Essential Clinical Anesthesia

The clinical practice of anesthesia has undergone many advances in the past few years, making this the perfect time for a new state-of-the-art anesthesia textbook for practitioners and trainees. The goal of *Essential Clinical Anesthesia* is to provide a modern, clinically focused textbook giving rapid access to comprehensive, succinct knowledge from experts in the field.

All clinical topics of relevance to anesthesiology are organized into 29 sections consisting of 184 chapters. The print version contains 167 chapters that cover all the essential clinical topics, whereas an additional 17 chapters and appendix on subjects of interest to the more advanced practitioner can be freely accessed at www.cambridge.org/vacanti. Newer techniques, such as ultrasound nerve blocks, robotic surgery, and transesophageal echocardiography, are included, and numerous illustrations and tables assist the reader in rapidly assimilating key information.

This authoritative text is edited by distinguished faculty, with contributors from many of the leading academic anesthesiology departments in the United States, and includes an introduction from Dr. S. Rao Mallampati.

Essential Clinical Anesthesia is your essential companion when preparing for board review and recertification exams, and in your daily clinical practice.

Charles A. Vacanti, M.D., is the Vandam/Covino Professor of Anaesthesia at Harvard Medical School and Anesthesiologist-in-Chief of the Department of Anesthesiology, Perioperative, and Pain Medicine at the Brigham and Women's Hospital. He has published more than 200 original articles, reviews, book chapters, and abstracts, and he holds more than 20 patents. In addition, he serves as the Director of the Laboratories for Tissue Engineering and Regenerative Medicine at the Brigham and Women's Hospital. He is the founding editor of the journal *Tissue Engineering* and founding president of the Tissue Engineering Society International. He is currently a member, and was previously president, of the Governing Council of the Society of Academic Anesthesiology Associations (SAAA).

Pankaj K. Sikka, M.D., Ph.D., is a staff anesthesiologist at the Emerson Hospital in Massachusetts. He completed an anesthesia residency at Yale New Haven Hospital, a cardiothoracic anesthesia fellowship at the Cleveland Clinic Foundation, and a doctoral program in pharmacology at Louisiana State University Medical Center. He was one of the first to culture rat kidney cells in vitro, making it easy and inexpensive to perform experiments. He is a member of a taskforce of the American Society of Anesthesiologists Self-Education and Evaluation program.

Richard D. Urman, M.D., M.B.A., is Assistant Professor of Anaesthesia at Harvard Medical School and a staff anesthesiologist at Brigham and Women's Hospital. He specializes in ambulatory anesthesia, co-directs the Center for Perioperative Management and Medical Informatics, and is the director of procedural sedation management and education for the hospital. He is also co-founder of the Institute for Safety in Office-Based Surgery. His academic interests include patient safety, novel anesthetic drugs, and operating room efficiency.

Mark Dershwitz, M.D., Ph.D., is Professor and Vice Chair of Anesthesiology and Professor of Biochemistry and Molecular Pharmacology at the University of Massachusetts Medical School. He is editor-in-chief of the Web site [AccessAnesthesiology](http://AccessAnesthesiology.com) and co-author of *The McGraw-Hill Specialty Board Review: Anesthesiology*. His research has focused on intravenous anesthetics, antiemetics, and intraoperative brain function monitoring.

B. Scott Segal, M.D., M.H.C.M., is Professor of Anesthesiology at Tufts University School of Medicine and Chairman of the Department of Anesthesiology at Tufts Medical Center. He is a senior editor of the American Board of Anesthesiology written examination and an oral examiner for the board. He is also co-founder of theanswerpage.com, an educational Web site serving thousands of physicians worldwide.

Every effort has been made in preparing this book to provide accurate
and up-to-date information that is in accord with accepted standards
and practice at the time of publication. Although case histories are
drawn from actual cases, every effort has been made to disguise the
identities of the individuals involved. Nevertheless, the authors,
editors, and publishers can make no warranties that the information
contained herein is totally free from error, not least because clinical
standards are constantly changing through research and regulation.
The authors, editors, and publishers therefore disclaim all liability for
direct or consequential damages resulting from the use of material
contained in this book. Readers are strongly advised to pay careful
attention to information provided by the manufacturer of any drugs or
equipment that they plan to use.

