recently defined third species, HRV–C, containing more than 60 genotypes identified and characterized entirely by molecular means. Their cousins, the four enterovirus species (EV-A, EV-B, EV-C, and EV-D), are also found in the airways at times. Most systematic and mechanistic studies of HRV etiology and pathogenesis have been informed by studies in adults, mostly prior to the discovery of HRV-Cs. Adults exhibit reduced symptoms from HRV infections because of prior exposure and the resultant protective immune memory which that imparts (see Sect. 7.3). Furthermore, many modern studies (1) draw conclusions about lower respiratory tract (LRT) disease using URT specimens and (2) infrequently sample, doing so across small cross sections of time. These limitations have hampered attempts to associate virus detection and disease. Current thinking is that HRV-Cs may be key players in asthma exacerbations although our inability to culture them routinely has hindered our progress in understanding their role. The impact of the HRVs has been underestimated for decades, and the concept of the HRVs as a very large assemblage of genetically, immunogenically, antigenically, and temporally distinct and stable viral entities remains rare; they are more commonly considered a single variable virus, a view that science does not support.

2 Historical Background

The disease most commonly associated with the airways and resulting from HRV infection is the common cold, a self-limiting coryzal illness [17–19]. The term dates back to ancient Greece, but evidence that the syndrome and asthma, another disease most frequently due to HRV infection, has been with us since ancient times can be viewed in writings on the Ebers papyrus, a medical document written in the sixteenth century BC [20, 21]. In 1930 the common cold was considered either to be due to exposure to the elements or to infection by bacteria [22]. It was later understood to be largely due to something in bacteria-free filtrates, and so the search for viral causes began [23, 24].

The Common Cold Unit (CCU) was established in Salisbury, UK, to seek solutions to the mysteries of the common cold, mostly through adult volunteer infection studies and careful systematic science [23]. The CCU functioned for 44 years (1946–1990), and it was here in 1953 that the first in vitro culture of an HRV was achieved using lung tissue from a particular embryo (Fig. 29.1) [25, 26]. Propagation failed once this tissue was expended [22, 33].

Once HRV isolation was possible, viral serotyping developed and culture techniques were further refined. This leads to an international effort to characterize and name the HRVs [27–30].

In 2006 renewed interest in HRV research was triggered by the description of a distinct clade of HRV types [31] found using molecular typing. The resultant flurry of HRV research raised questions about many earlier paradigms of rhinovirology and of the role of established respiratory viruses in ARIs. The novel clade was proposed as a new species, HRV-C, which was taxonomically confirmed in 2009 [32–34]. Prior to the discovery of the HRV-Cs, the genus *Rhinovirus* had been abolished and the HRV-A and HRV-B species assigned to the genus *Enterovirus* within the family *Picornaviridae* [35]. The HRV-Cs have been assigned a new naming scheme based on genetic sequence in the absence of antigenic or serological data. While the sequencing of all serotyped HRV genomes was completed in 2009, few of the HRV-Cs or apparently novel HRV-As or HRV-Bs have been similarly characterized, so the full spectrum of HRV genomes, the rhinovirome, remains incomplete. In this chapter we have described individual serotyped HRVs as the "classical" types, a type being the description for a single, genetically stable, stand-alone HRV.

3 Methods for Epidemiologic Analysis

3.1 The Pre-molecular Era

The original clinical definition of an HRV infection was written using data from cell and tissue culture and adult human infection studies. After 1953 in vitro isolation methods employed a virus interference test to more easily determine successful isolation; cultures suspected of infection with an uncharacterized HRV prevented infection by another, readily titratable virus [36]. Later, Price (1956; the JH strain) and then Pelon and co-workers (1957; 2,060 strain) developed culture systems that permitted HRV replication to be more easily identified [37, 38]. The early HRVs were initially classified as echoviruses (ECHO 28; later HRV-1) [39]. At the same time, propagation of the HGP (HRV-2) strain resulted from using increased acidity, lowered cultivation temperatures, and constant motion (rotation) [40, 41]. Despite the challenges [42], virus isolation was a more sensitive indicator of infection than an antibody rise in paired sera [43].

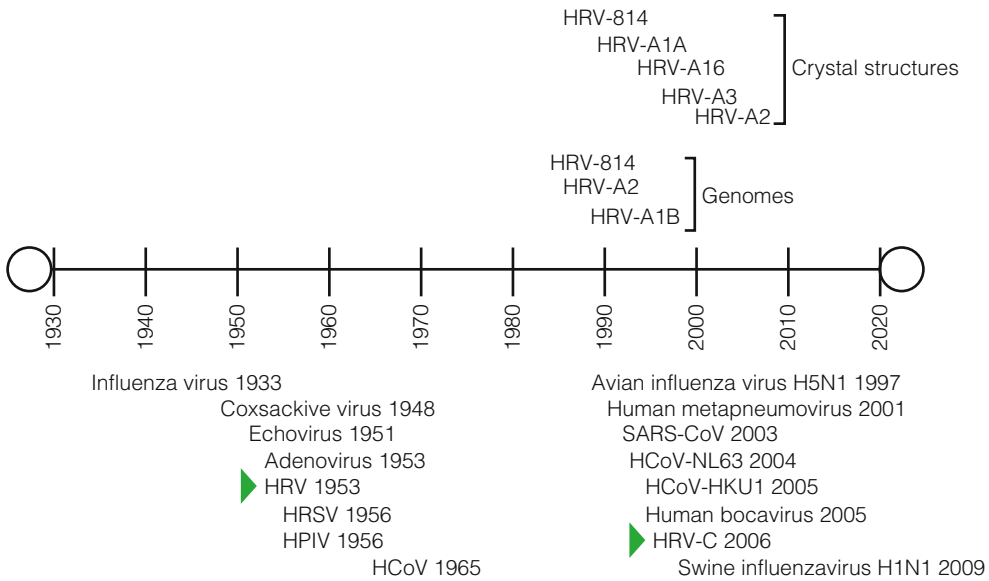

Fig. 29.1 A timeline of virus discovery from the human respiratory tract. The date of each virus's published description is shown, as are the dates the HRV crystal structures were defined and the first HRV genomes sequenced

It was found that several cell lines and methods were required to encompass virus concentrations ranging from 10^1 to 10^5 $TCID_{50}$/mL [44–47] and growth differences among the different virus types. Additionally, cell age after plating (<72 h), inoculum volume (relevant to the culture vessel), medium pH (6.8–7.3), and cell density were important factors for the reproducible appearance of HRV-induced plaques and for higher virus yields [48–51]. The HRVs can grow at temperatures above 35 °C (some prefer that under certain conditions) [52], but rolling at 33 °C, preceded by a 2–4-h stationary incubation period [41], has historically provided the highest yield and fastest in vitro HRV growth [36, 50, 53, 54].

Serodiagnosis grew increasingly impractical as the number of serotypes increased [49, 55]. However, antibody-based methods were essential for type-specific neutralization of infection [56] from which early epidemiology data were derived and around which the HRV nomenclature system evolved in 1967 [28]. The first classical strains were officially named in 1967 [57], the last in 1987 [30].

Today we know that cell culture-based methods are unreliable for accurately representing respiratory virus epidemiology; although enhanced by immunofluorescence, they are still used [58]. The HRV-Cs have not been successfully cultured in any cell lines or primary cell culture, although many attempts have been described [32, 59–62]. In 2011 HRV-C15 and W23 (another HRV-C) were shown to grow using organ culture [63]. Sinus tissue hosted increasing levels of viral RNA, as did adenoid, tonsil, and nasal polyp tissue, but much less effectively, as measured by in situ hybridization [63]. The sinus organ culture system also allowed testing of the first reverse engineered HRV-C (pC15) [63]. Isolation identified HRVs in ~23 % of adults with ARIs, associated with 0.5 illnesses per year [64].

3.2 The Molecular Era

Because culture is inefficient and subjective and requires expertise, even for the culturable HRV types, it is becoming an art lost to clinical laboratories the world over. It is unsurprising that PCR-based methods now prevail, providing a much improved understanding of the nature and scope of HRV infections. The virological and immunobiological cost of this improvement is a paucity of low passage "wild" HRV isolates to work with; thus, many research findings from recent years have employed easy to grow highly passaged and adapted HRV isolates. The impact of virus adaptation on the reliability of data from use of such viruses is unknown.

PCR-based assays have dramatically increased the frequency of HRV detection [65–70]. The improved sensitivity and reduced turnaround time have shown that HRVs, as a group, are usually the predominant viruses in ARI cases [71–73]. With reliable detection levels that extend from as few as 10^2 $TCID_{50}$/sample to well above clinically relevant loads, PCR can detect virus levels which are commonly shed during all stages of experimental infection studies [74, 75].

The common understanding of the systemic [76–78] or symptomatic [79, 80] context of HRV detections was established during the era of culture detection, and PCR has challenged these paradigms by detecting virus more often than culture. HRVs are sometimes found in "healthy controls"; however, it is likely that with more thoughtful definitions of "healthy," these detections would reduce. It is not uncommon to experience a feeling that one is "coming down" with something that never develops further. This is likely due to a transient infection or reinfection by an HRV or other respiratory virus that is eliminated quickly by the host response. It is possible to correlate viral nucleic acid load at the sampling site with disease severity; however, this is made difficult by the highly variable sampling efficiency of respiratory tract specimens which only permit the generation of reliable quantitative PCR (qPCR) data if serial specimens are available [81].

The 5′ untranslated region (UTR; Figs. 29.2 and 29.3) is the most common target for diagnostic oligonucleotides since the first HRV RT-PCR in 1988 [82], and the region has retained relevance for virus detection by its adaptation to reverse transcriptase real-time methods (RT-rtPCR) [53, 65, 66, 69, 74–76, 79, 83–103]. The 5′UTR is comprised of a number of conserved sequence "islands" (Fig. 29.2) that permit the robust detection of the majority of HRVs and those "respiratory EVs" which can be regularly detected in the respiratory tract [104, 105]. The detection of respiratory EVs in no way detracts from the importance of supporting clinical decision making using these assays. However, repositioning

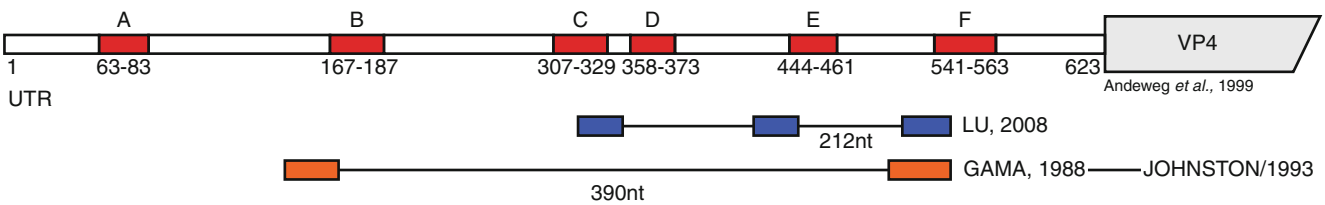

Fig. 29.2 A schematic of conserved sequence regions in a generalized HRV 5′ UTR, based on a map described by Andeweg et al. [68]. The PCR primers of broadly reactive conventional RT-PCR [82, 113] and RT-rtPCR [75, 114] assays are shown

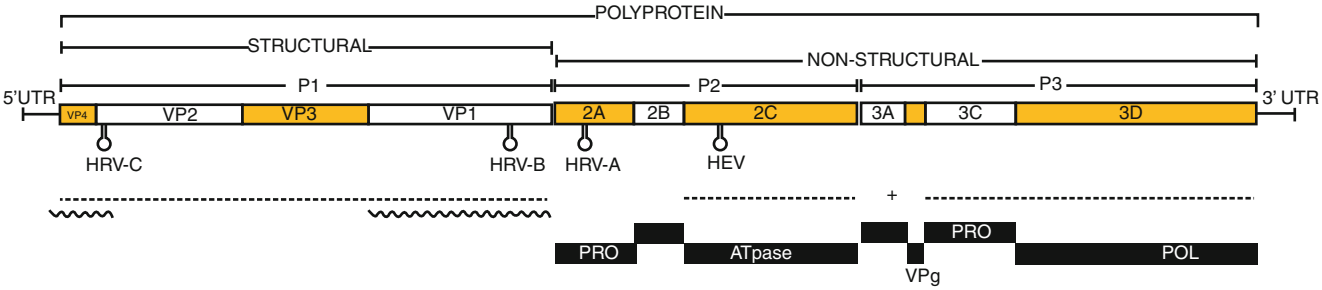

Fig. 29.3 A schematic of the ~7,200 nucleotide ssRNA genome and key regions of a typical HRV member of the genus *Enterovirus*. The polyprotein and precursory (*P1–P3*) and 11 matured peptides are named in genome boxes and functionally identified underneath. The RNA is polyadenylated at the 3′ end and covalently bound to the virion protein, genome (*VPg* encoded by *3B*) at the 5′ terminus. Regions essential for genus- and species-level identification are underlined (*dashed line*) as are those which are more commonly used in the clinical research setting (*wavy line*). The distinctively located HRV and EV cis-acting replication elements are shown as stem loop structures and protease (*PRO*) and polymerase (*POL*) functional regions are labeled (Adapted with permission from McErlean et al. [33])

these primers or changing the method of employing them [106–109] may undermine assay performance, as evidenced by predicted hybridization mismatches, uncommonly low detection frequencies [110], and by comparison of multiple primer sets using the same specimens [111]. The addition of an oligoprobe rtPCR method increases amplicon detection sensitivity and specificity, identifying 100-fold fewer $TCID_{50}$/mL or 10 fold fewer genome copies than agarose gel detection of amplicon [75, 79, 112].

Other molecular tools, capable of detecting multiple targets, have evolved in recent years [58, 70, 115–121], and some have gone on to be approved for clinical laboratory use [122]. Microarrays can detect thousands of viral targets, but are expensive for routine use (USD30–300 per sample) and not sensitive enough to avoid a pre-hybridization PCR amplification when using clinical specimens. At their most robust, microarrays, like PCR, rely on the existence of conserved regions of sequence to detect unknown viruses allowing them to detect previously unknown HRV types [123]. High-throughput or "deep" sequencing platforms have become less expensive and more readily available, and they have succeeded in finding new diversity within the HRV species [124]. The experiments remain costly so have not yet found a place for regular screening tasks and remain coupled to a need for pre-PCR steps. Rapid protein- or virion-based assays are not (yet) adequately sensitive [125, 126].

Because of the high number of HRVs and the high frequency of infections, genotyping methods have become an essential accompaniment for understanding HRV epidemiology. Nucleotide sequencing of the VP1, 5′UTR+VP4+VP2 (called hereafter VP4/VP2), or 5′UTR region has replaced traditional serological methods, because of its speed and need for fewer specialized reagents compared to serotyping. VP1 yields the most comprehensive subgenomic genotyping information and is essential for the minimal definition of a new HRV type [127]. The VP4/VP2 region (Fig. 29.3) is considered easier to use because it encompasses sufficient genetic diversity to confirm the identity of a clinical HRV type while also providing broad enough sensitivity to amplify the ~160 HRVs from a challenging biological substrate, clinical specimens [128]. Screening of airway specimens for HRVs is not routine [111] due to factors including cost and the perceived low clinical relevance of detection. Genotyping is mostly relegated to research facilities. Because of this, HRV molecular epidemiology studies tend to be smaller and focused on a specific disease or research question.

4 Biological Characteristics

Most in-depth molecular studies of HRV replication have focused on a single HRV type. Generally, it is presumed that results can be extrapolated to the other HRV types and to the in vivo situation. HRVs replicate in the cytoplasm (Fig. 29.4) [129] with membrane-associated replication structures containing double-stranded RNA (dsRNA) replicative intermediates (RI) which are formed in cells 4 h after infection [52, 130]. Single-stranded infectious RNA forms after RIs start to accumulate [130]. Genomic RNA (plus strand) is the template for complementary minus strand synthesis which in turn is the template for new genomic plus strands that become incorporated into virions [131]. Virions are synthesized from 4 to 7 h after infection and reach maximum release levels at 10–18 h [131].

HRV replication in epithelial cells may shut off host cell transcriptional activity via direct cleavage of transcription factors and nuclear pore complex components. Protease 2A ($2A^{PRO}$) of HRV-B2 may directly cleave eukaryotic initiation factor 4G (eIF4G) when bound to eIF4E [132, 133]. The eIFs have key roles in initiation and rate control of host cell translation [132]. Host cellular protein production is virtually replaced by HRV-B14 proteins after only 6 h of infection [134]. HRV-B14-infected cells also display reduced nuclear importing and degraded nuclear pore complex (NPC)

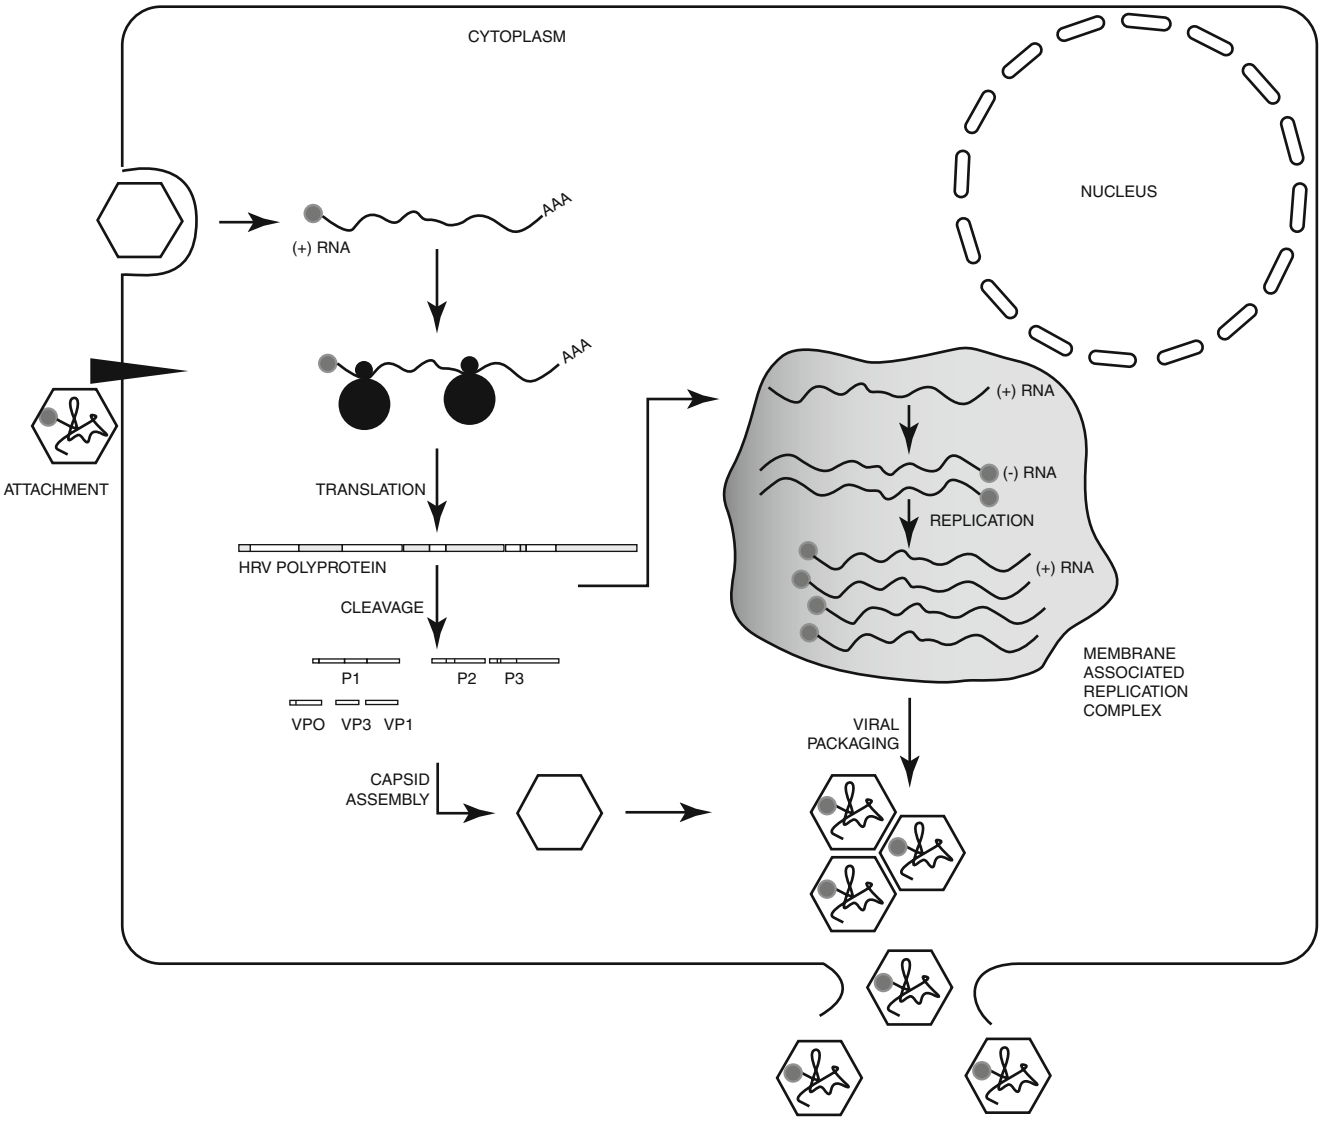

Fig. 29.4 Schematic of a general HRV attachment and entry process. Genome replication in association with membranes produces the viral polyprotein which is co- and posttranslationally processed by $2A^{PRO}$ and $3C^{PRO}$ into the proteins (*P1–P3*) and structural peptides (*VP1–VP4*; *VP2* and *VP4* derive from the VP0 precursor protein) that assemble into protomers, pentamers, and finally capsids. Nonstructural proteins are also released in these cleavages as well as through autoproteolytic cleavage. Mature HRV virions packaged with an ssRNA genome escape by cell lysis (Adapted with permission from Arden et al. [138])

components [135]. This may represent another HRV strategy for limiting the host response by preventing or reducing key signaling pathway molecules (e.g., IRF-3, STAT1, NF-κB) and shutting down host cell protein synthesis. Protease 3C ($3C^{PRO}$) from HRV-A16 targets the nucleus and can disrupt active and passive nucleocytoplasmic transport [129, 136]. Recombinant $2A^{PRO}$ protein from HRV-A16,HRV-A89, HRV-B4, HRV-B14, HRV-C2, and HRV-C6 exhibited differing specificities and kinetics against eIF4G as well as NPC components demonstrating functional diversity between HRV types [137]. This finding underscores the functional diversity within the HRV species and the risk of extrapolating too greatly from the study of single HRV types. It is apparent from a wealth of immunobiological data that HRVs still efficiently trigger a proinflammatory immune response that has considerable clinical impact among at-risk groups, and that their putative interruption of host cell machinery does little to hinder this.

4.1 The Rhinovirus Genome

The virion encapsulates an approximately 7 kb positive sense RNA genome (Fig. 29.3), which tends to be more adenine and uracil (A+U) rich than the EV genome [139]. In particular, A+U more frequently occupies the third or "wobble"

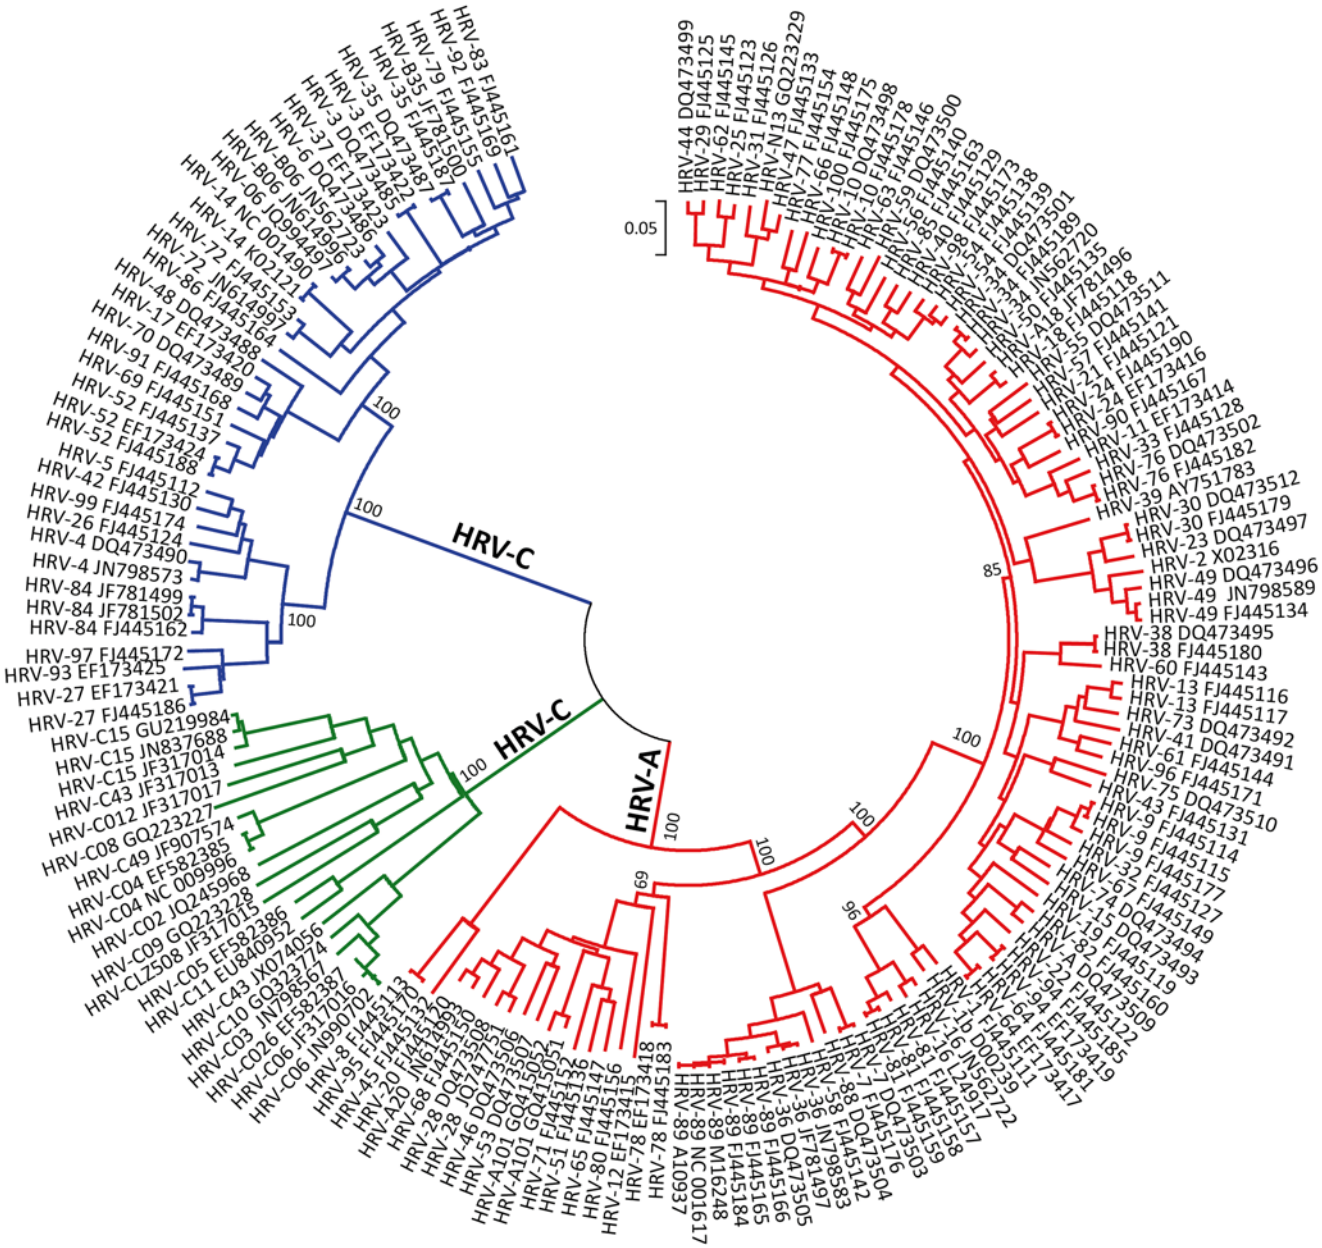

Fig. 29.5 The current spectrum of 168 complete HRV complete polyprotein amino acid sequences available on the GenBank database. The alignment was conducted using MAFFT within Geneious Pro v5.6 [148]. The phylogenetic and molecular evolutionary analyses were conducted using *MEGA* version 5 (Poisson model, 500 bootstraps with consensus support shown at the nodes where space permitted [149]) (Reprinted with permission from Miller and Mackay [150])

codon position. The single RNA "gene" acts as messenger RNA to encode the single multi-domain, proteolytically processed "polyprotein." The coding region is bracketed by UTRs which perform regulatory functions necessary for genome duplication [140]. These are very similar genomic, transcriptional, and translational features to those of their close cousins, the EVs. Most of the information currently required for virus identification by the International Committee on Taxonomy of Viruses (ICTV) can be found through analysis of the genetic features of HRVs (Fig. 29.3).

There are 158 complete HRV polyproteins on the GenBank database (Fig. 29.5). The first complete HRV genome sequence (HRV-B14) was described in 1984 [141] followed by HRV-A2 in 1985 [142] and HRV-A1b in 1988[143](Fig. 29.3). In 2007 Kistler et al. added 28 genomes [144] and Tapparel et al. 12, including one common to both studies [145]. Sequencing of the VP4/VP2 region was completed for all classical strains in 2002 [146], and the complete set of 1D regions were available in 2004 [147]. Currently there are at least 50 named HRV-C VP1 regions

available and 20 complete HRV-C genomes. Many more genomes are appearing as part of the Rhinovirus Consortium's efforts to complete and study the rhinovirome using high-throughput sequencing technologies to genetically characterize HRVs from their combined clinical specimen stores (http://www.international-rhinovirus-consortium.org/). Many 5′UTR and VP4/VP2 sequences reside on the GenBank database, most of which are labeled using in-house laboratory schemes rather than an approved nomenclature. Analysis of the full-length genomes supports the use of 5′UTR, VP1, and VP4/VP2 subgenomic regions for useful representation of HRV species and types [144, 147].

Recombination, the process of genetic exchange which results in a chimeric genome [151], can only be detected in mature viruses after the fact, and it must therefore be inferred indirectly through genomic analysis and comparison. Predictions of infrequent recombination among the HRVs [83] have been made based on examination of the available set of HRV coding and noncoding regions [152]. Intensive analyses reported that recombination is not a driving force for the evolution of HRV types [144, 153, 154]. Some discrepancies are likely because of the different number of sequences used, the different origins of the viruses used for sequencing, and the analysis methods employed. HRV-C evolution seems to have been more affected by prior recombination, than is apparent for members of HRV-A or HRV-B. This is similar to the EV species but with far fewer predicted recombination events than for EV evolution [114, 151, 155, 156]. Most of the recombination proposed to have affected the HRVs occurred between HRV-C and HRV-A and is often found within the 5′UTR or at the 5′UTR/VP4 junction [83, 157, 158] but rarely in coding sequence (2A [158] or 3C [83]). The high sequence diversity among the individual HRV polyprotein coding sequences may keep recombination events to a minimum in order to retain viral fitness [158]. The ability of HRVs to recombine in practice awaits empirical evidence; the extent of recombination among all HRV or EV types and the frequency with which viable recombinants arise are entirely unquantified.

4.2 The Rhinovirus Capsid

The 28–30 nm HRV virion has been visualized for only a handful of HRV-A and HRV-B types (including HRV-A1a, HRV-A2, HRV-B3, HRV-B14, and HRV-A16), but no HRV-C structures have been empirically determined to date. The first, HRV-B14, was described in 1985 [159] followed by HRV-A1a in 1989 [160], HRV-A16 in 1993 [161], HRV-A3 in 1996 [162], and HRV-A2 in 2000 [163]. HRV-C structure has only been predicted using computer modeling, but their basic structure seems to be that expected of an HRV (Fig. 29.6) [33]. The HRV capsid shell is composed of 60 protomers, each comprising one copy of the viral proteins VP4, VP3, VP2, and VP1. VP1, VP2, and VP3 (each ~30 kDa) are to some extent exposed on the capsid surface, whereas VP4 (~7 kDa) is internalized and associated with viral RNA. Five protomers come together at a point around a fivefold axis, and this cluster is called the pentamer. The fivefold axis is circumscribed by a cleft referred to as the "canyon." VP1, VP2, and VP3 are each formed by a convoluted set of protein sheets and loops [159]. The loops protrude beyond the external capsid surface and contain discontinuous antigenic sites. Of the HRV types studied, four neutralizing antibody immunogenic (NIm) regions have been identified on HRV-B14 and HRV-A16: NIm-1A (located in VP1), NIm-1B (VP1), NIm-II (VP2 and VP1), and NIm-III (VP3 and VP1) [159]. Antigenic sites identified on HRV-A2 are called A, B, and C [164]. The scope and location of antigenic and immunogenic moieties among the HRV-Cs is unknown. Using known receptor binding sequence as a guide for computer modeling (Fig. 29.6), it has been predicted that when discovered, the receptor for the HRV-Cs will differ from the major and minor receptors defined for the HRV-As and HRV-Bs [33].

4.3 Classification of the HRVs

The three HRV species within the genus *Enterovirus* are a genetically, immunogenically, and antigenically diverse assemblage of >160 viral types (Table 29.1). This accounts for the combination of HRV-A1a and -A1b, exclusion of HRV-87, which is actually EV-D68 despite confusion over acid liability [169–171] and combination of HRV-Hanks which is actually HRV-A21 [147]. Serological studies indicate that some HRV-A and HRV-B types may not be distinct enough to deserve a unique identity [147]. Species within the genus share >70 % amino acid (aa) identity in the polyprotein and in 2C+3CD and >60 % aa identity in P1 (Fig. 29.3) as well as their host cell receptors, a limited natural host range, a genome base composition (G+C) that varies by no more than 2.5 %, and a similar compatibility of proteolytic processing, replication, encapsidation, and genetic recombination [172]. A variant of the same HRV type shares 87–88 % aa identity or more in VP1 [129]. Much of the nongenetic criteria remain undefined for the HRV-Cs. In 2008 the genera *Enterovirus* and *Rhinovirus* were officially combined, retaining the former genus name *Enterovirus* with the *Human enterovirus* C as the prototype species. A genus in the order *Picornavirales*, family *Picornaviridae*, is at least 58 % different in its amino acid identity from any other genus. In 2009 a proposal establishing the species *Human rhinovirus C* was ratified by the ICTV. Formal HRV-C numbering commenced in 2010, and type numbers were initially assigned

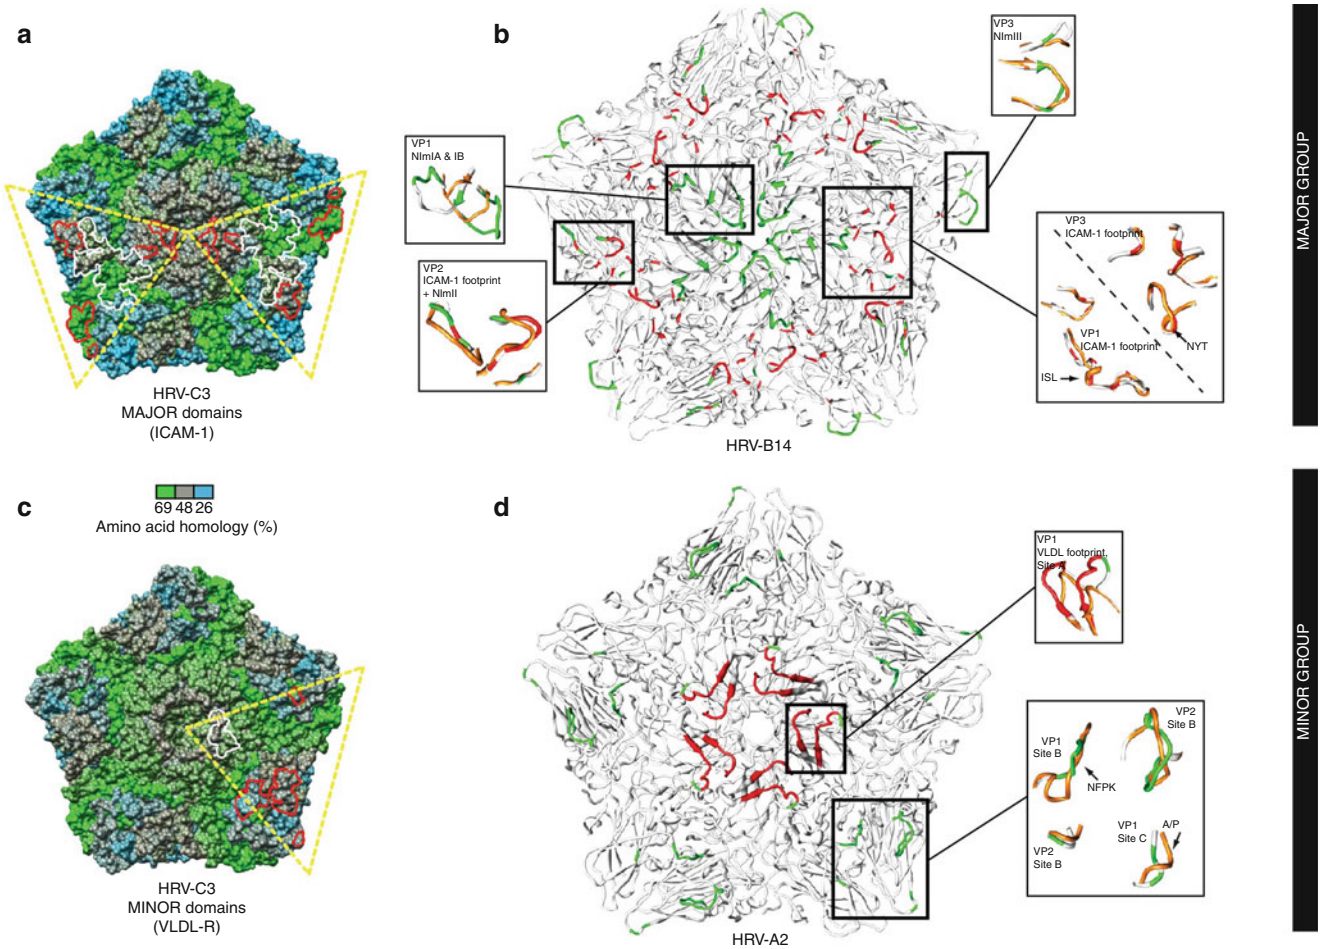

Fig. 29.6 Predicted HRV-C3 pentamers compared to major (HRV-B14) and minor (HRV-A2) group HRV pentamers which have been obtained from X-Ray crystallography. (**a**) HRV-C3 versus HRV-B14 SimPlot data projected onto a space filling depiction of the predicted HRV-C3 pentamer. Shading represents the amino acid identity (26–69 %). The *yellow-dashed triangle* represents a single icosahedral asymmetric unit ($T=p3$ conformation) composed of VP1 and VP2 from the same protomer and VP3 from an adjacent protomer. The major group domains of interest are divided between two asymmetric units for ease of viewing. Receptor (*white*) and antigenic (*red*) sites are shown in outline. (**b**) Bird's eye view of a major group HRV pentamer in ribbon form (HRV-B14, *gray*) with labeled antigenic neutralization sites (NImIA-III, *green*) and combined HRV-A16 and HRV-B14 intercellular adhesion molecule (ICAM)-1 receptor footprints (*red*) [165, 166]. Magnified areas of interest (*boxed*) highlight computer-based comparisons to the equivalent HRV-C3 (*orange*) predicted structures of interest. (**c**) HRV-C3 versus HRV-A2 SimPlot data projected onto the HRV-C3 pentamer. The domains of interest are mostly shown within a single asymmetric unit. (**d**) A minor group pentamer (HRV-A2, *gray*) including antigenic sites (sites **a**–**c**, *green*) and very-low-density-lipoprotein receptor (VLDLR) footprint (*red*) [167]. Attachment of the VLDL-R involves adjacent VP1 molecules. Magnified VP1 area represents one half of a VLDL-R footprint [168]. Amino acid substitutions (*arrowed*) contributed to the differences between minor group sites **b** and **c** (Adapted with permission from McErlean et al. [33])

based on the date of submission of relevant sequences to GenBank (HRV-C1, formerly NAT001; HRV-C2, f. NAT045; HRV-C3, f. QPM; HRV-C4, f. C024, etc.; Table 29.1) [127]. A clinical detection of an HRV-C can be considered a novel type principally based on its VP1 sequence or provisionally ("C_pat," Table 29.1) based on VP4/VP2 [146] and could be confirmed as a variant of a previously characterized HRV-C by identity thresholds to either region. The 5′UTR can be and still is used [173, 174] for HRV genotyping, but it is a more problematic region than VP1 or VP4/VP2 because of the recombination activity that affects this region, especially among the HRV-Cs [175]. This is presented as phylogenetic intermingling of some HRV-A and HRV-C types [114]. Nonetheless, careful application of sequence identity thresholds when comparing clinical sequences to the GenBank database (≥96 % identity required before assigning a clinical detection to a particular type) succeeds in characterizing HRV species and types [9]. There are currently 50 types within HRV-C (which includes the types once grouped together under HRV-"A2," HRV-X, and HRV-NY clades), 78 HRV-A types, and 25 HRV-Bs. The most up-to-date information on current taxonomic trends can be found at the ICTV Picornaviridae study group website (http://www.picornastudygroup.com/).