Contents

Section Editors xiii

Contributors xv

Preface xxix

Foreword xxxi

S. Rao Mallampati

1 **History of anesthesia** 1

Rafael A. Ortega and Christine Mai

Part 1 – Preoperative Care and Evaluation

B. Scott Segal and Angela M. Bader, editors

2 **Preoperative anesthetic assessment** 7

Sohail K. Mahboobi and Sheila R. Barnett

3 **Obstructive and restrictive lung disease** 16

Shannon S. McKenna

4 **Anesthetic goals in patients with myocardial ischemia and heart failure** 23

Sugantha Sundar, Jason M. Erlich, and Eswar Sundar

5 **Anesthetic goals in patients with valvular heart disease** 28

Sugantha Sundar, Devi Mahendran, and Eswar Sundar

6 **Obesity** 37

Liem C. Nguyen and Stephanie B. Jones

7 **Chronic renal failure** 43

Edward A. Bittner

8 **Liver disease** 49

Jason C. Brookman and Warren S. Sandberg

9 **Diabetes mellitus and perioperative glucose control** 56

Ruma R. Bose and Balachundhar Subramaniam

10 **Common blood disorders** 62

Jonathan D. Bloom and Edward A. Bittner

11 **The elderly patient** 70

Ruma R. Bose and Sheila R. Barnett

12 **Neurologic diseases and anesthesia** 77

Spiro G. Spanakis, John Lin, and Pankaj K. Sikka

13 **Anesthetic considerations in psychiatric diseases** 83

Houman Amirfarzan and Pankaj K. Sikka

14 **Substance abuse and anesthesia** 88

Thomas J. Graetz and Lisa R. Leffert

Part 2 – Airway Management

William H. Rosenblatt, editor

15 **Anatomy of the human airway** 95

Sarah H. Wiser

16 **Airway assessment** 98

Rahul Koka and B. Scott Segal

17 **Perioperative airway management** 102

Sibinka Bajic and Sarah H. Wiser

18 **Management of the difficult airway** 112

Essi M. Vulli and Wariya Sukhupragarn

Part 3 – Anesthesia Equipment

Yasodananda Kumar Areti, editor

19 **Medical gas supply, vacuum, and scavenging** 121

Jesse M. Ehrenfeld and Yasodananda Kumar Areti

20 **Anesthesia machine** 129

Yasodananda Kumar Areti

21 **Anesthesia ventilators** 138

Yasodananda Kumar Areti and Edward R. Garcia

22 **Anesthesia breathing apparatuses** 144

Jingping Wang and Charles A. Vacanti

23 **Electrical safety** 149

Jesse M. Ehrenfeld, Seetharaman Hariharan, and Stephen B. Corn

Part 4 – Patient Monitoring

Bhavani S. Kodali, editor

24 **Hemodynamic patient monitoring** 155

Amit Asopa, Theodore E. Dushane, and Swaminathan Karthik

- 25 **The electrocardiogram and approach to diagnosis of common abnormalities** 173
Usha B. Tedrow
- 26 **Pulse oximetry and capnography** 186
Zhiling Xiong and Bhavani S. Kodali
- 27 **Monitoring of neuromuscular blockade** 191
Kai Matthes and Neelakantan Sunder
- 28 **Thermoregulation and temperature monitoring** 198
Matthias Stopfkuchen-Evans, Elliott S. Farber, and Francis X. Vacanti
- 29 **Neurophysiologic monitoring** 203
Kai Matthes and Mary Ellen McCann
- 30 **Intraoperative awareness** 209
Scott D. Kelley
- Part 5 – Inhalation Anesthetics**
James H. Philip, editor
- 31 **Inhalation anesthetics** 213
Matthias Stopfkuchen-Evans, Lina M. Bolanos-Diaz, Alimorad G. Djalali, and Beverly K. Philip
- 32 **Pharmacokinetics of inhalational agents** 218
James H. Philip
- 33 **Pharmacodynamics of inhalational agents** 224
Jan Boublik and Richard D. Urman
- Part 6 – Intravenous Anesthetics and Adjunct Drugs**
Mark Dershwitz, editor
- 34 **Intravenous induction agents** 227
Aakash Agarwala and Mark Dershwitz
- 35 **Mechanisms of anesthetic actions** 233
Ken Solt and Douglas E. Raines
- 36 **Pharmacokinetics of intravenous agents** 236
Lisbeth Lopez Pappas and Mark Dershwitz
- 37 **Opioids** 242
Darin J. Correll and Carl E. Rosow
- 38 **Muscle relaxants** 251
Torin D. Shear and J. A. Jeevendra Martyn
- 39 **Reversal of neuromuscular blockade** 257
Thor C. Milland and Neelakantan Sunder
- 40 **Perioperative pulmonary aspiration prophylaxis** 261
John P. Broadnax and B. Scott Segal
- 41 **Perioperative antiemetic therapies** 263
John P. Broadnax and B. Scott Segal
- 42 **COX inhibitors and α_2 -adrenoceptor agonists** 268
Benjamin Parish and Mark Dershwitz
- 43 **Diuretics** 271
Edward R. Garcia
- 44 **Drug interactions** 274
Martha Cordoba-Amorocho and Jie Zhou
- 45 **Allergic reactions** 278
Karan Madan and David L. Hepner
- Part 7 – Pharmacology of Local Anesthetics**
Pradeep Dinakar and Gary R. Strichartz, editors
- 46 **Mechanism of action and pharmacokinetics** 283
Peter Gerner and Pradeep Dinakar
- 47 **Clinical applications of local anesthetics** 288
Pradeep Dinakar and Peter Gerner
- Part 8 – Anesthesia Techniques**
Sascha S. Beutler, editor
- 48 **Administration of general anesthesia** 295
Francis X. Dillon and Rana Badr
- 49 **Total intravenous anesthesia (TIVA)** 305
Amit Gupta and J. Lance Lichtor
- 50 **Monitored anesthesia care** 309
Shubjeet Kaur
- 51 **Patient positioning and common nerve injuries** 313
Christian D. Gonzalez
- Part 9 – Managing the Transition from Anesthesia**
Robert M. Knapp, editor
- 52 **Emergence from anesthesia** 317
Michael P. Storey and Richard D. Urman
- 53 **Postoperative complications in the PACU** 321
Ala Nozari and Edward A. Bittner
- 54 **Management of postoperative nausea and vomiting** 326
Robert M. Knapp
- 55 **Cognitive changes after surgery and anesthesia** 330
Joshua C. Vacanti, Gregory J. Crosby, and Deborah J. Culley

Part 10 – Regional Anesthesia

Mercedes A. Concepcion and Mark Dershwitz, editors

- 56 **Anatomy of the vertebral column and spinal cord** 335
Assia Valovska
- 57 **Spinal anesthesia** 340
Ivan T. Valovski and Assia Valovska
- 58 **Epidural anesthesia** 349
Richard S. Field and B. Scott Segal
- 59 **Principles of ultrasound-guided nerve blocks** 356
Tanja S. Frey and Adam B. Collins
- 60 **Upper extremity nerve blocks** 361
Eddy M. Feliz, Tanja S. Frey, Adam B. Collins, and Abdel-Kader Mehio
- 61 **Lower extremity nerve blocks** 370
Mônica M. Sá Rêgo and Adam B. Collins

Part 11 – Fluid and Electrolyte Balance

Selwyn O. Rogers Jr., editor

- 62 **Fluid replacement** 383
Silvia Pivi and Lorenzo Berra
- 63 **Acid–base balance in anesthesia and intensive care medicine** 388
George P. Topulos
- 64 **Ion balance** 396
Tommaso Mauri and Lorenzo Berra
- 65 **Total parenteral nutrition** 402
Mallory Williams and Gyorgy Frenzl