M and *H* indicate early cell tropism-based classification (monkey, human) abandoned in favor of a sequential numbering system [177]. HRV types were later divided into the major and minor groups defined by receptor tropism [184, 185]. Receptor-designated minor group HRV types are underlined, and major group types are shown in bold. Antiviral groups (A and B) are labeled [165, 194]. HRV-A8 and HRV-A95 are also likely the same serotype [147]. A full list of genetically close serotype pairings was presented by Ledford et al. [147] HRV-C nomenclature was defined in 2010 and currently includes a number of *p*rovisionally *a*ssigned *t*ypes (pat) which are confirmed once preliminary VP4/VP2 data can be confirmed with VP1 sequence and the provisional number removed (e.g., C_pat1 to C_pat13 have already been reassigned)

Historically a key feature distinguishing the HRVs from the EVs was the instability of the HRV capsid in the presence of acid and their lower preferred laboratory propagation temperature (33–34 °C versus 37 °C for EVs). Over time HRVs have been subclassified in different ways. The first was based on tissue tropism and host range. HRVs that preferred growth using monkey cells were called "M" strains and those (the majority) that grew only in human cell cultures, "H" strains [56, 176–180]. These two groups correlate with receptor usage [131] (Table 29.1) and possibly with the titer of the inoculum employed [181]. In 1962 it was proposed to abandon this terminology in favor of a sequential numbering system [177].

Picornaviruses recognize a variety of cellular receptors [169, 182, 183]. HRV types are also subdivided into major and minor groups defined by use of one of the two main receptor molecules [184, 185]. The capsid of the majority of classical HRVs ($n=89$) [184] interacts with the amino-terminal domain of the 90 kDa intercellular adhesion molecule (ICAM-1; CD54) [186–189]. Receptor binding destabilizes the HRV capsid, probably by dislodging the "pocket factor," and initiates uncoating [164, 182, 190]. ICAM-1 interacts with its receptor, leukocyte function antigen-1 (LFA-1), and plays a role in recruitment and migration of immune effector cells [191]. The minor group [184] of classical viruses employ members of the low-density lipoprotein receptor (LDLR) family to attach to cells [167]. Binding of VLDL-R occurs outside of the canyon employing a different destabilizing and uncoating mechanism. Heparan sulfate may act as a receptor under specific conditions [183, 192, 193].

In 1990 Andries et al. defined, and Laine et al. refined, two "antiviral groups" (A and B) based on their susceptibility to a panel of antiviral molecules [165, 194]. These groupings reflected the nature of the amino acid (and hence nucleotide) sequence of the region interacting with the antiviral molecules. These antiviral groups can also be visualized using phylogeny [194]. When sequences from other subgenomic regions, including P1, 2C, and 3CD, were examined by phylogeny, the species were found, in most cases, to inversely correlate with antiviral grouping labels (Table 29.1).

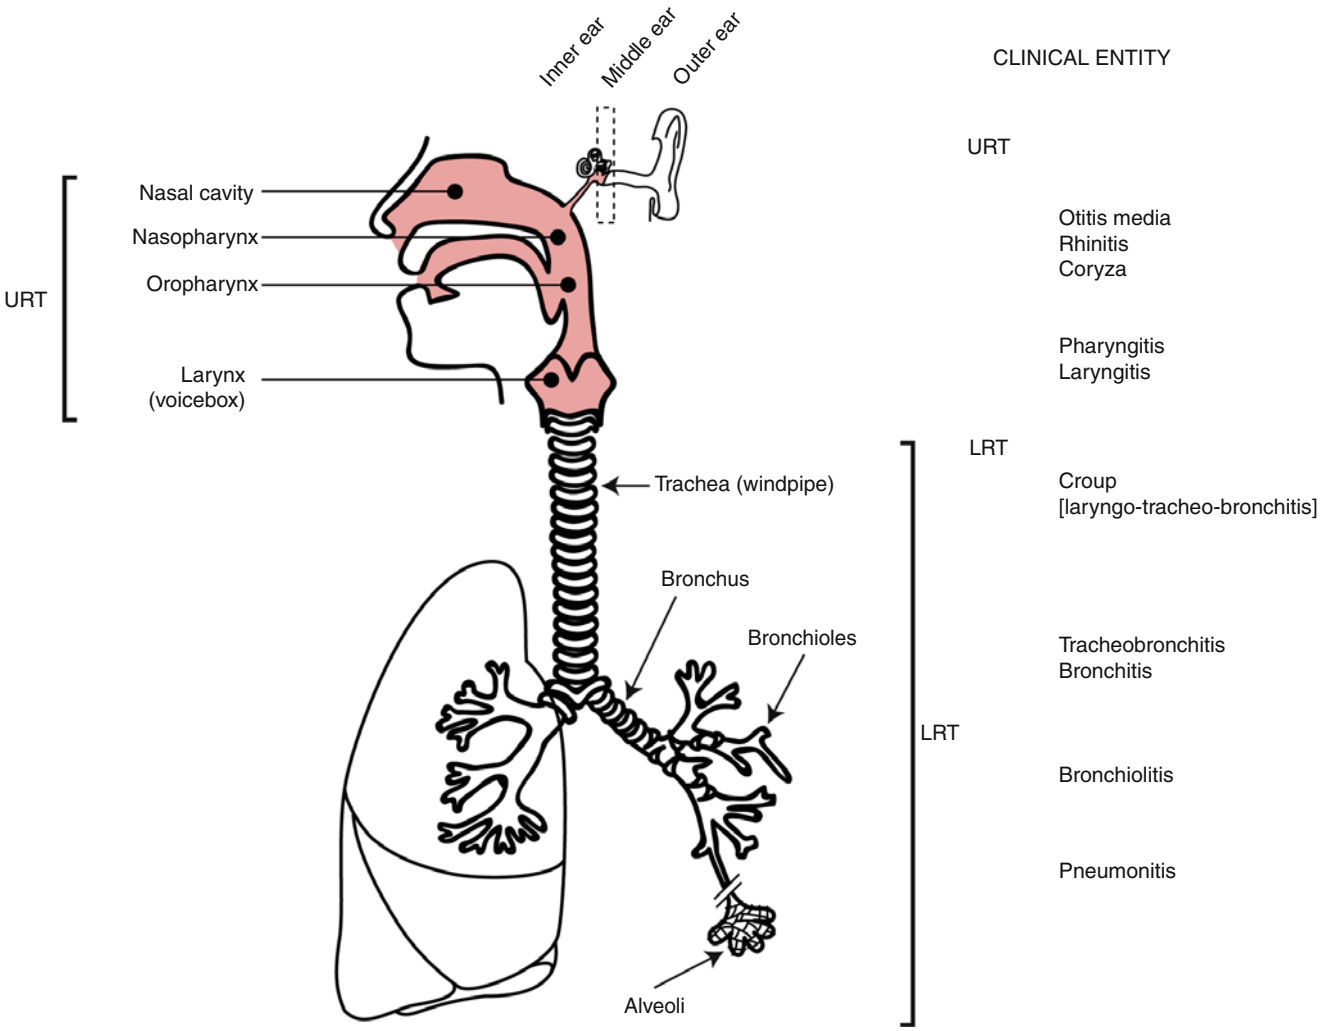

Fig. 29.7 A schematic representation of the human respiratory tract. The upper (*shaded pink*) and lower respiratory tract (*URT*/*LRT*) and the components of the ear are indicated as are the approximate locations of URT and LRT diseases associated with respiratory virus infection (Adapted from Mackay et al. [200] with permission from Caster Academic Press)

Today, sequencing and phylogeny play a central role in species classification within the genus, and together, they are surrogates for the important biological classification criteria [146, 147, 165, 195–197]. For the HRV-Cs, first described as the "HRV-A2" clade (not to be confused with the single virus, HRV-A2, this naming scheme appeared after the HRV-C clade's name was proposed) of viruses in 2006 [31], sequencing of 5′UTR and VP4/VP2 has provided the bulk of HRV information from clinical studies. While culture in primary sinus tissue has been reported [63], no receptor is yet defined.

5 Descriptive Epidemiology

HRVs are the most numerous and frequently detected of all the "respiratory viruses," so-called because of their predominant detection in and tropism for the human URT or LRT (Fig. 29.7). The circulation of HRVs varies with population age, underlying disease, immunocompromise, over time, and across distance. Circulation is influenced by the nature, strength, distinctiveness, and memory of the immune response HRVs trigger and by the nature and prevalence of other concurrently circulating respiratory, and perhaps non-respiratory, viruses. With the recent discovery of the unculturable HRV-Cs came the realization that previous HRV epidemiology was only reliable if conducted by one or more suitably broad-spectrum HRV PCR assays [111]; hence, prior to 1988, detection of the full spectrum of ≥160 HRVs did not occur. After 1988, the ability to detect all types very much depended on the nature of the PCR primers and detection methods used. The great number of distinct HRV types has burdened the search for answers to epidemiology-related questions. However, as for other important respiratory viruses including human respiratory syncytial virus (HRSV)

and the influenza viruses (IFVs), the virus types within a species show evidence of being both distinct and discrete viruses that are independently recognized by their host and consequently independently infect their hosts. Each HRV type is also genetically stable [144].

The HRV species circulate variably from year to year with evidence of epidemics of distinct types. A prospective longitudinal cohort study over 6 months examined HRV frequency and diversity in 272 specimens from 18 healthy children (0–7 years of age) [198]. A median of three HRVs and a maximum of six were detected per child. A similar outcome resulted from an Australian cohort study [9].

Genotyping reveals more of the HRV diversity at a single site than culture ever could with molecular studies finding between 34 and 70 distinct HRVs at a single location [9, 128, 199]. The number of additional HRV cases that occur in children outside of specifically defined symptomatic periods remain to be defined, with current studies indicating that a much higher number of HRV infections may occur. More comprehensive investigation of HRV type and illness will be undertaken during analysis of data from the Australian-based Observational Research in Childhood Infectious Diseases (ORChID) study (http://clinicaltrials.gov/show/NCT01304914).

Interestingly, the HRV-Bs are often underrepresented, even when accounting for the smaller number of known HRV-B types [128]. A number of studies have not found any robust patterns between the circulating HRV types or species and clinical outcome, but the majority of studies seeking this information are short and sample infrequently, limiting their ability to find the patterns they seek [128].

5.1 Specimen Collection

Studies into the relative sensitivities of nasopharyngeal aspirates (NPA) and swab sampling methods produce differing results, but generally, if seeking the best diagnostic yield for as many respiratory viruses as possible (i.e., seeking a laboratory diagnosis to support clinical decision making), NPAs are the sample of optimal choice. One study reported similar clinical sensitivities between swabs and NPAs for human coronaviruses (HCoVs), IFVs, and HRSV, but reduced sensitivities using swabs for HRVs, human adenoviruses (HAdVs), human metapneumovirus (HMPV), or parainfluenza viruses (HPIVs) [201]. A second study reported no difference in sensitivities for HRVs, HAdVs, and HPIVs but a reduced sensitivity for HRSV and IFVs when using swabs [202]. Nasopharyngeal washes also yield more viral culture success than either nasal or pharyngeal swabs. Nonetheless, many studies use nasal swabs as the sample of choice because they allow self-collection and involve much less discomfort than NPAs, and PCR has meant that infectious virus is not required, only viral nucleic acid which relaxes some limitations imposed by the need for rapid, careful, temperature-controlled, and expensive transport requirements [64, 203, 204]. Bronchoalveolar lavage samples are best for seeking LRT etiologies, especially in adults where nasal wash viral loads can be low compared to those in children, but this is an invasive method with some risk attached [205].

5.2 Host Population Distribution

HRVs infect all people, all around the globe. Spread of HRVs is most obvious and frequent from child to child and from child to parent [206]. In populations of mixed age, the majority of HRV detections occur in children [128]. Among 272 specimens from 18 healthy children, over a third (37 %) were HRV positive. Children less than 5 years of age (44 % of whom were HRV positive) were shown to have more HRV infections and a wider diversity of HRV types than children more than 5 years old (28 % HRV positive) [198]. Healthy adults in the military [54, 207], at university [208], at home [209–212], and in the workplace [209] have also featured prominently in historical, culture-based, and volunteer infection studies and heavily influenced our view of HRV infection outcomes [64, 206]. Although studies of children in hospital-based populations usually report more significant clinical outcomes (relating to the LRT) [213] than community-based studies, these data are still broadly applicable. Hospital populations originate from the community and reflect the more serious and perhaps first exposures to the virus. Hospital-based populations define the potential of a virus to cause severe clinical outcomes. Disease at this end of the spectrum has the strongest influence on future prioritization of therapeutic research and developments [214].

Modern air travel contributes to the rapid spread of respiratory viruses as seen in their often frequent detection among travelers [215] including those with febrile illnesses [216]. Apart from children, HRVs are found with the great clinical impact in the elderly (described as 60–90 years of age) with 50 % of ARIs positive for an HRV, sometimes with a greater burden of disease than IFVs [217]. Those with asthma or COPD are also affected by the ARI triggering exacerbations of wheezing illness (see Sect. 8.2). It is thought that this is not a different type of infection but rather a different response to infection by the host. Wheezing can also result from infection in atopic people who do not have underlying asthma or COPD. HRVs cause significant impact in the immunocompromised, and this group is the only population to date that has been found to host truly persistent HRV infections (see Sect. 5.7). Because the HRVs are the largest group of viruses to infect humans, it is not surprising that they confuse differential diagnoses during pandemics and have key roles in

co-detections and asymptomatic disease. The study of HRVs is the study of all respiratory viruses; while each can be considered in isolation, this will likely be detrimental to a greater understanding of respiratory virus pathogenesis.

5.3 Seasonality

HRVs circulate throughout the year but usually with a bimodal peak in temperate locations in both hemispheres. The highest peaks, mostly defined using adult populations, are in the autumn (fall) and spring [64, 66, 211] (and, peculiarly, on a Monday [218]). The major winter dip in HRV prevalence closely coincides with the peaks of other respiratory viruses, particularly IFVs [219] and HRSV [66]. One hypothesis states that a miasma exists in the school classroom, of particular relevance to those who suffer asthma exacerbations, and this miasma maintains immune stimulation, which subsequently wanes among school children during holidays, to be challenged anew upon return to school [220]. It is clear that an interplay or interference takes place between viruses at the population level, particularly evident among RNA viruses.

There is a correlation between spiking spring and autumnal HRV case numbers and an asthma exacerbation "season" 10–24 days after return to school from holidays, in a range of climates [220–223]. This was particularly obvious among asthma hospitalizations of children (5–15 years of age) in Ontario, Canada, which peaked at weeks 37–39 across a decade [223]. Upon investigation, HRVs were the most prevalent of the viruses found in a 1-year analysis of emergency room presentations in Ontario [223]. HRVs also predominate during "hay fever season" [172]. Although a defined seasonality is not always found in the tropics [224], this may sometimes be due to testing that does not include HRVs [222, 225] or only some HRVs [226].

5.4 Recurrence

All the HRV types continue to circulate today, including those named in the earliest of the nomenclature assignments. At a single site during 12–24 months, 70 or more types can co-circulate [8, 9] [174], dropping [198, 227] if the study time frame at the site is shortened. A recurring HRV type, defined using molecular tools, accounted for 1.6 % of any virus detected in a birth cohort followed for 12 months [8] and, in another cohort, occurred twice in two children, within a 6-month period [198].

Within a given year and across different years, it is apparent that HRV species exchange predominance [9, 36, 60, 227–229]. No evidence exists to satisfactorily explain this; however, herd immunity may be a factor.

5.5 Coinfection

The use of cell and tissue culture underestimated the frequency of multiple infections in patients, most likely because the dominant virus out-replicated any others, or due to viral load differences, specimen quality issues, differing cell tropisms, or the triggering of an antiviral state by the first virus. When the majority of respiratory viruses are sought using PCR techniques, multiple virus-positive specimens can comprise a third of those tested [230], dropping to around a fifth of ARI episodes when fewer viruses are sought [217]. There is sometimes an emphasis on the high number of HRV cases that are identified in the presence of another virus, and including HRV testing does raise the frequency of pathogen detection above one per sample [231]. Coinfections, or, more correctly for PCR-based studies, co-detections (since PCR cannot determine infectivity), have been found to either increase [71, 232–236] or have no impact on the clinical outcome in their host [237–241], and so the issue of clinical relevance of co-detections is still uncertain. In extreme cases, half of all HRV detections can be found concurrently with another virus. On the surface, this is a significant fraction, and yet 80 % or more of HRSV, HMPV, EV, and IFV detections and 71 % of HCoV-NL63 detections can be found in the company of another virus [242]. Other studies find different, but still higher proportions of co-detections involving non-HRVs [217]. Whether co-detections represent a particular synergism between the involved viruses, a differential capability to manipulate the host immune response, a sign of innocuousness for the most frequently involved virus [243], or a chance due to overlapping seasons remains unclear. It is clear, however, that co-detections are not an anomaly or an error due to "overly sensitive" PCR tests; they are evidence of further biological complexity that, until recently, remained hidden from us. Recent studies have shown that the initial impression of HRVs being overrepresented in these cases was incorrect. Closer analysis of viral co-detections has revealed patterns [231, 244]. These became clear when co-detections were examined bidirectionally, not just how many HRVs were positive for virus X but also how many of virus X cases were positive for an HRV. Whether in a hospital or a community setting, HRVs more often occur as the sole virus detected in ARIs [9, 244]. Considering their ubiquity, it is interesting that relatively low numbers of concurrent detections occur [245, 246], supporting the concept that HRVs have a direct role in the clinical outcome of their infection [247]. The HRV partnership with host immunity may be a mutualistic one, inadvertently imparting an advantage to the host by protecting against more cytopathic respiratory viral pathogens, while the host provides a vessel for HRV replication and transmission. Studies of single respiratory viruses without being in the context of the respiratory virome are of limited value in drawing conclusions about clinical impact.

5.6 Virus Interference and the HRVs

Much of the longitudinal epidemiology data previously relied upon to form assessments of HRV significance was acquired using culture-based techniques. With improved and more comprehensive testing, patterns can be seen among the interactions of HRVs and other respiratory viruses.

Virus interference is a type of virus-virus interaction (VVI) that has been known for decades. VVI has recently been categorized into types [248]. At the population level, it has been noted that during trials of live attenuated IFV (LAIV) vaccines, an interferon (IFN) response was triggered that protected vaccinees against off-target viruses for 7 days postvaccination [249]. This 1970 study went so far as to suggest such effects could be maintained for a prolonged period using a regime of consecutive schedule vaccinations, each separated by 7 days or more, during times of a prolonged epidemic [249]. A similar effect was produced using live EV vaccines (LEV) to replace pathogenic EV types and interrupt outbreaks [250]. Orally administered LEVs succeeded in their principal task but also reduced the incidence of ARIs during epidemics by 50 % overall [250]. This shows that immune activation in the gastrointestinal system generates an anatomically distinct protective effect and there may be a similar effect on the gut's inflammatory status after respiratory virus infection. In contrast to the LAIV results, the off-target protective effect was reversed in a study using a trivalent inactivated IFV vaccine [251]. The mechanism underneath these opposing outcomes is unclear.

During the heyday (1960s) of tissue culture for virus studies, a common biological assay for infection with HRV involved attempted infection of the culture with an enterovirus (EV) or HPIV-1 [252, 253]. Failure of the superinfecting virus to grow heralded the likely presence of a non-cytopathogenic HRV. Virus interference has been used to measure IFN in specimens through its inhibition of HRV growth [254]. More recently HRV-HAdV dual PCR-positive cases were found less often than expected and harbored lower viral loads of HRV than did specimens from cases of sole HRV infections [255]. Significantly, the majority of these instances of VVI involve RNA viruses [244]. It has been shown that dual infections of peripheral blood mononuclear cells (PBMCs) with viruses other than HRSV (including HRVs) induced immune responses similar to those of single infections, but coinfections including an HRSV resulted in reduced IFN-γ responses [71]. VVIs are affected by the ability of each to moderate the host response against them.

Virus interference has also been identified in virus positives as a series of patterns among respiratory specimens tested for up to 17 respiratory viruses (Fig. 29.8) [9, 244]. Statistical analyses supported that many of the co-detections occurred in patterns, in particular that fewer co-detections involved an HRV than would have been expected by chance alone ($p \leq 0.05$). For some period, RNA virus infection, especially the HRV group, may render the host less likely to be infected by other viruses and, by extrapolating to the community level, help constrict the epidemic periods of other viruses by reducing the number of fully susceptible hosts.

Virus interference as a feature of respiratory virus epidemiology can also be seen in results of other studies [256]. During an 8-week period that spanned peak 2009 H1N1 pandemic influenza season in Wisconsin, it was influenza A virus (IFAV) that seemed to dominate HRV in children with asthma who were sampled weekly [236]. Whether this reflects all IFV-HRV interactions or just those involving a novel IFV such as 2009 H1N is unclear. It was found that PBMCs from these children exhibited normal immune responses [236].

5.7 HRV Shedding and Persistence

Reports of subjects with continuous and extended (greater than 2–3 weeks) periods of HRV positivity [3, 257] increased as PCR methods replaced cell culture for HRV detection. This had only rarely been recorded using culture [54]. HRV RNA has been detected days prior to symptoms commencing and for as long as 5 or more weeks after they cease [3, 258–261]. Studies that only define the period between ARIs in children as that time when specimens are RT-PCR negative [3] will not detect overlapping serial infections (Fig. 29.9). Epidemiology that incorporates HRV typing generally does not find chronic shedding [204]. HRV shedding normally ceases within 11–21 days, after signs and symptoms have stopped [3, 9, 44, 75, 85, 260]. Thus, the perception of persistence is probably due to serial or overlapping infections by multiple untyped strains [8, 54, 210, 262]. Few studies [263] have suitably addressed persistence in HRV infections involving healthy subjects since pre- and post-sampling clinical data are rarely described [80, 264].

To date, true persistence—an ongoing detection of a single confirmed HRV type—has been limited to individuals with underlying immunosuppression or immune dysfunction [260]. HRV-Cs were detected more than three times longer in immunocompromised young patients than in immunocompetent children, with a mean of 16 versus 53 days [265]. Multiple detection of the same HRV type (100 % identical HRV-1a sequence in each patient over time) extended to 4 months in hematopoietic stem cell transplant recipients.

5.8 Asymptomatic Infections

The proof of causality is as difficult to achieve as the proof of innocuousness when it comes to respiratory viruses and

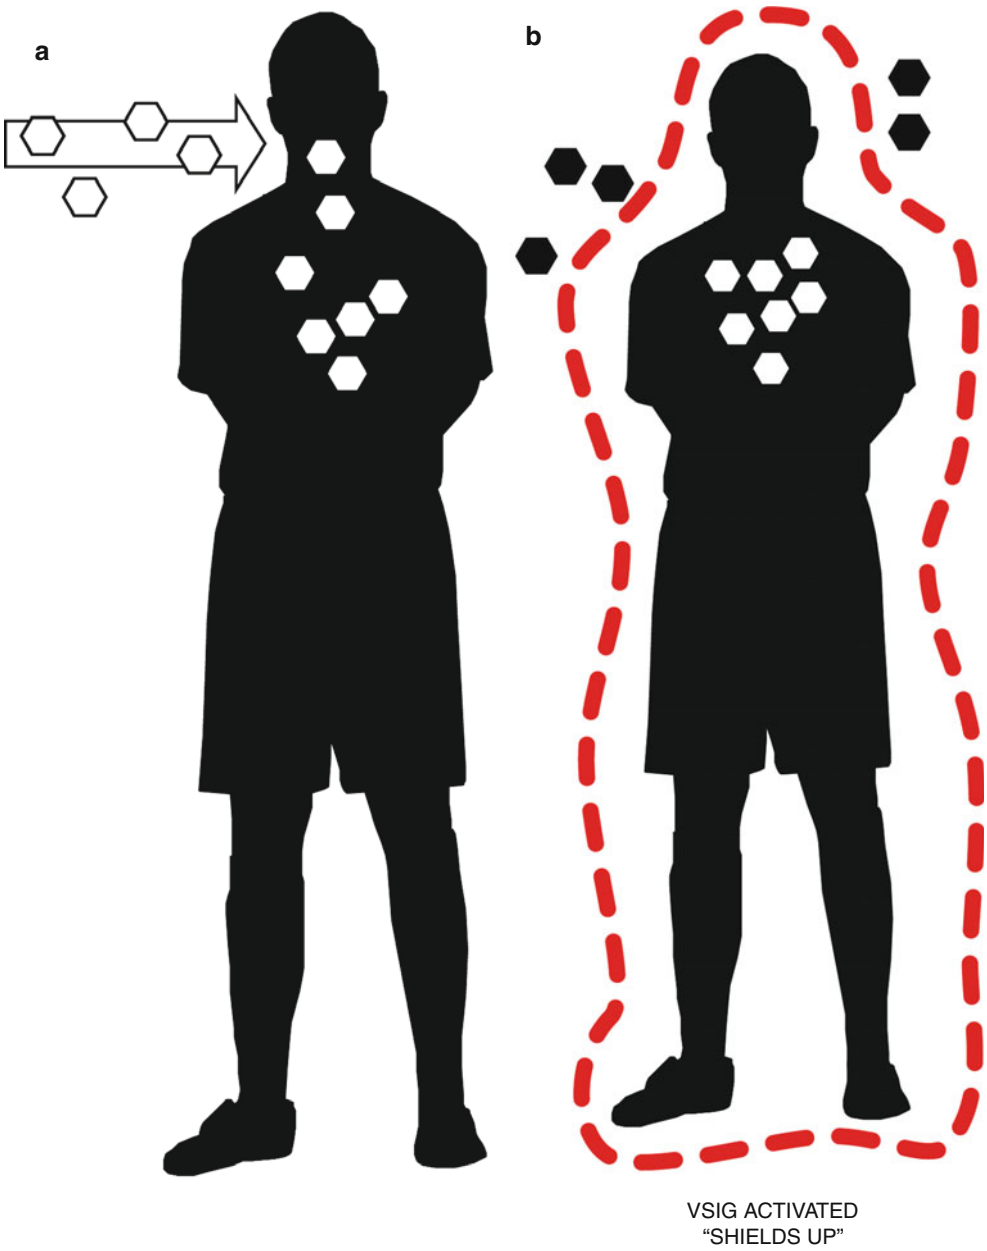

Fig. 29.8 A simplified representation of the impact of a first respiratory virus infection on subsequent respiratory virus superinfections. Very shortly after the host is infected, (**a**) the local early innate immune response creates an antiviral state in neighboring cells (see Sect. 7.1), perhaps also in distant epithelia, mediated by circulating immune cells. The resultant inflammatory response (**b**) creates a shield of sorts, reducing the likelihood of infection by a superinfecting virus mediated by viral stress-inducible gene (*VSIG*) products

ARIs. The definition of "well" subjects prior to or at the time of sampling or inoculation is sometimes not clear, especially for young children who cannot reliably report symptoms [3, 96, 204]. Often parents notice a symptomatic illness before an infection is detected in the laboratory [3], supporting the importance of diaries in longitudinal home-based community studies. Nonetheless, even with the support of telephone interviews and home visits, milder cold symptoms may be missed. It is not uncommon for an asymptomatic control to subsequently become symptomatic or have been symptomatic before sampling [8, 266]. Some studies employ sensitive symptom scoring systems [267], but the criteria for being symptomatic are usually designed to describe and clearly discriminate overt or more "severe" illnesses, those with obvious and measurable signs. Strict definitions help improve patient management and the commencement or better direction of treatment or cohorting. However, in research studies the arbitrary degree of severity required for reporting a symptomatic event often overlooks very simple changes in host biology due to a virus's replication. These changes to the norm are mild but nonetheless represent disease (a disorder of structure or function that produces specific symptoms or that affects a specific location and is not simply a direct result of physical injury) in the literal sense. Such minor or short-lived, often unrecorded [3], indications of infection include sinus pain, headache, sore throat, earache, watery eyes, fatigue, muscle aches and pains, and mood changes. Within families, HRVs are frequently transmitted from

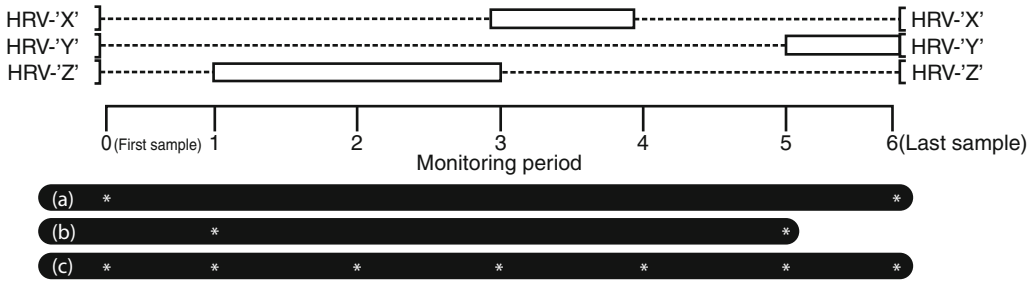

Fig. 29.9 The impact of HRV typing and of sampling based only on symptoms. The example provided here diagrammatically represents a single, hypothetical monitoring period, starting at time = 0, for a single individual. The period of potentially detectable HRV is indicated by an open box. If sampling occurred at each time point (*0–6*) and HRV positives were genotyped, it would be apparent that three different strains infected the individual, although discerning HRV-X from HRV-Z at time point *3* would require a molecular cloning approach. Illness, in different forms, may have continued over the entire period depending on the symptoms required/recorded and the period of time represented by the monitoring period. In this case a clinical diagnosis may record only a single symptomatic episode. Genotyping may not be performed, and sampling may be intermittent, and so association between viral type or species and disease is impossible. In the study examples indicated by (*a*) start and finish sampling or (*b*) symptomatic sampling, (*asterisks* mark sampling times in filled bars), the laboratory data would have made only one or two identifications, respectively. In the third example, (*c*) frequent sampling of this type has previously led to conclusions of HRV persistence or chronic shedding; when combined with genotyping, it becomes apparent that different HRV types are present

children who are usually symptomatic [204]. Infants frequently exposed to other children have more asymptomatic viral infections [8]. Among infected adult family members, asymptomatic infections are more likely [204]. Among older parents, whether their children live at home or not, asymptomatic infections are more frequent following HRV challenge than among adults without children or in younger parents [268]. In a study of viral species in age-stratified cases and controls, significantly lower viral loads were found in those without the required symptoms [269]. QPCR may prove useful to determine viral load cutoffs to address this issue in the future, although the respiratory tract is a difficult tissue for qPCR [200].

The high sensitivity of PCR-based methods has raised concerns over the clinical relevance of a virus-positive result [269]. It is clear that a proportion, around five to 28 % of study-defined asymptomatic control populations [90, 91, 269], are virus positive using sensitive PCR-based methods. This may vary up to nearly 50 % of cases when stratified by age, virus, and season or when including high-risk populations [8, 269]. Every respiratory virus, even IFVs and HRSV, can be found in cases without symptoms at the time of specimen collection even after specific inoculation of adults [137, 269, 270]. This is a complex and incomplete story in need of more research, and so it is frustrating that positivity in asymptomatic people is often used to rank viral importance. Better data are required from asymptomatic controls for any conclusion to be drawn about causality [266], but this requirement often disregards the memory of a normal functioning protective host immunity. It is the host response that defines the degree of clinical severity for the inflammatory disease that is the hallmark of an ARI [271]. It is well known that previous exposure to a virus affords protection from the full clinical spectrum of disease upon repeat exposure to that virus. It should come as no surprise then that HRVs, which usually cause brief infection anyway, could well produce only minor signs and symptoms upon reinfection. The unique and extremely personal infection history of each member of a control group cannot be determined unless they are part of a longitudinal cohort. So, what do cohort studies, supported by comprehensive PCR-based testing, tell us about asymptomatic virus infections?

Some cohort studies do not look in asymptomatic children, seeking samples only at times of symptomatic illness [66, 246, 272]. A birth cohort of children enrolled and sampled when ill and every 6 months for 24 months identified HRVs 14–28 % of infants and toddlers who had no nasal symptoms (defined solely by the presence of rhinorrhea) [273]. The Childhood Origins of ASThma (COAST) birth cohort followed 285 infants at high risk for allergies and asthma for 12 months and identified HRV infections as preceding (mean age of first detection, 4 months) those of HRSV (mean age at least 6 months), and HRVs were found in 35 % of asymptomatic versus 61 % of moderately to severely ill patients; the most frequently symptomatic children also had the greatest proportion of asymptomatic infections [8]. In a study of 58 children with asthma sampled weekly for 5 weeks during each of two peak HRV seasons, nearly two-thirds who were virus positive but not sensitized to at least one allergen showed no asthma symptoms, and nearly half showed no ARI symptoms; in the children who were sensitized, less than one-third showed no asthma symptoms, and only a fifth had no ARI symptoms [227]. A convenience population of 15 healthy children (1–9 years old) without asthma were followed during at least three seasons, and picornaviruses were detected in 5 % of 740 specimens (21 % of infections) not associated with symptoms,

although 9 of the 25 infections came from households with an infected sibling [3]. In summary, there is clear evidence for the presence of HRVs in asymptomatic controls. A precise proportion cannot yet be defined. Some study controls show signs of a "lead-in" period where RNA positivity precedes an ARI defined on follow-up, while others may have been defined as symptomatic if more symptoms had been accounted for.

6 Mechanisms and Routes of Transmission

6.1 Source of Infectious Virus

HRVs have been found at extra-respiratory sites. Viremia was determined in the blood of children with LRT infection or pericarditis [274, 275], and HRV-C was more commonly associated with viremia than was HRV-A, supporting possible increased pathogenicity [274]. Blood was also positive for HRV RNA and infectious virus from infants at necropsy [276, 277], and HRV RNA was detected in the plasma of children with asthma, bronchiolitis, or common cold [76]. An HRV was once isolated from feces [203], and more recently higher than expected loads of HRVs were detected in fecal specimens from children with suspected meningitis and fever of unknown origin [77], with gastroenteritis [278], and in a child with pericarditis [275]. Nonetheless, the nasopharynx is still considered the main site of focal virus production [279], regardless of inoculation route [280], and most studies of transmission routes have centered on the URT. In contrast to IFV and HRSV, HRV infection involves less destruction of tissue. Ciliated epithelial cells are sloughed off in proportion to the severity of an HRV ARI, but this damage is minimal and does not occur during the viral incubation period or with subclinical infections [137, 281]. The incubation period between infection and onset of virus shedding into nasal secretions is 1–4 days with shed viral titers peaking in adults between days 2 and 10 [44, 282]. The time until successful HRV transmission among adults in a childless family setting is usually 5–8 days and requires the donor to be shedding at least 10^3 $TCID_{50}$ at some stage, to have recoverable virus on the hands and in the nares, enough shared time, and a moderate to severe ARI [283].

The lungs have been shown to host replicating HRV [260], and the reader of such reports may be left with the perception that detection of HRV replication in the LRT explains all LRT symptoms. However, relatively few studies seek or identify true HRV replication in the LRT. While the overwhelming majority of LRT cases detect HRV from the URT, a correlation between URT positivity and LRT disease does exist [284].

6.2 Self-Inoculation and Virus Survival

It is well known from experimental inoculation studies that HRV infection can result from inoculation of the conjunctival sac after virus is moved through the nasolacrimal duct [280]. In these studies virus was commonly delivered by aerosol or intranasal instillation of 0.25 mL to 5 mL of suspension [43–46, 280, 285–287]. In the laboratory, HRVs can retain infectivity for hours to days on suitable, nonporous solid surfaces, especially if the inoculum remains damp [47, 287], which supports direct self-inoculation especially in the family setting and indirect inoculation via fomites [288]. In a trial to define the movement of virus from a contaminated donor to a recipient via multiple surfaces or by hand-to-hand contact, 13 % (donor to objects to recipient) and 6 % (donor to recipient fingers) of the virus recoverable from the donor's fingertips were recoverable from the recipients' [289]. Even under observation, eye rubbing (0.37 h^{-1}–2.5 h^{-1}) and nose-picking (0.33 h^{-1}–5.3 h^{-1}) occur frequently [47, 290], suggesting self-inoculation could outpace personal hygiene, particularly in the young.

6.3 Airborne and Intimate Contact Transmission

It was once thought strange that ARIs were so common, but isolation rates for the expected viruses were so low [36, 291]. With a better understanding of the importance of preexisting antibody (something common among the predominantly adult volunteers used by many studies), the discovery of a third, unculturable species of HRV (still causing ARIs but impossible to isolate or detect using antibody-based systems for which no reagents existed), and a vastly improved diagnostic sensitivity, this is much less confounding. In the past, household cross infection, determined by ARI, was low, about five exposures to infected members required for infection [17] despite viral loads in nasal washings peaking at 1.6×10^5 $TCID_{50}$/mL [44]. Experimental transmission was also reportedly inefficient [45]. In contrast, "naturally" close-quartered military populations, interacting over 1–4 weeks, experienced rapid spread of HRVs to >50 % of the group [54]. The use of PCR recently clarified this discrepancy, confirming that frequent transmission in families is more common than culture-based studies had identified, often resulting in asymptomatic infection among older siblings and parents [204]. PCR has helped define the scope of viral RNA, if not actual infectious virus, survival, and spread.

Transmission studies require infectious HRV, and so the HRV-Cs do not contribute to the historical data. Under crowded or intimate conditions and with more severe colds, transmission reaches 38–100 % [283, 292]. In some studies, both large- and small-particle aerosols proved inefficient,

supported by a low isolation rate from saliva (39 % compared to 65 % of hand washes and 50 % of nasal swabs)[44, 47, 293] and from only 8.3 % of participants exposed to large-particle aerosols [293]. In other human donor-recipient model studies however, aerosol proved to be the main transmission route among antibody-free adults [46, 282]. The discrepancy may have been due to insufficiently long or intense exposure in the earlier aerosol experiments [45, 267]. Apart from particle size, spread of virus by aerosol is affected by existing nasal obstruction which can divert secretions from the nares to contaminate saliva, the presumptive source of virus in coughs and sneezes [44]. When exposed to 10 liters of a small-particle aerosol, 10^1 $TCID_{50}$ of HRV-15 was associated with fever and prominent tracheobronchitis in antibody-free (<1:2) adult volunteers but not when delivered via nasal drops or a coarse aerosol [46]. It has also been found that simple breathing releases HRV RNA (the same type was also identified from nasal mucous) from at least a third of adults and children with symptomatic ARIs and infectious HRV could be isolated from a fifth [294, 295].

It is apparent that HRVs accumulate at sites with heavy human traffic, potentially forming a secondary source of infection. HRV RNA can be detected from 32 % of ~47-hour-old filters placed to sample air in office buildings [296]. In aircraft, high efficiency particulate air (HEPA) filters have been found to harbor HRV RNA more than 10 days after they were removed for servicing [297].

7 Immunity

HRV infections trigger a vigorous proinflammatory immune response that is thought to drive the symptoms experienced as illness [271, 298, 299], but they do not seem to actively prevent or interfere with the host's immune response the way most other viruses have evolved to do. There may be a role for repeated challenge by HRVs and other respiratory viruses leading to inflammation and tissue remodeling. The host response to HRV infection can be broadly broken into the innate (very fast, encoded in the germ line, nonadaptive) and adaptive (slower to develop, reliant on T cells, B cells, and the generation of antibody) responses. While the innate system is "always watching," it is significantly amplified by virus infection. The adaptive response is initiated by the host's first infection with a particular virus and then functions to limit subsequent infections through the production of neutralizing antibodies and amplification of existing cell-mediated immunity.