Part 12 – Transfusion Medicine

Richard M. Kaufman, editor

- 66 **Blood products** 407
Edward R. Garcia
- 67 **Blood transfusion** 411
Jonathan E. Charnin
- 68 **Massive transfusion** 417
Amy J. Ortman and Susan Vassallo
- 69 **Normovolemic hemodilution, perioperative blood salvage, and autologous blood donation** 422
Thomas J. Graetz

Part 13 – Cardiac Anesthesia

Stanton K. Shernan, editor

- 70 **Cardiac physiology** 427
Nelson L. Thaemert and Rena Beckerly
- 71 **Cardiovascular pharmacology** 438
Arti Ori and Douglas C. Shook
- 72 **Adjunct cardiovascular drugs** 447
Alexander C. Gerhart and Balachundhar Subramaniam
- 73 **Coronary artery bypass grafting utilizing cardiopulmonary bypass** 451
Theresa S. Chang and John A. Fox
- 74 **Off-pump coronary artery bypass** 461
Theresa S. Chang and John A. Fox
- 75 **Transesophageal echocardiography** 464
Karinne Jervis and Balachundhar Subramaniam
- 76 **Pacemakers and automated implantable cardioverter–defibrillators** 473
Sugantha Sundar and Eswar Sundar
- 77 **Ventricular assist devices** 479
Amanda A. Fox and John A. Fox
- 78 **Anesthetic considerations for surgical repair of the thoracic aorta** 485
Brian J. Gelfand and Amanda A. Fox
- 79 **Cardiac transplantation in the adult** 492
Martina Nowak, Prem S. Shekar, and Michael N. D'Ambra
- 80 **Persistent postoperative bleeding in cardiac surgical patients** 497
Walter Bethune, Michael G. Fitzsimons, and Edwin G. Avery IV

Part 14 – Vascular Anesthesia

Simon Gelman and Stanley Leeson, editors

- 81 **Carotid endarterectomy** 503
Brian J. Gelfand and Stanley Leeson
- 82 **Abdominal aortic aneurysm** 509
Fred Cobey, Simon Gelman, and Jonathan D. Gates
- 83 **Endovascular abdominal aortic aneurysm repair** 516
K. Annette Mizuguchi
- 84 **Peripheral vascular disease** 519
Laura H. Leduc and James L. Helstrom

Part 15 – Thoracic Anesthesia

Shannon S. McKenna, editor

- 85 **Respiratory physiology** 523
Shannon S. McKenna
- 86 **Oxygen and carbon dioxide transport** 530
Swaminathan Karthik and J. Taylor Reed
- 87 **Lung isolation techniques** 536
Shine Sun and Sarah H. Wiser
- 88 **Anesthetic management for pulmonary resection** 546
Sarah H. Wiser and Philip M. Hartigan
- 89 **Lung transplantation** 557
Vladimir Formanek
- 90 **Bronchoscopy and mediastinoscopy** 563
Sharon L. Wetherall and Philip M. Hartigan
- 91 **Management of mediastinal mass** 568
Ju-Mei Ng

Part 16 – Neuroanesthesia

Linda S. Aglio, editor

- 92 **Principles of neurophysiology** 575
Dennis J. McNicholl and Lee A. Kears Jr.
- 93 **Cerebral protection** 585
Grace Y. Kim
- 94 **Craniotomy** 591
Elizabeth M. Rickerson and Lisa J. Crossley
- 95 **Cerebrovascular diseases** 597
Grace Y. Kim
- 96 **Anesthesia for electroconvulsive therapy** 611
Lambertus Drop

Part 17 – Anesthesia for Renal and Urinary Tract Diseases

Paul D. Allen, editor

- 97 **Renal physiology** 617
Edward R. Garcia
- 98 **Urology** 621
Naveen Nathan and Tarun Bhalla
- 99 **Kidney and pancreas transplantation** 628
Thomas Edrich and Sayeed Malek

Part 18 – Anesthesia for General Surgical Procedures

Warren S. Sandberg, editor

- 100 **Anesthesia for intra-abdominal surgery** 631
Khalidoun Faris and Faraz Syed
- 101 **Laparoscopic surgery** 636
Kai Matthes and Bhavani S. Kodali
- 102 **Anesthesia for esophageal and gastric surgery** 640
Amy L. Kim and Warren S. Sandberg
- 103 **Anesthesia for gynecologic and breast surgery** 647
Bronwyn Cooper
- 104 **Anesthesia for liver transplantation** 651
Jason C. Brookman and Warren S. Sandberg

Part 19 – Anesthesia for Endocrine Diseases

Balachundhar Subramaniam, editor

- 105 **Thyroid disorders** 661
Emily A. Singer and Pankaj K. Sikka
- 106 **Parathyroid disorders** 666
David R. Moss
- 107 **Pheochromocytoma** 669
Deborah S. Pederson
- 108 **SIADH, diabetes insipidus, and transsphenoidal pituitary surgery** 673
John Summers and Balachundhar Subramaniam
- 109 **Disorders of the adrenal cortex** 676
John Summers and Balachundhar Subramaniam

Part 20 – Anesthesia for Neuromuscular and Collagen Diseases

Paul D. Allen, editor

- 110 **Malignant hyperthermia** 681
Matthew C. Martinez and John D. Mitchell
- 111 **Myasthenia gravis** 685
Tomas Cvrk
- 112 **Muscular dystrophy and myotonic dystrophy** 690
Jason M. Erlich and Sugantha Sundar

Part 21 – Anesthesia for Ocular, Ear, and Throat Diseases

D. John Doyle, editor

- 113 **Ophthalmic procedures** 695
J. Victor Ryckman and D. John Doyle
- 114 **Common otolaryngology procedures** 701
Naila Moghul and D. John Doyle
- 115 **Lasers, airway surgery, and operating room fires** 708
Alvaro A. Macias, Naila Moghul, and D. John Doyle

Part 22 – Anesthesia for Orthopedic and Trauma Surgery

Abdel-Kader Mehio and Kamen V. Vlassakov, editors

- 116 **Anesthesia for common orthopedic procedures** 713
Patricio Leyton, Gian Paolo Volpato, and Kamen V. Vlassakov
- 117 **Rheumatoid arthritis and scoliosis** 721
Kenji Butterfield, Abdel-Kader Mehio, and John D. Mitchell
- 118 **Anesthetic management in spine surgery** 726
Abdel-Kader Mehio and Swapneel K. Shah
- 119 **Anesthesia for trauma** 732
Bishr Haydar

Part 23 – Obstetric Anesthesia

William R. Camann, editor

- 120 **Physiologic changes during pregnancy** 739
Carlo Pancaro and William R. Camann
- 121 **Analgesia for labor** 744
Arvind Palanisamy and B. Scott Segal
- 122 **Anesthesia for cesarean delivery** 751
Lawrence C. Tsen
- 123 **Obstetric hemorrhage** 757
Cosmin Gauran and Lisa R. Leffert
- 124 **Preeclampsia** 761
Amy J. Ortman and Lisa R. Leffert
- 125 **Pregnant patients with comorbid diseases** 766
Anasuya Vasudevan and Stephen D. Pratt
- 126 **Anesthesia for fetal intervention** 772
Roland Brusseau and Linda A. Bulich

Part 24 – Pediatric Anesthesia

Lucinda L. Everett, editor

- 127 **Basic considerations for pediatric anesthesia** 777
Alina Lazar and Patricia R. Bachiller
- 128 **Preoperative evaluation of the pediatric patient and coexisting diseases** 787
Scott A. LeGrand and Thomas M. Romanelli
- 129 **Anesthetic considerations for common procedures in children** 795
Tonya L. K. Miller, Noah E. Gordon, and Mary Ellen McCann
- 130 **Neonatal surgical emergencies** 804
Noah E. Gordon and Mary Ellen McCann
- 131 **Congenital heart disease** 813
Denise M. Chan and Annette Y. Schure
- 132 **Management of postoperative pain in children** 824
Rahul Koka and Navil F. Sethna
- 133 **Neonatal resuscitation: clinical and practical considerations** 833
Denise M. Chan, Thomas J. Mancuso, and McCallum R. Hoyt

Part 25 – Ambulatory and Remote Location Anesthesia

Beverly K. Philip, editor

- 134 **Introduction to ambulatory anesthesia** 837
McCallum R. Hoyt and Naila Moghul
- 135 **Anesthesia outside the operating room** 841
Wendy L. Gross and Ramon Martin
- 136 **Office-based anesthesia** 846
Fred E. Shapiro

Part 26 – Management Aspects of Anesthesia Practice

Ross J. Musumeci, editor

- 137 **Patient safety, quality assurance, and risk management** 851
Miriam Harnett and Jeffrey B. Cooper
- 138 **Operating room management: core principles** 855
Richard D. Urman and Sunil Eappen

- 139 **Practice management** 859
Ross J. Musumeci
- 140 **Principles of medical ethics** 864
Robert J. Klickovich and Rae M. Allain
- 141 **Risks in the operating room** 868

Preface

Why another basic textbook of anesthesiology? Some of the most classic texts on this topic have been published in many editions and have enjoyed popularity for decades, especially among trainees. Major clinical textbooks have likewise evolved through many editions, providing trainees and practitioners with extensive reference works. Our goal was to develop a text that bridges this gap. *Essential Clinical Anesthesia* is designed to be read cover to cover by trainees, but also to serve as a succinct and compact reference for more experienced practitioners. The format differs from most other texts by featuring a large number of short chapters. The book contains 29 sections and 184 chapters. The majority of these are found in the print version and the remainder, including some of the more advanced topics, can be accessed on the Internet at www.cambridge.org/vacanti. We have endeavored to keep the length of each chapter short enough to be read comfortably in a single sitting yet comprehensive enough to cover the basics as well as the state of the art. References are sufficient to allow the interested reader to delve deeper yet reasonable in number to allow the reader to focus on the most important works on the subject.

We have followed the lead of major textbooks by making this text a multi-authored work. More than 150 authors, all experts in their fields, have written the chapters, and experienced

section editors have ensured accuracy and consistency of the format. The astute reader will note that many authors are from Boston teaching hospitals but overall are drawn from institutions nationwide and beyond. We hope this provides a broad perspective on the field of anesthesiology.

The editors wish to express their gratitude to Jerry Buterbaugh, Angela Butler, Jodi Edelstein, Dr. Joseph Garfield, Meghan Hurley, Dr. Robert Pilon, Dr. Matthias Stopfkuchen-Evans, Dr. George Topulos, and Barbara Walthall of Aptara, Inc. for providing valuable editorial assistance, and the editors appreciate the support of Cambridge University Press in the preparation of this textbook. We hope that *Essential Clinical Anesthesia* will prove to be a valuable textbook that will enrich the libraries of our readers and help advance the study of anesthesiology.

Foreword

“The practice of medicine is an art based on science.”

William Osler

Since William T. G. Morton administered ether to Gilbert Abbott at Massachusetts General Hospital on October 16, 1846, anesthesiology has evolved into one of the most complex disciplines of medicine. The past years have witnessed numerous scientific and technologic advances, resulting in a mountain of information to read and digest. Notable among these are receptor–drug interactions, genes and mutations, and genetic and acquired physiologic variables, to name a few. Variations in these processes among individuals as well as in an individual from time to time serve to explain the wide variations clinicians see in pain perception, stress response, and anesthetic requirements.

While these and other scientific advances provide a strong scientific foundation for clinical practice, art is equally or

perhaps more important to produce the best possible clinical outcomes. In this regard, the legacy of William Osler and other giants, who practiced medicine at a time when technologic tools were barely existent, is a constant reminder about the importance of art as well as science in the clinical practice of anesthesiology, a complex branch of medicine.

This book, in an easy-to-access format, is designed to present the essential scientific and non-scientific aspects of the knowledge base. The chapters are written by authors who are well versed in their respective areas of expertise. I am confident that this book will serve readers well in enhancing the art and science of anesthesiology in their clinical practice.