7.1 Innate Immunity and Interferon

After virus-receptor binding and internalization, the earliest host cell immune response to an HRV infection is elicited by the innate immune system (Fig. 29.10). Epithelial cells represent the front line against HRV invasion although alveolar macrophages and DCs are better equipped to respond [300] and do so despite not hosting HRV replication directly [16]. Virus detection is mediated by pattern recognition receptors (PRRs) that have evolved to recognize conserved molecular structures shared among diverse pathogens. Internal- or surface-mounted PRRs include sentinels that specifically recognize picornavirus RNA and protein and, in doing so, trigger an immune circuit that results in the production of IFNs and subsequently hundreds of IFN-stimulated gene products. The innate response to viral infection hinges on inducing two type I IFNs (initially IFN-ß then IFN-α), secreted cytokines that produce antiviral, antiproliferative, and immunomodulatory outcomes [301]. The type III IFNs

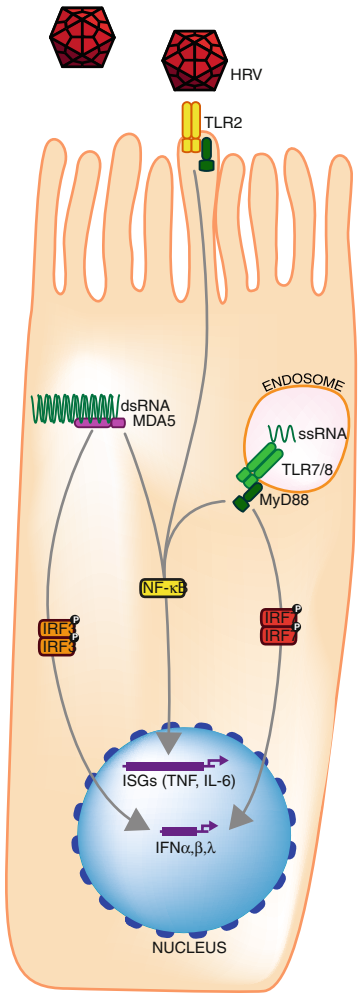

Fig. 29.10 A simplified representation of molecules involved in or that respond to the recognition and response to HRV infection of airway epithelial cells [302, 312–317]. *IFN* interferon, *IRF IFN* regulatory factor, *ISG IFN*-stimulated gene, *TLR* Toll-like receptor, *MDA5* Melanoma Differentiation-Associated protein 6; *NF-κB* Nuclear factor kappa-light-chain-enhancer of activated B cells, *MyD88* myeloid differentiation primary response 8

(IFN-λ1 or IL-29, IFN-λ2 or IL-28A, and IFN-λ3 or IL-28B) are also produced in response to viral infection in a range of cells, although their receptor is not as widespread [302]. The type II IFN, IFN-γ, is produced by activated T cells and natural killer cells rather than in direct response to virus [303]. Detection of viral components triggers protein signaling cascades that regulate IFN synthesis through the activation of viral stress-inducible genes (VSIGs) [301, 304]. These are sometimes expressed constitutively but upregulated after IFN induction following HRV infection [305]. Released IFN-ß binds to the IFN-α/IFN-ß receptor in an autocrine (the same cell) and paracrine (neighboring cells) manner, starting a positive feedback loop for type I IFN production, the "second wave." VSIGs include the antiviral proteins protein kinase R (PKR), 2′5′OAS/RNaseL, and the Mx proteins [306]. IFN-α upregulates expression of MxA, 2′4′-OAS, and PKR [307]. The Mx pathway is also induced after virus infection but is not constitutively expressed [307]. Depending on the sentinel system stimulated, there are different pathways to VSIG activation. Those VSIGs with antiviral properties (e.g., MxA, PKR, 2′5′OAS/RNaseL) inhibit different stages of virus replication and strengthen an antiviral state in the host. While this state is well known, the nature of its induction by different respiratory viruses and the impact of induction upon the replication of other respiratory viruses are topics for considerable ongoing research.

One pathway to IFN induction relies on the IFN-upregulated cytosolic sentinels retinoic acid inducible gene RIG-I-like receptors (RLRs) RIG-I (specific for IFAV and others) and melanoma differentiation-associated gene 5 (MDA5, specific for picornaviruses and others) [306, 308]. These RNA helicases recognize either RNA with a 5′-triphosphate or distinct dsRNAs, which results in activation of NF-κB leading to "classical" type I IFN induction [301, 306]. Studies into the innate response to HRV infection have been limited to the use of a very few easily cultured types. It is presumed that the result can be extrapolated to most if not all types. This is yet to be tested. RIG-I is degraded by HRV-A16 [309], IFN regulatory factor (IRF)-3 homodimerization is interfered with HRV-B14 which limits IFN-β induction [310, 311], and MDA5 is degraded by HRV-A1a but not HRV-A16 [312].

Another pathway for recognizing HRV infection involves the Toll-like receptors (TLRs), transmembrane PRRs that terminate in an intracellular signaling region. The endosomally localized TLR3, TLR7, TLR8, and TLR9 recognize nucleic acids and are also involved in innate antiviral responses. TLR7 and TLR8 identify G/U-rich ssRNA from endocytosed viruses, while TLR9 recognizes unmethylated CpG DNA present in DNA viruses [301, 318]. TLR2 and TLR4 are found on the cell surface and recognize HRV or HRSV proteins, respectively [318, 319], and TLR3 recognizes dsRNA. TLRs operate mainly, but not exclusively, in plasmacytoid DC [301]. The particular TLR that notifies of an HRV incursion may depend on the method of virus approach [319]. TLR7 activation can reduce 2′5′OAS and MxA mRNA expression and IP10 protein in adolescents with asthma compared to healthy controls [320]. TLR3 activation did not result in a similar disparity [320].

It has been suggested that HRVs may have evolved with humans to such an extent that their symbiotic relationship serves to help train the human immune system [321]. Intriguingly, within the HRV species, there are differences in the type and level of host response induced [322] which may reflect receptor usage, route of entry and cell type infected, HRV species, or the degree of laboratory-adapted virus used during in vitro studies.

7.2 Cellular Immunity and Inflammation

After initial HRV infection, the innate response results in production of proinflammatory cytokines, vasoactive peptides, and chemokines that attract leukocytes, granulocytes, DCs, and monocytes (Table 29.2) [321, 323, 324]. The T-lymphocyte response to viral intrusion can be broadly categorized as T_H-1-like and T_H-2-like. Other T-cell subsets exist, but most work in relation to HRV has been conducted on the earliest defined subsets. The T_H-1 cellular response is important in managing cellular immunity and producing interleukin (IL)-2 and IFN-γ. The T_H-2 cellular response manages humoral immunity and stimulates B cells via IL4 (initiating production of IgE), IL5 (influencing eosinophils), and IL13 (crucial component of allergen-induced asthma). These two T-cell responses act in concert with epithelial-derived chemokines (e.g., eotaxin) to promote the recruitment and activation of eosinophils and mast cells, contributing to chronic airway inflammation and the hyperresponsiveness of airways to a variety of nonspecific stimuli [325]. T_H-2 lymphocytes, opposing T_H-1 lymphocytes, contribute to an allergic inflammatory cascade, akin to what occurs to rid humans of parasites [326]. The T_{H-1} response can also be repressed by binding of microRNA, which leads to an altered balance favoring a T_H-2 state in mice and probably in humans [327]. Regulatory T cells (T_{reg}) suppress allergic inflammatory pathways and are therefore fundamental in protecting the airway from allergen sensitization [326].

Considerable immunobiological research has focused on asthma exacerbation, with which HRVs are intimately involved. Although upregulated by HRV infection, the T_H-1 response is comparatively deficient in people with asthma [328, 329]. This is problematic as an increased T_H-1-like cytokine response, deduced from higher sputum mRNA IFN-γ/IL5 values, speeds clearance of HRV and symptom amelioration [85]. One possible cause of the T_H-1 deficiency in people with asthma is inadequate maturation of type I and III IFN responses due to reduced exposure to infections early in life [330]. The

Table 29.2 Some important molecules involved in the response to HRV infection

Molecule	Role
IFN-α/IFN-β (type I IFN)	Produced by leukocytes and BECs; numerous subtypes; immunomodulator
IFN-γ (type II IFN)	Produced by many cell types after viral infection, especially BECs, PBMC, and DCs; a key T_H1 cytokine in intracellular defense through stimulation of antiviral molecules; macrophage and NK cell activation and B-cell proliferation
IFN-λ (type III IFN)	Participates in creation of an antiviral state; produced by and influences the maturation of DCs
IL-1β	Proinflammatory properties; enhances adhesion molecule expression including ICAM-1; induces IL-2 receptor
GM-CSF	A granulocyte and monocyte growth factor
IL-2	Stimulates growth and differentiation of T and B lymphocytes and cytotoxic activity of NK cells and monocytes
IL-4	T_H2 differentiation, promotes IgE synthesis
IL-6	Activation, differentiation, and proliferation effects on T and B lymphocytes; induces C-reactive protein stimulating pyrexia
IL-8/CXCL-8	Neutrophil chemoattractant resulting in neutrophilic, monocytic, and lymphocytic recruitment and degranulation activity
IL-10	Anti-inflammatory factor produced by monocytes that acts by inhibiting proinflammatory cytokines IL-1, IL-6, and TNF-α
IRF7	A master hub, regulating antiviral immunity
IP10/CXCL10	Chemoattractant for activated T_H1 and NK cells
TNF-α	Proinflammatory activity similar to IL-1 β; activates neutrophils; induces vascular permeability
MPC-1	A monocyte attractant
Bradykinin	Potent inflammatory mediator, increases vascular permeability
TSLP[3]	An IL-7-like cytokine that activates myeloid DCs to induce naive T cells into T_H2 cells producing IL-4, IL-13, and TNF-α; induced by HRV in the presence of IL-4

BEC bronchial epithelial cells, *DC* dendritic cell, *IRF* interferon regulatory factor, *IFN-γ* inducible cytokine protein, *NK* natural killer, *PBMC* peripheral blood mononuclear cells, *IL* interleukin, *TNF* tissue necrosis factor, *TSLP* thymic stromal lymphopoietin

"hygiene hypothesis" [331, 332] posits a pathway for an asthma etiology described [325] in terms of the young, unchallenged immune system, dependent on infections to stimulate the development of its T_H-1-like functions. One theory suggests that HRVs play a central role in developing that efficacious antiviral immunity, particularly in infancy, via their frequent, usually mild self-limiting infections [333].

Genome-wide expression analysis of BECs from healthy and asthmatic adult subjects after HRV-A1a infection revealed some significant differences that were found between cell types and response to infection [61]. These included immune response genes (IL1B, IL6, IL8, IL1F9, IL24) and airway remodeling genes (LOXL2, MMP10, FN1) and an overall proinflammatory response and metabolic slowdown consistent with proteolytic cleavage of transcription factors by some HRVs [133, 334–336] in the infected cells. This study further noted some similarities to gene expression changes observed in brushings from people with mild asthma after allergen exposure and in BAL cells from subjects with corticosteroid-resistant asthma [61]. Overall, HRV replication and the host transcriptional response to it were similar in normal or asthmatic BEC cells [61]. This indicated, at least in adults, that something beyond the epithelial cell is an important contributor to more severe clinical outcomes in asthma.

The application of inactivated HRV-B14 was found to promote release of IL10 from monocytes (an immunosuppressive cytokine) and to inhibit the stimulation of IL12 (drives T_H-1 development) [337]. However, neither IL10 nor IL12 was significantly induced in asthmatic adult volunteers in response to HRV-A16 compared to healthy subjects [338]. While IFN-α was detected after transfection of DCs with HRV-B14 ssRNA, low TNF-α and IL12 levels were also noted [16]. It was posited that the reduced IL12 could indicate negatively affected local immunity possibly predisposing to secondary infections [337]. Infection of stromal lung cells by HRV-B14 triggered exaggerated levels of the pleiotropic IL11 (an IL6-type cytokine), akin to those triggered by HRSV, which were also detected in nasal secretions from children with wheezing [339].

Other cytokine changes have been identified in atopic adult volunteers challenged with HRV-A16. G-CSF and IL8 (chemo-attractant for neutrophils) levels rose in the URT (as examined by protein detection in nasal lavage) and LRT (mRNA detection in sputum) with concomitant rises in blood and nasal neutrophil numbers [85, 203, 340]. The nasal epithelial cells of atopic individuals, especially in season, express more ICAM-1 than those of nonatopic adults [341] as do normal subjects infected by the major group HRV-B14 [341]. By contrast, IFN-γ and IL8, which appear later postinfection, downregulate ICAM-1 expression in infected cells [191] and encourage infiltration of neutrophils [342], respectively. Changes in ICAM-1 levels may modify

T-lymphocyte-mediated cytotoxic or T_H interactions with HRV-infected cells, upregulating receptor expression and encouraging eosinophil and T-cell infiltration into the lower airways of asthmatic individuals [187, 343].

7.3 Antibodies

Before an HRV can enter a cell, it must pass through a defensive barrier of secreted anti-HRV antibody, mostly IgA. The ease with which this passage occurs is proportional to the progression of clinical disease. Healthy adult volunteers were found to develop IgA by at least 3 days to 2 weeks after inoculation—about the same time as serum antibody—and retain peak levels for at least 8 weeks [178, 344–346], falling faster than serum levels [347, 348]. There is also some evidence for a degree of nasal immune memory [347]. Volunteers with pre-study serum antibody could still be infected in some studies [46, 210, 292], but not in others [349]. Infection is more clear in volunteers without preexisting nasal antibody to experimental challenge virus; they become infected, exhibit more severe ARI, and shed more virus for longer [292, 347]. IgA does not seem to modify illness severity or virus shedding, but high levels prevent reinfection by the initiating virus type. Low levels or absence of IgA does not prevent reinfection by the same HRV type, which may manifest as symptomatic or asymptomatic disease [349].

Older children, adolescents, and adults have greater amounts of HRV-neutralizing antibody than young children [42], accompanying a trend toward decreasing numbers of symptomatic ARIs with increasing age [218, 350]. This feature raises an issue: did the use of older subjects in many common cold studies underplay the pathogenic potential of the HRVs because protective or partially cross-protective antibodies moderated the impact of infection? Consequently, quantifying levels of type-specific serum antibody became routine practice prior to some studies. Adult volunteer studies determined that no infections resulted if preexisting neutralizing antibody titers ≥1:16 existed; as levels grew from 0, so did levels of resistance to infection [43, 210]. Adults were protected by serum titers of 1:3–1:8 [209, 210]. The trend was interrupted by adults in the 20–39 year age group, presumably because they had begun families and their young children acquired and amplified currently circulating types from the community and transmitted them into a household that was either immune naïve or lacking sufficient antibody or cell-mediated memory for protection [351].

Traditional vaccine strategies were quickly ruled out as a prophylactic intervention for HRV illness because of the extensive antigenic variability that is a hallmark of the genus *Enterovirus* [178, 325]. However, if it were possible to identify "master" strains [352] that exhibit sufficient antigenic cross-reactivity to induce broad heterotypic responses against many other HRV strains, then an effective vaccine could still be possible. In fact, boosting host immunity to an HRV type by repeat infection does heighten immunity to one or more other types [44, 353]. The highest of these heterotypic antibody titers develop against those types with the highest preexisting antibody levels [352]. The first description of a unifying HRV numbering system recounted the appearance of minor serological cross-reactions, which were removed by modification of the technique [57]. Subsequently, cross-reactions were better defined during experimental inoculation when multiple HRV immunogens and antigens were used to deduce the extent of heterotypic responses [56, 210, 352, 354].

Less promising for HRV vaccinology was the description of antigenic variation within HRV types which suggested that immunity to one variant of the type might not protect against infection by other variants [355, 356]. The "prime strain" is a specific antigenic variant of a prototype HRV type that is neutralized to a lesser extent by antisera from the prototype, while yielding antisera that effectively neutralize both itself and the prototype [357]. Another form of this cross-neutralization is ascribed to the "intertypes," which are HRV isolates that share a lower-level serological relationship with a pair of HRV strains, which themselves share neutralizing reactivity, e.g., HRV-A36 and HRV-A58 [358]. The low-level reciprocal neutralizing activity was not equivalent in both directions; anti-HRV-A36 sera had a higher titer for HRV-A58 than anti-HRV-A58 sera did for HRV-A36 [358]. Over 40 strains were linked directly by such one- or two-way cross-reactions or indirectly through two or more strains. HRV-A67 and HRV-A28 are linked via HRV-A11, HRV-A13, and HRV-A32 (anti-A11 serum neutralizes HRV-A28, anti-A13 neutralizes HRV-A11, and anti-A32 neutralizes both HRV-A13 and HRVa-A67[358, 359]). A surrogate molecular method which provided insight into these interrelationships, perhaps expanding upon them to identify useful patterns for vaccine immunology purposes, would be most welcome.

In summary, heterotypic immunity and HRV intertypes might be exploitable features of HRV immunobiology that could confer maximum protection upon the host from the minimum number of HRV types [358].

8 Pathogenesis and Host Response

HRVs circulate in great numbers, and any specific roles for distinct HRV types in initiating disease remain to be defined. The relatively inconsequential common cold is the most frequent manifestation of viral infection in humans, with 30 to >80 % of colds positive for an HRV [69, 360, 361]. Furthermore, ARIs due to HRV infection can exacerbate or

result in a much greater burden of disease in those with asthma, COPD, or cystic fibrosis. Other complications include otitis media, pharyngitis, and wheeze in atopic people without asthma. The role of viruses in the origin of some of these diseases or their exacerbation is still unresolved. The LRT disease may mask the URT nature of the infection, favoring clinical diagnosis of an LRT illness. Interestingly, during the 2009 H1N1 pandemic, much of the parent-initiated healthcare visits from a birth cohort in the United States were not due to pandemic virus but HRV and HRSV [362]. There is no known natural murine rhinovirus on which to base a small animal model of HRV infection, and mice are not natural hosts for HRVs. A recently developed model of airway disease using mengovirus (a Picornavirus infecting rodents) may yield valuable in vivo airway infection and inflammation data [363].

HRVs are often detected in neonates and infants with LRT signs and symptoms because the very young have narrow, immature airways and are more significantly affected by airway swelling, excessive secretions, and smooth muscle contraction [364]. This may also be due to the relatively naive immunity of very young children. Much of the more severe disease in HRV-positive children occurs in the youngest of them. Some key examples are addressed below.

8.1 Common Cold

For the common cold, as for any illness, accurate epidemiology and burden of disease data underpin the prioritization of preventing, treating, and further researching the etiological agent. To assign funds for researching the agent, health policy makers also need to understand how efficacious and cost-effective the development of an intervention will be [365]. The host immune response to HRV replication is the main cause of the signs (quantifiable fever, rhinorrhea) and symptoms (feeling of fever, myalgia, headache, fatigue, and mood change) of a cold that the host experiences [321, 366, 367]. A feature of common colds is increased vascular permeability which, enhanced by kinins, results in increased plasma protein (albumin and immunoglobulin [Ig] G) levels in mucus, approaching the levels in serum [368]. Histamine levels do not rise in nasal secretions of otherwise healthy cold sufferers [368]. During the resolving phase of the ARI, glandular proteins (lysozyme, sIgA) predominate [346].

The common cold syndrome is also described as rhinosinusitis (the agglomeration of rhinitis and sinusitis since they frequently clinically coexist) [369, 370]. This consists of nasal discharge or rhinorrhea, nasal obstruction, sore throat, sinus pain, headache, sneezing, watery eyes, cough, fever, fatigue, muscle aches and pains, and mood changes [367, 371]. These are caused directly or indirectly by viral infection; cough is the result of vagus nerve irritation by mucus; sneeze results from trigeminal nerve irritation; sore throat is likely due to the action of prostaglandins and bradykinins; and fever, psychological effects, fatigue, and myalgia are mediated by cytokines [367]. Hypertrophic adenoids have also been found to have a high proportion of viral, especially HRV, occupation regardless of host symptomatic state [372]. Observation of natural culture-confirmed HRV colds in adults noted that cough usually started by day 1 and was more persistent up to 9 days later [264, 373]. Rhinorrhea, sneezing, and sore throat were reported by half or more of patients and headache by at least a quarter of cases [207, 373]. As neutrophils accumulate at the site of primary URT infection, the myeloperoxidase in their azurophilic granules creates the yellow-green coloration of nasal mucus that was once considered a sign of bacterial superinfection [271, 367]. A common cold caused by an HRV cannot be clinically distinguished from one that caused by any of the other respiratory viruses [207, 371]. As is likely for a single HRV type, once the host has been infected by an HMPV, HPIV, IFV, etc., a secondary exposure to that same virus type will produce less severe clinical outcomes due to pre-primed host immunity.

8.2 Asthma and Atopy

Asthma is a clinical diagnosis made on the basis of patient history, physical examination, assessment of airway obstruction or reversibility, and response to bronchodilators [374]. It is a complex chronic respiratory disease involving airway inflammation, airflow obstruction, and airway hyperresponsiveness, which manifests as recurrent reversible attacks with deteriorating asthma control that are generated by interactions between infectious agents and other environmental and genetic factors that remain incompletely characterized [375]. The mechanistic role for HRVs in asthma inception and exacerbation is not yet defined [364, 376] but is being revealed as the extremely complex interplay between inflammation due to virus versus that due to atopy is explored [315]. Possible virus-host interactions include (i) severe HRV infection of healthy infants which may result in subsequent development of asthma; (ii) HRVs may trigger asthma in children with a genetic predisposition toward atopy; (iii) repeated mild infections may protect against more asthmogenic/cytopathic viruses or the overdevelopment of the T_H2-type response; and (iv) HRVs may simply exacerbate that which already exists [377]. It is unclear if the risk of atopic asthma during infancy is increased by ARIs which affect the development of the immune system, or whether ARIs lead to asthma development in children with a genetic predisposition to more severe responses to infection [325, 343, 378], or a mix of both. In children with asthma, viruses have been detected in at least 77 % of exacerbations (65 % picornaviruses, probably HRVs [379]) and in 50 % of adults [380].

Acute wheezing episodes (including bronchiolitis and acute asthma) are a frequent, epidemic, and seasonal LRT manifestation of URT respiratory virus infection of children from all ages, especially during the first year of life [214, 381–385]. Bacteria are not major factors in wheezing exacerbations [386]. Wheezing is blamed for high socioeconomic and healthcare costs, overuse of antibiotics, being the primary cause of hospitalization among children, and, rarely, for death [109, 387, 388].

Traditionally HRSV infection has most often been the virus causally associated with expiratory wheezing, wheezy bronchitis, or asthma exacerbations because of the virus's well-known ability to infect the LRT, its more frequent detection in some studies [386], and the low perceived likelihood of URT viruses such as HRVs replicating in the warmer LRT. Nonetheless, periods of epidemic wheezing in the absence of high rates of HRSV detection are common [383, 389]. HRVs even predominated in some culture-based studies of wheeze [384, 390]. The COAST study used sampling criteria that were intentionally designed to investigate the role of HRSV in illness, but instead indicated that HRVs were the most important predictor of subsequent wheezing in early childhood, and this is supported worldwide [224, 391, 392].

The asthmatic airway is characterized by an infiltration of eosinophils and Th2-type T cells (Th2 cells) [393]. In those with an atopic background, eosinophilia was more common, and the virus isolation rate was higher than in the nonatopic group [394]. The cytokine and eosinophil activation profiles for HRSV-induced wheezing differ from those induced by HRV in which IL5 is significantly higher in serum and nasal aspirates than for HRSV [118]. IP10 was the only cytokine significantly elevated in all symptomatic wheezing groups [118]. Significantly higher rates of HRV detection with more obvious LRT symptoms are more common in children with asthma than in non-asthmatic populations [380, 388, 395, 396]. Exacerbations of asthma are often preceded by a symptomatic rather than asymptomatic HRV infection [17, 379, 388, 397–399] although, in some instances, an exacerbation is the only sign of infection [400]. Reduced peak expiratory volume in children is especially associated with detection of respiratory picornaviruses [379]. Severe "wheezy bronchitis," a historical term describing an acute illness with preceding ARI and characterized by cough, wheezing, breathlessness, and mucous production, was more often positive for a virus than mild disease [394]. Even the use of culture found that HRVs predominated in both URT and LRT (sputum containing BECs) or combined respiratory tract samples [394]. Bacteria were often present with IFV, but not with HRVs [394].

The airway epithelial cells form a physical barrier in addition to their roles in immune surveillance and regulatory control [393]. However, the asthmatic bronchial epithelium is compromised by incomplete tight junctions that are more sensitive to airborne pollutants [401] and most likely to allergens and respiratory viral infections. This is further specifically disturbed by HRV infection which reduces expression levels of tight and adherens junction proteins [402]. In those with asthma, the presence of an HRV can induce illness that, while often more severe than in non-asthmatics, has been associated with significantly different HRV load or duration of HRV RNA detection in people with asthma compared to those without [403]. HRV-C types are often detected in more serious clinical outcomes than HRV-A or -B [265] although hospitalizations may be fewer for HRV-Cs than the other species [404].

8.3 Acute Otitis Media

AOM is diagnosed by middle ear effusion (otorrhea) with simultaneous signs and symptoms of ARI including fever, earache, rhinitis, cough, sore throat, chest wheeze, nocturnal restlessness, irritability, poor appetite, diarrhea, and vomiting. Transient abnormal (negative) ear pressure upon tympanometry occurs in two-thirds to three quarters of uncomplicated colds among healthy children [405, 406]. AOM is a frequent reason for outpatient antibiotic therapy which can reduce the time to resolution of symptoms in infants and has been attributed to reducing the overall hospital burden of AOM [407–412]. Since a longitudinal day-care study in 1982, the association between AOM and viral URT infection has been coalescing, and it is now clear that AOM often occurs with or shortly after a viral ARI, most frequently in the young and occurring more often during winter than summer [413, 414]. The use of influenza vaccines reduced AOM occurrence by a third during an epidemic period [415], but the use of pneumococcal vaccine did not reduce the occurrence of AOM overall, just that relatively small fraction (6 %) due to the target bacteria [416]. The isolation by culture and PCR detection of viruses from middle ear fluids and the refractory nature of some AOM cases to antibiotic therapies confirmed that viruses play an important role in this illness [409, 414, 417]. Studies relying on underperforming culture-based techniques underestimated the role for viral ARIs [414, 418], but other studies using PCR techniques and including HRVs found them to be the most frequently detected virus in middle ear fluids and nasopharyngeal secretions [409, 417].

The use of PCR has identified respiratory viruses, most often HRVs, in nasal secretions of 50–70 % of children with AOM [66, 413]. Because virus is often detected in the nasopharynx at the same time as the middle ear fluid, the question of the relevance of a PCR positive is a valid one [419]. Picornaviruses have been detected in 30 % of nasopharyngeal swabs taken during cold season from AOM-prone

infants and young children, and large quantities of HRV RNA have been detected by in situ hybridization of adenoid tissues from 65 % of children with recurrent AOM and/or adenoid hyperplasia [259, 420]. In a cohort of children followed from 2 to 24 months and using culture-RT-PCR, HRVs in the URT were the second most frequent pathogens associated with AOM, after HRSV [66]. Viruses, most often HRVs (30.8 % of AOM with ARI), were also detected concurrently with non-ARI periods associated with AOM episodes (14 % of AOM without ARI)[418] suggesting that AOM may be the only manifestation of some HRV ARIs, just as wheezing sometimes is. In the United States, 180 subjects were enrolled and followed in a birth cohort until the first AOM episode or between 6 and 12 months of age 362]. HRVs accounted for 55 % of viruses detected and 69 % of specimens with a single virus detected. This dominance was maintained even through the 2009 H1N1 influenza pandemic [362].

In the day-care AOM study mentioned above, primary acquisition of *Streptococcus pneumoniae* or *Haemophilus influenzae* had minimal importance as an initiation factor for AOM with effusion, but nasopharyngeal colonization was important [413]. Animal studies have shown that virus-bacteria interactions have a role in nasopharyngeal colonization and AOM development [414]. Positive correlation has been made between HRV detection in AOM-prone children and *Moraxella catarrhalis* infection as well as a tendency toward the copresence of *Streptococcus pneumoniae* [259]. The presence of HRV-B14 was shown to increase adherence of *S. pneumoniae* in human tracheal epithelial cell cultures [421]. It is believed that these three bacterial pathogens can colonize without symptoms until a viral ARI shifts the balance toward a cytokine-mediated inflammatory state [419].

8.4 Other Diseases in Which HRVs Are Often Detected

8.4.1 Chronic Obstructive Pulmonary Disease

This disorder of older patients encompasses emphysema (alveolar destruction) and chronic bronchitis (large airway inflammation with chronic mucous production) and describes a long-term obstruction to airflow in the lung (compared to asthma which is a reversible obstruction with normal flow between exacerbations). While bacteria are found in half of all exacerbations, antibiotic therapies have often yielded poor outcomes [422]. HRV infections result in more COPD exacerbations (~66 % of cases [92]) than any other virus identified to date [422, 423]. An experimental human model of HRV infection in COPD provided preliminary evidence that HRVs cause exacerbations [286]. Viral culture associated symptomatic HRV infections with exacerbations among chronic bronchitics, including cases of isolation from sputum (LRT sample) in the absence of HRV in the URT [424]. Adding the measurement of an inflammatory marker in the serum, like IL-6, further improves the speed of predicting an infectious etiology for exacerbations of COPD [425].

8.4.2 Pneumonia

Pneumonia is a disease that often occurs early in life, is responsible for millions of deaths each year [426], and is caused by viral and/or bacterial infections. A diagnosis of pneumonia requires a radiologically confirmed inflammatory infiltration of the lung tissue. Childhood community-acquired pneumonia (CAP) is common in developing countries [427]. CAP also complicates existing chronic medical conditions and takes advantage of immunosenesence [428].

The role of HRVs in contributing to the development of bacterial pneumonia is likely underestimated [426, 429]. Determining an etiology is confounded by the rarity of obtaining LRT specimens, by short-term studies, and by the complex milieu of viruses and bacteria involved. Less invasive sampling of the URT permits more routine sampling and screening, and so convenience and reduced risk have led to the detection of putative pathogens in the URT with the general assumption that they account for LRT disease, especially in children under the age of 5 years [430]. Pneumonia studies are complicated by the lack of a suitable control group; sputum is not produced from the healthy lower airway and needle aspiration, while a gold standard is also a hospital procedure with some risk [431].

Studies that are comprehensive and use sensitive molecular testing are also rare for the study of CAP etiology. When used for CAP investigations, PCR methods almost double the microbiological diagnoses over conventional culture and serology techniques, especially improving the identification of mixed infections and fastidious viruses [432]. Rapid diagnosis aids management and helps make decisions about treatment, while prolonged searching for an etiological agent leads to further invasive testing [256, 433]. At least a quarter of clinical CAP cases remain unsupported by microbiological findings [241, 432].

Infections causing pneumonia vary with age and vaccination status [433]. Viruses can be detected in up to 90 % of infants (1–12 months of age) with pneumonia, and these cases follow a seasonal pattern [427, 433]. Bacteria can also be detected in over 90 % of infants and older children, the elderly, and those with severe CAP [432, 434]. Studies that predated the use of PCR pronounced HRSV, followed by HRVs, the major viral contributors to CAP, with viruses comprising 27–72 % of childhood pneumonia cases [429, 434]. In the PCR age, the role of HRVs has received increasing attention, and they are increasingly the major viral group detected from both URT and LRT (sputum) specimens of children with CAP. This holds true even when studies extend across 1 or more years, which presumably

would account for seasonal variation in virus prevalence [241, 256, 426, 434]. It is suspected that viruses such as HRV prepare the way for subsequent bacterial infection in some direct or indirect fashion [65, 259, 420, 435]. There are laboratory data which support this [436] as well as observational data showing a high proportion of HRV-bacterial co-detections [256, 437].

Mixed infections including viruses are a possible cause of antibacterial treatment failure and sometimes a puzzle for physicians. Mixed infections occur frequently in LRT diseases such as pneumonia, which is not surprising since new techniques make it clear that the lungs are not the sterile environments we once thought [427, 434, 438, 439]. Viral-bacterial coinfections can comprise 15 % of patients, while viral-viral (2–30 %) and bacterial-bacterial (1–7 %) are much less common [230, 241, 256, 434, 437]. HRSV or HRV is often co-detected with *S. pneumoniae* in URT samples [256, 437, 440]. HRV detections dominate in younger children with pneumonia during peak HRV seasons, although frequently in co-detections with other viruses [230].

8.4.3 Acute Bronchitis

Acute bronchitis (less than 4-week duration in children) is defined as a sudden cough that often results from large airway infection and frequently involves viruses. Croup or laryngotracheobronchitis (viral or recurrent [441]) is a common LRT illness in children that includes the trachea and larynx as well as the larger airways, resulting in a barking cough. Patients with croup most often have a viral infection with some role for HRVs, although the extent of this is unclear [441, 442]. Despite testing, a third of cases remain without a viral etiology [441]. Tracheobronchitis resulted from some HRV-A15 infection of volunteers [46]. Chest pain and cough have been reported in half or more of adults with HRV infection [207] as well as in children and adults with HRVs detected during exacerbations of bronchitis, with or without an associated ARI [443, 444].

8.4.4 Bronchiolitis

Bronchiolitis occurs seasonally, especially in winter, in infants (1–12 months of age), affecting the small peripheral bronchioles. Winter is the peak season for HRSV circulation, but not usually for HRV. Bronchiolitis is a clinical diagnosis encompassing various disease entities and is most often reported in association with detection of HRSV, a winter virus [445, 446]. However, HRVs make up the majority of HRSV-negative bronchiolitis cases [128], and HRVs are co-detected with HRSV for which hospitalization is prolonged compared to cases positive for either virus alone [447]. Those children positive for an HRV during a clinically diagnosed bout of bronchiolitis have a significantly higher risk of recurrent wheezing in the subsequent year than those in whom another virus is detected [446]. HRVs were reported in over fivefold more cases of bronchiolitis than HRSV among patients in a 2-year prospective cohort of very low birth weight infants in Buenos Aires, Argentina [448].

8.4.5 Sinusitis

After a viral ARI, some proportion of infections may be complicated by sinusitis (inflammation of the sinus mucosa), the extent of which may be underestimated in children if the ARI is mild and unattended by parents [11]. Symptoms may include sinus pain, headache, facial pain, discolored nasal discharge, postnasal drip, cough, sore throat, malaise, and sometimes fever (more so in children) [367, 449]. The precise role for viruses and bacteria in sinusitis is still unclear [450]. Sinusitis is a common comorbidity in those with asthma [451]. The in situ presence of HRV-B14 RNA in maxillary sinus epithelium was reported in seven of 14 adults with acute sinusitis [452]. HRVs were also detected by PCR in half of adults with acute maxillary sinusitis; half of the HRV positives were negative for any bacteria [65]. The common cold is often associated with computed tomographically confirmed sinus cavity occlusion or abnormality in adults with self-diagnosed ARIs [367, 453]. Magnetic resonance imaging identified reversible abnormalities of the paranasal sinuses in a third of healthy adult volunteers following challenge with HRV-A39 [454]. Further evidence of the tropism of HRVs for sinus tissue comes from it being, so far, the only successful host for in vitro HRV-C replication [63].

8.4.6 Cystic Fibrosis

Culture- and serology-based testing has shown that virus infections in cystic fibrosis (CF) patients occur with the same prevalence as the general community, but the consequences of infection are more obvious or severe. These include deterioration of lung function, cough, increased expectoration and weight loss, and a synergistic increase in bacterial growth or acquisition of new bacterial infections [107, 455–458]. The mechanism behind the acquisition of new bacteria is still unknown and not always observed [459], but may involve a reduction in the host's immune response or viral damage to the respiratory epithelium. There is circumstantial evidence that HRV infections have been associated with respiratory exacerbations in cystic fibrosis patients [459, 460], albeit in very low numbers by nonmolecular studies [461] and without a significantly different clinical outcome from non-HRV ARIs in these patients [107]. Molecular methods have not yet been applied regularly, thoroughly, and systematically, but they generally find HRVs to be prominent among CF children

with ARI-associated respiratory exacerbation and involved in mixed viral-bacterial infections [459].

9 Control and Prevention

Hand washing and disinfectant wipes have been shown to be effective methods of interrupting transfer from fomites to the nose or to conjunctivae [87, 288, 293]. However, with eye rubbing, face touching, and nose-picking occurring frequently [47, 290], self-inoculation often outpaces personal hygiene, particularly in the young.

Hand disinfection is frequently recommended for prevention of HRV infection but has not been supported by controlled clinical trials in a natural setting [462] despite good results in experimental tests [463]. Ethanol-containing disinfectants were more effective than simple hand washing with soap and water for removal of HRV-A39 inoculum, as assessed by culture, and the inclusion of organic acids afforded a residual antiviral effect [463–465]. However, continual hand washing with extra ingredients resulted in skin irritation [462]. The experimental testing [463, 464] may have been biased by short study periods, the absence of a mucus carrier to mimic natural surface deposition and overly stringent control over virus application/hand disinfection compared with the natural study. Additionally, the natural setting study used PCR [462] which detects HRVs more often than culture. The disparity between outcomes may also reflect the contribution of airborne HRV transmission.

Because of the absence of a vaccine or specific antiviral, the most popular method of intervention in uncomplicated HRV ARIs is treatment of the symptoms. This is achieved using analgesics, decongestants, antihistamines, and antitussives. Due to a lack of studies, data are limited on the effectiveness of over-the-counter common cold medications for children [466]. Anticholinergic agents have proven useful to reduce rhinorrhea [467]. For controlling symptoms in those with exacerbated asthma, most of which do not require hospitalization, bronchodilators and oral corticosteroids are the main treatments [468]. The interruption of proinflammatory immune responses or specific signaling pathways using steroids, or other novel therapeutics, may prove to be a more robust approach for treating HRV infections; they have not been successful for HRSV [325].

When initiated early in the illness, a combination of antiviral (IFN-α2b) and anti-inflammatory (chlorpheniramine) components showed promise for interrupting nasal viral replication and symptoms [469].

Antiviral agents (Table 29.3) require early application to effectively precede the pathogenic immune response to HRV infection [325], but they often fail to reproduce their in vitro successes in vivo. Most antirhinoviral drugs are based on capsid-binding agents (Fig. 29.11). Additionally, oral delivery can complicate drug safety because this route increases the risk of systemic side effects compared to a nasal or topical route, but these risks must be considered alongside the disease to be treated; drug side effects are disproportionately severe compared to a common cold than to a severe asthma exacerbation. A systemic route is beneficial if an effect is sought on HRV replication sites that are otherwise inaccessible, such as those not associated with respiratory tract illness [470].

10 Unresolved Questions and Problems

The recent discovery of the new species, HRV-C, has shone a bright light on how little was known about the HRVs. The HRV-Cs and also the newly discovered HRV-As and HRV-Bs are fastidious in culture, with a single report of HRV-C growth in primary sinus tissue, and the identity of a cellular receptor still unknown. Thus, it is difficult to proceed in many areas, including basic virology, seroepidemiology, immunobiology, and antiviral testing. Determination of the receptors for these new HRVs would aid the search for a more accessible culture system. There would be great interest in a vaccine for some or all of the HRVs, but with increasing evidence of the interactions between HRVs, their hosts, and other respiratory viruses, it may not be wise to interfere before we fully understand what the impact of losing a constantly circulating HRV challenge would be. Antivirals specifically targeting the HRVs may be a better bet, but routine HRV testing and genotyping will first need to be more widespread as surveillance for antiviral resistance will be an important component of monitoring the success of any intervention.

Studies to determine whether there are differences in clinical and immunobiological impact between the many different types are lacking but would greatly improve our ability to plan future routine testing, understand all the clinical responses to the diverse HRVs and to outbreaks of ARI, and improve HRV epidemiology. It is interesting to note that the HRV-Bs are significantly underrepresented in HRV detections. We do not yet know their niche or clinical impact. It may be possible that HRV-Bs are the most well adapted of the HRVs, causing little to no detectable clinical impact, or they may create a different impact than that which we expect, or they may be a species in decline.

The jury remains out on whether HRVs cause or are involved in the development of asthma or merely trigger exacerbations once asthma is established. With a very high healthcare impact from asthma around the world and atopic conditions that may be exacerbated by HRVs on the rise, this is an important area for further investigations.

Table 29.3 Preventive and therapeutic compounds affecting HRV infections

Therapeutic agent	Primary role	Effect	Evaluation	Reference
IFN-α	Elicit cellular antiviral effects	Decreased shedding if administered within 24 h	Toxicity	[471–475]
Pirodavir (R77975)	Capsid binder	Intranasal formulation useful against both HRV antiviral groups; three to six doses per day	Variable efficacy, irritation, and mucosal bleeding	[471, 476, 477]
WIN54954	Capsid binder	Broadly active in mice	Reduced efficacy in humans	[471, 478]
WIN56291	Capsid binder	Active against HRV-C15	Effect only in organ culture so far	[161, 479] [63]
Pleconaril (WIN63843)	Capsid binder	Resolved symptoms 1–2 days earlier than placebo. Some types are resistant	FDA issued "not approvable" letter because of side effects	[471, 477]
Vapendavir (BTA798)	Capsid binder	Potent binding in animal models	Good bioavailability and safety profile in animals. Phase IIa trial complete	[477, 480]
Rupintrivir (AG-7088)	3C protease inhibitor	Insignificant impact	Discontinued	[470, 471, 481, 482]
Enviroxime	Replication inhibitor	Potent anti-replicative activity in vitro	Side effects in vivo	[406, 472]
Tremacamra	Soluble ICAM-1 molecule	Could reduce experimental cold symptoms and the quantity of virus shed if administration occurs before or after inoculation but prior to the development of symptoms		[483]
Tiotropium	Anticholinergic agent (bronchodilator)	Reduced HRV-B14 viral load and RNA levels, decreased susceptibility of cells, reduced ICAM-1 mRNA levels and IL-1β, IL-6, and IL-8 protein levels in culture	No obvious change to cell viability in culture	[484]
Levofloxacin	Quinolone antibiotic	Reduced HRV-B14 and HRV-A15 viral load (major group HRVs; not the minor group virus, HRV-A2) and RNA levels, decreased susceptibility of cells, reduced ICAM-1 mRNA levels and IL1β, IL6, and IL8 protein levels in culture	No obvious cytotoxicity in culture	[485]
Pellino-1	Regulates IRAK-1	Controlled primary epithelial cell non-IFN response to HRV-A1; knockdown by siRNA reduced CXCL8 in primary BECs	Did not cause unwanted shutdown of an antiviral response. Target unknown	[486]
Azithromycin	Macrolide antibiotic	Significantly increased IFNs and ISG mRNA and proteins resulting from HRV-A1 and HRV-A16 infection in primary BECs. Reduced HRV replication and release	Modest effect in cell culture at relatively high concentration. Mechanism unknown	[487]

FDA US Food and Drug Administration, *ICAM-1* intercellular adhesion molecule 1, *IFN* interferon, *IRAK-1* interleukin-1 receptor-associated kinase-1, *BEC* bronchial epithelial cells

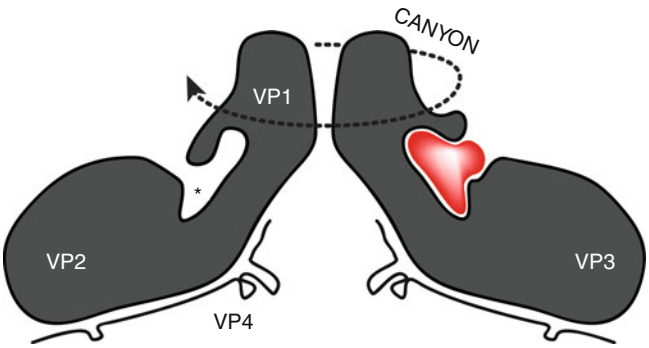

Fig. 29.11 A simplified depiction of two protomers in opposition on a cross section of a pentamer. The positions of the structural peptides are indicated as is the canyon that circumscribes the central axis of the pentamer. The pocket (*asterisked*) at the base of the canyon is shown without the pocket factor or occupied by a stylized capsid-binding molecule (*red*). *VP1-VP4* Viral protein (Adapted from McErlean et al. [61])

Acknowledgments We wish to sincerely thank the following for valuable discussions: John Upham, Anne Chang, Danielle Wurzel, Michael Nissen, Ron Turner James Gern, and Stephen B. Liggett. We are grateful for the extreme patience of Corin and Ronan Mackay, slightly less so for their frequent provision of our firsthand experience in HRV clinical symptoms.