Boston, Massachusetts

History of anesthesia

Rafael A. Ortega and Christine Mai

It has been said that the disadvantage of not understanding the past is to not understand the present. Knowledge of the history of anesthesia enables us to appreciate the discoveries that shaped this medical field, to recognize the scope of anesthesiology today, and to predict future advancements (Table 1.1).

It is generally agreed that the first successful public demonstration of general inhalation anesthesia with diethyl ether occurred in Boston in the 19th century. Prior to this occasion, all but the simplest procedures in surgery were “to be dreaded only less than death itself.” Throughout history, pain prohibited surgical advances and consumed patients. Imagine the sense of awe and pride when William Thomas Green Morton (1819–1868), a dentist from Massachusetts, demonstrated the use of ether to anesthetize a young man for the removal of a tumor. The celebrated demonstration in 1846 at the Massachusetts General Hospital heralded a new era of pain-free operations. As Johann Friedrich Dieffenbach, author of *Ether against Pain*, stated, “Pain, the highest consciousness of our earthly existence, the most distinct sensation of the imperfection of our body, must bow before the power of the human mind, before the power of ether vapor.”

Anesthesia prior to ether

The first forays into the field of anesthesiology occurred much earlier than Morton’s demonstration. The Greek physician Dioscorides (A.D. 40–90), for instance, reported on the analgesic properties of mandragora, extracted from the bark and leaves of the mandrake plant in the first century. Agents such as ethyl alcohol, cannabis, and opium were inhaled by the ancients for their stupefying effects before surgery. Alchemist and physician Arnold of Villanova (c. 1238–c. 1310) used a mixture of opium, mandragora, and henbane to make his patients insensible to pain.

From the ninth to the 13th century, the “soporific sponge” was used to provide pain relief. These sponges were impregnated with a liquid made from boiling a combination of mandrake leaves, poppies, and herbs. Prior to surgery, the sponge was reconstituted with hot water and placed over the nostrils of the afflicted to deliver the anesthetic. Alcohol fumes also were used in the surgical setting during the Middle Ages, but proved to be of poor value because of their inadequacy both in pain

relief and in minimizing the recollection of unpleasant memories of the surgical procedure.

In the 16th century, Paracelsus (1493–1544) produced laudanum, an opium derivative in the form of a tincture. Laudanum, or “wine of opium,” was used as an analgesic but also was inappropriately prescribed for meningitis, cardiac disease, and tuberculosis. Still, alcohol and opium were regarded as of practical value in diminishing the pain of operations by the mid-1800s, despite their relative ineffectiveness.

In 1804, decades before Morton’s demonstration, Seishu Hanaoka (1760–1835), a surgeon in Japan, administered general anesthesia. Hanaoka used an herbal concoction containing a combination of potent anticholinergic alkaloids capable of inducing unconsciousness. The patients drank the preparation known as “Tsusensan” before Hanaoka performed surgery. It is also known that Chinese physicians have used acupuncture to ease surgical pain for centuries.

Nitrous oxide

Joseph Priestley (1733–1804), an English clergyman and chemist, first described nitrous oxide’s properties as an anesthetic. Like ether, nitrous oxide was known for its ability to produce lightheadedness and inebriation. Sir Humphry Davy (1778–1829) noted the gas’s effect on respiration and the central nervous system. In his book *Nitrous Oxide*, Davy commented on its effects of transiently relieving headaches and toothaches and its capability to alleviate physical pain during surgical procedures. The term *laughing gas* was coined by Davy because of its ability to trigger uncontrollable laughter. This gas remains the oldest inhaled anesthetic still used today.

Diethyl ether

The compound diethyl ether has been known for centuries. It may have been first discovered by the Arabian philosopher Jabir ibn Hayyam in the eighth century. Credit also is given to the 13th century European alchemist Raymundus Lullius, who first called it “sweet vitriol.” This compound later was renamed *ether*, which in Greek means “the upper, pure bright air.” By the 16th century, Paracelsus recognized and recorded the analgesic properties of ether. He noted that it produced drowsiness in chickens, causing them to fall asleep and awaken unharmed.

Table 1.1. Timeline of the history of anesthesia

First century A.D.	Greek physician Dioscorides reports analgesic properties of mandragora
Ninth–13th century	Soporific sponge method for delivering pain relief
16th century	Paracelsus introduces laudanum, “wine of opium.” Spanish conquistadores’ account of curare in South America
18th century	
1773	Nitrous oxide first introduced by Joseph Priestley
19th century	
1800	Humphry Davy publishes <i>Nitrous Oxide</i>
1804	Seishu Hanaoka of Japan administers general anesthesia
1842	Crawford Long administers diethyl ether inhalational general anesthesia
1844	Horace Wells administers nitrous oxide for dental analgesia
1846	William Morton’s public demonstration of diethyl ether at Massachusetts General Hospital
1847	James Young Simpson administers chloroform for general anesthesia in England
1853	John Snow administers chloroform to Queen Victoria for the birth of Prince Leopold
1857	Claude Bernard discovers the effects of curare located at the myoneuronal junction
1884	Carl Koller introduces the use of cocaine for ophthalmic surgery
1885	William Halsted describes techniques of anesthetizing nerve plexuses using cocaine
1889	August Bier performs the first surgical spinal anesthesia
20th century	
1903	Phenobarbital synthesized by Fischer and von Mering
1905	Procaine introduced as a local anesthetic Long Island Society of Anesthetists founded
1911	Long Island Society of Anesthetists becomes the New York Society of Anesthetists
1927	Ralph Waters establishes first anesthesiology postgraduate training program at the University of Wisconsin–Madison
1932	Thiopental and thiamylal synthesized
1934	Thiopental used by both Waters and Lundy for induction of anesthesia
1935	Emery Rovenstine organizes an anesthesia department at Bellevue Hospital, NY
1936	New York Society of Anesthetists becomes the American Society of Anesthetists
1938	The American Board of Anesthesiology founded
1940	William Lemmon introduces concept of continuous spinal anesthesia
1942	Drug form of curare, intocostin, introduced
1943	Lidocaine introduced as local anesthetic by Lofgren and Lindquist of Sweden
1944	Edward Tuohy invents the Tuohy needle
1945	American Society of Anesthetists becomes the American Society of Anesthesiologists (ASA)
1949	Daniel Bovet synthesizes succinylcholine
1951	Halothane introduced into clinical practice
1960	Methoxyflurane introduced into clinical practice; its use was limited by nephrotoxicity
1962	Ketamine synthesized
1964	Etomidate synthesized
1965	Isoflurane first introduced; it was marketed in the 1970s
1977	Propofol synthesized
1983	Archie Brain develops the laryngeal mask airway
1985	Anesthesia Patient Safety Foundation established
1986	Standards for basic anesthesia monitoring approved by the ASA House of Delegates
1992	Desflurane introduced into clinical practice
1994	Sevoflurane introduced into clinical practice
1995–present:	The past decade has seen advances in a variety of areas, including refinements in anesthesia delivery apparatus, ultrasound applications for regional anesthesia, transesophageal echocardiography, depth of anesthesia monitors, total intravenous anesthetics, supraglottic airway devices, and other innovations, helping to make the administration of anesthesia safer.

Before ether became known as a general anesthetic, it was marketed as a pain reliever. It also was used as an inexpensive recreational drug during “ether frolics.” Many famous British scientists, such as Robert Boyle (1627–1691), Isaac Newton (1643–1728), and Michael Faraday (1791–1867), examined the properties of ether. However, they did not make the connection between its analgesic qualities and the possibility of complete surgical anesthesia. It was not until later that ether was used as a general anesthetic. Crawford Williamson Long (1815–1978), a physician from Georgia, administered ether on March 30, 1842, to James M. Venable for the removal of a neck tumor. Long also

conducted comparative trials of procedures, with and without ether, to demonstrate that alleviation of pain was a result of the drug rather than individual pain threshold or hypnotism.

Horace Wells (1815–1848) was first in attempting to publicly demonstrate general anesthesia. Wells, a dentist, knew of the analgesic effects of nitrous oxide and used it for tooth extractions. Understanding its effects, he attempted to demonstrate a painless tooth extraction at Harvard Medical School in 1845. Perhaps because of the low potency of nitrous oxide, during the procedure the subject moved and groaned. Wells was discredited for his display. Deeply disappointed by the

Figure 1.1. The Ether Dome, designed by architect Charles Bulfinch, was originally known as the Surgical Amphitheater of Massachusetts General Hospital.

failed demonstration, he committed suicide in 1848. Nevertheless, his idea inspired individuals such as Morton to persist in demonstrating the efficacy of these drugs. On October 16, 1846, Morton administered ether, allowing surgeon John Collins Warren (1778–1856) to painlessly remove a mandible tumor from Edward Gilbert Abbott. This event took place in the surgical amphitheater at Massachusetts General Hospital, which is now known as the Ether Dome, a designated national historical landmark (Fig. 1.1). The account of the ether demonstration appeared the next day in the *Boston Daily Journal*, and within months the discovery of surgical anesthesia was known worldwide.

The ether controversy

Ether anesthesia proved to be controversial from the start. Morton wanted to capitalize on the discovery and initially refused to divulge the identity of the agent in his inhaler (Fig. 1.2). Wells and chemist Charles T. Jackson (1805–1880), Morton's advisor, both claimed the discovery belonged to them. Jackson, a Boston physician and chemistry professor, was well aware of the failed public demonstrations of the past and had advised Morton to use ether rather than nitrous oxide in his historical debut. For this contribution, Jackson adamantly argued it was he who should be credited for the “idea” of administering

Figure 1.2. A replica of Morton's inhaler as used at the first public demonstration of ether anesthesia on October 16, 1846.

Figure 1.3. Bas-relief on the Ether Monument in Boston representing a surgical procedure in a hospital, with the patient under the influence of ether. To the left, an assistant is washing his hands in a basin, denoting an appreciation for early attempts at antisepsis.

ether-inhaled anesthesia. Wells contended that he had successfully administered general anesthesia with nitrous oxide on several occasions. However, he never convincingly proved it. Long also claimed he had demonstrated the uses of ether in rural areas well before Morton. However, Long did not publish his experiences until 1849, three years after Morton's demonstration. These debates have collectively been referred to as “the ether controversy.”

In 1868, to commemorate the first public demonstration of ether in Boston, a monument was erected in the city's Public Garden. The Ether Monument, with its marble and granite images and inscriptions, addresses universal themes such as the suffering caused by war, the desire on behalf of loved ones to relieve pain, and the triumph of medical science (Fig. 1.3 and Fig. 1.4). Perhaps no other monument related to medicine is so rich in history, controversies, and allegories. The Ether Monument, however, makes no mention of any of the claimants to the discovery.

Acceptance of anesthesia in the Western world

In some ways, what matters most is not *who* discovered anesthesia, but rather *where* and *when* it was discovered. Some scholars believe that a spirit of humanitarianism and political freedom were necessary for the development of anesthesia to occur in the 19th century. Initially, there were religious objections to anesthesia. Certain individuals believed it was against the will of God to alleviate pain. The use of anesthesia in labor and delivery was particularly contentious, in part because of the “curse of Eve,” which states, “In sorrow thou shalt bring forth children” (Genesis 3:16). Also on biblical grounds, others supported anesthesia, reasoning that God himself performed the first operation under “anesthesia” when he removed Adam's rib: “The Lord God caused a deep sleep to fall upon Adam and he slept...” (Genesis 2:21). Other objections to anesthesia were based on morality rather than the religious implications of pain relief. Some argued that anesthesia's disinhibiting effects threatened

Figure 1.4. The Ether Monument in the Boston Public Garden, with evening illumination and working fountains.

the virtue and decency of women. In 1853, Queen Victoria effectively silenced all opposition when John Snow anesthetized her with chloroform during the birth of Prince Leopold.