Rotaviruses

30

Monica Malone McNeal and David I. Bernstein

1 Introduction

Before the use of rotavirus vaccines, rotaviruses were recognized as the single most important cause of severe infantile gastroenteritis worldwide and were estimated to be responsible for >600,000 deaths annually [1–3]. Today, rotavirus disease is much less common where the vaccines are available, but rotaviruses continue to cause disease and death in the most impoverished nations where vaccine is not yet available to most [4]. Transmission of rotaviruses occurs primarily by the fecal-oral route, providing a highly efficient mechanism for universal exposure that circumvents differences in cultural practices and public health standards [5]. Nearly all children less than 5 years of age have experienced at least one rotavirus infection [6–8].

The most common symptoms associated with rotavirus disease are diarrhea and vomiting accompanied by fever [8, 9]. Rotavirus illness can be mild and of short duration or produce severe dehydration leading to hospitalization and mortality if not treated. Severe disease occurs primarily in young children, most commonly between 4 and 24 months of age, and the treatment of rotavirus illness is largely limited to supportive measures such as oral or intravenous rehydration.

2 History of Rotavirus

The first rotaviruses to be described, based on pathology and epidemiology, were murine strains which were classified under the general description as the agents responsible for "epizootic diarrhea of infant mice," i.e., EDIM [10, 11]. Murine rotaviruses were also among the first to be visualized by electron microscopy [12], along with viruses obtained from the rectal swabs of monkeys that contained viruses with comparable morphologic features [13]. These agents were described as 70-nm particles that had a wheel-like appearance and were later designated "rota" viruses from the Latin word for wheel [14, 15]. In 1969, Mebus and colleagues demonstrated the presence of these particles in stools of calves with diarrhea, thus associating these viruses with a diarrheal disease [16]. The correlation between these viruses and severe diarrhea in young children was reported first in 1973 by Bishop and colleagues, who used electron microscopy to examine biopsy specimens of duodenal mucosa from children with acute gastroenteritis [17, 18]. Within a short time, other investigators confirmed the association between the presence of rotavirus in feces and acute gastroenteritis.

In addition to their distinctive morphologic features, human rotaviruses, along with their animal counterparts, share a group antigen [19, 20] and are classified as members of the *Rotavirus* genus within the *Reoviridae* family [21]. In 1980, particles that were morphologically indistinguishable from established rotavirus strains but lacked the common group antigen were discovered in pigs [22, 23]. This finding led to the identification of rotaviruses belonging to six additional groups (B to G) based on common group antigens, with the original rotavirus strains classified as group A [24]. Recent sequencing of the gene responsible for the group antigen has led to additional groups (F to H) [25]. Only groups A to C have been associated with human diseases, and most known cases of rotavirus gastroenteritis are caused by group A strains. Although there have been large outbreaks associated with non-group A strains

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_30,

reported in China and Japan, particularly among adults [26–28], group A rotaviruses are the strains to which vaccine development has been directed.

3 Properties of the Virus

Rotavirus is a double-stranded RNA virus. When the genome of rotavirus is extracted from viral particles and separated by polyacrylamide gel electrophoresis, 11 bands are visualized by silver staining as shown in Fig. 30.1.

Each rotavirus strain has a characteristic RNA profile or electropherotype. The characteristic RNA electrophoretic pattern of group A rotaviruses consists of four size classes containing segments 1–4, 5 and 6, 7–9, and 10 and 11 [5]. A short pattern is seen when the segment 11 runs slower than segment 10.

The genome of rotavirus encodes six structural proteins—VP1 to VP4, VP6, and VP7—and six nonstructural proteins, NSP1 to NSP6 [29, 30]. Each segment encodes one rotavirus protein except segment 11 which encodes both NSP5 and NSP6 using alternative open reading frames [31]. The genome segments range in size from approximately 660–3,300 base pairs with a molecular weights of approximately 12,000–125,000 [29]. The known functions of these 12 proteins are briefly described in Table 30.1.

Computer-generated images of rotavirus particles obtained by cryoelectron microscopy show it is ca. 100 nm in diameter and is composed of three concentric protein layers depicted in Fig. 30.2 [32–34].

The outer layer contains 780 molecules or 260 trimers of the VP7 glycoprotein and 60 trimers of the VP4 protein [35–37] which forms spikelike projections that extend through and 11–12 nm beyond the VP7 layer [32, 33]. The VP4 protein is anchored to the intermediate layer of the particle composed of the VP6 protein, also arranged as trimers. There are 132 aqueous channels in the outer layer that are positioned over 132 channels within the perforated VP6 intermediate shell. Besides interactions between the two layers of VP7 and VP6, both proteins interact with VP4 in these aqueous channels [38]. The innermost layer contains 120 molecules of the VP2 protein that interact with 12 molecules each of the viral transcriptase (VP1) and the guanylyltransferase (VP3) along with the 11 segments of the double-stranded RNA genome [29, 39].

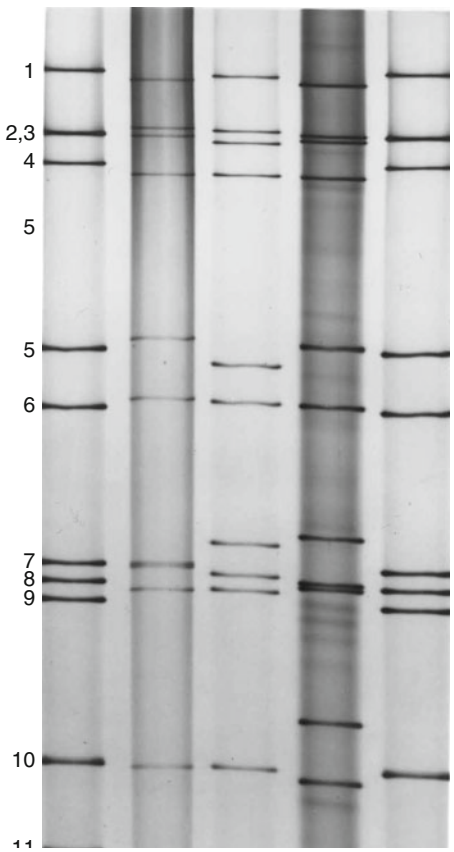

Fig. 30.1 Polyacrylamide gel electrophoretic patterns of genomic RNAs obtained from group A human rotaviruses and visualized by silver staining. The patterns demonstrate the characteristic four size classes of RNA separated into groups of 4, 2, 3, and 2 segments each. Human rotavirus strains included (from left to right) lane 1, Wa; lane 2, 248 strain; lane 3, 456 strain; lane 4, DS 1; lane 5, Wa.

4 Virus Entry and Replication

Rotaviruses must attach to and enter a cell prior to replication. The VP4 protein on the outer shell is involved in cell attachment. Cellular receptors have not completely been determined, but studies have indicated that sialic acid, heat shock cognate 70 protein (hsc70), ganglioside compounds, and integrins, including $\alpha 2\beta 1$, are probably involved in virus attachment and entry [40–45]. A recent study has shown that a rotavirus having a specific VP4 protein (P[14], see classification below) was able to bind to a glycan characteristic of A-type histo-blood group antigen (HBGA) [46]. Additional studies have shown that other rotavirus strains having different VP4 proteins, including strains that commonly infect humans, were able to bind to specific HBGAs found in saliva and milk [47, 48]. HBGAs have been shown to be important receptors for noroviruses. This finding may have importance to determining susceptibility to rotavirus infections in the human population.

Rotaviruses are activated by cleavage of the outer capsid VP4 protein by trypsin-like proteases into proteins termed VP5* and VP8* which remain associated with the virus. Studies to determine how rotavirus enters a cell after attachment have suggested endocytosis or a process similar to enveloped-virus fusion as the mechanism for viral internalization, but again, the process is not fully elucidated [43, 49, 50]. From a number of studies, it has been shown that the outer capsid proteins, VP5* and VP8*, undergo conformational changes that may also involve the VP7 protein during attachment and entry into the cell [49–52].

For replication to begin, the outer capsid proteins must be removed to yield a double-layered particle. The RNA-dependent

Table 30.1 Rotavirus gene segments and properties of the encoded proteins

RNA segment	Encoded protein	Properties of protein
1	VP1	Structural inner core protein RNA transcriptase and RNA binding
2	VP2	Structural inner core protein RNA binding
3	VP3	Structural inner core protein Complexes with VP1, RNA binding, guanylyltransferase, and methyltransferase activity
4	VP4	Outer capsid protein Receptor binding, hemagglutinin, and neutralization protein
5	NSP1	Nonstructural protein RNA binding, possible suppression of host innate antiviral response
6	VP6	Intermediate capsid protein Group and subgroup antigen, necessary for transcription
7	NSP3	Nonstructural protein RNA binding and control of viral translation, inhibits host translation
8	NSP2	Nonstructural protein Multifunctional enzyme activity, interacts with NSP5 in formation of viroplasm
9	VP7	Outer capsid protein Neutralization protein
10	NSP4	Nonstructural protein Multifunctional protein, essential for replication, transcription and morphogenesis, enterotoxin
11	NSP5	Nonstructural protein Binding to NSP2 to form viroplasm
	NSP6	Nonstructural protein Not encoded by all rotavirus strains, RNA binding, role not clearly determined

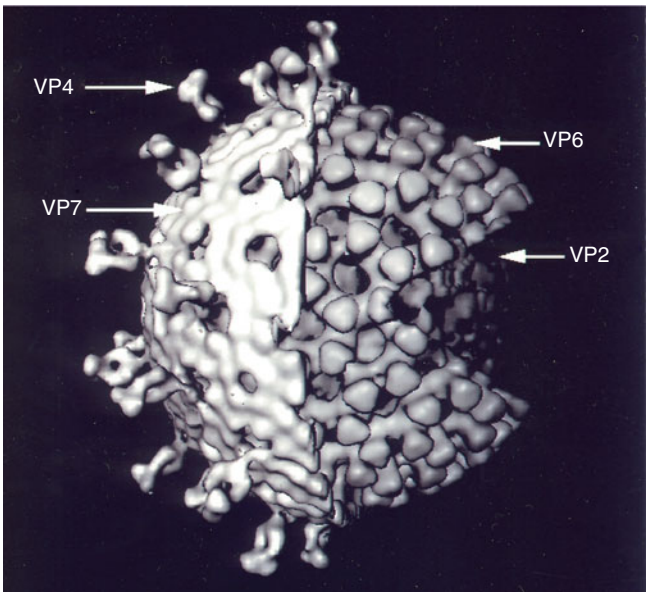

Fig. 30.2 Computer generated image of the triple shelled rotavirus particle obtained by cryoelectron microscopy. The cut away diagram shows the outer capsid composed of VP4 spikes and VP7 shell, intermediate VP6 shell, and inner VP2 shell surrounding the core containing the 11 double stranded RNA segments and VP1 and VP3 proteins. (Courtesy of Dr. B. V. V. Prasad, Baylor College of Medicine, Houston, TX.)

RNA polymerase (i.e., the VP1 transcriptase) associated with the inner shell is then stimulated to synthesize the 11 viral mRNAs that are capped by VP3 [53–55]. The mRNAs are extruded from the virus cores through channels in the VP2 and VP6 protein layers at the 12 vertices of the viral particles and subsequently translated into viral proteins [56, 57]. A number of studies using the technique of adding "short interfering RNAs" (siRNAs) have helped to elucidate the various steps of viral replication and how the different viral proteins are involved [58]. Two nonstructural proteins, NSP2 and NSP5, have been found to be involved in the formation of large inclusions or viroplasms [59]. Particle assembly may be initiated by the formation of complexes within the viroplasm that contain plus-strand RNAs from the 11 genome segments along with VP1 and VP3. Although the mechanism is not fully known, the virus assembles and packages one of each of the plus-strand RNAs within individual precursor viral complexes. Upon interactions with VP2, the minus-strand RNA is synthesized and the 11 ds RNA genome segments are produced [60]. VP6 trimers interact with the VP2 core and a double-layered particle is completed [61–63]. The double-layered particles then bud into the rough endoplasmic reticulum (ER) after their association with the NSP4 transmembrane glycoprotein [64]. VP4 is either added prior to entry into the ER or sometime thereafter. The other rotavirus

glycoprotein VP7, which becomes sequestered within the rough ER, is added to complete the formation of mature viral particles [65, 66]. These mature viruses accumulate within the lumen of the rough ER until cell lysis occurs.

5 Serotypes

The two outer capsid proteins, VP7 and VP4, contain the only neutralization epitopes for this virus [67, 68]. Early studies using sera from hyperimmunized animals in cross-neutralization assays described a number of different serotypes from infected humans and animals based on the VP7 protein [68, 69]. Viruses were given a G type referring to the glycosylated structure of this protein. When animals were hyperimmunized, most of the neutralizing antibody was directed against the VP7. However, after oral infection, VP4 appeared to be the dominant neutralization protein [70–73]. A dual serotyping scheme for both VP7 and VP4 was therefore developed.

VP7 serotypes are determined by cross-neutralization and by using panels of monoclonal antibodies [74–76]. VP4 serotype determination, however, is more difficult [77–79]. Two numeric systems were established to classify the VP4 protein, or P type referring to the protease sensitivity of this protein. The P serotype is based on neutralization assays using antisera against recombinant-expressed VP4 proteins or viruses with specific VP4 genes [80, 81]. A second classification system, one that is now more widely used to characterize rotavirus isolates, is based on sequence analyses, and rotaviruses are described as different genotypes [82, 83]. The P serotype is indicated by an open number and the genotype is noted with a bracketed number. For example, the most common P type worldwide belongs to serotype P1A and genotype 8 and is therefore designated P1A [8]. Currently, rotaviruses are most often only classified by genotyping for the P protein, i.e., P [8]. To date, 27 G types and 35 P types have been identified on the basis of sequence analyses from animal and human isolates [84–86]. Recently, all 11 gene segments of rotavirus isolates have been sequenced. The data from this analysis have importance in determining the evolution of different rotavirus strains [87]. However, as discussed below, only a few G- and P-type combinations account for the vast majority of human infections.

Rotaviruses, similar to other viruses with segmented genomes, have the ability to form reassortants. This ability to reassort has contributed to the diversity of G and P types found throughout the world. In addition, as will be discussed, a number of reassortant viruses have been used as vaccine candidates including the currently licensed vaccine, RotaTeq™. During replication, if a coinfection has occurred, gene segments from each parent virus can be incorporated into new progeny viruses. The gene segments from different viruses can segregate independently, and the new viruses produced can contain genes from either parent. Although numerous human isolates appear to be animal strains or animal-human rotavirus reassortants as determined by sequence analyses, the number of cross-species infections appears to be low [88–91].

6 Epidemiology of Rotavirus

6.1 Disease Burden

6.1.1 United States

Before the use of vaccines, nearly every child was infected with rotavirus by the age of 5, and rotavirus illness resulted in 20–70 deaths annually in the United States [92–94]. Infection with rotavirus often resulted in more severe illness than other pathogens, and therefore, rotavirus accounted for a higher percentage of gastroenteritis episodes requiring medical intervention [95, 96]. During peak rotavirus seasons, 70 % of all gastrointestinal hospitalizations were due to rotavirus-associated gastroenteritis [97]. It is estimated that 1 child in 7 required a doctor's visit at a clinic or emergency room, and about 1 in 75 were hospitalized because of a rotavirus illness [93, 98]. Based on these estimates, rotaviruses were responsible for 5–10 % of all gastroenteritis episodes in children under 5 years of age leading to over 50,000 hospitalizations. Depending on how hospital surveillance studies were conducted, these estimates may be lower than the actual numbers of rotavirus-related hospitalizations [92, 99, 100]. Similar estimates of the disease burden due to rotavirus have been reported in studies conducted in European countries [101–103].

6.1.2 Worldwide

Globally, rotavirus disease has an even more dramatic and significant impact on infant health. Although rates of rotavirus illness among children are similar throughout the world, the resulting mortality differs substantially. It is estimated that rotavirus illness is responsible for over 600,000 deaths annually, representing 5 % of all deaths in children younger than 5 years of age worldwide [2]. More than 90 % of these deaths occur in Africa and Asia (Fig. 30.3). More than 100,000 deaths occur in India and sub-Saharan Africa and 35,000 occur in China [2, 104, 105].

6.2 Distribution of Human Rotavirus Serotypes

Early studies using cross-neutralization assays and monoclonal antibodies to determine serotypes found that four main G types (G1, G2, G3, and G4) accounted for 90 % of the strains isolated from humans. However, with the development of

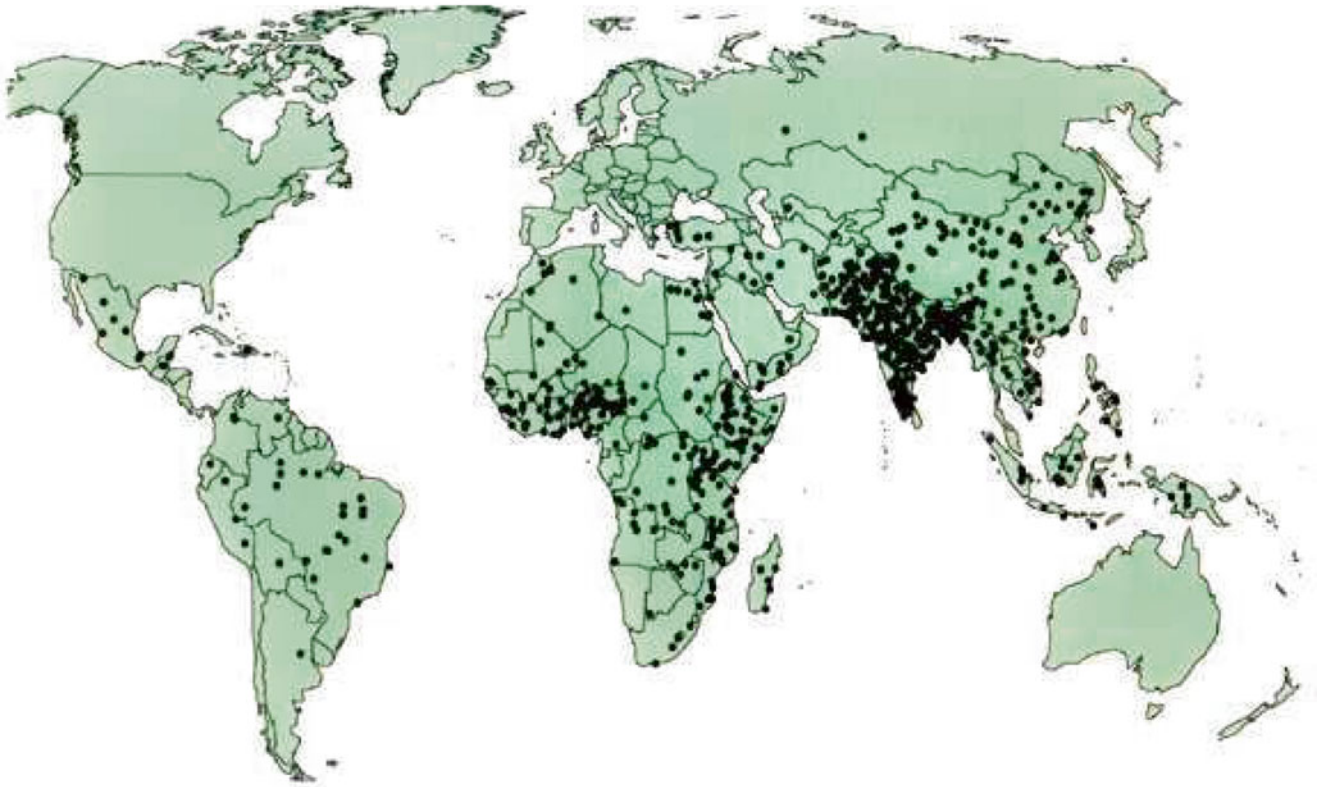

Fig. 30.3 Each dot on this figure represents 1,000 deaths. It is estimated that there are over 600,000 deaths worldwide. Edited from Parashar et. al. Emerg Infect Dis. 2003;9:565–72

surveillance studies using reverse transcription-polymerase chain reaction (RT-PCR) genotyping and automated nucleotide sequencing of VP7, for G type, and VP4, for P type, more strains have been identified and genotyped. The global distribution of G and P serotypes can vary greatly by location and time or, as was found in some studies, vary little over sequential seasons [74, 106]. Over 42 different P-G combinations of human strains containing 10 different G types and 11 different P types have been described [85].

In North America, Europe, and Australia, the G1P [8] strain has been responsible for over 70 % of rotavirus infections. In European countries, G1, G2, G3, G4, and G9 were the predominant G serotypes found, although the incidence varied by country [107]. Similar findings were reported from Central and South-Eastern Europe [108]. In the United States, the most prevalent strain in the pre-vaccine era was G1P[8] (78.5 %) followed by G2P[4] (9.2 %), G9P[8] (3.6 %), G3P[8] (1.7 %), and G4P[8] (0.8 %) [109]. Rarer genotypes included G2P[6], G6P[9], and G3P[9]. These studies also demonstrate that strain circulation can vary greatly in the same location over time.

A more global perspective has been described in two reviews. A review by Santos and Hoshino [84] summarized rotavirus serotypes from 124 studies performed between 1989 and 2004 and included data on 45,571 strains collected from 52 countries on five continents. The four common G types, G1, G2, G3, and G4, with either P[8] or P[4], represented over 88 % of the strains identified worldwide during this period. Serotype G9, containing either P[8] or P[6], was found to be an emerging strain in a number of different locations. In the second review by Gentsch et al. [85], data from studies conducted in 35 countries, involving over 20,000 strains, were analyzed. In this study the four common strains, G1P[8], G2P[4], G3P[8], and G4P[8], represented 72 % of all strains with G9 containing either P[6] or P[8] identified in over 2 % of the isolates. In South America and Asia, the incidence of G1P[8], about 30 %, is lower than in the United States and Europe, while in Africa, it was even lower (20 %). In Latin America [110], the most common G types were G1 (34.2 %), G9 (14.6 %), and G2 (14.4 %), while the most common P types were P[8] (56.2 %), P[4] (22.1 %), and P[1] (5.4 %). A recent review of rotavirus infections in Africa suggested that strain diversity was increasing and identified a total of 24 P/G combinations [111]. A review of studies from China showed that G1 was the overall predominate strain but that G3 viruses were becoming more common [112, 113].

In summary, although the most common G types still remain, G1 through G4, common strains now also include G5, G8, G9, G10, and G12 (especially G9) in various regions around the world [109–111, 114, 115]. The most common

types for the P protein are P[8] and P[4] but also include the more recently described P[6] and P[1] as well as P[9] and P[14]. The effect of rotavirus vaccine introduction in countries around the world on the diversity of circulating rotavirus strains remains to be determined. Surveillance programs are important to monitor the changes in rotavirus strains.

7 Effect of Age and Seasonality

Severe human rotavirus disease occurs most commonly between 4 and 24 months of age [7, 116], but the age may be lower in less developed countries [117, 118]. Neonatal rotavirus infections, which are often asymptomatic, occur and appear to be endemic in some newborn nurseries [119, 120]. The asymptomatic nature of neonatal rotavirus infections is due, at least partially, to protection from transplacental antibody that can persist for the first months of life. The onset of rotavirus disease in infants has been reported to coincide with the decline of maternal IgG antibody [121].

Older children and adults, including elderly patients, are susceptible to reinfections with rotavirus. Infections typically cause mild disease but rarely can be severe and require hospitalization [122–126]. The reduced severity of rotavirus disease in older children and adults is due primarily to the immunity induced by previous rotavirus infections. One of the interesting and somewhat unanticipated results of the introduction of rotavirus vaccines has been the impact on disease in older children and even adults [127].

As with other respiratory and enteric viruses, distinct seasonality is associated with rotavirus disease [29, 128–131]. This seasonality is particularly evident in temperate climates, where rotaviruses are responsible for the large increase in hospitalizations and deaths due to diarrheal diseases found during the winter season [97]. The seasonality of rotavirus disease is less apparent in tropical climates, but disease is still more prevalent in the drier, cooler months [129]. The cause for the seasonality of rotavirus disease remains unknown.

8 Clinical Disease and Treatment

Following an incubation period of 1–3 days [132], the onset of rotavirus disease is often abrupt with fever and vomiting followed by explosive, watery diarrhea. About two-thirds of children with rotavirus disease have diarrhea, vomiting, and fever [133–135], but children can also present with any two or only one of these symptoms [9]. Stools are non-bloody and generally lack fecal leukocytes, but mucus may be found. Rotavirus infections are typically more severe than those caused by other viral gastrointestinal agents and therefore more likely to result in hospitalization [134, 135]. In one study [134] vomiting and diarrhea lasted longer in patients infected with rotavirus than other causes of gastroenteritis, while in another study, the severity of rotavirus diarrhea was almost twice that of other causes of diarrhea [136]. The disease lasts about 4–8 days, with a range between 2 and 22 days [137], while virus shedding has ranged from 4 to 57 days with a peak at about day 3 [138, 139].

Virus replication was initially thought to be limited to the intestine, but it is now known that both antigenemia and viremia are common [140–145]. The dissemination of virus may be responsible [142] for other clinical manifestations including encephalitis and meningitis [146, 147], upper and lower respiratory infections including otitis media and pneumonia [134, 148, 149], and mild hepatitis [150]. Recently, cases of encephalitis have been confirmed by identification of rotavirus RNA in the cerebrospinal fluid using reverse transcription-polymerase chain reaction (RT-PCR) analysis [147]. Rotavirus infections are also often more severe in immunosuppressed persons, including bone marrow transplant recipients, patients infected with human immunodeficiency virus, and those who are malnourished.

The treatment of rotavirus gastroenteritis is mainly supportive, aiming to restore fluid balance in dehydrated patients. Emphasis has shifted away from intravenous rehydration to oral rehydration with glucose-electrolyte solutions. However, should oral rehydration efforts fail, or in cases of severe dehydration and shock, fluids are administered intravenously. Other experimental approaches to treatment include bismuth subsalicylate [151, 152] and probiotics (reviewed in [153, 154]). Racecadotril (acetorphan), an enkephalinase inhibitor with antisecretory and antidiarrheal properties, has been shown to be effective in the treatment of diarrhea in adults and children [155–157], while another drug, nitazoxanide, licensed to treat *Giardia intestinalis* and *Cryptosporidium parvum* infections [158, 159], has shown some effectiveness in the treatment of rotavirus infection.

9 Pathogenesis

The incubation period for rotavirus is approximately 1–3 days [132]. In children with symptoms, the onset is often abrupt, with fever and vomiting followed by explosive, watery diarrhea. Vomiting may precede the diarrhea in approximately half the cases [160]. Fever occurs commonly during rotavirus illness, with estimates of between 45 and 84 % of patients [134, 135]. The disease is usually self-limited, lasting 4–8 days, although the duration of symptoms ranged between 2 and 22 days in a Guatemalan study [137]. In a study conducted in the United States, 63 % of hospitalized children with rotavirus infection had fever, vomiting, and diarrhea at presentation, but children also presented with combinations of only one or two of these symptoms [9].

After fecal-oral transmission of rotavirus, infection is initiated in the upper intestine and typically leads to a series of histologic and physiologic changes. Studies in calves revealed that rotavirus infection caused the villus epithelium to change from columnar to cuboidal, which resulted in a shortening and stunting of the villi. The cells at the tips of the villi became denuded, while in the underlying lamina propria, the number of reticulum-like cells increased and mononuclear cell infiltration was observed. The infection appears to start at the proximal end of the small intestine and then advances distally [161, 162]. From the few studies examining the pathologic changes in the intestines of humans, the changes appeared to be similar to those found in animals [163, 164].

Although rotaviruses cause severe diarrhea in numerous species, including humans, the mechanisms responsible for the illness have not been completely determined but are due to multiple factors (reviewed in [165]). From various studies in animals, malabsorption of carbohydrates, sodium and calcium fluxes, retarded differentiation of uninfected enterocytes, activation of the enteric nervous system, and toxin (NSP4) have been found to be involved in causing diarrhea. It is clear that infection of mature enterocytes of the small intestines leads to damage and functional abnormalities, but the degree of damage does not appear to correlate with the severity of diarrhea. Further, diarrhea can occur before evidence of intestinal pathology. Thus, although damage to the mature enterocytes leads to loss of the enzymatic activities of the brush border leading to malabsorption of electrolytes and glucose/amino acids, other mechanisms are also involved.

Diarrhea has been induced in infant mice and rats by intraperitoneal inoculation with the rotavirus NSP4 protein as well as with a 22-amino acid peptide derived from this protein [166, 167]. NSP4 possesses membrane destabilization activity that may result from increased intracellular calcium concentrations, resulting in cytoskeleton disorganization and cell death [168–170]. NSP4 is also an enterotoxin that binds to surface receptors and initiates signal transduction pathways that leads to mobilization of intracellular Ca and chloride secretion. NSP4 increases the levels of intracellular calcium [171] by activating a calcium-dependent signal transduction pathway that mobilizes transport of this ion from the endoplasmic reticulum [172, 173].

Another factor that may have a role in rotavirus-induced diarrhea is the enteric nervous system underlying the villus epithelium. It has been reported that rotavirus infection can activate this system in mice and drugs that block nerve activity, attenuate rotavirus-induced fluid secretion in vitro, and attenuate diarrhea in vivo [174]. Whether this is a major mechanism of diarrhea occurring after rotavirus infection in humans remains to be determined.

The tissue tropism of rotavirus infection in humans was thought initially to be restricted to the villi of the small intestine. Because no consistent evidence of extraintestinal replication of rotavirus had been shown, the general assumption was that rotavirus pathology is strictly intestinal. However, instances of non-gastrointestinal rotavirus-associated disease, including the association with abnormal liver function, as well as respiratory and nervous system involvement were reported [175–180]. This spread was explained when it was reported that both antigenemia (presence of rotavirus protein in the blood) and viremia (presence of live rotavirus in the blood) were found during rotavirus infection in several strains of animals and in humans [140]. Since that time, this observation has been confirmed by a number of studies in humans [144, 145, 181–184].

10 Immunity

After more than 30 years of research involving studies of natural rotavirus infection, vaccine studies, and animal studies, the mechanisms of immunity to rotavirus infection remain incompletely understood. Humoral antibody responses include an early IgM response followed by the production of rotavirus IgG and IgA [185, 186]. Infection also induces local, intestinal antibodies that are predominantly IgA [187–190]. T cell responses have been difficult to measure in humans, but several rotavirus proteins have been identified that contain T cell epitopes and have been used to measure T cell responses after rotavirus infection [191–193].

As stated before, virus neutralization epitopes are found on the VP4 and VP7 proteins located on the surface of the virion, and neutralizing antibody to the infecting virus can be detected after infection or vaccination. However, VP6 appears to be the most immunogenic protein, although antibody made against VP6 is not neutralizing. One of the important questions concerning the development of immunity to rotavirus infection is whether or not neutralizing or serotype-specific antibody is necessary for protection. Studies evaluating natural rotavirus infections were used initially to understand rotavirus immunity and the role of serotype-specific antibodies. Many investigators reported that natural rotavirus infections produce incomplete protection, but most showed that previous infections protected against severe disease [194–199]. In a large study conducted in Mexico, protection from both rotavirus reinfection and rotavirus diarrhea increased with each new infection [198]. However, sequential infections even with the same serotype have been reported. In an early study reporting rotavirus disease with reinfection by the same serotype, the investigators noted that protection of young children in a Japanese orphanage lasted 6 months then declined after 1 year. This study noted a close correlation between titers of serotype-specific antibody and protection [200]. This study is often cited to support the idea that neutralizing antibody is necessary for protection. While it is generally accepted that if present at a

sufficient titer, neutralizing antibody will protect, it is still unclear whether only neutralizing antibody is necessary for protection.

Although reinfections with rotavirus are common, other studies have shown that protection lasts at least 1 year. Neonates infected within the first 2 weeks of life were protected against severe disease but not against reinfection in one study [119]. In another study, infants who developed a symptomatic or an asymptomatic rotavirus infection during the first year of the study were protected against contracting a subsequent rotavirus illness or even an asymptomatic reinfection during the following year [195]. Similarly, in another study, a natural rotavirus infection in the first year was found to be 93 % protective against a symptomatic reinfection in the second year. This protection occurred even though the G1 strains that circulated during the first year were responsible for only 66 % of rotavirus disease in the second year [197]. In a recent cohort study conducted in India, it was found that rotavirus infections generally occurred early in life with 56 % of children infected by 6 months of age. Reinfections were common, and protection against moderate or severe disease increased with the order of infection. However, protection was only 79 % after three infections and there was no evidence of homotypic protection [201]. Protection from the current vaccines appear to last at least 2–3 years (discussed below).

Correlations of serotype-specific neutralizing antibody and protection have not been supported in other larger studies. In the largest study, conducted in Bangladesh during a 2-year period when the four major G serotypes circulated, the titers of both preexisting homologous and heterologous neutralizing antibody were significantly lower in patients with acute rotavirus disease than in matched control subjects. Further analysis, however, could not find a correlation with serotype-specific neutralizing antibody, and protection seemed to correlate better with the magnitude of the response rather than with specific neutralizing responses [202]. Differences in the studies evaluating the role of serotype-specific antibody and the protection provided by natural infection may be due to many factors including the viral strains circulating, overall health of the child, or duration of protection. Studies of the monovalent G1P[8] vaccine, Rotarix™, discussed later, provide strong support for cross-protection between serotypes.

Due to the difficulties associated with human studies, animal models using mice, rabbits, and gnotobiotic pigs have been developed [203–205]. Early studies in mice showed that while CD8 T cells are involved in the resolution of an infection, antibody is necessary for protection against reinfection [206–208]. In one study, mice given an oral immunization of a fully heterotypic rotavirus were almost completely protected from shedding when later challenged, and this protection was dependent on the ability of rotavirus-specific IgA to be transported through intestinal epithelial cells or be present at the intestinal mucosa [209]. In a recent study using mice deficient in IgA, shedding of murine rotavirus after primary infection was prolonged, and mice were not protected against subsequent infection with the same strain of virus [210]. The role of rotavirus-specific serum IgG is not clearly defined but has been shown in some animal models, using passive transfer of IgG antibodies, to have some protective effect [211]. If these animal studies mirror what is needed in humans, then local antibody may provide protection and may involve antibody that is not serotype specific.

Serum levels of rotavirus-specific IgA appear to be a good correlate of protection, because it appears to parallel antibody levels in the gut [190, 212]. However, studies in vaccinated infants showed only a low correlation between protection from disease and circulating rotavirus-specific memory B cells expressing α4β7 intestinal homing phenotype [190, 212, 213].

11 Control and Prevention

11.1 Rotavirus Vaccines (Table 30.2)

Public health institutions around the world made the development of an effective rotavirus vaccine a high priority [214].

Table 30.2 Selected rotavirus vaccines used in clinical trials

Candidate	Origin	G and P type	Comments
RIT4237	Bovine	G6P[1]	In small trials, safe but variable results. No efficacy in developing countries. Discontinued development
WC3	Bovine	G6P[5]	Safe but variable results. Virus used to make reassortants containing human genes
MU18006 (RRV)	Simian	G3P[3]	Some incidence of fever in vaccinees. Inconsistent protection. Virus used to make reassortants containing human genes
LLR	Lamb	G10P[12]	Used in China, limited efficacy data
RRV-TV	Simian	G1,G2,G3,G4,P[3]	Licensed as Rotashield™ (Wyeth) and then withdrawn because of association with intussusception
RV5	Bovine	G1, G2, G3, G4, P[8]	Currently licensed as RotaTeq™ (Merck)
RV1	Human	G1, P[8]	Currently licensed as Rotarix™ (GlaxoSmithKline)
116 E	Human	G9, P[11]	

Numerous cost-effectiveness analyses in many countries have documented the need and benefit of a rotavirus vaccine [105, 215–217]. Because natural rotavirus infections can induce excellent protection, at least against severe rotavirus disease, vaccine efforts have been directed mostly at the development of live attenuated rotavirus vaccines given orally. The introduction of rotavirus vaccines has profoundly altered the burden of rotavirus disease in the United States [218–221] and wherever it has become available [222–224].

Early efforts concentrated on the use of animal rotavirus strains, labeled the Jennerian approach because it relies on the natural attenuation of animal viruses in humans for safety and largely heterotypic immune responses for protection. The initial efforts with animal rotavirus vaccines yielded inconsistent results. Therefore, in an attempt to make the vaccines more closely related to human strains, human rotavirus genes coding for the proteins that induce neutralizing antibody, VP4 and VP7, were introduced into these animal strains by creating reassortant viruses as described earlier. Another approach was the use of attenuated human rotaviruses, either isolated from asymptomatic infections in human neonates or attenuated by cell-culture adaptation and passage.

11.1.1 Animal Strains

The first vaccine trial was conducted 10 years after the identification of rotavirus as an agent of severe diarrhea. This vaccine candidate was based on a bovine rotavirus strain, RIT4237, which is a G6P[1] virus [225]. The initial studies of the RIT4237 vaccine produced variable results. The vaccine was safe and effective in Finland, thus supporting the hypothesis that heterotypic protection was possible since this virus shared neither G nor P serotypes with the predominant human types and also suggested that protection may be greater than immunogenicity would indicate [226, 227]. However, later studies in developing countries and in a Navajo reservation were disappointing [228–231], and ultimately, the development of this vaccine was discontinued.

The initial studies of another bovine vaccine, WC3, conducted in Philadelphia appeared promising, during a season that had predominantly G1 strains [232]. Unfortunately, later trials in Cincinnati [233] and in less developed Central African countries [234] showed no significant protection. This virus was later used to develop reassortant vaccines and is the backbone of the RotaTeq™ vaccine now used around the world.

The next major vaccine candidate was a simian (rhesus monkey) termed MMU18006 or more commonly known as RRV. This vaccine is a G3P[3] strain and thus shared the G type with a human strain. RRV vaccination was associated with mild side effects, including low-grade fever and mild diarrhea, especially when it was given to older children who had lost maternal antibodies [235–237]. Protection with this vaccine was also inconsistent, ranging from greater than 50 %, even in developing countries, to moderate (20–50 %) to nonexistent [238]. This virus was later used to make the reassortants containing human rotavirus VP7 genes that became Rotashield™ vaccine, the first licensed rotavirus vaccine that was subsequently withdrawn from the market (see below).

One additional animal strain that has been developed into a vaccine is a G10P[12] strain isolated from a lamb, designated LLR. This vaccine produced by the Lanzhou Institute of Biological Products was introduced in China [239] but was only recently demonstrated to be effective [240].

11.1.2 Reassortant Vaccines

Because of the belief that homotypic immunity, or the development of serotype-specific antibody responses, might increase the protection seen with rotavirus vaccines and because of a lack of consistent protection after vaccination with heterotypic animal strains, the next vaccines developed were reassortant vaccines. These vaccines contained the genes encoding VP7 or the VP7 and VP4 proteins of human rotavirus strains, with the remainder of the genes from an animal strain. As discussed earlier, these proteins were chosen because they induce neutralizing antibody.

Rotashield™

The simian strain, RRV, was used as the background to make three different reassortant viruses containing the VP7 gene from human strains D (G1 serotype), DS-1 (G2 serotype), and ST-3 (G4 serotype) with the G3 serotype represented by RRV itself. The initial trials with monovalent viruses yielded varying results [241]; therefore, all four strains were incorporated into a tetravalent vaccine, RRV-TV, later licensed as Rotashield™. Extensive evaluations of the RRV-TV were completed before licensure. In two large trials conducted at centers across the United States, the RRV-TV vaccine was found to be safe, with the subjects developing a slight increase in temperature after the first dose. Protection against severe disease was 80 % [241, 242]. Similar results were reported from Finnish studies except that fever occurred somewhat more commonly and efficacy was somewhat enhanced [243]. Protection similar to that seen in the US studies was also demonstrated when it was evaluated in a less developed country, Venezuela [244].