Chloroform

Because ether was such a safe anesthetic, its administration was relegated largely to nonphysicians in the United States, whereas in England chloroform quickly became the anesthetic of choice. This preference might have arisen out of a sense of national pride, being that ether anesthesia was introduced in America, which had relatively recently gained its independence. Chloroform, a more dangerous drug than ether, required more skillful and careful titration. The resulting challenges of chloroform administration attracted the attention of brilliant physicians and investigators, including the Scottish obstetrician James Young Simpson (1811–1870) and the English anesthetist John Snow (1813–1858). This may explain why there were few

developments in anesthesia within the United States for many decades after the introduction of ether while in Britain, great progress was made.

Modern inhaled anesthetics

The search for an ideal inhaled anesthetic led to the introduction of many chemicals, including ethyl chloride, ethylene, cyclopropane, and other volatile agents, during the first half of the 20th century. However, their use faded because of varied disadvantages, such as strong pungency, weak potency, and flammability. These agents soon were replaced by fluorinated hydrocarbons. Fluorination made inhaled anesthetics more stable, less combustible, and less toxic. In 1951, halothane was recognized as a superior anesthetic over its predecessors. In the 1960s, methoxyflurane was popular for a decade, until its dose-related nephrotoxicity discouraged its use. Enflurane and its isomer, isoflurane, were introduced in 1963 and 1965, respectively. Enflurane's popularity was limited after it was shown to produce cardiovascular depression and seizures. Isoflurane was more difficult to synthesize and purify than enflurane. However, once the purification process was refined and further trials proved its safety, isoflurane was marketed in the late 1970s and remains a popular anesthetic. For 20 years, no further developments occurred until the release of desflurane in 1992 and sevoflurane in 1994. Today, these three agents, in addition to nitrous oxide, constitute the mainstay of inhalation anesthetics.

Regional anesthesia

Although chloroform and ether provided analgesia for obstetric pain, disadvantages such as inadequate uterine contractions and neonatal respiratory depression were noted. The invention of the hollow needle in 1853 by Alexander Wood allowed for the development of regional anesthesia techniques as an effective alternative to inhaled anesthetics.

In 1884, Carl Koller (1858–1944), an ophthalmologist, introduced the use of cocaine for ophthalmic surgery. Within a year of his reports, injections of cocaine were described to anesthetize nerve trunks and the brachial plexus by William S. Halsted (1852–1922). The idea of spinal anesthesia first was conceived in 1885 by a neurologist, Leonard Corning (1855–1923). Although his writings described the administration of cocaine, the injection was extradural rather than in the subarachnoid space. Corning's technique was improved by the German physician Heinrich Quincke (1842–1922), who described the level below which it was safest to perform a lumbar puncture. In 1899, using Quincke's technique, August Bier (1861–1949) performed the first spinal anesthesia for a surgical procedure. The Swiss obstetrician Oscar Kreis recognized the advantages of regional anesthesia in obstetrics and administered the first spinal anesthesia for control of labor pain at the start of the 20th century.

Early cases of regional anesthesia were noted to have side effects, such as high incidences of postdural puncture headache, vomiting, and the propensity for the those administering it to

become addicted to cocaine. The addictive nature of cocaine and its toxicity led to the discovery of safer local anesthetics, such as procaine in 1905 and lidocaine in 1943. In 1940, the introduction of continuous spinal anesthesia was credited to William T. Lemmon, who advocated the administration of repeated small doses of procaine through a malleable needle connected to a rubber tubing and syringe. Four years later, Edward Tuohy (1908–1959) of the Mayo Clinic introduced two important modifications: the invention of the Tuohy needle and the idea of threading a catheter into the epidural space for incremental doses of local anesthetics. A technique for locating the epidural space was made popular by the writings of Achille M. Dogliotti (1897–1966), who identified it using the “loss of resistance.”

Over the past 60 years, intrathecal and epidural administration of local anesthetics, opioids, and steroids has become commonplace for analgesia throughout the course of labor and for managing chronic pain. The development of plexus blocks and other regional anesthesia techniques progressed to incorporate the use of nerve stimulators and ultrasound to facilitate locating nerves, thus enhancing the quality of the block.

Neuromuscular blocking agents

Neuromuscular blocking agents were introduced into anesthetic practice nearly a century after the administration of inhalational anesthesia. Curare, the first isolated neuromuscular blocking agent, originally was used in hunting and tribal warfare by natives of South America. Curare alkaloid extracts from lianas (vines) were applied to arrow darts, which natives propelled using blowguns to poison their prey. Accounts of these Amazon jungle poisons by 16th century Spanish conquistadores intrigued the European medical community and triggered early experiments on animals, which determined that the agent paralyzes muscle function. The collaborative work of Benjamin Brodie (1783–1862) and Charles Waterton (1783–1865), demonstrated that animals injected with curare could survive with artificial ventilation. In 1857, Claude Bernard (1813–1878), a French physiologist, determined that the effect of the drug was located in neither the nerve nor the muscle, but at the junction of the two. Initially, there were limited medical applications for curare, such as ameliorating muscle spasms caused by tetanus, reducing trauma during seizure therapy, and treating Parkinson-like muscle rigidity. However, with the advent of tracheal intubation and mechanical ventilation, the use of curare to prevent laryngospasm during laryngoscopy or to relax abdominal muscles during surgery remarkably altered the practice of anesthesia.

On January 23, 1942, the drug form of curare, intocostin, was introduced into anesthesia practice by anesthesiologist Harold R. Griffith (1894–1985) and his resident, Enid Johnson, at Montreal Homeopathic Hospital. The facilitation of tracheal intubation and abdominal muscle relaxation produced by intocostin during cyclopropane anesthesia heralded

a new era for neuromuscular blocking agent development. Subsequent muscle relaxants, such as gallamine, decamethonium, and metocurine, were studied. However, their popularity was limited because of undesirable autonomic nervous system effects. In 1949, succinylcholine, a depolarizing neuromuscular agent, was synthesized by Nobel laureate Daniel Bovet (1907–1992). Nondepolarizing neuromuscular drugs, such as the aminosteroids pancuronium, vecuronium and rocuronium and the benzylisoquinoliniums atracurium and *cis*-atracurium, were introduced in the late 20th century.