As a result of these studies, RRV-TV or Rotashield™ was licensed in the United States in 1998 and recommended for general use in all infants [245]. However, less than 1 year after licensing, 15 cases of intussusception that occurred shortly after vaccination were reported to the Vaccine Adverse Events Reporting System (VAERS). Intussusception is a form of intestinal blockage caused when a segment of the bowel prolapses into a more distal segment of the intestine [246]. Initial publications reported an increased risk of the development of intussusception from 3 to 14 days after

receipt of the first dose of Rotashield™ and a smaller risk after administration of the second dose [247–249]. The initial estimate that one case of intussusception attributable to vaccination with RRV would occur for every 4,670–9,474 infants vaccinated was later revised to approximately 1 in 10,000 [250]. The risk of intussusception appears to be age related and increased substantially in children greater than 90 days of age [251, 252]. Based on these findings, the use of Rotashield™ was discontinued. Because of these findings, the FDA also recommended that future trials using live oral rotavirus vaccines should be conducted with more than 60,000 children to ensure that the risk of intussusception from a new vaccine would be less than was attributed to Rotashield™ [253].

The pathogenic mechanism underlying the association of the Rotashield™ vaccine and intussusception has not been defined [254]. Several studies have investigated the possible infectious etiology of intussusception, but these studies have had a small sample size, and several different pathogens, including adenoviruses, have been identified [255, 256]. It is unclear if wild-type rotavirus causes intussusception as there is a lack of seasonal variation for intussusception that might be expected to occur if rotavirus was a major cause of intussusception [257–259].

RotaTeq™

Initially, a monovalent vaccine containing the VP7 gene of a human G1 rotavirus (WI79-9) and the remainder of the genes from WC3 was developed after the inconsistent results with WC3. This vaccine was reported to be effective [70, 260], but because of the idea that serotype-specific protection was necessary, a quadrivalent vaccine containing three viruses with gene substitutions of the VP7 gene with human G1, G2, or G3 and one virus containing a VP4 gene substitution with a human P[8] was developed and shown to be safe and effective [261]. Finally, by adding a reassortant virus containing a human G4 VP7 to the above four viruses, a pentavalent vaccine, RotaTeq™, was developed by Merck Research Company [262].

Because of the association of Rotashield™ with intussusception, the large pivotal trial of RotaTeq™ included over 70,000 infants from 11 countries. The vaccine was shown to be safe and, unlike Rotashield™, it did not induce fever [263]. Most importantly, there was no association with intussusception. The vaccine was highly effective, reducing all G1–G4 rotavirus gastroenteritis by 74.0 %, severe rotavirus gastroenteritis by 98.0 %, and hospitalizations and emergency room visits by 94.5 % [263]. RotaTeq™ was licensed in 2006 by the US Food and Drug Administration (FDA) for use in infants.

Since the pivotal trial was published, there have been multiple trials of RotaTeq™ conducted around the world [264–268]. Efficacy has been excellent, but as appears to be true for all rotavirus vaccines, the vaccine appears to less effective in less developed areas of the world [269, 270]. In the poorest settings such as Africa and Asia, efficacy has only been 40–50 % [265, 271, 272]. In general this correlates with the lower immune response in these settings [273, 274]. The reasons for this decrease are not well understood. Possible contributing factors include higher levels of transplacental and breast milk antibody that could inhibit vaccine virus replication, malnutrition, micronutrient deficiencies, interfering gut flora, and differences in the epidemiology [275].

Post-licensure evaluations of the vaccine have shown substantial decreases in rotavirus diseases wherever evaluated [224, 276, 277]. Surveillance studies and laboratory monitoring conducted in the United States have shown remarkable reductions in rotavirus disease every year since vaccine introduction [219, 278]. Interestingly this has included not only those immunized but older children and adults suggesting a high level of herd immunity [127, 219, 278]. Safety has also been monitored. Except for a small increase in the rates of intussusception identified in Australia (relative risk 5.3 and 3.5 for the 1–7 and 1–21 days after the first dose of RotaTeq™, respectively, in infants 1 to <3 months of age), the vaccine has been shown to be safe [279]. The increased risk detected in Australia has not been confirmed in studies conducted in the United States [280].

Bovine UK Reassortant Vaccine

The bovine UK strain, which is also a G6P [5], similar to WC3, was used to make a reassortant with G1, G2, G3, or G4 human rotaviruses on a 10-gene UK background. The tetravalent UK vaccine appears to be safe and immunogenic [281]. Clinical trials are ongoing to evaluate this UK reassortant vaccine. There has been additional work done to develop UK-based reassortants containing additional VP7 genes for some of the emerging viruses such as G8 or G9 strains, creating a hexavalent reassortant vaccine [282].

11.1.3 Human Strains

The use of human strains for vaccine candidates is based on the data that show that natural infection can provide protection against subsequent infection or disease. The human strains considered as vaccine candidates are either naturally attenuated, as thought to be the case with neonatal strains, or attenuated by culture adaptation and multiple passage. The candidates discussed below are each composed of one strain and, therefore, rely on homotypic and heterotypic mechanisms of protection.

Neonatal Strains

The first natural history study showed that asymptomatically infected neonates had a subsequent reduction in the frequency and severity of rotavirus diarrhea, thereby generating

interest in the use of neonatal strains as vaccine candidates [119]. One of the first human strains to be tested as a rotavirus vaccine was a neonatal, G1P[6] strain identified as M37. Several small studies showed that the vaccine was safe but only moderately immunogenic, inducing neutralizing antibody responses to the M37 strain but not to other G1 strains [283]. In an efficacy study of Finnish infants, there was no protection against predominantly G1 strains, and this vaccine candidate was not pursued [284].

RV3, another vaccine candidate, is a G3P[6] human rotavirus that was isolated in a nursery in Melbourne, Australia, where it caused endemic, asymptomatic infections in newborn infants in the 1970s. Neonates infected with this virus were 100 % protected against severe rotavirus disease, caused primarily by heterotypic G2P[4] strains, for their first 3 years of life [119]. The vaccine was moderately immunogenic and protective in later studies [285, 286]. This vaccine is also being evaluated in clinical trials.

Two other more recent vaccine candidates were derived from two neonatal strains isolated from asymptomatically infected neonates in India in the mid-1980s: one from New Delhi and the other from the Bangalore region of India. Both of these strains are natural reassortants between bovine and human strains. The strain from New Delhi, 116E, a G9P[11] strain, contains a VP4 gene segment from a bovine rotavirus and the other ten genes are from a human strain [89]. The other strain, I321, is a G10P[11] strain and contains nine genes of bovine origin and only gene segments for two nonstructural proteins from a human strain [287]. Both I321 and 116E vaccine candidates were tested in a small, placebo-controlled trial, which showed only the 116E strain elicited significant immune responses [288]. Therefore, only the 116E strain is being pursued as a vaccine candidate in India. The most recent trials showed good immunogenicity for this vaccine candidate [289], and efficacy trials are under way.

Rotarix®

This vaccine was first licensed in Mexico in 2005 and has since been approved in countries around the world including developed, less developed, and developing nations [223, 290]. The product is based on the attenuated human strain, 89–12 obtained from an infant with rotavirus gastroenteritis in Cincinnati, Ohio, and is a G1P[8] strain, representing the most common strain worldwide. The isolate was attenuated by multiple passages in tissue culture. Results of a multicenter efficacy trial showed that two doses of this vaccine provided 89 % protection against any rotavirus disease and 100 % protection from severe disease [291]. The 89–12 strain was further purified by limiting dilution and passaged in tissue culture by GlaxoSmithKline. The final product was called RIX4414 and is now marketed as Rotarix® (GlaxoSmithKline), a two-dose oral vaccine. Initial testing showed that the vaccine was safe, immunogenic [292–294], and did not interfere with other concomitantly administered childhood vaccines [295, 296]. In the initial efficacy trial conducted in Finland, the vaccine was 73 % protective against all rotavirus gastroenteritis and 90 % protective against severe illness even though a relatively low dose was used [297].

Similar to RotaTeq™, the pivotal vaccine trial with RIX4414 involved over 63,000 infants but was performed in Latin America and Finland [298]. The RIX4414 vaccine ($10^{6.5}$ median cell-culture infective dose) given in a two-dose schedule at approximately 2 and 4 months of age was safe, did not induce fever, and again, most importantly, was not associated with intussusception. During the entire study, there were 25 cases of intussusception, 16 in the placebo group and 9 in the vaccine group. Efficacy data from a subset of 20,000 infants from this trial showed 85 % protection against severe rotavirus diarrhea and hospitalization. Protection against more severe gastroenteritis was 100 %. It was also demonstrated that protection was high (86 %) not only against severe rotavirus diarrhea caused by G1P[8] strains but also against G3P[8], G4P[8], and G9P[8] strains which all shared the VP4 P[8] genotype. Efficacy against the few G2P[4] infections (a strain that is not matched for either VP4 or VP7) was 41 %. However, in an integrated analysis, efficacy against G2[P4] was 71.4 % against severe disease and 81.0 % against disease of any severity [299]. More recently a study in Mexico showed efficacy of over 90 % against a fully heterotypic G9P[4] rotavirus strain in Mexico [300].

In a subsequent trial of RIX4414 conducted in six European countries, protection was 87 % against any rotavirus gastroenteritis, 96 % against severe disease, and 100 % against hospitalization due to rotavirus. In this study, efficacy against G3, G4, and G9 strains was similar to that against G1 strains and was over 95 %. Efficacy against the unrelated G2 strains was 85 %, suggesting that heterotypic or nonneutralizing antibody responses are also involved in protection [301, 302]. Similar to other rotavirus vaccines, efficacy in less developed countries is decreased. In a study of African infants, efficacy against severe disease was 61.2 % and was even lower in Malawi infants, 49.4 % compared to 76.9 % in South Africa [303]. Despite this lower efficacy, it is important to understand that, because of the higher mortality rates, more lives will be saved in counties like Malawi compared to those with lower mortality despite the lower efficacy with either vaccine.

The post-licensure effectiveness of Rotarix® has been verified in several studies (reviewed in [223, 264]). Perhaps, most importantly, vaccination has been associated with reduced mortality from diarrheal-associated disease in Mexico [304] and in Brazil [305].

Similar to RotaTeq™, post-licensure safety of Rotarix® is being monitored. Studies conducted in Mexico and Brazil

[307] revealed an increased rate of intussusception after the first dose in Mexico (1 per 51,000 infants) and a small increase only after the second dose in Brazil (1 per 68,000 infants). In an Australian study that evaluated both RotaTeq™ and Rotarix®, there was an increased relative risk for intussusception of 3.5 and 1.5 for the 1–7 and 1–21 days, respectively, after Rotarix immunization in infants 1 to <3 months of age [279].

12 Nonliving Rotavirus Vaccine Candidates

In addition to live oral rotavirus vaccines, a number of nonliving vaccine candidates have been developed and evaluated in animal models. Nonliving vaccine candidates were developed in an attempt to formulate a vaccine that would be more effective than live oral vaccines, since even natural infection does not always result in 100 % protection from reinfection or to be safer. In addition, these candidates were often studied in an attempt to better define mechanisms of protection, including determinations regarding the protective efficacy of various viral proteins. Finally, after the association of Rotashield™ with intussusception, possible safety concerns with live virus vaccines added to the possible need for nonliving vaccine candidates. The nonliving candidates studied include DNA vaccines [307, 308], inactivated purified triple- and double-layered virus particles [309, 310], recombinant virus-like particles (VLPs) containing VP2 and VP6, with or without VP4 and VP7 [311], inactivated virus [312], and recombinant-expressed proteins including VP6 and portions of VP8 protein [313, 314]. To date none of these candidates have been tested in humans.

Using animal models, each of the above candidates have shown significant levels of protection, especially in the adult mouse model which uses reduction of viral shedding as its measure of protection. Of note, VLPs did not induce protection from illness when used in the gnotobiotic pig model, currently the only illness animal model [315]. Except for DNA-based vaccines, the other candidates often require the use of an effective adjuvant, usually recombinant formulations of bacterial toxins, to induce protection [316, 317]. The use of this type of adjuvant in humans greatly increases the safety concerns associated with these vaccine approaches. The immunogenicity and protection of a candidate inactivated rotavirus vaccine, human strain CDC-9 (G1P[8]) formulated with aluminum phosphate, was recently evaluated in gnotobiotic piglets. The vaccine was immunogenic and protected animals following oral challenge with a homologous virulent human strain Wa (G1P[8]) [318]. It remains to be seen whether these strategies will have a role as alternative approaches to rotavirus immunization. If the present licensed live oral vaccines, RotaTeq™ and Rotarix®, or other live oral rotavirus vaccines prove to be ineffective or have safety issues, nonliving vaccines may be further developed.

Rubella Virus

31

Walter Orenstein and Susan E. Reef

1 Introduction

Rubella (German measles) is usually a mild febrile viral rash illness in children and adults. However, infection early in pregnancy, particularly during the first 16 weeks, can result in miscarriage, stillbirth, or an infant born with birth defects known as congenital rubella syndrome.

2 Historical Background

German physicians, in the mid-eighteenth century, were the first researchers to distinguish the rubella disease from other exanthems. Even though they named it Rotheln, rubella is recognized today by its common English language eponym German measles [1]. In 1841, a British physician reported an outbreak in a boys' school in India and coined the term rubella, a Latin diminutive meaning "little red" [2]. Even though, in the late nineteenth century, rubella was considered different from measles or scarlet fever [3], not until 1941 the significance of rubella was noted. In 1941, Norman McAlister Gregg, an Australian ophthalmologist, linked congenital cataracts to maternal rubella. In his practice, Gregg had noticed an unusual number of infants with cataracts [4]. It is noted that a crucial clue was a conversation he overheard in his waiting room between 2 mothers who were discussing the rubella they both had sustained in pregnancy during the Australian outbreak of 1940 [5]. Gregg's original observation was followed by reports of Australian [6], Swedish [7], American [8], and British [9] epidemiologists and teratologists confirming his observations and also noting infants presented with heart disease and deafness. Thus, the characteristic congenital rubella triad was established.

After Gregg's discovery, it was 20 years before the isolation of the causative agent, rubella virus. During this time, various estimates of the risk of fetal disease after maternal rubella were made. However, the wide range of estimates stemmed from the absence of a definitive diagnostic test and consequent misdiagnosis of rubella in the mother. In late 1962, the rubella virus was isolated by two different groups: Weller and Neva [10] in Boston and by Parkman, Beuscher, and Artenstein [11] in Washington, DC.

In 1962–1965 a worldwide rubella epidemic started in Europe and spread to the United States. In the United States an estimated 12.5 million cases of rubella occurred in the United States, resulting in 2,000 cases of encephalitis, 11,250 fetal deaths, 2,100 neonatal deaths, and 20,000 infants born with CRS, a constellation of birth defects that often includes blindness, deafness, and congenital heart defects. The economic impact of this epidemic in the United States was estimated at $1.5 billion [12, 13]. The pandemic led to the recognition of an expanded congenital rubella syndrome (CRS), which added hepatitis, splenomegaly, thrombocytopenia, encephalitis, mental retardation, and numerous other anomalies to the already described deafness, cataracts, and heart disease [14, 15]. The pandemic also made it obvious that a vaccine was needed, and many groups set to work.

The global epidemic spurred development of rubella vaccines and emphasized the need to develop and implement strategies for using these vaccines to prevent this devastating health burden [3]. Between 1965 and 1967, several attenuated rubella strains were developed and reached clinical trials [16–18]. In 1969 and 1970, rubella vaccine was introduced in Europe and North America. Since the late 1970s, vaccination has had a major impact on the epidemiology of rubella and CRS resulting in the interruption of endemic rubella virus transmission in 2001 [19].

3 Methodology

3.1 Mortality Data

Deaths associated with rubella are rare enough that they have no impact on the epidemiology of the rubella.

3.2 Morbidity Data

In the United States, rubella and CRS became nationally reportable to the National Notifiable Disease Surveillance System (NNDSS) in 1966. In 1969, Centers for Disease Control and Prevention established the National Congenital Rubella Syndrome Registry (NCRSR). The reporting efficiency for clinical cases is estimated to be only 10–20 %. As part of the process for documenting the elimination of rubella and CRS in 2004, the adequacy of surveillance was evaluated by reviewing five different sources. The conclusion was that the surveillance system was adequate and was able to support the elimination of endemic rubella transmission [20].

3.3 Serological Surveys

Serological surveys of healthy population groups have been of major importance for understanding the pre-vaccine rubella epidemiology including age specific to identify the target age groups and strategy for vaccine introduction [21]. In addition, serosurveys are used to monitor the impact of the vaccination program, provide evidence for modifying the vaccination strategy, and support the documentation of elimination of rubella/CRS [22].

Prior to the licensure and introduction of the rubella vaccine, the World Health Organization sponsored collaborative serosurveys in 1967–1968 assessing the rubella seropositivity in five continents; however, most of the studies were conducted in the Americas and Europe. In 12 of the 25 studies conducted, the seropositivity rate was 80 % or greater among women aged 17–22 years of age [23]. In the United States, serological surveys conducted in the pre-vaccine era showed seropositivity ranging between 80 and 92 %.

In some regions and countries, post-vaccination serosurveys are used to monitor the vaccination program. However, interpretation of serological studies can be complicated due to variations in the sensitivity of the assays. In the European Region, European Sero-epidemiology Network, the aim is to standardize the serological survey of eight vaccine preventable diseases in 22 countries [24]. By standardizing the methodology, international comparisons can be made to allow to evaluate the effectiveness of different immunization programs and to coordinate vaccine policy to ensure that adequate levels of immunity exist throughout Europe.

In the United States, the most recent use of post-vaccination serosurveys was to support the documentation of elimination of rubella and CRS [25]. Two nationwide seroprevalence studies were conducted through the population-based National Health and Nutrition Examination Survey. Sera were tested for rubella immunoglobulin G antibodies during 1988–1994 and 1999–2004. From the earlier to the later period, the overall age-adjusted rubella seroprevalence in the US population 6–49 years of age rose from 88.1 to 91.3 % was statistically a significant increase. Additional analyses showed that seroprevalence either remained at the same level or higher for the groups (i.e., children of both sexes, women of childbearing age) that were targeted for vaccination.

3.4 Laboratory Methods

3.4.1 Virus Isolation/Detection

In persons with acquired rubella, the rubella virus can be isolated from the blood and nasopharynx during the prodromal period and from the nasopharynx for as long as 2 weeks after eruption. However, the likelihood of virus recovery is sharply reduced by 4 days after the rash. Rubella virus can be isolated using several different cell lines: Vero cell line, primary African green monkey kidney cells, or the RK13 cell line. Through the World Health Organization Global Laboratory Network, laboratories are trained to use either Vero/SLAM cells or Vero cells to isolate rubella virus [26, 27]. The method for detection of the rubella E1 glycoprotein is by using monoclonal antibodies in either an immunofluorescent or an immunocolorimetric assay.

Another recently developed method for virus detection is the polymerase chain reaction (PCR). The most important roles of RT-PCR in rubella control are to characterize the virus genetically and to detect inactivated virus. RT-PCR can be used to detect virus before the IgM is positive and used to detect inactivated particles when the person is shedding only small amounts of virus. The polymerase chain reaction (PCR) has been adapted to the detection of rubella RNA by reverse transcription and amplification.

3.4.2 Antibody Tests

Sera

After the isolation of the rubella, laboratory confirmation of rubella infection was available. Over the last 40 years, several different testing methodologies were developed (Fig. 31.1). These include the following: neutralization assays (NT), hemagglutination-inhibition (HI) assays, enzyme immunoassay (EIA), single radial hemolysis (SRH), and latex agglutination. NT assays were the first to be developed [28], but they are seldom used today, as they are demanding and require use of cell cultures. HI assays were

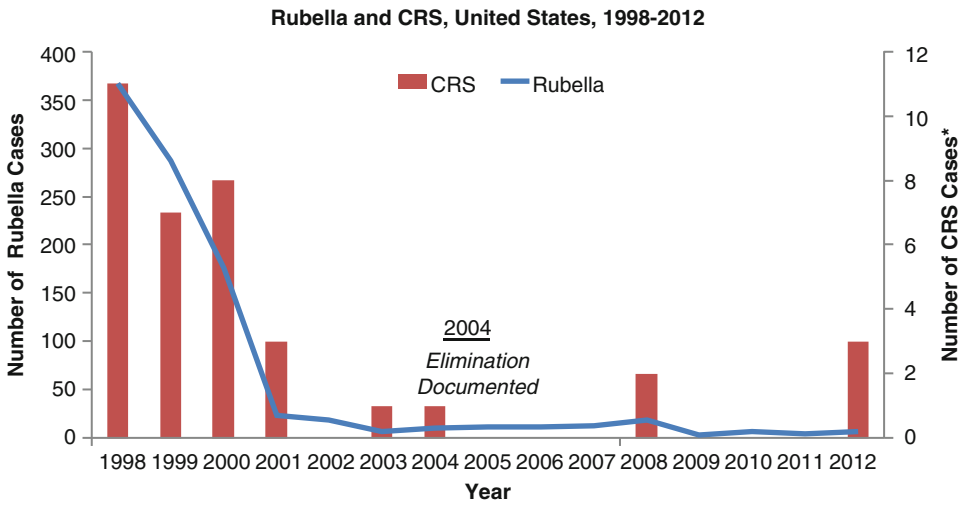

Fig. 31.1 Rubella and CRS, United States, 1998–2012 (*By year of birth)

developed in 1967 [29] and results were shown to correlate well with NT. However, HI is also labor intensive. HI is no longer recommended for routine testing; however, the HI is used as a reference method to establish a calibration standard for other rubella assays. Other more recent assays developed included enzyme immunoassay (EIA), single radial hemolysis (SRH), and latex agglutination, which have been used extensively for rubella antibody screening [30].

Nowadays, EIA is the most frequently used test for rubella antibody screening and diagnosis, as it is a sensitive and an adaptable technique and is readily automated. EIA can also be adapted to detect class-specific antibodies (e.g., IgM, IgG1, IgG3, IgA) and is the method of choice for detection of rubella-specific IgM [31–33]. Indirect and M-antibody capture EIAs are available commercially for detection of rubella IgM. Another adaptation of EIAs is the IgG1 avidity assay. The avidity assays are useful for diagnostic purposes, particularly to distinguish primary rubella from rubella reinfection and to identify persistent IgM responses and nonspecific IgM [34]. The most common diagnostic method employs a denaturating agent (6–8 M urea or DEA) to elute low avidity antibody from antigen-antibody complexes in an EIA (reviewed by Thomas et al. [34]; Best and Enders [30]). Depending upon the strength of this binding, the complex formed may or may not be easily dissociated. Antibody avidity is low after primary antigenic challenge, becomes higher with time, and usually involves IgG antibodies [51, 52]. However, IgG avidity assays can be difficult to establish, standardize, quality control, and interpret; they are therefore recommended only for laboratories experienced in using these assays [35].

Oral Fluids

Since the early 1990s, the use of oral fluid sampling has been used successfully for the detection of rubella antibodies as part of the surveillance system in the United Kingdom [35] Oral fluid sampling can also be used for detecting RNA. In a recent study, the use of oral fluids for detection of RNA was superior to testing of sera or oral fluid for rubella IgM within the first few days after rash onset [36]. Oral fluid samples are easy to collect, noninvasive, and more acceptable to the population. Its use enables field workers to obtain more complete sampling of suspected cases.

4 Biological Characteristics of the Vaccine

Rubella virus is a member of the *Togaviridae* family and the genus *Rubivirus*. Rubella virus is a single-stranded enveloped RNA with a single antigenic type. It measures 50–70 nm in diameter and has two envelope proteins (E1,E2) and a core protein (c). The core protein is surrounded by a single-layer lipoprotein enveloped with spike-like projections that contain the two glycoproteins, E1 and E2. Humans are the only known reservoir.

The rubella virus is relatively temperature labile but is more heat stable than measles virus; it is inactivated after 30 min at 56 °C, 4 min at 70 °C, and 2 min at 100 °C. It degrades rapidly with conventional freezing at −20°, but the virus is stable at −60 °C and below and when freeze-dried with stabilizers. When stabilized with protein it can be repeatedly frozen and thawed without loss of titer. Lipid solvents, weak acids and alkalis, and UV light inactivate the rubella virus. It is also susceptible to a wide range of disinfectants and is inactivated by 1 % sodium hypochlorite, 70 % ethanol, and formaldehyde [37].

Over the last 15–20 years, the study of molecular epidemiology has evolved. In 2005, a systematic nomenclature was adopted by the WHO [38, 39]. The genetic characterization of rubella virus has identified two clades that differ by 8–10 % at the nucleotide level. Clade 1 is divided into 10

genotypes (1a, 1B, 1C, 1D, 1E, 1 F, 1G, 1 h, 1i, and 1j), of which 6 are recognized and 4 are provisional (designated by lowercase letters). Clade 2 contains 3 genotypes (2A, 2B, and 2C) [40]. For rubella isolates collected before 2000, isolates from North America, Europe, and Japan are closely related to each other and form clade I, whereas clade II comprises some strains from China, Korea, and India [41]. However, in China between 2001 and 2007, there was a shift of genotypes toward predominance of IE and 1F [42]. Of rubella isolates collected between 2005 and 2010, three genotypes (1E, 1G, 2B) had wide geographic distribution whereas others occurred sporadically or were geographically restricted [40].

The genetic differences between clades do not appear to translate into antigenic differences, despite amino acid changes of 3–6 % in viral proteins. Isolates from CRS cases are not genetically distinct from isolates from acquired rubella.

5 Descriptive Epidemiology

5.1 Incidence and Prevalence

Our understanding of pre-vaccine era epidemiology of rubella in the United States is from surveillance conducted from 1928 to 1983 in 10 selected areas in the United States. During the 1962–1965 the United States experienced an epidemic with an estimated 12.5 million cases of rubella, resulting in 2,000 cases of encephalitis, 11,250 fetal deaths, 2,100 neonatal deaths, and 20,000 infants born with CRS, a constellation of birth defects that often includes blindness, deafness, and congenital heart defects.

In 1969, live-attenuated rubella vaccines were first licensed in the United States [43], and a vaccination program was established with the goal of preventing congenital infections, including CRS. Before the introduction of vaccine, rubella incidence was highest among children aged <9 years [44]. The new rubella vaccination program targeted a dose of vaccine to children aged 1 year to puberty [45]. To increase coverage among school-aged children rapidly, mass campaigns were conducted, particularly in schools. By 1977, reported vaccination levels were approximately 60 % for children aged 1–4 years, 71 % for those aged 5–9 years, and 64 % for those aged 10–14 years [46]. The number of reported rubella cases declined 78 %, from 57,686 cases in 1969 to 12,491 cases in 1976. As anticipated, the greatest decreases in rubella occurred among persons aged <15 years; however, incidence declined in all age groups, including adults. This decrease in rubella also resulted in a decline in the number of reported CRS cases, from 68 cases reported in 1970 to 23 reported in 1976 [47]. The total number of rubella cases continued to decline overall during the late 1970s; however, in subsequent years a resurgence of rubella occurred among older adolescents and young adults, with outbreaks occurring among students in high schools, colleges, and universities and among persons on military bases and workers in hospitals. Rubella incidence was highest among young adults [48]. In addition, the number of reported CRS cases increased, from 23 in 1976 to 57 in 1979; however, the annual number of CRS cases never reached the level reported during the 1960s in the pre-vaccine era. Serologic studies at that time suggested that 10–20 % of adults remained susceptible to rubella [49].

The resurgence of rubella and its increased incidence among young adults focused attention on the need for additional strategies. In 1978, the changing epidemiology of rubella prompted the Advisory Committee on Immunization Practices (ACIP) to additionally recommend that rubella vaccine be targeted to susceptible postpubertal females, in addition to adolescents, persons in military service, college students, and persons in certain work settings (e.g., hospitals) [50]. Efforts to increase overall childhood vaccination coverage to greater than 90 % for all vaccine-preventable diseases, including rubella, had begun in 1977, with the first National Childhood Immunization Initiative [51]. In 1978, a program was undertaken to eliminate indigenous measles in the United States; the use of combined vaccines, either measles-rubella (MR) vaccine or measles-mumps-rubella (MMR) vaccine, was encouraged. These efforts to increase immunity among selected adults and children resulted in substantial decreases in the numbers of both rubella and CRS cases. During 1977–1981, reported rubella cases declined from 20,395 to 2,077. During 1979–1981, reported CRS cases decreased from 57 to 10 [52]. For the 1981–1982 school year, rubella vaccination coverage was 96 % for children entering school (i.e., into kindergarten or first grade) in the 50 states and the District of Columbia [53]. Efforts to maintain high coverage through enforcement of school immunization laws produced a continuing decrease in reported rubella cases.

In 1979, a new formulation of live-attenuated rubella vaccine (RA 27/3) replaced the previous rubella vaccines in the United States. RA 27/3 vaccine had been determined to induce higher antibody titers and produce an immune response more closely paralleling natural infection than previous vaccines [54].

By 1979, rubella vaccination had eliminated the characteristic 6–9-year epidemic cycle of rubella in the United States [52]. In 1980, national health objectives for 1990 were established for rubella and CRS, calling for reductions in the annual number of rubella cases to fewer than 1,000 and CRS cases to fewer than 10 [55]. During the 1980s, the number of reported rubella cases continued to decline steadily, and overall incidence continued to decrease in all age groups. By 1983, the 1990 objectives already had been achieved, with 970 rubella cases and four CRS cases reported. During the early 1980s, outbreaks continued to be reported in health-care settings, universities,

workplaces, and prisons. In 1981, ACIP recommendations increased emphasis on targeting these settings to ensure vaccination coverage among students and staff members [56].

In 1988, state health departments reported an all-time low of 225 cases of rubella; however, in 1989, a total of 396 cases were reported, and in 1990, the number increased to 1,125 [57]. Most cases were associated with outbreaks that occurred in settings where unvaccinated adults congregated, including colleges, workplaces, prisons, and in religious communities that did not accept vaccination. Outbreaks among these populations accounted for 56 % of CRS cases in the 1990s. In 1989, a goal was established to eliminate indigenous rubella transmission and CRS in the United States by 2000 [58]. With establishment of the 1993 Childhood Immunization Initiative, the number of annual rubella cases continued to decline in the mid-1990s. Outbreaks continued to be associated with settings where adults had close contact; however, the demographic characteristics of rubella patients changed. Before 1995, most persons with rubella were non-Hispanic; beginning in 1995, most were Hispanic [59]. Beginning in 1998, data on country of origin were collected for rubella patients. These data revealed that, during 1998 and 1999, approximately 79 and 65 % of patients whose country of origin was known were foreign born. Of these, 91 % in 1998 and 98 % in 1999 were born in the Western Hemisphere, and 43 % in 1998 and 81 % in 1999 were born in Mexico. These persons were either unvaccinated or their vaccination status was unknown. During 1998–2000, a total of 23 CRS cases were reported to CDC. The infants in 22 (96 %) of these cases were born to Hispanic women, and 22 of the mothers with known country of birth were born outside the United States. The countries of origin of these mothers were Mexico (14 mothers), Dominican Republic (four), Honduras (two), Colombia (one), and Philippines (one). Since 2001, the annual numbers of rubella cases have been the lowest ever recorded in the United States: 23 in 2001, 18 in 2002, seven in 2003, and nine in 2004. Approximately half of these cases have occurred among persons born outside the United States, of whom most were born outside the Western Hemisphere. During 2001–2004, four CRS cases were reported to CDC; the mothers of three of the children were born outside the United States. In 2004, the panel convened by CDC concluded that sustained transmission of rubella has been interrupted. Since 2004, the United States has maintained elimination of rubella and CRS. From 2005 to 2011, a median of 11 rubella cases was reported each year in the United States (range: 4–18). In addition, two rubella outbreaks involving three cases, as well as four total CRS cases, were reported [60]. In 2012, as part of the documentation process for PAHO, the United States convened an independent external panel to evaluate if elimination of measles, rubella, and CRS had been maintained.

The incidence of CRS has been evaluated mainly in developed countries over the last 60 years. Initially in the United States, the incidence of CRS roughly paralleled the incidence of rubella in individuals over 15 years; however, with the interruption of endemic rubella virus transmission, CRS cases became very rare and occurred mainly among mothers who are foreign born [61].

In most developing countries, there is little documentation to illuminate the epidemiology of either rubella or CRS. The epidemic pattern for developing countries is similar to the developed countries with cycles 3–7 years. Globally, it is estimated that approximately 103,000 infants with CRS were born in 2010 with the greatest burden in regions where rubella vaccine uptake is limited. A review of worldwide data concerning CRS revealed rates in developing countries varying between 0.6 and 2.2 per 1,000 live births, similar to rates seen in developed countries before universal vaccination [62, 63]. It has been estimated that the incidence of CRS is 0.1–0.2 per 1,000 live births during endemic periods and 1–4 per 1,000 live births during epidemic periods [64]. Where rubella virus is circulating and women of childbearing age are susceptible, CRS cases will continue to occur.

5.2 Epidemic Behavior

Rubella usually occurs in a seasonal pattern, with epidemics every 5–9 years. However, the extent and periodicity of rubella epidemics is highly variable in both industrialized and developing countries. From published literature, epidemics have been reported every 6–7 years in Hong Kong [65] and São Paulo, Brazil [66]; every 4–5 years in Panama [67]; and every 4–7 years in Argentina [68] and Bangkok, Thailand [69–71].

5.3 Geographic Distribution

Prior to the establishment of the rubella and CRS elimination goal in the Region of Americas, rubella had a worldwide distribution. However, in 2009, the last endemic rubella case in the Region of the Americas was documented in Argentina [72]. Rubella continues to circulate in the Eastern Hemisphere. In 2012–2013, rubella epidemics have been documented in several countries (i.e., Romania [73], Poland [74], Japan [75], Ethiopia) in three different continents.

5.4 Temporal Distribution

Prior to the elimination of endemic rubella virus in the United States, the largest number of rubella cases occurred in late winter and spring, in both high and low incidence. Because

of the acceleration of measles control, the understanding of rubella seasonality can be documented in developing countries. Using the measles case-based surveillance in African region, rubella seasonality could be detected with variation of seasonality by subregion [76]. In the West subregion, during 2003–2009, marked seasonality of rubella occurred each year with sharp increases in reporting during January with peaks in March–April followed by sharp declines in May, leading to troughs during October– December each year. However, in the South subregion, a distinct annual seasonality was observed with consistently few cases reported during January–June each year, followed by gradual increases in June–July and peaks in September–October.

5.5 Age and Sex

In the pre-vaccine era in the United States, rubella was primarily a disease of school-aged children; however, rubella occurred also in preschool children. In many countries, this is the pattern for rubella infection. However, in other countries such as Caribbean islands and Southeast Asia, young adult females show high susceptibility, which can result in cases among pregnant women with subsequent CRS.

In the pre-vaccine era, there were no differences in attack rates by sex for children. In the post-vaccination era, in countries where adolescent girls were targeted for vaccination, outbreaks among adolescent and adult males have been documented [71]. However, in countries that have not targeted females only in vaccination, attack rates in males and females are similar.

6 Mechanisms and Routes of Transmission

Rubella virus is spread from person to person via respiratory droplets. Individuals with acquired rubella may shed virus from 7 days before rash onset to ~5–7 days thereafter. Both clinical and subclinical infections are considered contagious.

After primary implantation and replication, subsequent viremia occurs, which in pregnant women often results in infection of the placenta. Placental virus replication may lead to infection of fetal organs. Infants with CRS may shed large quantities of virus from bodily secretions, particularly from the throat and in the urine, up to 1 year of age. Outbreaks of rubella, including some in nosocomial settings, have originated with index cases of CRS. Thus only individuals immune to rubella should have contact with infants who have CRS or who are congenitally infected with rubella virus but are not showing signs of CRS.

7 Pathogenesis and Immunity

Although the pathogenesis of postnatal (acquired) rubella has been well documented, data on pathology are limited because of the mildness of the disease. Primary implantation and replication in the nasopharynx are followed by spread to the lymph nodes. This is followed by viremia and shedding of virus from the throat.

For acquired rubella, the rubella virus induces both circulating and cell-mediated immune (CMI) responses. HI and NT antibodies develop very rapidly and may be detectable, while the rash is still specific antibodies, rubella-specific IgM appears first and is closely followed by IgG1, IgG3, and IgA [31]. IgM is transient; it peaks on about day 7 and persists for 4–12 weeks after illness and occasionally for about a year [77].

The role of CMI in protection from rubella has not been determined. Rubella infection induces a fall in total leukocytes, T cells, and neutrophils, and a transient depression in lymphocyte responses to mitogens and antigens (e.g., purified protein derivative, PPD), but the mechanism responsible for the mild immunosuppression has not been elucidated. Studies of cytokine secretion demonstrate the strongest responses in persons with a recent history of rubella [78, 79]. Lymphoproliferative assays show that CMI responses develop a few days after onset of rash and persist at low levels for many years.

The pathology of CRS in the infected fetus is well defined, with almost all organs found to be infected; however, the pathogenesis of CRS is only poorly delineated. In tissue, infections with rubella virus have diverse effects, ranging from no obvious impact to cell destruction. The hallmark of fetal infection is chronicity, with persistence throughout fetal development in utero and for up to 1 year after birth.

The immune response to the intrauterine rubella infection starts while in pregnancy. However, the development of the fetal humoral immune system appears to be too late to limit the effects of the virus. Cells with membrane-bound immunoglobulins of all three major classes—IgM, IgG, and IgA—appear in the fetus as early as 9–11 weeks gestation [80]. However, circulating fetal antibody levels remain low until mid-gestation, despite the presence of high titers of virus. At this time, levels of fetal antibody increase, with IgM antibody predominating [81]. As in the case with other chronic intrauterine infections, congenital rubella infection may lead to an increase in total IgM antibody levels [82]. At the time of delivery of infected infants, levels of IgG rubella antibodies in cord sera are equal to or greater than those in maternal sera, even if the infant is born prematurely. IgG is the dominant antibody present at delivery in rubella-infected infants and is mainly maternal in origin. In contrast, the IgM levels are lower but are totally fetus derived.

8 Patterns of Host Response

In acquired rubella, the ratio of inapparent to apparent infections has been estimated to be from 1:1 to as high as 6:1 [83, 84]. Age probably influences the clinical expression of infection. Children usually develop few or no constitutional symptoms.

8.1 Clinical Manifestations

8.1.1 Acquired Infection

The average incubation period is 14 days with a range of 12–23 days. During the first week after exposure, there are no symptoms. During the second week after exposure, there may be a prodromal illness consisting of low-grade fever (<39.0 °C), malaise, mild coryza, and mild conjunctivitis, which is more common in adults. Postauricular, occipital, and posterior cervical lymphadenopathy is characteristic and typically precedes the rash by 5–10 days. Children usually develop few or no constitutional symptoms. Rarely, rubella may mimic measles in its severity of fever and constitutional symptoms, but Koplik's spots are absent.

At the end of the incubation period, a maculopapular erythematous rash appears on the face and neck. The rubella rash occurs in 50–80 % of rubella-infected persons and is sometimes misclassified as measles or scarlet fever. The maculopapular erythematous rash of rubella starts on the face and neck and progresses down the body. The rash, which may be pruritic, usually lasts between 1 and 3 days. The rash is fainter than measles rash and does not coalesce, and it may be difficult to detect, particularly on pigmented skin.

Rubella disease is usually mild, resulting in very few complications apart from the serious consequences of congenital rubella infection. Transient joint symptoms (e.g., arthritis, arthralgias) may occur in up to 70 % of adult women with rubella. They usually begin within 1 week after rash onset and typically last for 3–10 days, although occasionally they may last for up to 1 month. Other complications include thrombocytopenic purpura (1 in 3,000 rubella cases) and encephalitis (1 in 6,000 rubella cases). In outbreaks in the Kingdom of Tonga (2002), the Independent State of Samoa (2003), and Tunisia [85], encephalitis was seen more commonly, with an estimated rate of 1 in 300 to 1 in 1,500 cases. Long-term sequelae with such progressive rubella panencephalitis (PRP) are rare. PRP has similarities to subacute sclerosing panencephalitis (SSPE) caused by measles.

8.1.2 Congenital Rubella Infection

The risk of congenital infection is related to the gestational age at the time of maternal infection. The outcome of a primary rubella infection during pregnancy includes the following: spontaneous abortion, stillbirth/fetal death, infant born with CRS, infant born with congenital rubella infection without congenital defects, and birth of a normal infant.

The most common defects of CRS are hearing impairment (unilateral or bilateral sensorineural), eye defects (e.g., cataracts, congenital glaucoma, or pigmentary retinopathy), and cardiac defects (e.g., patent ductus arteriosus or peripheral pulmonic stenosis). Other clinical manifestations may include microcephaly, developmental delay, purpura, meningoencephalitis, hepatosplenomegaly, low birth weight, and radiolucent bone disease (Table 31.1).

Children with CRS may develop late-onset manifestations including endocrine abnormalities (e.g., diabetes mellitus, thyroid dysfunction), visual abnormalities (e.g., glaucoma, keratitic precipitates), and neurological abnormalities (e.g., progressive panencephalitis), in addition to developmental manifestations which include autism [86].

When pregnant women are infected with rubella during the first 11 weeks of gestation, up to 90 % of live-born infants will have CRS; thereafter the rate of CRS declines until 17–18 weeks' gestation when deafness is the rare and only consequence. Reinfection with rubella may occur, but if this occurs early in pregnancy, transmission to the fetus is rare, and the risk of congenital rubella defects is probably less than 5 %.

8.2 Serological Responses

Antibodies to rubella virus develop promptly and can sometimes be detected on the day of rash onset. The IgM and IgG classes rise rapidly; IgG persists, but IgM begins to wane

Table 31.1 Common transient and permanent manifestations in infants with congenital rubella syndrome

Transient manifestations	Permanent manifestations
Hepatosplenomegaly, hepatitis	Hearing impairment (deafness)
Thrombocytopenia with purpura/petechiae Dermal erythropoiesis (blueberry muffin syndrome)	Congenital heart defects (e.g., patent ductus arteriosus, pulmonary arterial stenosis)
Long bone radiolucencies Intrauterine growth retardation	Eye defects (cataracts, pigmentary retinopathy, congenital glaucoma, microphthalmos)
Meningoencephalitis Interstitial pneumonitis	Central nervous system involvement (e.g., microcephaly, mental and motor delay, autism)

(see Sect. 7). However, in a small percentage of persons, IgM persists for long period of time [30]. This persistence can be confused with acute infection. To help differentiate IgM associated with acute infection, testing for seroconversion of IgG or avidity testing is recommended.

9 Control

9.1 Vaccine Development

As noted earlier, the development of vaccines was spurred by the 1962–1965 epidemics in Europe and the United States. Shortly after the isolation of rubella virus, investigators attempted to develop an inactivated virus vaccine, but their attempts were unsuccessful. Either the vaccines were not antigenic or if antibodies were produced, it was questionable if the preparation was contaminated with live virus [87].

With the issues of the inactivated vaccine, several groups were interested in developing a live-attenuated vaccine in the 1960s. Parkman and colleagues were the first to successfully attenuate RV with 77 passages in African green monkey kidney cell cultures and to give the attenuated strain HPV77 [88]. Between 1969 and 1970, three vaccines were licensed in the United States, including HPV-77.DK12 (dog kidney), HPV-77.DE5 (duck embryo), and Cendehill (rabbit kidney) [46]. The Cendehill vaccine was licensed in Britain in 1969, and shortly thereafter, the RA 27/3 vaccine (human diploid cells) was licensed in Europe. In Japan, the initial vaccines licensed were the Takahashi (rabbit kidney) and Matsuura (Japanese quail-embryo fibroblasts) vaccines. Three additional vaccines were licensed in Japan: Matsuba (rabbit kidney), DCRB 19 (rabbit kidney), and TO-336 (rabbit kidney) [89].

By 1979, all three of the vaccines licensed in the United States were replaced by RA27/3. RA27/3 vaccine generally induces higher antibody titers and produces an immune response more closely paralleling natural infection than the other vaccines. HPV-77.DK12 was withdrawn due to the higher incidence of side effects as compared to other vaccines.

After the development and licensure of the initial rubella vaccines globally, additional vaccines were licensed in various geographic locations. In 1980, a rubella vaccine (BRD-2) was developed in the People's Republic of China using a local RV strain from a child, isolated in human diploid cells. In a trial comparing the BRD-2 vaccine and RA 27/3 vaccine, the seroconversion rate and mild side effects were similar [90]. In Japan, currently, five different rubella vaccines are in use, including the TO-366 vaccine [91]. Even though additional vaccines have been licensed and developed, RA27/3 continues to be the most widely used vaccine strain globally.

Rubella-containing vaccine is available as either a single antigen or combined with measles (MR), measles and mumps (MMR), and measles, mumps, and varicella (MMRV).

9.2 Response

9.2.1 Clinical Reactions

Vaccines can develop mild rubella, including rash, lymphadenopathy, fever, sore throat, and headache. However, the incidence of each of these side effects varies directly with age, being almost absent in infants and increasing with age. Fortunately, the minor side effects are seldom severe enough to cause days to be lost from school or work [92–94].

In a double-blind study of vaccination with MMR in twins, there was a 1 % incidence of arthropathy and little evidence of other reactions [95]. In 1991, the Institute of Medicine of the National Academy of Sciences published a committee report on four possible adverse effects of rubella vaccine: acute arthritis, chronic arthritis, neuropathies, and thrombocytopenia [96]. The committee concluded that RA27/3 causes acute arthritis. With regard to chronic arthritis, the committee stated doubtfully, "The evidence is consistent with a causal relation between the currently used rubella vaccine strain (RA27/3) and chronic arthritis in adult women, although the evidence is limited in scope and confined to reports from one institution." Since that time, large vaccination campaigns conducted in millions of Latin Americans, including women of childbearing age, have not been accompanied by additional reports of significant chronic arthropathy [64].

In 2011, IOM was asked to review adverse events associated with several vaccines. In their report, the IOM concluded that the evidence is inadequate to accept or reject the causal relationship between MMR vaccine and chronic arthralgia or arthritis in women [97].

9.2.2 Shedding of Virus

Because of the risk of spreading of vaccine virus to susceptible persons including pregnant women, considerable effort has been made to detect the spread of vaccine virus to susceptible contacts. Early contact studies documented no evidence of spread to susceptible contacts. However, there was a rare asymptomatic seroconversion that could not be explained fully [98, 99].

Virus has been recovered from breast milk of women vaccinated postpartum. Transmission of the virus to the infant has been documented, but the infection is asymptomatic and transient.

9.2.3 Serological Response

Rubella vaccine is usually administered ≥12 months of age, since maternal antibodies have usually disappeared by that age. The seroconversion rate for children ≥12 months is >95 %. The age at first vaccination does not appear to be as critical for rubella as for measles vaccine. Passively transmitted maternal antibodies to rubella have been found in approximately 5 % of infants from 9 to 12 months and 2 %

from 12 to 15 months of age. Studies of rubella-containing vaccine administered at 9–12 months of age has demonstrated a seroconversion rate of >90 %. Rubella vaccine is usually offered to children with measles vaccine (MR) or measles and mumps vaccines (MMR).

9.3 Rubella Vaccination Strategies: Their Impact on Rubella and Congenital Rubella

9.3.1 Epidemiological Approach

The goal of rubella vaccination programs is the prevention of the intrauterine infection that causes CRS. There initially were two basic approaches: the US (indirect protection) (see Sect. 5.1) and the UK (direct protection). However, with over 30 years of experience with introducing rubella vaccine into countries, the strategies have evolved.

In 2000, the WHO convened a meeting to review the worldwide status of CRS and its prevention [100, 101]. Since the previous international meeting on CRS and rubella in 1984, some of the changes included availability of more data on the CRS disease burden in developing countries, an increase in the number of countries with national rubella immunization programs, and advances in laboratory diagnosis. In 1996, only 83 countries/territories used rubella vaccine in their national immunization programs. Since the 2000 meeting, additional countries have introduced rubella-containing vaccine, two WHO regions (Regions of the Americas and Europe) have established rubella elimination goals by 2010 and 2015, respectively, and one WHO region (Western Pacific) has established an accelerated rubella control and CRS prevention goal by 2015. As of 2010, this number had increased to 130 countries.

In 2011, the WHO rubella vaccine recommendations were updated [64]. The WHO recommends that countries that have not introduced rubella vaccination take the opportunity offered by accelerated measles control and elimination to introduce rubella vaccine. The measles vaccine strategy platform provides the opportunity to use combined vaccine and an integrated measles-rubella surveillance system. The preferred strategy for introduction of rubella vaccination is to begin with MR/MMR vaccine in a campaign targeting a wide range of ages together with immediate introduction of MR/MMR vaccine into the routine program. In 2011, GAVI (formerly the Global Alliance for Vaccines and Immunization) opened a window for introduction of rubella-containing vaccine into GAVI eligible countries (for more on GAVI, see Chap. 1. Of the remaining 63 countries that had not introduced rubella vaccine in 2011, 51 (81 %) are GAVI eligible. GAVI funding will support MR vaccine for catchup campaigns targeting children 9 months to 14 years 11 months and introduction grant. It is estimated that 30 countries will have introduced rubella vaccine by the end of 2015, and all GAVI eligible countries will have introduced it by 2018. With GAVI support, the goal of rubella eradication may be within reach.

9.3.2 Vaccination in Pregnancy

Although there is now abundant evidence for the safety of RA 27/3 for the fetus, pregnancy remains a contraindication to rubella vaccination, and women are advised to take precautions against pregnancy for 1 month (28 days) after vaccination. Prior to the efforts to eliminate rubella from Latin America, there was limited data on vaccination of unknowingly pregnant women [102]. To eliminate rubella and CRS in the region of the Americas, countries conducted campaigns in adult. As part of the campaigns in several countries, women who were vaccinated and subsequently learned that they were pregnant at the time of vaccination were followed up. On the basis of serological evaluation, 2,894 (10 %) women were classified as susceptible at the time of vaccination; of their pregnancies, 1980 (90 %) resulted in a live birth. Sera from 70 (3.5 %) of these infants were rubella IgM antibody positive, but none of the infants had features of CRS as a result of rubella vaccination. The maximum theoretical risk for CRS following rubella vaccination of susceptible pregnant women was 0.2 %. In all the available literature on vaccination of pregnant women, approximately 3,000 susceptible women with live births have been followed up and none of the infants had features of CRS.

9.3.3 Persistence of Vaccine-Induced Immunity

Studies on the long- term persistence of antibodies after rubella immunization of susceptible persons have documented that immunity probably persists for life in the majority of vaccines. Although antibody titers fall over time, sometimes to very low levels, immunological memory persists, and a secondary immune response will occur on exposure to rubella.

Follow-up studies have shown that 95–100 % RA27/3 vaccines are seropositive 10–21 years after immunization [103]. The high seroconversion rate, the persistence of antibodies, and an amnestic response when revaccinated do not support the need for a second dose of rubella vaccine. However, based on the indications for a second dose of measles- and mumps-containing vaccine, a second dose of MMR is now offered in most industrialized countries, and this helps to boost low rubella antibody concentrations.

9.3.4 Reinfection

Reinfection is usually subclinical and is more likely to occur in persons with vaccine-induced immunity than in those whose immunity is naturally acquired. It is not due to antigenic variants of rubella virus [104]. Reinfection is defined as a significant rise in antibody concentration in a person with

preexisting antibodies. In a clinical situation, preexisting antibodies can be confirmed by testing an earlier stored serum, but if no such serum is available, evidence of preexisting antibody may be accepted if there are at least two previous laboratory reports of antibodies ≥10 iu/ml obtained by reliable techniques (not HI) or a single result of antibodies ≥10 iu/ml obtained after documented rubella vaccination [105].

The concern for reinfection is a pregnant woman as it might lead to fetal infection. Several challenge tests have been conducted with some attempting to document viremia. In one of these studies [106], the viremia was detected in persons with low levels of antibody titers. The risk of congenital infection following reinfection in the first 12 weeks of pregnancy has been estimated in the United Kingdom to be about 8 %, while the risk of congenital rubella defects is probably no more than 5 %, which is considerably less than the >80 % risk of primary rubella during the same period of pregnancy [107]. Thus, it is important to be able to use laboratory tests to distinguish reinfection from primary rubella in pregnancy.

Viruses Causing Acute and Chronic Syndromes and/or Malignancy

Hepatitis Viruses: Hepatitis B and Hepatitis D

32

Alison A. Evans, Chari Cohen, and Timothy M. Block

1 Hepatitis B Virus

The hepatitis B virus (HBV) virus is a small, partly double-stranded enveloped DNA virus and is the etiological agent of human hepatitis B infection. HBV is the world's most common cause of chronic viral hepatitis and hepatocellular carcinoma (HCC). The latter condition is covered extensively in Chap. 34. It is estimated that there are up to 400 million people chronically infected with HBV around the globe, most of whom are unaware of their infection status [1–3]. The virus is >50 times more transmissible than HIV, but an effective vaccine is available and is having an impact on the global burden of disease caused by hepatitis B [1]. The viral infection and its control has been the focus of intensive scientific research since its discovery.

1.1 Historical Background

Hepatitis as a syndrome has been recognized since ancient times, but the distinction of two forms – one usually transmitted via the fecal-oral route and one more often parenterally transmitted – began to emerge in the early- to mid-twentieth century [4, 5]. Although it could be shown that the parenterally transmitted agent had properties consistent with a virus with a long incubation period [6], identification of the agent itself eluded researchers until the mid-1960s when Blumberg, Alter, London, and colleagues discovered a serum protein, named the "Australia" antigen, present in the blood of some Australian aborigines, individuals with Down syndrome, and oncology patients [7, 8]. The initial evidence suggested that the presence of this protein might be a marker of risk for development of leukemia. Through an exhaustive series of epidemiologic studies, it became clear that the Australia antigen might instead be associated with an infectious agent. This hypothesis took precedence when it was demonstrated in a clinical study that a subject previously negative for the antigen became positive, coincident with biochemical evidence of liver inflammation [4, 9].

Further studies led to the visualization of the virus particle (called the Dane particle) by electron microscopy [10, 11] and demonstration of its transmissibility in animal studies and via blood transfusion [4, 9]. Using banked blood from transfusion recipients, Prince [12] showed that the circulating antigen was first detected during the incubation period for posttransfusion hepatitis, was likely a component of the virus particle, and was persistently detected for long periods after apparent recovery in some patients, consistent with what was then referred to as serum hepatitis, i.e., a hepatitis with a long incubation period and an asymptomatic carrier state [12]. Studies by Krugman et al. in institutionalized developmentally disabled patients had separately identified sera that were capable of transmitting serum hepatitis with clinical characteristics similar to those seen by Prince [5].

Since "infectious hepatitis" transmitted via the fecal-oral route was known as hepatitis A, the serum hepatitis virus was called the hepatitis B virus (HBV). The Australia antigen was shown to be the surface protein of the viral particle, now called hepatitis B surface antigen or HBsAg. The test for HBsAg quickly became an important tool for prevention of posttransfusion hepatitis by its use in screening blood donations [9].

Two major discoveries quickly followed confirmation of the association of HBsAg with serum hepatitis. The first of

these was the observation that noninfectious HBsAg particles could be used to produce an effective vaccine against HBV [13]. Shortly after this came the confirmation that chronic HBV infection is a major cause of hepatocellular carcinoma worldwide [14, 15].

1.2 Methodology Involved in Epidemiologic Analysis

1.2.1 Source of Mortality Data

Mortality from acute HBV infection is uncommon although as many as 1 % of the primary infections lead to decompensated liver disease and failure and death. However, most HBV-related deaths are from hepatocellular carcinoma (HCC) or liver cirrhosis (LC). The World Health Organization (WHO) estimates that 600,000 individuals worldwide die each year as a result of HBV infection [16]. In the United States, the number of deaths is approximately 3,000 per year [17]. In vital statistics data, HBV-related deaths may be undercounted because HCC and LC deaths are often not attributed to specific viral etiologies on death certificates [18, 19]. Among 1,788 deaths in the United States where HBV was listed as a cause of death, the demographic groups with the highest standardized mortality rates were found in males (approximately 3-fold higher than females) and non-White/non-Black racial groups (approximately 5-fold higher than Whites). Age- specific mortality rates peaked in the 55–64-year-old age group [18]. In areas of the world where the prevalence of chronic HBV infection is high, its impact on mortality is reflected directly in HCC and LC death rates.

1.2.2 Sources of Morbidity Data

Acute HBV infection is a reportable disease in many parts of the world. In populations where the infection is endemic, however, the majority of infections occur at younger ages and are likely to be asymptomatic and to result in chronic infection, which is not generally included in reportable disease statistics. In recent years, the United States has seen a dramatic decline in reported acute HBV cases, falling from 8,036 cases nationwide in 2000 to 3,350 in 2010. In 2010, the age group with the highest incidence rate for reported cases was the 30–39-year-olds. Among those with risk factor reported, sexual behaviors (sexual partner with known or suspected HBV infection, multiple sexual partners, and/or men who have sex with men) were found more frequently than injection drug use and medical or occupational exposure [18]. Chronic HBV has been a reportable disease since 2007, but only a few states routinely report cases. Because of the difficulties in determining chronicity, enhanced surveillance programs provide the most reliable data [20]. In 2010, the CDC received reports of 10,515 chronic cases from eight reporting sites. The peak prevalence was found in the 25–54-year age group and in Asian/Pacific Islanders [18].

1.2.3 Serologic Surveys

General population serosurveys have examined the prevalence of HBV markers in many populations worldwide [21–23]. These data have been used to define the general epidemiologic patterns of chronic HBV infection seen worldwide (see Sect. 1.4). In a 2012 systematic review, Ott et al. [24] used 396 published articles with data from general populations to estimate global HBsAg prevalence at 3.7 %. Surprisingly, age-specific prevalence was highest in children in West Africa (~8.5 %). East Asian age-specific prevalences exceeded those of West Africa only in adults age 45 and older.

Carefully constructed large-scale national serosurveys in China, conducted in 1992 and repeated in 2005, have been used to estimate the impact of disease control measures, particularly immunization, on age-specific prevalence of HBV markers. In these two studies, the prevalence of HBsAg in children under 5 years old declined from 9.7 % in 1992 to 1.0 % in 2005, but no change was seen in prevalence in adults age >20 years. All age groups showed a reduced prevalence of anti-HBc, however, suggesting that overall exposure to HBV has been reduced in the population through immunization of infants and other public health measures [25]. Within countries such as the United States, general surveys such as the National Health and Nutrition Examination Surveys (NHANES), good indicators of the health status of the majority of the population, have underestimated prevalence of HBV and other diseases that affect the minority or disadvantaged groups not fully included in the sampling approach. The CDC-adjusted estimate of chronic HBV seroprevalence in the United States was 1.2 million persons in 2012 [17]. The true prevalence may be as high as 2–2.2 million, the difference being largely due to undercounting of foreign-born persons [26, 27].

1.2.4 Laboratory Diagnosis

A number of laboratory tests are available for the detection of current and past HBV infection and immunity. The markers and their interpretation in combination are summarized in Table 32.1. Most markers are detected by standard enzyme immunoassay (EIA) or radioimmunoassay (RIA) and reported as either positive or negative. Some markers may also be quantitated by these methods.

HBsAg is the viral surface (envelope) glycoprotein coat. While HBsAg is not itself infectious, its detection in the circulation is an indication of current infection and the potential for infectiousness to others. It is present in large amounts in the circulation of most infected persons, both as full viral particles and as large numbers of empty particles, round or filamentous in shape, which contain no viral DNA [28, 29].

Table 32.1 Patterns of serologic markers of HBV infection and their usual significance [1, 31]

	HBsAg	Anti-HBs	Anti-HBc	IgM anti-HBc	HBeAg	Anti-HBe	HBV DNA
	Viral glycoprotein coat	Antibody to HBsAg	Total antibody to viral core	IgM class antibody to viral core	e antigen, associated with viral core	Antibody to HBeAg	Viral DNA
Susceptible	–	–	+/–	–	–	–	–
Natural immunity (past infection)	–	+	+	–	NA	NA	–
Vaccine-induced immunity	–	+ (≥10 mIU/mol considered adequate)	–	–	NA	NA	–
Early acute infection	+	–	+	+	+	–	+
Chronic infection	+ Presence for ≥6 months indicates chronic infection	–	–	–	+/–	+/–	+/–
Resolved or resolving infection	–	+	+	–	–	–	–
"Occult" infection	–	–	+	–			+/–

NA not applicable

These subviral particles may be present at 100-fold or more excess in relation to viral particles [29, 30].

HBsAg is detectable in serum beginning 1–2 months after infection, sometimes much earlier, and prior to the onset of symptoms. Persistence for 6 months or longer is an indication that chronic infection has been established. In acute infection, HBsAg levels begin to subside after the onset of symptoms and disappear by 1–5 months after infection, as symptoms resolve [31, 32]. In chronic infection, HBsAg remains detectable for extended periods, often for the lifetime of the infected individual. In general, circulating antigen load decreases after the first few months of chronic infection but remains easily detectable by standard assays [28, 32]. Quantitation of circulating antigen load is emerging as a clinical marker of disease stage or treatment response in chronically infected individuals [30].

The so-called occult HBV, i.e., apparently HBsAg-negative HBV infection (defined by HBV DNA in the liver or blood), has been described in some populations. In some cases HBsAg is present but in a variant form not recognized by standard commercial assays. In other cases, HBsAg is present but suppressed to very low levels by host immunologic state, viral mutation, and/or coinfections with other viruses (e.g., HIV, HCV). In some cases, serologic markers such as anti-HBc and anti-HBs may be absent as well [33]. Clinically, occult infections are significant because blood and body fluids from patients may still be infectious and some occult HBV patients are at high risk of HCC and chronic liver disease [34, 35].

Antibody to HBsAg (anti-HBs) becomes detectable in the serum of acutely infected individuals after the decline of HBsAg [32]. It indicates the development of protective immunity in natural infections and in response to HBV vaccination. It can be quantitated by routine clinical assays, and a level of ≥10 mIU/ml is an indicator of protective immunity [31]. While rare, the co-occurrence of HBsAg and anti-HBs positivity have been reported in some chronic infections [36].

Antibody to hepatitis B core protein (anti-HBc) is non-neutralizing, is detectable in all HBV infections, and persists indefinitely. It is not detected in persons who are immune to HBV through vaccination [31]. It arises first as IgM class anti-HBc, after the appearance of HBsAg in both acute and chronic infection [28, 32]. A high level of IgM anti-HBc is an indication of recent infection, and a predominantly IgM response may be detectable for a short time even after resolution of HBsAg in acute infection. Thus, high-titer IgM anti-HBc in the absence of HBsAg is accepted as the laboratory component of the case definition for reportable acute HBV infection [31, 37]. Nevertheless, IgM anti-HBc may also occasionally be detected in chronic HBV infection as well, often in the course of seroconversion from HBeAg to anti-HBeAg positivity [38].

Hepatitis B e antigen (*HBeAg*) is a soluble protein secreted from HBV-infected hepatocytes and encoded in the open reading frame (ORF) for the C protein, with an alternate initiation site. Its precise function is not fully understood. Its presence is not necessary for viral replication, but clearance of circulating HBeAg usually coincides with a reduction in viral load [28]. HBeAg is present during acute infection but clears usually prior to the clearance of HBsAg [39]. In chronic infection, it persists for a variable period, influenced by host characteristics and viral genotype. In some chronically infected persons, HBeAg may reappear and disappear repeatedly over the course of infection [40].

The appearance of *antibody to HBeAg (anti-HBe)* accompanies or follows clearance of HBeAg in both acute and chronic infections. In chronic infection, this is usually an indicator of transition to less active disease, evidenced by

lower liver transaminases and low to undetectable viral load. In 10–30 % of anti-HBe seroconversions, however, active hepatitis will continue, with elevated liver transaminases and detectable viral load. In another 10–30 % who initially have less active disease after the development of anti-HBe, more active disease returns at a later time [41].

HBV DNA can be detected in circulation and in liver tissues. Commercial assays using hybridization or amplification methods for quantitation of circulating viral load are now widely available on several commercial platforms. Many assays are able to detect viral loads as low as 6 IU/ml (30 viral copies/ml) [42]. HBV DNA is first detected in blood very early in both acute and chronic infection, the earliest of the virus-specific markers. In acute infection, it drops to very low levels by the time of HBsAg clearance, but using very sensitive methods, HBV DNA can still be detected at times in the circulation of subjects who otherwise appear to have cleared infection [28, 43]. In chronic infection, viral load is high initially but may drop to low or undetectable levels later [28]. Very high viral loads (>200,000 IU/ml) occur when the host immune system does not recognize the virus as foreign. During active immune response, viral loads diminish and may drop to at or below the limits of detection when disease moves into the inactive phase [41]. Viral isolation or viral culture are not used in the routine detection or monitoring of HBV infection.

1.3 Biological Characteristics of the Organism

HBV is classified as a Hepadnavirus, a family of DNA viruses that also includes mammalian (woodchuck, ground squirrel) and avian (duck) viruses that are similar in structure and in their hepatotropism. Viral replication occurs in hepatocytes through a reverse transcription step that is unique to this family of viruses [44, 45]. Infections of cells other than hepatocytes, if they occur, do not appear to cause significant disease [29]. Humans appear to be the only natural host for HBV, but infections of nonhuman primates have been produced in the laboratory [31].

The circular, partially double-stranded viral genome is small, ~3,200 nt, and encodes four distinct proteins in overlapping reading frames. These are the polymerase (P), the envelope (S), the nucleocapsid or core (C), and the X protein. Within the S ORF, three different surface proteins are encoded by different initiation codons – the S, pre-S_1, and pre-S_2. Similarly, the C region encodes the core (HBcAg) and e antigens (HBeAg) [28, 44]. Upon entry into the host cell, viral genomes contained in core particles are repaired to form covalently closed circular DNA (cccDNA), which in turn acts as the transcription template for viral mRNA and genomic viral RNA. Genomic copies are packaged in the cytoplasm, after which the viral polymerase reverse transcribes the template into the DNA in the partially double-stranded form found in viral particles in the circulation. In addition to these particles, smaller subviral particles composed of envelope proteins but no genetic material are secreted from infected cells in great excess [28]. In a chronic infection, as many as 10 [11] viral particles per day may be released into circulation, with a half-life of approximately 1 day [46].

Serotypic variants of envelope proteins, designated as adr, adw, ayr, and ayw, have long been noted in HBV infection. While these do not appear to strongly associated with differences in clinical disease, they vary considerably by geography and have been used epidemiologically to study transmission and potential vaccine escape mutants [47, 48].

Genotypic variants of HBV have been classified into ten different types (A–J) with >8 % diversity at the nucleotide level, each with a characteristic geographic distribution [44, 49, 50]. Genotypes A–H are considered to be the major ones worldwide and have been the most extensively studied. Subgenotypes (diversity of 4–8 %) have been described for most of the major genotypes. HBV genotypes differ in the frequency with which clinically significant mutations in the precore (PC), basal core promoter (BCP), and pre-S1 regions are found [41, 47, 49]. The clinical significance of different HBV genotype and mutation combinations is an area of ongoing research. This is briefly reviewed below (Sect. 3.19).

HBV remains intact under many environmental conditions, but under most circumstances it can be handled safely at Biosafety Level 2. It is resistant to freezing, ether, and acid. When dried on surfaces at room temperature, it can remain intact for at least 1 month. Boiling for at least 1 min or heating to 60 °C for at least 1 h will inactivate the virus as will standard autoclaving or dry heat methods. Hypochlorite, glutaraldehyde, formaldehyde, alcohol, and some other commonly used disinfectants can inactivate HBV with sufficient exposure time. HBsAg is resistant to UV irradiation [1, 45, 51].

1.4 Descriptive Epidemiology

The World Health Organization (WHO) has described three epidemiologic patterns of HBV infection based on the prevalence of serologic markers (Fig. 32.1). In the lowest-risk regions (North America, Australia, Northern/Western/Central Europe), the prevalence of HBsAg is <1 % in the general population and 4–6 % for anti-HBs. The intermediate-risk regions (Eastern Europe, Central/South America, Mediterranean, Southwest Asia) have HBsAg in up to 7 % and anti-HBs inasmuch as 55 %. In the highest-risk regions (Southeast Asia, China, sub-Saharan Africa), the HBsAg prevalence may be as high as 20 % and anti-HBs positivity is nearly universal, ~95 % [52].

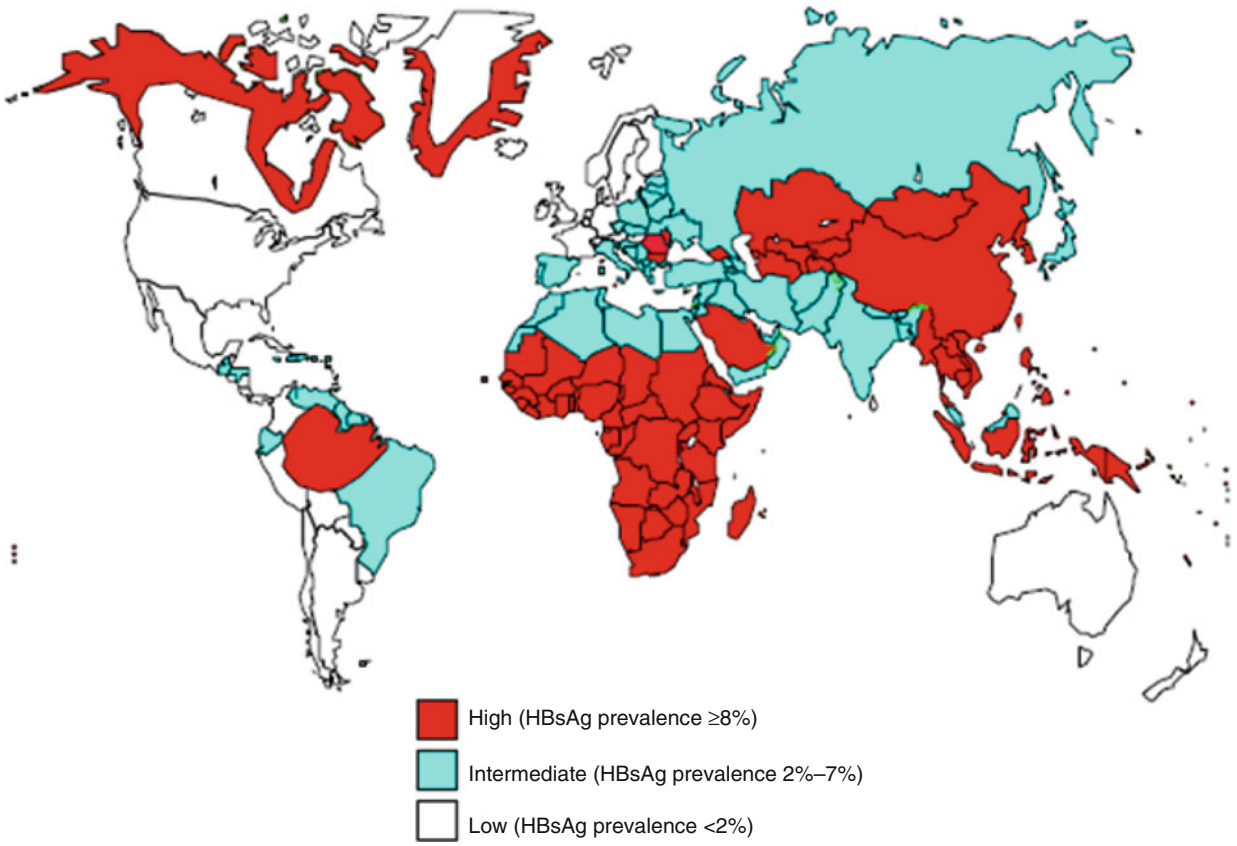

Fig. 32.1 Worldwide areas of high, intermediate, and low prevalence of HBsAg (From WHO [53])

1.4.1 Prevalence and Incidence

The prevalence of chronic HBV infection is the best indicator of the geographic burden of disease (Fig. 32.1). In areas of high prevalence, i.e., ≥8 % HBsAg positive, 70–90%of the population may become infected with HBV prior to 40 years of age. In these areas, infection in the perinatal period or early childhood is common and is responsible for the bulk of chronic infections. Acute hepatitis B is rarely seen since most people are exposed early in life. High rates of LC and HCC in adults in these populations reflect the impact of these early life infections. The high prevalence areas include about 45 % of the world's population [1, 31, 53].

In areas of intermediate prevalence (2–7 % HBsAg positive), acute hepatitis B is more common since age at infection is shifted to older groups. Lifetime risk of infection may be as high as 20–60 %, including both perinatal/early childhood infections and parenteral and sexual exposures later in life. The intermediate areas comprise about 43 % of the world's population.

In the low prevalence regions (<2 % HBsAg positive), most new infections occur in adults through parenteral, sexual, and occupational routes. Lifetime infection risk is <20 %. Immigrants from higher-risk areas of the world may comprise a significant proportion of chronically infected individuals in the population. The low prevalence areas represent about 12 % of the world's population [1, 31, 54].

1.4.2 Epidemic Behavior

Widespread epidemics of hepatitis B infection have not been reported frequently. Small outbreaks may go unrecognized if links between apparently sporadic cases are not identified. In recent years, detected outbreaks in the United States have been most frequently associated with nosocomial exposures in nonhospital settings. Improper infection control procedures in the use of blood glucose monitoring equipment have been involved in multiple outbreaks in long-term care facilities. Hemodialysis and other outpatient medical settings have been implicated as well [55, 56]. Similarly, in the United Kingdom, outbreaks are most frequently associated with nosocomial exposures [57] but have also been documented in groups with shared risk behaviors such as injection drug use and heterosexual intercourse [58]. In the past, nosocomial infections caused by infected health-care workers' contacts with patients have been reported but have decreased in incidence with the widespread use of HBV vaccination and universal precautions against blood-borne infections [54].

1.4.3 Age

Age-specific risks of infection with HBV differ by populations, as described above in *Prevalence and Incidence*. Age at infection is a strong determinant of chronicity in HBV infection. Infants infected perinatally have a risk of developing chronic infection of about 90 %. When infection occurs after the perinatal period through about 5 years of age, the risk of chronic infection is reduced to 25–30 %. In older children and adults, about 5–10 % of infections become chronic [59, 60]. Most chronic infections are asymptomatic for long periods following infection. In acute infections, the development of symptoms is also age dependent, with young children showing symptoms in only 5–15 % of infections but older children and adults in 33–50 % [60, 61].

1.4.4 Sex

HBV infection rates are higher in males in many populations due to two factors. The male predominance in acute infection may be due to higher numbers of males in risk groups for parenteral exposure such as injection drug users. The prevalence of chronic infection is also higher in males in most populations worldwide, even where prevalence of markers of past HBV infection does not differ by gender. This may be due to a predisposition in males to develop chronic infections or to a higher prevalence of other predisposing factors among men, e.g., immunosuppression [52, 61, 62].

1.4.5 Race

Race may be considered a risk factor for HBV infection insofar as it reflects origins in populations of high endemicity, i.e., Asians, Pacific Islanders, Alaska Natives, and Africans.

1.4.6 Occupation

Persons employed in any setting where there is risk of contact with blood or body fluids are at increased risk of HBV infection. Health-care and public safety workers [63, 64], embalmers [65], staff in residential facilities for the developmentally disabled [63], and body piercers and tattoo artists [66] are among those for whom measures to prevent bloodborne infections, including HBV immunization, have been recommended.

1.5 Mechanisms and Routes of Transmission

Humans are the only natural reservoir of HBV infection. Transmission occurs through parenteral routes, percutaneously or permucosally. Body fluids and tissues of infected persons that have been shown to contain HBV and are therefore potential sources of infection include blood and blood products; body secretions that contain blood, semen, vaginal secretions; and cerebrospinal, peritoneal, pericardial, synovial, and amniotic fluids [67]. Saliva of infected persons contains small amounts of virus, and transmission through bites is possible, while other contacts with saliva (e.g., through kissing) have not been shown to transmit infection. Breast milk from infected mothers has not been shown to be a source of HBV infection but caution is recommended if nipples are cracked or bleeding [68, 69]. Natural transmission of HBV by urine, feces, tears, sweat, or respiratory droplets has not been reported [31, 70].

1.5.1 Direct Parenteral Exposure

Without prophylaxis, mother-to-child transmission occurs most often when mothers are HBeAg positive and/or have high circulating viral load during pregnancy. Babies born to these mothers have rates of infection as high as 70 % [71, 72]. In mothers who are HBsAg positive without HBeAg, perinatal transmission risk is lower, about 10 % [31]. Most vertical transmission occurs in the perinatal period, but a small proportion of cases show evidence of intrauterine transmission [73, 74].

Other parenteral exposures contribute to HBV infection as well. In medical settings, transmission from patient to patient has been frequently documented where infection control practices or blood donation screening methods are inadequate [59, 75]. Unsafe injections in medical settings were estimated to be responsible for 21 million new HBV infections worldwide in 2000, nearly one third of all new infections [76]. Injection-associated risk can be attributed to the reuse of needles and other devices used for immunizations, finger-stick devices, and acupuncture needles [61]. Hemodialysis settings are particularly problematic because of the high potential for environmental contamination [77, 78]. Transmission from infected health-care providers has been reported, particularly in the past when universal precautions and immunization were less frequently used. In recent years in the developed world, such transmission has been reported only rarely, and risk appears to be found largely in individuals with high viral loads who performed invasive procedures [79].

Injection drug users are at risk for HBV infection through sharing of injection equipment, particularly in communities where there is prevalent infection and low rates of immunization [31]. Receipt of tattoos in prison or other settings where sterile equipment is not available has also been shown to be associated with HBV transmission, while tattoos performed with sterile equipment are not associated with transmission [80–82].

1.5.2 Inapparent Parenteral Exposure

While HBV infections occur in settings without obvious direct parenteral exposures, it is thought that inoculation

occurs through openings due to skin conditions, injuries, or insect bites rather than through intact skin or mucosal surfaces [59, 83]. The ability of HBV to remain infectious for long periods in the environment contributes to infections that occur through inapparent parenteral means. Horizontal transmission may occur within families, particularly among children due to their high viral loads [60, 70, 84] and from infected mothers to their children even after the perinatal period [54]. Prolonged sharing of living quarters and communal use of personal items such as razors and toothbrushes is associated with infection in households where at least one person is already infected [67, 85]. Risk of infection continues through early childhood in children of infected mothers [54].

Unprotected sexual contact is a common means of transmission of HBV infection, in both heterosexuals and men who have sex with men (MSM). In age-adjusted HBV marker prevalence data among US adults, increasing numbers of lifetime sexual partners, earlier age at first intercourse, and MSM were associated with higher prevalence of HBV infection [86]. Nonimmune sexual partners of HBV-infected persons have a high rate of incident infection [87]. History of other sexually transmitted infections and anal intercourse have also been identified as risk factors.

1.6 Pathogenesis and Immunity

Pathogenesis in HBV infection is primarily but not exclusively confined to the liver. Extrahepatic manifestations such as polyarteritis nodosa, glomerulonephritis, joint inflammation, and skin rashes can occur in both acute and chronic infections [88, 89] as a result of deposition of immune complexes [90]. While there is some evidence that viral replication is possible in cells other than hepatocytes, there is no consistent evidence that this contributes to pathogenesis [29]. Moreover, HBV replication is usually not directly cytotoxic to hepatocytes. During incubation, there is a long period during which viral replication is ongoing, but there are no symptoms, no biochemical evidence of liver inflammation, and no detectable immune response [28, 90]. It is when immunologic response to infection is detected that there is evidence of liver damage. This is consistent with the idea that it is the immunologic response rather than the virus itself that is largely responsible for hepatocellular damage [28, 29]. Possible exceptions to this may be in fulminant hepatitis B where some viral variants associated with this outcome have in vitro characteristics that may be cytotoxic in vivo [91] and in fibrosing cholestatic hepatitis, a rare outcome after liver transplant in HBV-infected patients [92]. Otherwise, the observed sequence of appearance of serologic markers indirectly supports the lack of direct cytopathic effect of HBV infection.

Shortly after exposure, there is high-titer viremia, followed by the detection of HBsAg, usually at 4–10 weeks after infection, and then HBeAg. Humoral immune response is first detected as anti-HBc, several weeks after the appearance of viral antigens, by which time most of the hepatocytes have been infected [28, 29, 92]. Infected individuals with immature or suppressed immune response are more likely to develop immune tolerance to infection and become chronically infected without evidence of significant liver damage [28, 92].

In acute transient infections, specific T lymphocyte responses to many HBV antigens are detectable only after several weeks of infection during which viral particles and antigens are present circulating at very high levels [28, 90]. Once this response is initiated, circulating viral load begins to drop, and infection is rapidly cleared from nearly all hepatocytes [28]. The exact means by which clearance is accomplished is not fully understood but appears to require the rapid replacement of infected hepatocytes killed by CTLs along with releases of cytokines that reduce viral replication in the remaining infected cells without killing them [28, 29, 93]. Circulating HBsAg and HBeAg diminish as well and generally clear by 4–6 months after infection [32]. While transaminase levels may rise to very high levels during this period leading up to clearance, it appears to occur without massive destruction of infected hepatocytes [28, 29]. Even after apparent recovery, patients who have had acute HBV infections may have detectable HBV DNA in circulation for long periods of time [28, 92].

In infections that become chronic, the specific cellular immune responses to viral antigens, especially cytotoxic T lymphocyte responses, are much weaker and narrower than in acute infections [90]. Humoral response, however, is similar to that seen in acute infection except in that anti-HBs is rarely detected [28]. An immunosuppressive role for HBeAg has been postulated as partial explanation for the failure to clear infection [29]. Because chronic infection is a more likely outcome in infections of very young or immunosuppressed individuals, the functional capacity of host immune response clearly has a role as well. Over time, however, chronically infected individuals may exhibit many changes in circulating markers of viral infection, liver damage, and immune response. These are dependent on both host and viral characteristics.

1.7 Patterns of Host Response

HBV infection produces a variety of host responses ranging in severity from self-limited asymptomatic infection to lifetime chronic infection. In acute symptomatic infection, signs and symptoms are nonspecific and similar to other forms of acute hepatitis, including malaise, nausea, vomiting, rash,

joint pains, and abdominal pain. Acute hepatitis may occur with our without jaundice [67].

Chronic infections often do not begin with obvious symptoms, and their manifestations differ between individuals and over the same individual's lifespan. Three defined phases of chronic infection – immune tolerant, immune active, and inactive hepatitis – are defined by the combination of HBeAg/anti-HBe, viral load, and evidence of liver inflammation.

Chronic infections occurring later in life usually begin in the immune-active phase with HBeAg present [41, 94]. Immune tolerant is the initial phase for individuals infected perinatally, and it may persist for decades with positive HBeAg and high viral load but little or no evidence of liver damage [95]. Many of these individuals eventually progress to the immune-active phase in adulthood though the triggering events for this transition are poorly understood [95].

These later acquired infections usually begin in or quickly transition to the immune-active phase with some evidence of immune response to infection. In this phase, viral loads are lower than in the immune-tolerant phase but still readily detectable, and HBeAg is present. Immune-mediated liver damage results in elevations of ALT and histologic evidence of liver inflammation as well as fibrosis in some. The risk of the most serious morbidity and liver-related mortality increases with the duration of the phase. For some, however, there is successful transition to less active disease, indicated by HBeAg to anti-HBe conversion, reduction of viral load, and normalization of liver enzymes. Prior to this transition, there may be a transient hepatitis flare. After HBeAg clearance, most individuals enter the inactive hepatitis phase, characterized by lower viral load, normalization of ALT, and reduction of histologic evidence of liver damage [2, 41].

After seroconversion to the anti-HBe-positive state, a subset of individuals will continue to have moderate to high viral loads and evidence of liver inflammation. This is referred to as anti-HBe-positive active hepatitis and is associated with ongoing hepatocellular damage [96, 97]. Others who convert to anti-HBe positive and enter the inactive phase may experience one or more reversions to HBeAg-positive immune-active phase, during which viral load rises and liver inflammation increases [96, 98], and the risk of cirrhosis is high compared to those who sustain transition to inactive hepatitis [97].

1.7.1 Serologic Patterns of Infection

The incubation period of acute HBV infection is usually between 60 and 90 days from the time of infection to the onset of jaundice or ALT elevation [32, 63]. The first detectable serologic marker is HBV DNA, followed by HBsAg, both of which appear before the onset of symptoms. The length of the incubation period is related to both the amount and route of inoculation as well as host factors [67]. Serologic markers and the patterns associated with different clinical manifestations of infection are summarized in Table 32.1. Table 32.2 summarizes the serologic patterns seen in the different phases of chronic infection [2, 41].

1.7.2 Clinical Outcomes of Infection

In acute, self-limited infections, about 70 % are asymptomatic. Among the remaining 30 %, symptoms range from mild to severe and can persist for some months [32, 39]. Recovery from infection is accompanied by the appearance of anti-HBs, an indicator of immunity to reinfection [63]. Some 1 % of acute infections develop into fulminant hepatitis with massive hepatic necrosis [67]. Risk of fulminant hepatitis is increased by coinfection with other hepatotropic viruses, e.g., HCV or HDV [2].

Chronic infections often begin with no obvious symptoms, especially in infants and young children. Some decades may pass before signs and symptoms of liver inflammation occur as the host transitions into the immune-active phase. Chronic infections do sometimes resolve spontaneously, at a rate of clearance of HBsAg 0.5–1 % per year, usually during the immune-inactive phase [41]. It is estimated that 10–30 % of chronically infected individuals will eventually develop LC or HCC [15, 39, 99]. In addition to disease activity, age, gender, family history, and lifestyle habits (e.g., alcohol consumption) can affect risk [100–102]. Conversion and reversion between HBeAg positive/negative or high-titer HBV DNA positive/negative are also associated with higher risk of HCC [40, 103].

There is considerable evidence for variation in the natural history of disease for different HBV genotypes and subgenotypes, but the full range of comparisons is not possible because of the geographic specificity and rarity of some variants. Moreover, some observed differences in natural history between genotypes/subgenotypes may not be direct effects of genetic variation. For example, a variant that appears to be more likely to cause chronic infection may do so indirectly through prolonging the HBeAg+ period in chronic infection which would in turn lead to higher rates of perinatal transmission and, consequently, younger age of infection, which itself is associated with increased risk of chronic infection. There are also known differences between genotypes and subgenotypes in the prevalence of viral mutations that are independently associated with disease progression [49, 104, 105], and these cannot always be taken into account in natural history studies due to limitations of sample size or laboratory resources.

Despite this caveat, within populations some clear genotype/subgenotype differences in natural history have become apparent. The best studied is the comparison outcomes in genotype B vs. genotype C in Asian populations where both are found. In Taiwan, adults with genotype B chronic infection had higher age-specific prevalence of HBeAg and higher

Table 32.2 Characteristics of the phases of chronic HBV infection

	Immune tolerant	Immune active	Inactive hepatitis
HBeAg	Present	May be present or absent	Absent, conversion to anti-HBe+
Viral load	High (>200,000 IU)	>20,000 IU/ml (HBeAg+ form) >2,000 IU/ml (HBeAg− form)	Low or undetectable (<2,000 IU/ml)
Usual ALT level	Normal	Elevated	Normal
Liver biopsy findings	Normal or minimal inflammation/fibrosis	Inflammation, often with fibrosis	Minimal inflammation, resolving fibrosis
HBsAg	Present throughout	Present throughout	Present but may resolve
Duration	Often many years	Variable	Variable
Risk of cirrhosis/HCC while in phase	Very low	Increases with duration	Low but increases with reversion to immune-active phase

Adapted from [2, 41]

incidence of spontaneous clearance of HBeAg compared to genotype C patients [49, 106]. Infection with genotype C in Taiwan is also associated with higher risk of HCC in HBeAg− individuals [102].

Studies in Alaska have been particularly revealing because several HBV genotypes are represented in Native Alaskan populations, facilitating within-population comparisons. In a large longitudinal study with a median follow-up time of 20 years, Livingston et al. identified subjects with genotypes A, B, C, D, and F at baseline, and age-adjusted HBeAg+ status was associated more strongly with genotypes C, D, and F than with A and B. For those HBeAg+ at baseline, genotype C subjects were much less likely than those with other genotypes to have seroconverted to HBeAg− by the end of follow-up. Genotype C patients also had a significantly older age at HBeAg− seroconversion than all other genotypes (47.8 years vs. 16.1–19.4 years) [107].

Within genotype A, there are three defined subgenotypes, A1–A3. Of these, A1 is the most common genotype in sub-Saharan Africa. In a case–control study in South Africa, Kew et al. [108] found that genotype A was associated with a 4.5-fold risk of HCC compared to all other genotypes. Moreover, all of the genotype A cases who were subgenotyped were subgenotype A1. Genotype A cases also occurred in significantly younger individuals than the cases of other genotypes; this observation is consistent with the known pattern of HCC in this part of Africa, where the risk in younger, HBeAg− men appears to be higher than in other parts of the world [105].

The significance of HBV genetic variation is an evolving area of research. Of particular importance are studies that include both genotyping and viral mutant detection and represent the full range of variability seen in HBV worldwide. The functional significance of many genotype and subgenotype differences has yet to be characterized. There are indications in some clinical studies that viral genetic variants may play a role in treatment response to antiviral therapies, especially interferons [109, 110]. The potential for HBV variants to inform future drug discovery remains to be fully explored. Equally important is further study of the approximately 60 % of chronically infected individuals who never develop serious liver disease [32, 39, 41]. Protective factors are not well understood.

1.8 Control and Prevention

1.8.1 Immunization

The development of the first HBV vaccine was undertaken by Blumberg and Millman in 1969, based upon the observation that some infected persons appeared to develop protective antibodies upon recovery and that antibodies to HBsAg were usually absent in those with apparent chronic infections [111]. Empty HBsAg particles, i.e., particles that do not contain viral DNA, are abundant in the circulation of chronically infected individuals. The first vaccine was produced by the separation and purification of these particles from donor sera. The purified particles were demonstrated to produce a protective immune response in HBV-naïve individuals [13, 111]. A vaccine was formulated and in randomized, placebo-controlled trials was shown to be highly effective in preventing clinical hepatitis or asymptomatic antigenemia [4, 112].

Safe and effective vaccines against HBV infection have been available since 1981. Their use as a routine vaccination has been shown to reduce incidence of acute and chronic infection. In Taiwan, the impact of universal infant HBV immunization, begun in 1984, has been reflected in reductions in HCC incidence in the vaccinated age cohorts [113]. Worldwide, however, many populations at risk for HBV do not have good access to routine immunization. In 2011, 180 countries had included HBV vaccine in routine childhood immunization programs. The average three dose series completion rate in these countries is 75% [114]. Using estimates of prevalence of HBsAg and HBeAg among women of childbearing age, Goldstein et al. [115] modeled the potential impact of different HBV immunization strategies on HBV-related mortality globally and by region in the year 2000 birth cohort. Potential global reduction in HBV-related

mortality was estimated for 90 % vaccine coverage at between 68 and 84 %, depending on whether the vaccine was given at birth.

Early HBV vaccines were derived from the empty HBsAg particles in the blood of infected donors. Current vaccines are made from yeast-derived recombinant subunits of HBsAg and contain no viral DNA. The vaccine does not contain thimerosal. It may be delivered as a single-antigen vaccine or in combination with other antigens. It is given intramuscularly, and three doses are usually the recommendation though these may vary with different vaccine manufacturers and age/risk groups.

When given as directed in healthy persons, the vaccine is both highly immunogenic (stimulates the production of antibodies) and has a high protective efficacy (reduces infection rates in vaccinees). In infants, 80–95 % develop protective antibody titers after two doses, and 98–100 % after three doses. Protective antibody titers are seen in up to 95 % healthy vaccinated children after three doses. In adults, immunogenicity of standard vaccine regimens decline with age, so that by age 60 only 75 % of those receiving three doses have protective titers. For this reason, older adults and individuals of any age with chronic conditions causing immunosuppression (e.g., hemodialysis) may require higher and/or increased numbers of doses [31]. In those who do produce protective antibody, the vaccine is 80–100 % effective in preventing HBV infection or clinical hepatitis. Antibody titers decline with age, but in most cases an anamnestic response is elicited when individuals are exposed to HBsAg, demonstrating that immune memory remains intact [116, 117]. Booster doses are not recommended for most populations [61, 118].

1.8.2 Prevention of Perinatal Transmission

Transmission of HBV infection from mother to child during the perinatal period is a major cause of chronic HBV infections worldwide, particularly in populations with high seroprevalence of HBsAg with HBeAg and/or high viral loads. Several approaches to prevention of perinatal transmission have been proposed in different settings, their use being dependent on a population's resources and rate of perinatal vs. other forms of HBV transmission [53]. When the infection status of the mother is known, the most effective intervention to prevent perinatal infections is the administration of the first dose of hepatitis B vaccine ("birth dose") and one dose of hepatitis B immune globulin (HBIG) within 24 h of birth (preferably within 12 h), followed by completion of the standard 3-dose regimen for Hep B vaccine. This strategy has been shown to be 85–95 % effective in preventing perinatal HBV transmission in infants of infected HBeAg-positive mothers [119–121].

Implementation of this strategy, however, depends on the availability of accurate prenatal HBsAg screening for pregnant women [122] and doses of both HBV vaccine and HBIG in birthing centers. Routine delivery of a birth dose of HBV vaccine is recommended in all infants in the United States, regardless of known maternal HBV infection status, to provide early protection in case of erroneous or unavailable maternal HBsAg status at birth [121]. This is the approach recommended by the WHO as well in countries where perinatal HBV infection risk is high [53]. In regions where many births occur outside of medical facilities, HBV vaccine doses can be made available to community health workers and birth attendants. Vaccine administration as soon as possible after birth is recommended for maximum protection. In these settings it is usually not possible to provide HBIG as well, due to cost of purchase and maintaining appropriate storage conditions [53].

1.8.3 Treatment

There are seven widely approved antiviral therapies for chronic HBV infection, two interferons and five nucleos(t)ide analogs, designed to inhibit activity of the viral DNA polymerase [123]. These treatments are effective in reduction of viral load and/or HBeAg seroconversion in some patients, and expert groups worldwide have produced detailed guidelines for the selection of appropriate patients for their use [124–131]. The relatively short-term endpoints achievable with antiviral therapies, however, do not necessarily translate into long-term reductions of morbidity and mortality from HCC and liver cirrhosis [2]. Antiviral treatment may reduce but does not eliminate the risk of HCC among chronically infected individuals who achieve long-term control of viral replication and improvement of liver histology [132, 133, 134]. Not all treated patients reach these endpoints, however, and those who do often require costly long-term therapy to achieve it, bringing with it risk of antiviral resistance mutations and medication side effects [133]. Many chronically infected individuals who might benefit from antiviral treatment lack access to it because they are unaware of their infection status, are not receiving appropriate medical monitoring, or cannot afford the medications [3, 135]. Moreover, the majority of chronically infected individuals do not fall within the current antiviral treatment guidelines since available medications have not been shown to be effective in some classes of patients, notably those in the immune-tolerant or immune-active phases [136].

1.9 Unresolved Problems

Since the discovery of HBV, great strides have been made in reducing its impact on human health. Nevertheless, hundreds of millions of people worldwide are chronically infected with HBV. Millions more will become infected every year. In addition to immunization, public health mea-

sures for prevention of perinatal HBV transmission and prevention of exposure to blood-borne agents have the potential to reduce or eliminate new HBV infections if implemented appropriately and consistently. For those already chronically infected, current antiviral treatments have the potential to substantially reduce the burden of disease and mortality, but they are not widely available in endemic populations due to cost and medical care access limitations [137]. Even in the developed world, many chronically infected individuals do not know their infection status or do not receive appropriate medical management for it [3]. Cost reduction for antiviral agents and better education of medical professionals on their appropriate use will require new resources and strategies within the already burdened health-care systems.

Continued basic research in HBV virology, immunology, and therapeutics are needed. Despite intensive research, key elements in the natural history of infection such as how the virus gains entry into hepatocytes and how infections are cleared are still unknown [29, 90, 138]. Currently available antivirals are not effective in many groups of chronically infected individuals. Novel approaches and new targets for therapeutics are needed [136, 138, 139]. The staging of liver disease, assessment of treatment response, and early detection of cirrhosis and HCC in the clinical setting would be more accessible and safer for patients with the use of noninvasive methods in the place of liver biopsy, and further work in this area is needed to identify better approaches [139, 140].

Worldwide eradication or elimination of HBV may be an achievable goal [141]. To achieve it, however, will require not only basic science and clinical advances but public health innovation and actions to bring the means of HBV control to all populations.

2 Hepatitis Delta Virus (HDV)

2.1 Historical Background

First reported by Rizzetto et al. [142] in 1977, the hepatitis delta virus (HDV) was initially identified as a novel antibody-antigen system found in the blood and liver of persons infected with HBV and associated with more severe liver damage. The delta antigen was detected in the nuclei of hepatocytes. Transmission studies in chimpanzees demonstrated that the so-called "delta agent" was distinct from HBV but dependent on the presence of HBV infection [143–145]. Further studies characterized the agent as a single-stranded circular RNA virus, defective in that it cannot establish or maintain infection without the copresence of HBV. HDV does not share sequence homology with HBV but is similar to some known plant viroids [146–148].

2.2 Methodology Involved in Epidemiologic Analysis

2.2.1 Morbidity and Mortality Data

It is estimated that about 15 million people worldwide are infected with HDV, mostly in areas of high HBV prevalence or in immigrants from those areas [149]. Population-level data on HDV epidemiology is not widely available since it is not usually part of reportable disease surveillance systems. Exceptions to this are found in areas of higher prevalence of HDV infection, including Italy, Greece, and Australia [150–153]. Even in areas where the disease is reportable, HDV prevalence and disease burden may be underestimated since screening and diagnosis are undertaken only in those known to be infected with HBV. In the United States, some states include HDV in reportable disease statistics but consider these to be underestimates of prevalence or incidence [154]. In the United Kingdom, Cross et al. [155] noted that many laboratories do not routinely test HBV-infected patients for HDV markers. This is likely the case in many populations, and it would lead to underestimation of disease burden [156]. The impact of HDV is also hard to ascertain from vital statistics mortality data since liver disease and HCC deaths are often not attributed to specific viral etiologies in death certificates. Furthermore, in vital statistics data, HBV-related deaths may be undercounted because HCC and LC deaths are often not attributed to specific viral etiologies on death certificates [19].

2.2.2 Surveys

Because of the unique relationship with HBV infections, HDV prevalence surveys worldwide have focused in populations at risk for HBV infection. Geographic areas of HDV endemicity have been identified in the Mediterranean, Middle East, and parts of Asia and Africa [156–158]. Both within and outside of those geographic areas, high prevalence of HDV infection has been reported among injection drug users, people with many sex partners, and other groups at high risk for blood-borne infections in some populations [159–162]. Prevalence of HDV infection worldwide had been declining in some areas where HBV immunization coverage is good, e.g., many parts of Southern and Western Europe [159]. However, the decline of prevalence in Europe observed through the 1990s appears to have halted more recently [156], possibly due to immigration from areas of higher prevalence [158, 163]. Prevalence may be increasing in some parts of the world not originally considered endemic areas for HDV because of immigration from known areas of endemicity [159]. There is some evidence that more effective treatment for HIV infection has indirectly led to either stable or increasing prevalence of HDV infection among these high-risk groups in Europe because of increased survival [160].

2.2.3 Laboratory Diagnosis

Laboratory criteria for diagnosis of HDV infection require the detection of antibody to HDV (anti-HDV), HDV RNA, and/or HDV antigen (HDAg) in blood or liver tissue. Commercial availability of these tests is variable. For epidemiologic studies of the prevalence of HDV exposure, total anti-HDV is the best single marker; however, this approach may underestimate prevalence of recent infections (<30 days) [164] and past infections [157]. Anti-HDV is not an indicator of protective immunity against HDV infection.

Clinically, the distinction between HDV/HBV coinfection (i.e., infections occurring simultaneously) and superinfection (HDV infection occurring in established chronic HBV infection) is considered important. Upon initial infection in either of these, HDV RNA and HDAg are at least transiently present in the liver and blood. Detection of HDAg in blood is not always feasible, however, because of the presence of neutralizing antibodies [165–167]. Unless there is documentation of existing HBV infection, it can be difficult to distinguish co- and superinfections at presentation. Coinfections usually have a longer incubation period – 3–7 weeks from exposure to ALT elevation and onset of symptoms – depending on the size of the inoculum. Superinfection incubation periods are shorter – as little as one week [159, 168].

Coinfection: When HBV/HDV infections occur simultaneously, HBV markers (HBsAg, HBeAg, HBV DNA) are detectable in the blood before any HDV markers appear. HDV RNA and HDAg appear transiently, and HDAg is seen in blood only in about 25 % of patients [165]. A more useful marker in coinfection is IgM anti-HDV (IgM class antibody to HDV), which appears during the acute phase in >90 % of coinfections [167]. Resolution of acute coinfection is accompanied by a rise in IgG anti-HDV (IgG class antibody to HDV). Persistence of IgM anti-HDV beyond the acute phase indicates the development of chronic infection. In resolved coinfection, all HDV markers including IgG anti-HDV may eventually clear. As a result, there is no consistent marker of past infection [157].

Superinfection: When an individual already infected with HBV is superinfected with HDV, HDV RNA, and/or HDAg, detection in serum coincides with a decline in HBsAg, sometimes to undetectable level [166]. This may lead to difficulties in diagnosis in the early phase of disease since HDV testing is often not considered unless the presence of HBV infection is evident. Appearance of HDV DNA is followed by detection of anti-HDV. The persistence of IgM anti-HDV is more frequently found in superinfection rather than in coinfection and is an indicator of chronicity.

2.3 Biological Characteristics

HDV is a defective single-stranded RNA virus that requires HBV to establish infection. Specifically, HDV uses the protein coat of HBV (HBsAg) to encapsulate its RNA genome. HDV cannot survive or replicate without the presence of HBV. With a genome of 1.7 kb, HDV is the smallest known animal virus and the only known animal virus to have a circular RNA genome. Because of these unique qualities, HDV is classified as its own separate genus, *Deltavirus*, of which it is the only known member [165]. Initially, HDV has classified into three major genotypes worldwide, each with both geographic and demographic differences in prevalence [169]. Recent work has further broken down the genotypes into on into eight clades: HDV-1 is found worldwide; HDV-2 (HDV-IIa) is localized to Japan, Taiwan, and Yakutia, Russia; HDV-3 to the Amazon basin; and HDV-4 (HDV-IIb) also to Taiwan and Japan; and HDV-5, HDV-6, HDV-7, and HDV-8 are found in Africa [170]. Coinfections with more than one HDV genotype have been reported [171]. The clinical significance of HDV genotypes and genetic variants is not fully understood. Humans are the only known natural host for HDV infection though experimental infections of chimpanzees and woodchucks infected with HBV or WHV (woodchuck hepatitis virus) are possible [67, 171].

2.4 Descriptive Epidemiology

2.4.1 Prevalence and Incidence

It is estimated that 5 % of those infected with HBV are also infected with HDV, leading to a worldwide prevalence of approximately 15 million individuals. Good epidemiologic data on HDV prevalence are not available for much of the world, and highly affected subpopulations may not be reflected in national-level data. In 2001, the WHO designated the areas of highest prevalence as the Mediterranean Basin, Middle East, Central Asia, West Africa, Amazon Basin, and specific islands of the South Pacific. In contrast, most areas of East Asia have lower prevalences. In North America, Australia, and Western Europe outside of the Mediterranean Basin, prevalence is very low [168]. Even in areas of the world where it is suspected that HDV is endemic, such as sub-Saharan Africa, few or no data on its prevalence or geographic distributions are available [172].

The global picture of HDV endemicity does not necessarily coincide with that of HBV infection [149]. This may be due to assortative contact patterns within populations of HBV-infected persons. For example, HDV is rare among HBV-infected chronic liver disease patients in Hong Kong except in those who are injection drug users, where HDV prevalences of >90 % have been reported [173]. Among HBV-infected persons across the Asia Pacific region, the highest HDV infection rates have been reported among those with behavioral risk factors (e.g., sexual activity, injection drug use) and in some medical settings (e.g., hemodialysis) [174]. Since the discovery of HDV in the late 1970s, some

populations (e.g., in the Amazon basin and Southern Italy) have seen a clear reduction in HDV prevalence because of HBV immunization and measures to prevent transmission of other blood-borne diseases [156]. In other populations where HDV had previously been rare, there have been reports of increasing prevalence and HDV-associated acute hepatitis outbreaks due to migration or increases in injection drug use [149, 161, 175, 176].

2.4.2 Specific Risk Groups

Individuals infected with hepatitis B are at risk for acquiring an HDV superinfection. Those who are susceptible for HBV infection, especially those who are in high-risk groups for hepatitis B infection, are at risk for developing HBV/HDV coinfection.

Ethnicity/Race

Those individuals born in parts of the world where HDV is prevalent are at higher risk for HDV infection. There is no evidence for a biological difference in risk due to race or ethnicity.

Behavioral

Behavioral risk factors for HDV infection are similar to those for other blood-borne infections, i.e., injection drug use, high-risk sexual activities, close contact with persons at high risk, and unsafe tattooing and piercing [161, 173, 175, 177, 178].

Other

HBV-infected individuals who receive unscreened blood or blood products are at increased risk of HDV infection, particularly in higher prevalence areas. Other exposures in medical settings may carry risk [178]. HBV-infected hemodialysis patients in developing countries, for example, may be at high risk for superinfection [179].

2.5 Mechanisms and Routes of Transmission

HDV is transmitted similarly to HBV, through direct contact with blood and infected body fluids. There is a risk of HDV transmission through sexual contact, though it is lower than HBV [159, 171]. HDV is rarely transmitted vertically from mother to infant [168]. Horizontal intrafamilial transmission may occur through inapparent percutaneous or permucosal means but not through casual contact [180].

2.6 Pathogenesis and Immunity

In the clinical setting, HDV infection is associated with more severe liver disease compared to infection with HBV alone. Nevertheless, some infected individuals are asymptomatic and have little to no histologic evidence of liver disease [95, 149, 157, 181]. The pathogenesis of HDV infection is not well understood. Damage to infected hepatocytes is increased with the level of HDV replication, but whether this is a direct cytopathic or indirect immune-mediated effect is not clear [169]. HDV replication requires the presence of HDAg, but HDAg appears not to be cytopathic [182, 183]. As with HBV infection, adaptive immune response in HDV infection is thought to play a role in pathogenesis, but this is not fully understood [159].

2.7 Patterns of Host Response

Initially, HDV infection presents with signs and symptoms of acute hepatitis, whether in co- or superinfection with HBV, with variable severity but generally more severe than what is seen in HBV monoinfection [159]. This initial phase may be more severe than in other viral hepatitides, with 2–20 % leading to fulminant hepatitis [169]. In most (80–95 %) of HBV/HDV coinfections, the course is self-limited and results in clearance of both viruses [159, 169]. Only 2–5 % become chronic. In HBV/HDV superinfections, as many as 20 % may resolve spontaneously [169], but 70–80 % become chronic infections with more rapid progression of liver disease than is seen in HBV monoinfection [149, 159]. Chronic HDV infection leads to cirrhosis in up to 80 % of cases, and it is associated with greater risk of developing chronic liver disease and dying from liver disease than HBV infection alone [168]. The association of HDV infection with the development of HCC is not clear. A review by the International Agency for Research on Cancer (IARC) in 1994 found the evidence for HDV's carcinogenicity inadequate [184]. Nevertheless, several cohort studies since that time have shown a risk of HCC in HBV/HDV infections of 2–6-fold over HBV infection alone [185, 186]. Whether this is a direct carcinogenic effect of HDV or an effect mediated through the higher risk of cirrhosis in HDV infection remains to be seen.

2.8 Control and Prevention

There are no specific measures for prevention of HDV. HBV immunization and general measures to prevent blood-borne infections are the most commonly used and effective means of prevention. Individuals who are already chronically infected with HBV may reduce the risk of HDV superinfection by undergoing antiviral treatment for HBV as well as avoiding behaviors that increase the risk of parenteral infections. In those where HDV/HBV infection is already established, treatment with interferon-alpha has shown some benefit [149].

2.9 Unresolved Problems

Despite many years of study, the epidemiology of HDV infection is not fully understood in some populations due to the lack of population-based data. In addition to viral genetic variability, host characteristics and environmental factors need to be better described. The role of other virus infections such as HCV and HIV may be key to the rapidity of liver disease development in some populations, but has not been widely studied outside of clinic populations. The aims could be accomplished by better availability of surveillance data worldwide.

HDV infection, particularly when it presents as fulminant hepatitis, is a significant clinical challenge. Further studies of natural history and aspects of HDV pathogenesis are needed, with the hope that these may lead to better therapies. Until new therapies or preventive strategies are discovered, more focus is needed on eliminating HBV infection, to continue to decrease the reservoir of susceptibles for future HDV infections. More active campaigns are also needed to educate people on safe practices to prevent HDV infection in those already infected with HBV.

Hepatitis Viruses: Hepatitis C

33

Ponni V. Perumalswami and Robert S. Klein

1 Introduction

Hepatitis C virus (HCV) is a bloodborne human pathogen with a current global prevalence rate of approximately 2–3 %, representing approximately 130–180 million infected individuals [1–5]. Infection with HCV may cause acute hepatitis, but the majority of persons with acute infection are asymptomatic. Persons chronically infected with HCV are at risk of chronic hepatitis and of developing serious hepatic complications such as cirrhosis, hepatocellular carcinoma (HCC), or liver failure. In the developed world, HCV is the leading cause of cirrhosis and primary liver cancers [6, 7] and the major cause of end-stage liver disease leading to liver transplantation [8, 9]. A recent report commissioned by the Institute of Medicine (IOM) of the National Academies estimates that up to 75 % of HCV-infected persons have not been diagnosed [10].

2 Historical Background

The recognition of what was eventually identified as HCV began in the 1970s with the first descriptions of posttransfusion hepatitis not attributable to hepatitis A virus (HAV) or hepatitis B virus (HBV). This disease entity was termed at that time "non-A, non-B" (NANB) hepatitis [8, 11, 12]. Hepatitis C virus was discovered in 1988 and was shown to be the primary etiologic agent of parenterally transmitted NANB hepatitis [8, 11–14]. Leading up to the discovery of HCV, both cohort and case-control studies of persons with NANB hepatitis demonstrated specific risk factors associated with acquiring the disease, including transfusion of blood and blood products, occupational exposure to blood, sex with known infected partners, injection drug use, and sex with multiple partners [15–21]. Together, these studies led to the conclusions that the primary etiological agent of NANB was predominantly both transfusion related and community acquired.

3 Methods for Epidemiologic Analysis

3.1 Sources of Morbidity and Mortality Data

Morbidity and mortality data on HCV infection are acquired from a variety of sources including death certificates, hospital admissions, surveys, research studies, and required reporting of cases. In the USA, HCV is a separate reportable disease, and health-care providers, hospitals, and laboratories are required to send reports of cases of HCV infection to state and local health departments that include them within their jurisdiction.

Among HCV-infected persons, there are a rapidly increasing number of deaths, which in the USA now surpass deaths among HIV-infected persons. US multiple-cause mortality data from 1999 to 2007 of approximately 21.8 million death certificates demonstrated an increase in the mortality rate from HCV infection over that time period [22]. A statistically significant average annual age-adjusted mortality rate increase of 0.18 death per 100,000 persons per year related to HCV was observed ($P = 0.002$). In addition, the relatively young ages at death (45–64 years) of most HCV-infected persons portend a large and ever-increasing health-care burden in the years to come. In the USA alone, estimates forecast a peak in the number of incident cases of end-stage liver disease due to HCV of approximately 38,600 in the year 2030, 3.9 times the predicted annual incidence in 2010 [23].

DOI 10.1007/978-1-4899-7448-8_33,

The annual number of liver transplants and deaths are forecast to peak about 2–3 years later at approximately 3,200 transplants and 36,100 deaths. Of the approximately 2.9 million pre-cirrhotic patients infected with chronic hepatitis C in 2005, it is estimated that without treatment, 24,900 or 0.9 % will have died from hepatitis C by 2010; 379,600 or 13.1 % by 2030; and 1,071,229 or 36.8 % by 2060. Globally, estimates indicate that up to four million persons are newly infected each year, 170 million people are chronically infected and at risk of developing cirrhosis and liver cancer, and 350,000 deaths occur annually due to all HCV-related causes [24, 25].

3.2 Surveys

The National Health and Nutrition Examination Survey (NHANES) refers to a series of assessments that have periodically collected data on the health and nutritional status of a large sample of adults and children in the USA. The information includes HCV prevalence, based on interview, physical examination, and laboratory testing, allowing clinicians to target at-risk groups with educational services and therapeutic options. The latest NHANES survey from 1999 to 2002 included 15,079 total participants and is the largest epidemiological study ever conducted on HCV prevalence in the USA. According to NHANES, 1.6 % or 4.1 million persons in the USA, most of whom were born between 1945 and 1964 were anti-HCV seropositive [3]. The survey, however, sampled from a noninstitutionalized civilian population and did not include certain high-risk persons, namely, the incarcerated, homeless, nursing home residents, hospitalized patients, those in active military service, and immigrants. The survey also missed some groups with an expected high prevalence of HCV infection (e.g., health-care workers and persons on long-term hemodialysis) because of their underrepresentation in the sample studied. As a result, data from NHANES may have underestimated the true prevalence of HCV in the USA by at least one million infected persons [26, 27].

Globally, the prevalence of HCV varies geographically. Recent developments in modeling allow the seroprevalence of anti-HCV to be used to estimate the global burden of disease for HCV infections. Specifically, an international collaborative, The Global Burden of Diseases, Injuries, and Risk Factors 2010 (GBD2010) Study, is an effort to estimate the global burden of HCV infection. The GBD Study defined 21 regions such that detailed data in one country can plausibly be extrapolated to other countries in the region in order to create burden estimates [25, 28]. Based on a systematic review and meta-analysis of primary national data sources and articles published for peer review between 1980 and 2007, the following global estimates of HCV have been made: Central and East Asia and North Africa/Middle East are estimated to have a high prevalence of HCV infection(>3.5 %), and South and Southeast Asia; sub-Saharan Africa; Andean, Central, and Southern Latin America; Caribbean; Oceania; Australasia; and Central, Eastern, and Western Europe have moderate prevalence (1.5–3.5 %), whereas Asia Pacific, Tropical Latin America, and North America have low prevalence (<1.5 %).

3.3 Laboratory Diagnostics

There are two different types of assays that are used in the diagnosis and evaluation of HCV infection— serologic and molecular assays. Serologic assays detect antibody to HCV (anti-HCV) and can be used to screen for and diagnose prior or current HCV infection. Serological assays include widely used enzyme immunoassays (EIAs) with specificities greater than 99 % and therefore remain the best screening tests for the diagnosis of hepatitis C. False-negative anti-HCV testing may occur, albeit rarely, in the setting of severe immunosuppression such as HIV infection, solid organ transplantation, agammaglobulinemia, or in patients on hemodialysis [29–32]. False-positive anti-HCV with EIA tests may also occur, particularly in populations with a low prevalence of HCV infection. Signal to cut-off ratios (>4.0 associated with true HCV exposure or infection) with EIAs can be used to help guide whether further confirmatory testing with recombinant immunoblot assay (RIBA) can be helpful. The RIBA test assesses the serological reaction of a patient to multiple HCV antigens and is a confirmatory test to the anti-HCV EIA test. A positive RIBA in conjunction with a positive anti-HCV antibody test indicates a true past or present infection with HCV. A negative RIBA in conjunction with a positive anti-HCV antibody test indicates a false-positive anti-HCV antibody test, and the patient can be reassured without further testing [33]. In persons with positive HCV screening tests, molecular assays to detect viral nucleic acid, and therefore active viral infection, are recommended and can be either qualitative or quantitative. Real-time polymerase chain reaction (PCR)-based assays and transcription-mediated amplification (TMA) assays have largely replaced qualitative molecular assays and are widely used for monitoring during response-guided therapy. These assays have sensitivities of 10–50 IU/mL and have excellent specificity (98–99 %). Serologic and molecular assays do not assess disease severity or prognosis. Additionally, the most current consensus proposal distinguishes six genotypes based on phylogenetic cluster analysis of complete genomes. Genotype testing is performed in the evaluation of HCV infection in order to maximize the chance of successful treatment outcome for each individual patient as treatment type, duration, dose, and effectiveness are influenced by genotype. While phylogenetic analysis with

direct sequencing of an HCV genomic region is considered the gold standard for identifying different HCV genotypes, this method is expensive and time consuming. For this reason, commercial genotyping kits were developed for routine determination of HCV genotypes.

4 Biological Characteristics

A member of the family Flaviviridae, HCV is classified within a separate genus, Hepacivirus, due to differences from other members of the family in the organization of the structural proteins that make up the amino terminal third of its polyprotein. The virus has an enveloped, positive-sense, single-strand RNA genome of approximately 9.6 kb in length with extraordinary genetic diversity [34]. The RNA contains a single large open reading frame that encodes for a 327 kD polyprotein of approximately 3,000 amino acids that is flanked by nontranslated segments [35]. The polyprotein is processed by host cell peptidases and viral proteases that cleave it into structural and nonstructural proteins needed for viral replication [36]. The 5′-end includes structural proteins (core, E1, and E2) that encode nucleocapsid and envelope proteins, and the 3′-end includes nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B) required for replication (see Fig. 33.1).

The nonstructural proteins have distinct enzymatic functions including production of proteases (NS3, NS4A), helicases (NS3), and polymerases (NS5B). The HCV genome contains both highly conserved and highly variable regions. Six major genotypes of HCV have been described, and there are subtypes within each genotype. The genotypes are differentiated by sequences in the relatively conserved core, E1 and NS5B regions [36]. Pairwise differences in the nucleotide sequences of the six HCV genotypes are on the order of 31–33 % and the geographic distribution of specific genotypes varies [34]. In the USA, genotype 1 is the most common (75 %). In Europe, genotypes 1 and 3 are most common, while in Egypt genotype 4 predominates. Additional variants, known as quasispecies, are present in infected individuals and are a result of the high error rate of the viral RNA polymerase during replication.

5 Descriptive Epidemiology

5.1 Morbidity and Mortality

Global morbidity and mortality from HCV infection are a tremendous public health burden. Available estimates indicate that worldwide, there were 54,000 deaths and 955,000 disability adjusted life years associated with HCV infection [25]. The major burden from HCV infection comes from sequelae from chronic infection. Estimates indicate that three to four million persons are newly infected each year, 170 million people are chronically infected and at risk of developing liver disease including cirrhosis and liver cancer, and 350,000 deaths occur each year due to all HCV-related causes [24, 25].

5.2 Prevalence and Incidence

The available data suggest that the global prevalence of HCV infection has increased from 2.3 % (95 % uncertainty interval [UI]: 2.1–2.5 %) to 2.8 % (95 % UI: 2.6–3.1 %) and >122 million to >185 million between 1990 and 2005 [4, 24]. These estimates are based on systematic reviews of published prevalence data, including volunteer blood donor studies, and therefore they may underestimate the true population prevalence [37]. Although HCV infection is endemic worldwide, there is a large degree of geographic variability in its distribution (see Fig. 33.2).

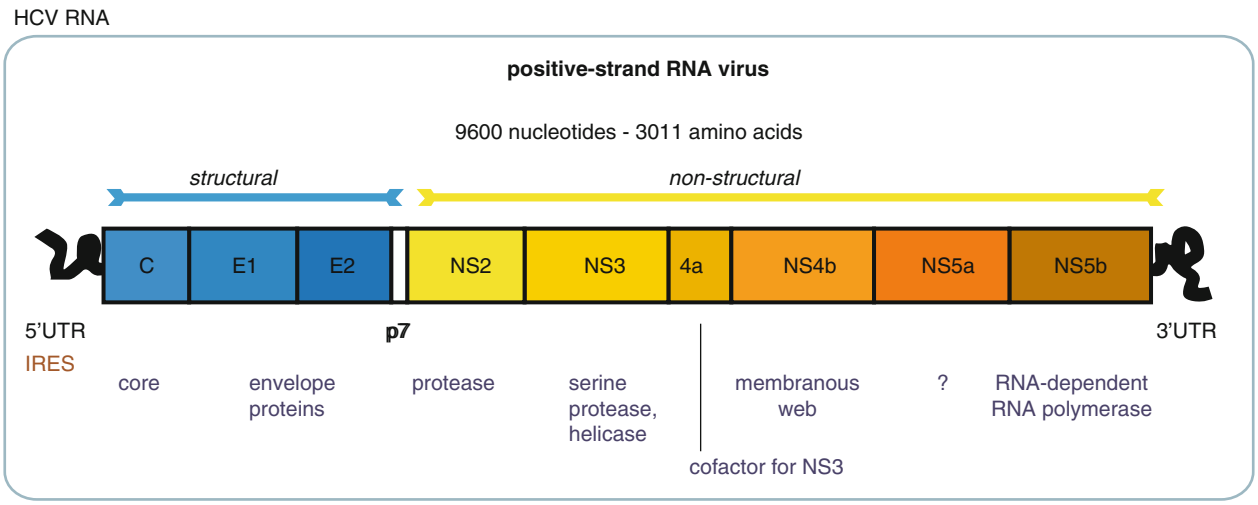

Fig. 33.1 HCV RNA (Data from Heim [262])

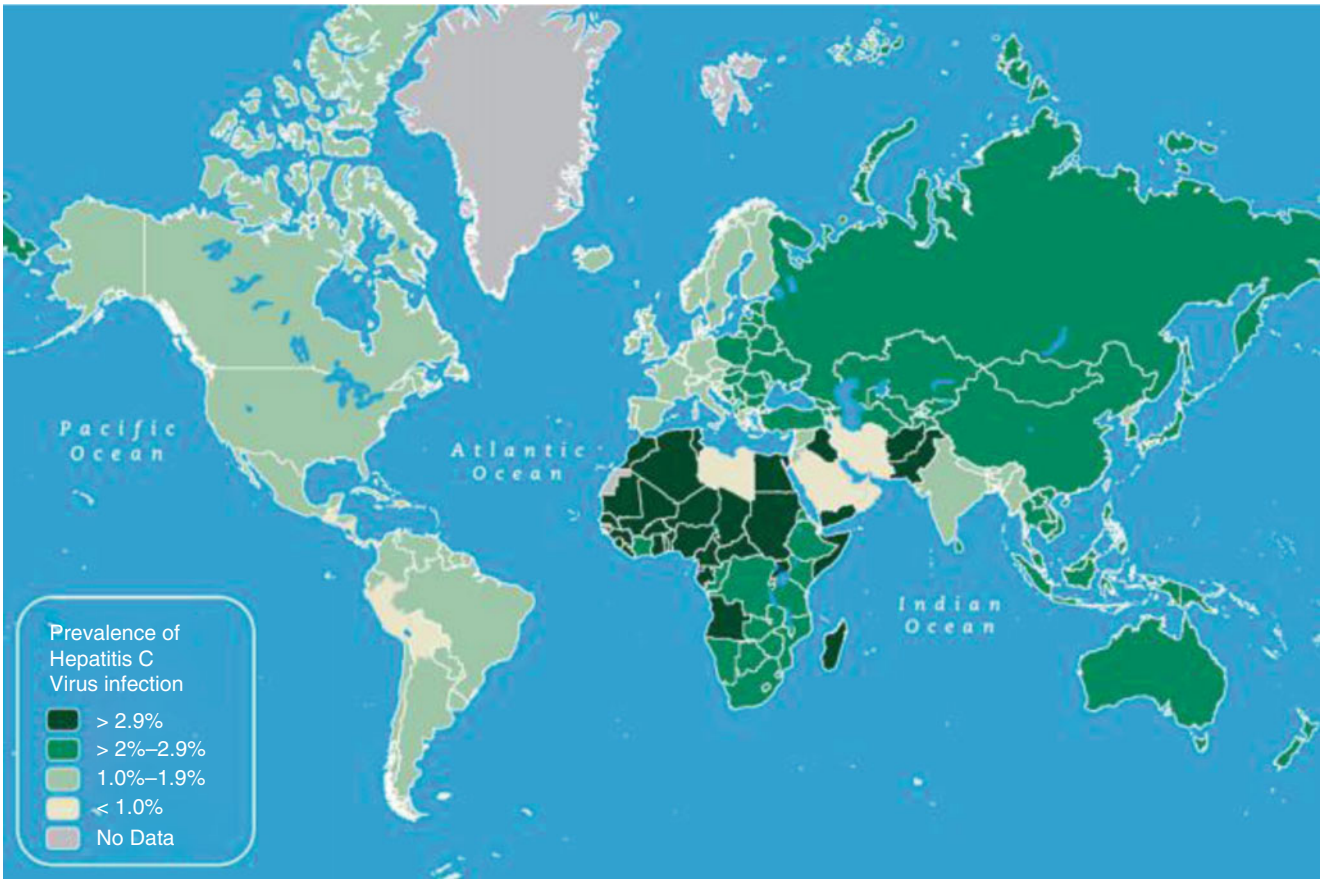

Fig. 33.2 Geographic prevalence of hepatitis C virus infection (Data from the CDC accessed online September 19, 2012 from http://www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/viral-hepatitis-figure5.html)

The prevalence of anti-HCV antibody is quite variable throughout the general population, with the highest rates among persons with repeated percutaneous exposures through injection drug use. Additional risk groups include hemophiliacs, patients on hemodialysis, patients transfused with unscreened blood and blood products, inmates of long-term correctional facilities, and persons with occupational exposure [38–45]. Data regarding the incidence of HCV infection are difficult to obtain, since most acute infections (60–70 %) are asymptomatic and there is no widely available test to distinguish acute from chronic infection [46, 47]. Surveillance data from the CDC demonstrate a decrease in the annual number of incident cases (see Fig. 33.3). These data are derived by adjusting rates from the Sentinel Counties Study of Viral Hepatitis (1982–2006) and the Emerging Infection Program (2007) for underreporting and asymptomatic infection.

5.3 Epidemic Behavior

Outbreaks of hepatitis C are limited in scope because of the predominantly bloodborne route of transmission. Historically, most early outbreaks of HCV infection were reported in the setting of hemodialysis and blood or plasma donation [48–52]. However, many outbreaks have occurred in other health-care settings as a result of poor infection control practices; failure to use aseptic technique during preparation or delivery of therapeutic injections has commonly led to cross-contamination from reused needles and syringes, multidose saline vials, infusion bags, heparin solutions, and pain treatments [53–64].

Additionally, outbreaks of acute HCV infection have been reported in IDUs and HIV-infected MSM [65, 66].

5.4 Geographic Distribution

Data from the WHO and CDC concur in their indication that the prevalence of HCV infection varies in different geographic regions [67]. Data from GBD2010 estimates higher prevalences of HCV in East and Central Asia (3.7–3.8 %), Eastern Europe (2.9 %), North African (3.6 %), and central and west sub-Saharan Africa (2.3–2.8 %), while prevalence is lower in North America (1.3 %) and Latin America (1.2–2.0 %) [5, 68]. Additionally, there are variances with respect to age and peak prevalence [24]. The highest prevalence of HCV is

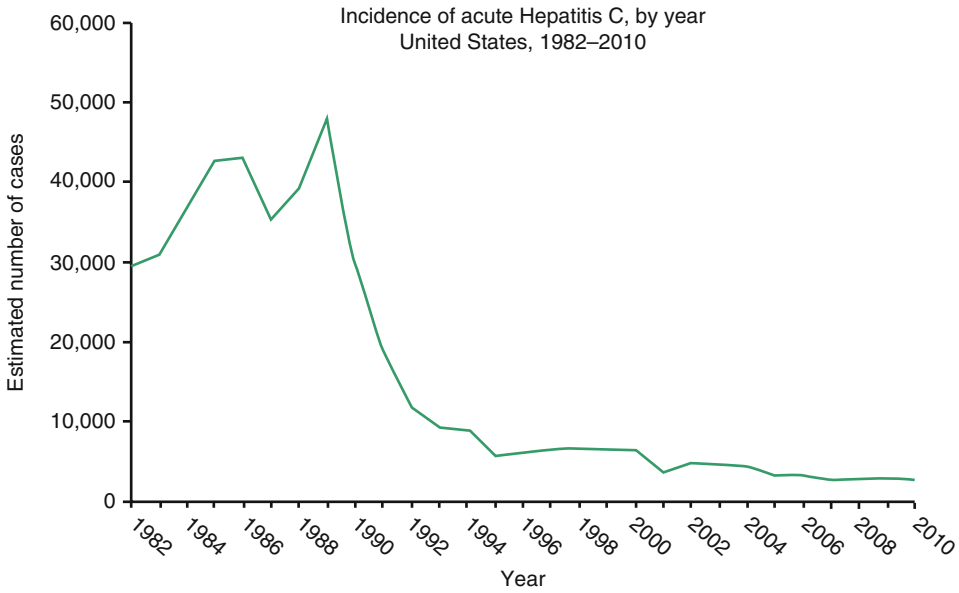

Fig. 33.3 Decrease in the number of acute HCV cases, by year in the USA (Data from the CDC. Accessed online September 19, 2012 from http://www.cdc.gov/hepatitis/Statistics/index.htm)

15 % in Egypt, while the lowest reported prevalences are <1.0 % in the UK and Scandinavia [24, 67].

5.5 Temporal

Countries with similar overall prevalence of HCV infection have different age-specific prevalence patterns; three main patterns have been described [67]. The first pattern, found in the USA and Australia, is characterized by a low age-specific prevalence among persons less than 20 years and greater than 50 years with the majority of HCV infection occurring in persons 30–49 years old. This pattern suggests that most HCV transmission occurred in the last 20–40 years and primarily in young adults [3, 69, 70]. The second pattern, found in a number of countries including Turkey, Spain, Italy, Japan, and China, is characterized by low age-specific prevalence in children and young adults with the majority of infections occurring in persons over 50 years old [71–74]. This pattern suggests a cohort effect where most HCV transmission occurred 30–50 years ago. The third pattern, found in Egypt, is characterized by high prevalence of infection among persons in all age groups with HCV infection increasing steadily with age [75, 76]. This pattern suggests increased risk in the distant past followed by ongoing high risk of transmission.

5.6 Age

Acute hepatitis C infection may occur in all age groups but appears to occur mostly among young adults. According to US data from NHANES, prevalence of anti-HCV increased with age from 1.0 % in those 20–29 years of age to a peak of 4.3 % in those 40–49 years of age [3]. Two-thirds of HCV-positive cases in this survey were born between 1945 and 1964. Among young injection drug users, the annual incidence of HCV infection ranges from 10 to 36 % [77–81]. The overall age distribution of disease is likely related to patterns of exposure (injection drug use in young and middle-aged adults; transfusion in older adults) and possibly to age-specific variation in clinical expression of disease.

This is in contrast to the age-specific prevalences of HCV infection which increase steadily with age in many countries as outlined above [72–74, 82–84]. This suggests a cohort effect in which the risk for HCV infection was higher in the past. Where the emergence of HCV infection occurred in the distant past, the burden of HCV-related chronic disease might already have reached its highest magnitude. However, changes in disease transmission patterns that result in younger persons acquiring infection could lead to future increases in chronic disease as this cohort ages. In Egypt, where there has been an ongoing high risk for decades, the high magnitude of the current burden of HCV-related chronic disease is predicted to continue [85].

5.7 Sex

Data from the USA demonstrates that HCV infection is more common in men (2.1 %) than women (1.1 %). It is not well understood why this difference exists, although differences by gender in risk factors such as injection drug use likely contributes [3]. Males with HCV infection are more likely (2.5 times) to develop cirrhosis and hepatocellular carcinoma when compared with females, suggesting that estrogen may have protective effects against fibrosis progression [86–88].

5.8 Race

Hepatitis C occurs worldwide in all racial/ethnic groups studied. In the USA, data from the most recent NHANES demonstrated a higher overall prevalence among non-Hispanic black persons (3.0 %) compared with non-Hispanic white persons (1.5 %) and was almost entirely attributable to differences among older participants [3]. According to Armstrong and colleagues, this finding suggests that younger non-Hispanic black persons may not be subject to the disproportionately high burden of disease that was seen in the previous generation. However, the authors do note that the small number of younger anti-HCV-positive participants limits definitive conclusions [3]. Although sparse data make comparisons difficult, observed racial differences in prevalence or mortality rates are likely due to the differences in exposures and risk factors in different locations.

5.9 Occupation

The route of acquisition of HCV is similar to that of hepatitis B virus (HBV) in the developed world, with exposure to blood playing the principal but not exclusive role in transmission. HCV is not transmitted as efficiently as HBV through occupational exposures to blood and is largely confined to health-care workers who have sustained contaminated needlestick injuries. The average incidence of anti-HCV seroconversion after accidental percutaneous exposure from an HCV-positive source is 1.8 % (range: 0–7 %) [89–91]. Transmission has been associated with hollow-bore needles, deep injuries, HIV coinfection, and a high titer of HCV in the source patient's blood [89–93]. Study of dentists has demonstrated an increased risk of HCV infection compared to controls (1.75 % vs. 0.14 % OR 12.9, 95 % CI 1.7–573), particularly among oral surgeons, as has also been shown for HBV [94].

6 Mechanisms and Routes of Transmission

HCV entry into hepatocytes is assumed to be a multistep process that requires sequential interactions between cellular factors and viral proteins. Replication depends on viral and host proteins and occurs in association with intracellular membranes [95]. Historically, HCV research has been hampered by a lack of adequate in vitro and in vivo model systems. In vivo study of HCV infection is restricted to humans and chimpanzees due to a lack of small animal models. Another major limitation in the study of the HCV life cycle is the inability to culture wild-type strains of HCV efficiently in cell culture. Much has been learned regarding RNA replication from replicons, each of which contains an adapted HCV genome encoding a selectable marker [96]. However, replicons do not reproduce other aspects of the life cycle such as virion production and infection [96, 97]. Two additional advances came in 2003 and 2005 with the development of retroviral pseudoparticles bearing unmodified HCV glycoproteins (HCV gp) and the discovery that a genotype 2a isolate (JFH1) from a patient with acute fulminant hepatitis could undergo the complete virus life cycle in cell culture, respectively [98].

Direct percutaneous exposure to blood is the most efficient mode of HCV transmission. Higher rates of transmission occur with large and repeated percutaneous exposures such as injection drug use and with transfusions or transplantation from infectious donors (see Fig. 33.4) [99]. Lower rates of transmission occur with single, small dose percutaneous exposures such as accidental needlesticks [91, 99]or by mucosal exposures to blood- or serum-derived fluids (e.g., birth to an infected mother, sex with an infected partner) [99–101].

6.1 Iatrogenic Exposure

Transfusion-associated HCV infection was a major worldwide risk before HCV testing became available in 1989. Prior to screening of the blood supply, transmission of HCV occurred in 5–18 % of people receiving a transfusion [102–104]. In some groups who were transfused large amounts of blood or pooled blood-derived products prior to screening, such as hemophiliacs, prevalence of HCV infection ranged from 59 to 99 % [105, 106]. The risk of acquiring HCV via blood transfusion has been virtually eliminated in countries that have implemented routine HCV testing of donors (less than one in a million per unit transfused) [107]. However, some countries have not prioritized blood transfusion safety and/or lack the resources to implement donor screening, and in these countries blood transfusion remains an important source of infection [108].

Worldwide, there is a substantial preventable burden of HCV due to iatrogenic transmission. There is a high prevalence of transfusions, reuse of needles and syringes, needlestick injuries among health-care workers, and unnecessary medication injections [109, 110]. It has been estimated that contaminated health-care injections cause approximately two million of the HCV infections acquired annually and may account for up to 40 % of all HCV infections worldwide [111]. In addition to unsafe injection practices, in some countries, poor or nonexistent infection control in health and dental care facilities may be a source of HCV transmission [112]. In Egypt, where the prevalence of HCV is the highest in the world, the reuse of glass syringes during the parenteral therapy campaigns to control endemic schistosomiasis is a widely suspected to be the source of iatrogenic transmission [113]. However, there may have been considerable other concurrent iatrogenic exposure at the time [114]. More recent evidence

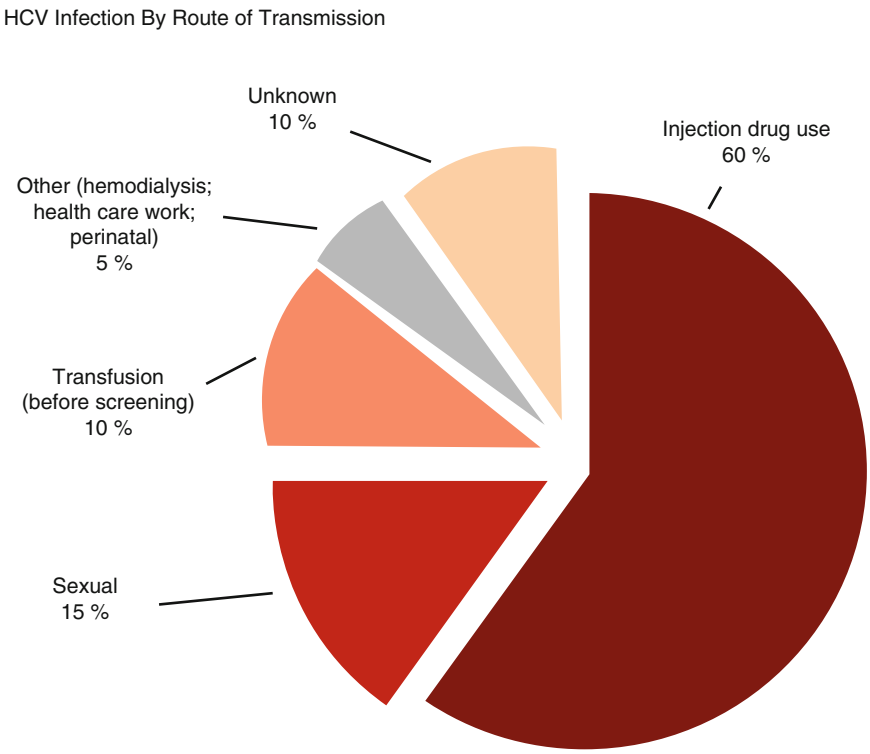

Fig. 33.4 HCV infection by route of transmission (Data from the CDC. Accessed online September 19, 2012 from: http://commons.wikimedia.org/wiki/File:Hepatitis_C_infection_by_source_(CDC)_-_en.svg)

in Egypt supports a continuation of iatrogenic exposures including unsafe medical and dental practices that is contributing to ongoing HCV transmission [112, 115].

Iatrogenic transmission of HCV is not limited to resource poor countries. Outbreaks of HCV transmission have occurred in resource-rich countries as well [55, 56, 59, 61–63]. Most of these outbreaks were reported in the setting of hemodialysis and poor infection control leading to cross-contamination from reused needles and syringes, multidose saline vials, infusion bags, heparin solutions, and pain treatments.

6.2 Injection Drug Use

Injection drug users (IDUs) have the highest overall prevalence of HCV infection compared with any other risk group. Worldwide, it is estimated that 16 million people injected drugs in 2007 [116]. Data from one systematic review suggests that ten million IDUs globally are HCV seropositive [117]. Anti-HCV prevalence is noted to be as high as 60–80 % in IDUs. Injection drug use has been the leading mode of transmission during the past four decades in the USA and Australia and now accounts for most newly acquired infections in many countries in Europe. Eastern Europe, East Asia, and Southeast Asia have the largest populations of IDUs infected with both HBV and HCV.

The WHO recommends that IDUs be a key target group for prevention and treatment of HCV (WHO Resolution A63/15 2011). Indirect drug sharing and preparation practices including back loading and using cotton (filters), cookers (drug solution containers, such as spoons), and rinse water have all been associated with HCV transmission [81, 118–120].

6.3 Sexual Transmission

Sexual practices and exposures predictive of anti-HCV positivity include the number of recent and lifetime partners, high-risk sexual practices, other STDs (HSV-2 and Trichomonas), and HIV infection particularly in MSM [71, 121–128]. The magnitude of risk for transmission of HCV infection by sexual activity has been controversial. Sexual transmission of virus occurs when infected body secretions or infected blood are exchanged across mucosal surfaces [99]. The presence of virus in body secretions or blood is necessary but may not be sufficient for transmission to occur [101]. Other factors that may influence transmission include the titer of virus in body fluids, the integrity of the mucosal surfaces, and the presence of other genital infections. Studies to detect HCV RNA in semen, vaginal secretions, cervical smears, and saliva have yielded mixed results [121, 122, 125, 129, 130]. Studies have demonstrated that when HCV RNA is detected in these secretions, it is present in lower concentrations than in blood. Low levels of virus in genital secretions may be one reason that HCV is sexually transmitted less efficiently than HBV or HIV. Also, the absence of appropriate

target cells in the intact genital tract may require the presence of abnormal mucosa for transmission. A review of the literature demonstrated that the risk for sexual acquisition of HCV appeared to be related in large part to HIV coinfection [131]. There have been at least two cross-sectional studies demonstrating increased risk of acquiring HCV infection among heterosexual HIV-infected persons [132, 133].

The clearest and least equivocal sexual risk behavior that leads to HCV transmission is unprotected sex among HIV-positive men who have sex with men (MSM) [131]. The risk of HCV transmission by sexual activity differs by the type of sexual relationship. Persons in long-term monogamous partnerships are at lower risk of HCV acquisition (up to 0.6 % per year) than persons with multiple partners or those at risk for sexually transmitted infections (up to 1.8 % per year) [101]. Data from the CDC Acute Hepatitis Sentinel County Surveillance program demonstrated that 18 % of individuals with acute HCV infection reported no other risk factor except sexual contact with an anti-HCV-positive person in the preceding 6-month period or multiple sexual partners.

HIV coinfection appears to increase the rate of HCV transmission by sexual contact although the precise mechanism is unknown. Cross-sectional studies from the USA have demonstrated a two- to fourfold higher risk of heterosexual HCV infection in HIV-infected than in HIV-uninfected subjects [132, 134]. Epidemics of sexually transmitted HCV infection among HIV-infected MSM have emerged in Northern Europe, the USA, and Australia in the last decade [65, 128, 135–138]. Risk factors for transmission in HIV-infected MSM include multiple partners, fisting, use of sex toys, and presence of genital ulcerative disease [139].

6.4 Mother-to-Child Transmission

Prior to the testing of blood for HCV in 1992, blood transfusion was the predominant mode of acquisition for HCV infection in children. Since then, mother-to-child transmission has become the leading source of HCV infection in children where blood screening is routine. The rate of perinatal transmission of HCV is 4–7 % per pregnancy and requires detectable HCV RNA in maternal serum at delivery [67]. The exact timing of transmission of HCV from the mother to the child is unknown. Both in utero and intrapartum infections are possible. The outcome of perinatal transmission of HCV in twin pregnancies is often discordant, with transmission of HCV more likely to affect the second twin and with neonatal HCV RNA undetectable at delivery; these observations suggest that intrapartum transmission may be more frequent than in utero transmission [140]. Risk factors for vertical transmission include higher maternal serum HCV RNA levels (above ten [6] copies per mL), prolonged labor after membrane rupture, internal fetal monitoring, and coinfection with HIV [100, 141–150]. There is no apparent increased risk of vertical transmission of HCV with the mode of delivery except in women who are also infected with human immunodeficiency virus (HIV). The increased risk of perinatal HCV transmission in mothers coinfected with HIV may be related to higher HCV viral loads in coinfected persons as a result of HIV-mediated immunosuppression [145]. Other factors may increase perinatal transmission in HIV-coinfected mothers. One such factor is facilitation by HIV infection of HCV entry into blood cells with subsequent replication; another is concomitant use of injection drugs by coinfected mothers [151–153]. The reason for increased risk of vertical transmission in coinfected mothers who are IDUs is not known. It has been postulated that greater maternal peripheral blood mononuclear cell (PBMC) infection confers an increased risk for vertical transmission. Internal fetal monitoring and prolonged rupture of membranes should be avoided if possible in all HCV-infected pregnant women. Patients should be advised that breastfeeding is permissible since there is no evidence that breastfeeding increases risk of HCV transmission.

6.5 Hepatitis C Virus Transmission to Health-Care Workers

HCV is not transmitted efficiently through occupational exposures to blood. Nosocomial transmission is largely confined to health-care workers who have sustained contaminated needlestick injuries. The average incidence of anti-HCV seroconversion after accidental percutaneous exposure from an HCV-positive source is 1.8 % (range: 0–7 %) [89–91]. This risk is intermediate between that resulting from similar exposures to HIV (~0.3 %) and in a susceptible person from exposure to HBV (6–30 %) [154]. Transmission has been associated with hollow-bore needles, deep injuries, HIV coinfection, and a high level of HCV viremia in the source patient [92, 93]. Transmission rarely occurs from mucous membrane or non-intact skin exposures to blood, and no transmission to health-care workers has been documented from intact skin exposures to blood [155]. The prevalence of HCV infection among health-care workers is no greater than in the general population, averaging 1–2 % [67]. Even more rarely, HCV-infected health-care workers have transmitted HCV to patients through needlestick injuries or other percutaneous exposure, with an extremely low risk—averaging about 0.5 %, even for those episodes involving surgeons.

6.6 Hepatitis C Virus Transmission in Other Settings

Percutaneous exposure to blood can occur in a variety of other practices, during which transmission of HCV may occur. These exposures include but are not limited to tattooing, body

piercing, intranasal drug use, ritual scarification, circumcision, acupuncture, and cupping. There are currently insufficient data to determine the extent to which these risks factors may contribute to overall HCV transmission.

7 Pathogenesis and Immunity

The majority of people with acute HCV infection progress to chronic infection (85 %) [156–159]. The key features of acute and chronic hepatitis C virus infection are reviewed in this section.

7.1 Acute Infection

The natural history of HCV infection generally begins with a subclinical and unrecognized acute phase following infection. Symptomatic acute hepatitis occurs within 2 weeks to 6 months of infection in only a minority of cases (10–15 %) and is clinically indistinguishable from acute hepatitis of other causes—with a combination of fever, fatigue, loss of appetite, nausea and vomiting, dark urine, jaundice, and liver tenderness, accompanied by elevated levels of serum bilirubin and alanine and aspartate aminotransferases (ALT and AST, respectively) [160]. The majority of cases of HCV infection progress to chronic infection, but in up to 15 % of people, infection may resolve spontaneously. Evidence suggests that patients with symptoms in the setting of acute HCV infection tend to have a higher rate of spontaneous clearance [161–163]. Other factors that might contribute to spontaneous clearance include infection in infants and young women, selected host polymorphisms near the gene encoding IL28b, infection with HCV genotype 3, having a low peak viral load, Caucasian race, and rapid decline in viral load within the first four weeks of diagnosis [161–166]. Persons with alcohol consumption and HIV coinfection are less likely to spontaneously clear acute HCV infection [159, 163, 167].

Early detection of progression to chronic HCV infection can be difficult, as it almost always occurs in the absence of symptoms. The differentiation of acute from chronic HCV infection depends largely on the clinical presentation including presence of symptoms, recognition of a time-limited exposure, and documentation of ALT elevation and its duration. After exposure, HCV RNA is usually detectable before antibody appears in serum. HCV RNA can be identified as early as 7–21 days following exposure, whereas anti-HCV is generally not detectable before 8–12 weeks [30, 156, 168, 169]. When symptoms of acute HCV infection occur, they may include malaise, fatigue, myalgias, nausea, and right upper quadrant pain. Fulminant hepatic failure is a rare presentation of acute HCV infection unless other underlying chronic liver disease is present [170, 171].

7.2 Chronic

Individuals with chronic hepatitis C (CHC) are at increased risk of liver-related morbidity and mortality. The majority of persons with CHC are asymptomatic. The most common symptom of CHC infection is fatigue [172, 173]. Other symptoms may include myalgias, nausea, anorexia, arthralgias, and difficulty concentrating. Progressive hepatic fibrosis leading to cirrhosis is the major complication of chronic HCV infection and accounts for almost all HCV-related morbidity and mortality [9]. In patients who develop cirrhosis, symptoms include worsening fatigue and anorexia, fluid overload, difficulty concentrating or confusion due to hepatic encephalopathy, and gastrointestinal bleeding. Physical examination findings can include signs of chronic or end-stage liver disease including palmar erythema, spider angiomas, ascites, and asterixis. Laboratory changes include abnormal liver tests including transaminase elevations.

8 Patterns of Host Response

Persons with CHC are at risk for progression to cirrhosis, liver failure, and/or hepatocellular carcinoma (HCC). However, the disease course in persons with CHC is generally protracted and variable (see Fig. 33.5) [174]. The risk of developing cirrhosis is 5–25 % over 25–30 years [175, 176]. There are a number of host, viral, and environmental factors that are associated with disease progression.

Host factors associated with more rapid fibrosis progression include older age (above 40 years old), longer duration of infection, male gender, obesity, hepatic steatosis, insulin resistance, and hepatic iron overload [67, 86, 176–186]. Age appears to be the predominant risk factor for more accelerated fibrosis progression [86, 177]. Data from Poynard and colleagues indicate that median time to cirrhosis was 44 years in patients infected at under 20 years of age, 30 years in patients infected between 31 and 40 years of age, and 12 years in patients infected over the age of 50 years. The concept that the aging liver is more susceptible to fibrosis is also supported by experience with liver transplantation, where older donor age is a strong risk factor for rapid fibrosis in the graft [187, 188]. A number of mechanisms have been proposed to explain this: increased vulnerability to oxidative stress, a reduction in hepatic blood flow, and mitochondrial capacity [189–191]. Additionally, there are genetic factors that influence the natural history of HCV and treatment response. Both the innate and adaptive immune responses are important for clearance of an acute HCV infection. After an HCV infection, the innate immune response is initially important for controlling viral replication with the adaptive immune response peaking at 8 weeks after infection [192]. Ultimately, a coordinated effort between the innate and adaptive immune

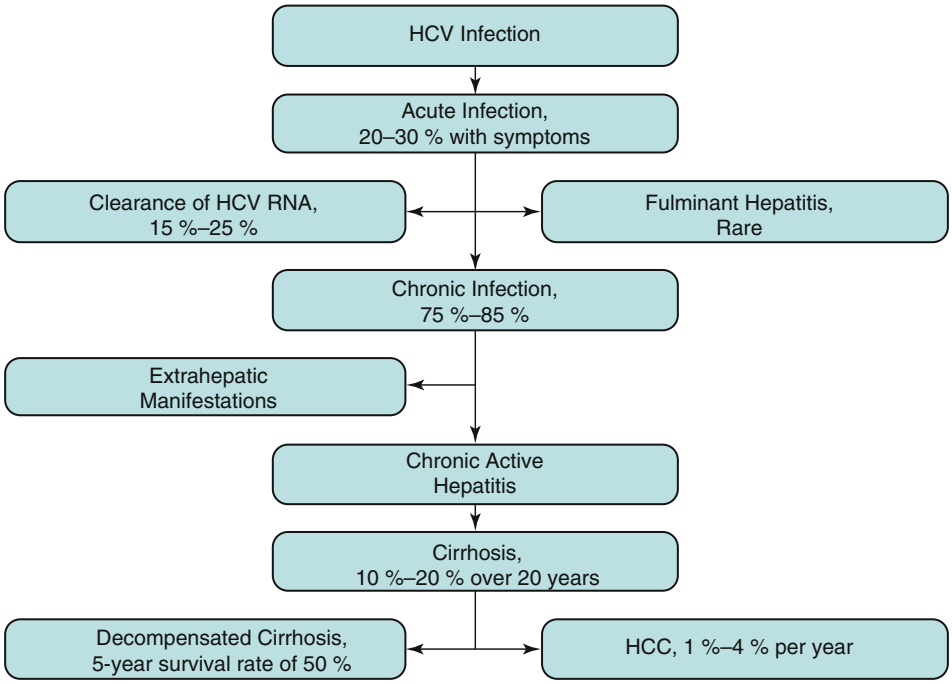

Fig. 33.5 Natural history of HCV infection (Reprinted with permission from International Journal of Medical Sciences. Chen and Morgan [174]. Available from http://www.medsci.org/v03p0047.htm)

responses is necessary to eliminate HCV from the liver [192]. Genetic variation of the host immune system may affect fibrosis progression rates by way genetic factors that may influence activators of hepatic stellate cells, the family of proteolytic enzymes known as matrix metalloproteases (MMPs), and the tissue inhibitors (TIMPs) of MMPs.

Coinfection with HIV and/or HBV is also associated with progression of CHC [193–198]. While viral interactions with interference between HBV and HCV in patients with HBV-HCV dual infection with inhibition of the replication of one of the viruses have been described in several studies [199–205], this phenomenon is incompletely understood, and the mechanism by which this occurs is yet to be established [206, 207]. Dual infection with HBV and HCV is characterized by one virus dominating over the other and can result in more accelerated progression to cirrhosis [193, 194]. Approximately 15–30 % of HIV-infected persons are coinfected with HCV [208]. With HIV coinfection there is an increased rate of end-stage liver disease, hepatocellular carcinoma, and death, in addition to the increased progression to cirrhosis [195–198, 209–211]. Accelerated fibrosis progression is also seen with high alcohol intake (daily consumption >50 g of alcohol) and marijuana use [212–215].

While the incidence of HCV infections is decreasing in the USA and other developed nations, due to the prolonged course of CHC, the number of infected people with complications related to end-stage liver disease is still increasing. The prevalence of hepatitis C-related cirrhosis and its complications, including hepatic decompensation and HCC, is expected to continue to increase through the next decade [216]. Patients with HCV-related cirrhosis are at increased risk of hepatic decompensation with signs/symptoms of liver failure and/or portal hypertension including ascites, portosystemic encephalopathy, and portal hypertension-related gastrointestinal bleeding [217, 218]. Patients with HCV-related cirrhosis are at an approximately 3 % per year risk for developing hepatocellular carcinoma [219–221].

8.1 Extrahepatic Manifestations

Chronic HCV infection can have serious consequences for organ systems other than the liver. HCV infection may affect the central nervous system, endocrine system, lymphatic system, eyes, kidneys, blood vessels, skin, joints, and peripheral nerves [222, 223]. Approximately 38 % of patients with chronic HCV infection will manifest at least one symptomatic extrahepatic manifestation during the illness [224]. Most extrahepatic manifestations of chronic HCV infection are immunologically mediated, and chronic infection seems to be necessary for their development. The most prominent manifestations include mixed cryoglobulinemia (MC) vasculitis, lymphoproliferative disorders, renal disease, insulin resistance, type 2 diabetes, sicca syndrome, and rheumatoid arthritis-like polyarthritis. Presence of these conditions can have a substantial impact on patient management as they can affect morbidity and mortality (for a detailed review, see [223]).

9 Control and Prevention

9.1 Public Health Approaches

Prevention of HCV-related liver disease should remain a key focus of clinical and public health interventions [10]. Major steps to prevent new HCV infections have been taken in several countries including routine screening of blood donors, implementation and enforcement of standard precautions, eliminating reuse of injection equipment, and facilitating safer drug injecting behaviors with adoption of harm reduction programs. Interventions using combined strategies of education, behavioral interventions, substance-use treatment, syringe access, and syringe disinfection can reduce the risk of HCV seroconversion by 75 % [225]. Therefore, efforts to prevent infection, reduce harms, and treat HCV-infected IDUs are essential. These steps should be extended worldwide. As part of secondary prevention, HCV-infected individuals should be counseled to minimize their risk of transmitting HCV and referred for medical evaluation and consideration of antiviral therapy. Of course, the latter approaches rely on the identification of persons with chronic HCV infection. In the USA, the CDC estimates that although 27 % of the population was born during the interval 1945–1965, they account for approximately three-fourths of all HCV infections and 73 % of HCV-associated mortality, and they are at greatest risk for hepatocellular carcinoma and other HCV-related liver disease. As a result, CDC has recently revised prior recommendations to include onetime testing for persons born during 1945–1965 without prior ascertainment of HCV risk [226]. This recommendation for onetime screening in persons born during the 1945–1965 has now been endorsed by the US Preventive Services Task Force [227].

To address occupational risk of HCV infection, individual institutions should establish policies and procedures for HCV testing of persons after percutaneous or mucosal exposures to blood, and they should ensure that all personnel are familiar with these policies and procedures. Health-care professionals who provide care to persons occupationally exposed to HCV should be knowledgeable regarding the risk for HCV infection and appropriate counseling, testing, and medical follow-up.

Finally, while there is currently no approved vaccine for HCV, attempts toward developing a vaccine are currently underway. Despite difficulties associated with extreme variability and mutability of hepatitis C virus (HCV), several vaccines that prevent initial infection or viral persistence, or that clear viremia in individuals with chronic HCV infections, are currently in development [228]. The likely goal for a prophylactic vaccine against HCV is to present persistence of the virus, rather than to prevent primary infection. The is based on the fact that a small proportion of people infected with acute HCV spontaneously clear it and this appears to be prominently mediated by cellular immunity [229]. Current HCV vaccine approaches include peptide, plasmid DNA, recombinant proteins, and vector-based vaccines. Virally vectored vaccines are the most promising in terms of T-cell induction—in particular adenoviral and modified vaccinia Ankara vectors. An understanding of the combination of functions possessed by the T-cell population is needed to effectively assess HCV vaccine efficacy. Parameters of interest when assessing a vaccine-induced HCV-specific T-cell population include breadth, cytokine production, cytolytic capacity, magnitude, phenotype, and proliferative capacity. A major challenge in HCV vaccinology will be the assessment of vaccine efficacy in well-characterized at-risk populations. Early phase vaccine trials are currently underway.

9.2 Treatment

The first successful therapies for HCV infection became available with the use of interferon to treat NANB hepatitis in 1986 [230]. Sustained virological response (SVR) is analogous to a cure and the goal of treatment. An SVR is defined by the absence of detectable HCV RNA in a patient's blood 6 months after the conclusion of antiviral therapy. Viral genotype testing is performed in the evaluation of HCV infection in order to maximize the chance of successful treatment outcome for each individual patient as treatment type, duration, dose, and effectiveness are influenced by genotype. Historically, persons infected with HCV genotypes 1 and 4 have required longer durations of treatment and have had lower SVR rates. Since the early treatments, significant and rapid progress has been made in establishing effective therapy for HCV infection. There are now an increasing number of potent options for treatment.

The standard of care for HCV treatment for the last decade until 2011 has been a combination of pegylated interferon and ribavirin [30]. Pegylated interferon alfa is a potent inhibitor of HCV replication that acts by inducing interferon-stimulated host genes that have antiviral functions, and given its diverse actions, it is not associated with viral resistance [95]. Ribavirin acting synergistically with pegylated interferon alfa is an integral component of the treatment for HCV, although the mechanism of action is not well known. Treatment for HCV infection varies according on genotype.

The first major advancement in HCV treatment in over a decade, occurred in 2011 with introduction of the first generation direct-acting antiviral agents (protease inhibitors) in combination with pegylated interferon and ribavirin [231–235]. Challenges with these new regimens included additional side effects, increased pill burden, increased drug-drug interactions, and antiviral resistance [95]. Additionally, use of these agents in real world practice had lower SVR results than reported in registration trials [263].

At the end of 2013, another major advancement of HCV therapy was realized with approval of second generation direct-acting antiviral agents, Sofosbuvir and Simeprevir [236]. Sofosubuvir, a nucleotide analogue NS5B polymerase inhibitor, is a component of the first all-oral, interferon-free regimen approved for treating chronic hepatitis C. Interferon-free therapy for treatment of hepatitis C reduces the side effects associated with use of interferon [237, 238, 239, 240, 241]. Many additional agents with different mechanisms of actions, improved safety profiles and cure rates greater than 95 % in registration trials are currently in various stages of clinical development [242, 243]. The short-term prospects for continued improvements in treatments with other direct acting antivirals in conjunction with pegylated interferon and ribavirin are in the pipeline and are quite promising, and these advances will likely lead to increased rates of cure in the coming years [244–246]. Additionally, all oral interferon-free regimens are now on the horizon, which will lessen treatment side effects and likely increase patient adherence and tolerability [240, 241]. However, it is important that both patients and providers be aware that there is no protective immunity and reinfection is possible with ongoing risk behavior and exposure.

Successful treatment of HCV infection eliminates transmissibility by eradication of viral infection (i.e., cure). It is reasonable to assume that transmissibility is likely reduced by reduction in HCV viral load even if cure is not accomplished.

9.2.1 Perinatal HCV Infection

Immune globulin and antiviral agents are not recommended for postexposure prophylaxis of infants born to HCV-positive women. Children born to HCV-positive women should be tested for HCV infection. Early diagnosis of HCV infection can be done by testing for HCV RNA at age 1–2 months and should be repeated after 3 months within the first year [100, 153, 247, 248]. Umbilical cord blood should not be used for the diagnosis of perinatal HCV infection because cord blood can be contaminated by maternal blood. Testing of infants for anti-HCV should be performed no sooner than 15–18 months of age, when passively transferred maternal anti-HCV declines below detectable levels. If positive for either anti-HCV or HCV RNA, children should be evaluated for the presence or development of liver disease, and those children with persistently abnormal ALT levels should be referred to a specialist for medical management.

9.3 Postexposure Management

It has been estimated that in the year 2000, 16,000 HCV infections may have occurred worldwide among health-care workers due to their occupational exposure to percutaneous injuries [249]. Although no immediately prophylactic regimen exists for HCV, effective treatment is available. When a needlestick, percutaneous injury from other sharp instruments, or mucosal exposure to blood occurs, the human source of the exposure should be tested for antibody to HCV (anti-HCV), and all repeatedly reactive results by enzyme immunoassay should be confirmed by RIBA for anti-HCV. If the source is anti-HCV positive, the exposed person should be tested for anti-HCV and alanine aminotransferase level at baseline and follow-up (e.g., at 4–6 months) [250, 251]. For earlier diagnosis of HCV infection, testing for HCV RNA may be performed at 4–6 weeks. There are no recommendations for restriction of activities during the postexposure follow-up period. There is consistent evidence that treatment reduces the risk that acute hepatitis C will evolve to chronic infection [252, 253]. Currently, the American Association for the Study of Liver Diseases (AASLD) practice guidelines recommend treatment initiation in patients with acute HCV if serum HCV RNA is not eliminated spontaneously within 12 weeks of HCV transmission [30]. When HCV infection is identified early, the individual should be referred for medical management to a specialist knowledgeable in this area.

10 Unresolved Problems

Although effective diagnostic tools and treatments are available, HCV remains a major public health problem. In many countries, including the USA, HCV-associated disease is the leading indication for liver transplantation, and it is a leading cause of HCC in the USA [37, 89, 254]. HCC and cirrhosis have been increasing among persons infected with HCV [255, 256], and these outcomes are projected to increase substantially in the coming decade [23, 257]. HCC is the fastest growing cause of cancer-related mortality, and infection with HCV accounts for approximately 50 % of incident HCC [7].

Transmission of HCV infection continues despite current prevention strategies. Early diagnosis of persons with HCV infection has been difficult. Because 80 % of acute HCV infections are asymptomatic, and more than 60 % of persons with chronic HCV infection are asymptomatic [156, 163], early diagnosis has relied on screening for asymptomatic infection and disease. Most persons with HCV do not know they are infected, are not evaluated for treatment, and do not receive needed care (e.g., education, counseling, and medical monitoring) [258–260]. In the USA alone, 75 % of infected persons remain unaware of their infection [261]. Additional strategies for and resources to support prevention and treatment of HCV are still needed. Education of persons at risk, implementation of standard precautions and infection control, and screening of blood donors for HCV are partially or entirely lacking in many parts of the world.

Finally, not all persons with HCV infection progress to end-stage liver disease or cirrhosis. However, we currently have no good predictors of who will suffer disease progression and therefore have only limited ability to target therapy toward those individuals. The morbidity and mortality associated with this disease continue to rise rapidly along with the costs of care. While treatment regimens with newly licensed drugs and others in clinical trials are evolving at a rapid pace, the challenge will be to make these therapies available and affordable to all persons with infection.

Acknowledgments We would like to acknowledge Dr. Scott L. Friedman, Fishberg Professor of Medicine, Dean for Therapeutic Discovery and Chief, Division of Liver Diseases at Mount Sinai School of Medicine, for his review and input on this chapter.