Intravenous anesthetics

The first intravenous induction agent was phenobarbital, a barbiturate synthesized by Emil Fischer (1852–1919) and Joseph von Mering in 1903. As a hypnotic, phenobarbital caused prolonged periods of unconsciousness and slow emergence. Hexobarbital, a short-acting oxybarbiturate, was introduced in 1932 but was subsequently replaced by a sulfated barbiturate, thiopental, a potent agent with rapid onset of action and few excitatory side effects. In 1934, both Ralph Waters (1883–1979) at the University of Wisconsin and John Lundy (1894–1973) at the Mayo Clinic successfully administered thiopental as an intravenous anesthetic agent. Furthermore, John Lundy’s continued research on intravenous anesthetics popularized its use in clinical practice. His concept of “balanced anesthesia” emphasized combining multiple anesthetic drugs and techniques to provide hypnosis, muscle relaxation, and analgesia. This approach led to the optimization of operating conditions and reduction of side effects, thereby making anesthesia administration safer for patients. The widespread use of thiopental stimulated the development of other classes of intravenous hypnotics, including ketamine (1962), etomidate (1964), and propofol (1977). Benzodiazepines, opioids, antiemetics, and other drugs have enriched the intravenous pharmacologic armamentarium, and their combined use represents an extension of Lundy’s approach of balanced anesthesia.

Anesthesiology as a medical specialty

The field of anesthesiology as a recognized medical specialty developed gradually in America during the 20th century. For decades, formal instruction in anesthesia was nonexistent and the field was practiced only by a few self-taught individuals. In the 1910s, Ralph Waters described the environment he encountered in which nurses administered anesthesia because there were few physicians trained as proficient anesthesiologists. He advocated the development of dedicated anesthesia departments and training programs. Subsequently, several anesthesiologists, including Thomas D. Buchanan and John Lundy, established anesthesia departments at New York Medical College and the Mayo Clinic, respectively. The first anesthesiology postgraduate training program was established by Waters at the University of Wisconsin–Madison in 1927. His department was a milestone in establishing anesthesiology

within a university setting. Waters's influence in anesthesiology determined the commitment of this specialty to education and research. Successful application of the Wisconsin model was best reflected by the work of Waters's academic descendants, such as Emery Rovenstine at New York's Bellevue Hospital and Robert Dripps at the University of Pennsylvania.

Modern anesthesiology practice

Although advances were made in the early 1900s, including Sir Robert Macintosh's and Sir Ivan Magill's contributions to airway management, the modern practice of anesthesiology evolved in the latter half of the 20th century with an emphasis on safety. In 1985, the Anesthesia Patient Safety Foundation was established with a mission "to ensure that no patient is harmed by anesthesia." The introduction of additional monitoring tools, such as capnometry and pulse oximetry, remarkably decreased mortality rates during anesthesia. The refinements in current anesthesia delivery systems would have been unimaginable for anesthesiologists of yesteryear.

Today, the practice of anesthesiology in the United States depends on guidelines provided by the American Society of Anesthesiologists (ASA). The stated goals of this professional organization are to establish "an educational, research and scientific association of physicians organized to raise and maintain the standards of anesthesiology and to improve the care of patients."

The history of anesthesiology is vast and complex; this chapter is meant to serve as a brief overview. The best repository for documents and artifacts relating to the history of anesthesia is

the Wood Library–Museum at ASA headquarters in Park Ridge, Illinois.

Preoperative anesthetic assessment

Sohail K. Mahboobi and Sheila R. Barnett

The preoperative assessment is a vital part of any procedure requiring anesthesia. The assessment itself may vary considerably, from a simple interview and limited physical examination on the day of surgery to an extensive medical evaluation including invasive cardiac testing and radiologic examinations weeks in advance of the surgery. The choice and type of the preoperative assessment depend on several variables, including the patient's age and medical history as well as the type and degree of risk of procedure planned. Patient and physician preferences should also be considered.

The preoperative assessment

Preoperative assessment provides an evaluation of the patient's anesthetic risk from the proposed procedure and allows recommendations to be made that may minimize risk and ensure a smooth transition from surgical booking to the operating room and beyond. Recommendations may include further testing, consultations, adjustments of medication, or simply reassurance and a consequent reduction of anxiety. Practically, the preoperative assessment may also identify special needs, such as the need for a latex-free environment, special blood products, interpreters, or airway equipment. Failure to plan for these needs may lead to surgical delays. In addition, instructions for fasting and medications, as well as expectations for the day of surgery and postoperative course, should all be provided (Fig. 2.1).

A preoperative assessment should include a medical history focusing on active medical issues, medication usage and past anesthetic and surgical experiences, a limited physical examination, an airway assessment, and additional testing as indicated. The anesthetic risk is derived from the knowledge of the patient and the surgery. The preoperative interview should include a discussion with the patient about the risks and benefits of different anesthetic techniques. Informed consent for anesthesia administration should be obtained. There are several alternative approaches to preoperative assessment (primary physician clearance, telephone interview, preoperative health survey, Internet health quiz), and the choice depends on hospital resources and the type of surgical facility.

The preoperative history

The preoperative history includes a thorough systematic review of the patient's medical problems, including an evaluation of available medical information. Organ systems and selected disorders that have particular impact preoperatively are briefly reviewed, highlighting major issues that should be covered in the course of a preoperative assessment.

Cardiovascular system

Cardiovascular complications may result in significant morbidity and mortality, and a thorough preoperative assessment of cardiovascular status should be part of any routine preoperative evaluation. Questions should be directed at assessing the status of current cardiac problems and eliciting evidence suggesting occult cardiac disease. A complete cardiovascular history also includes assessment of functional capacity (Table 2.1) and ascertains whether symptoms that may indicate significant

Figure 2.1. Goals of preoperative assessment

Table 2.1. Functional assessment scale

1 MET	Can you take care of yourself? Eat dress, use the toilet? Walk indoors around the house? Walk 1–2 blocks on level ground at 2–3 mph? Do light housework?
4 MET	Climb a flight of stairs? Carry groceries? Walk on level ground at 4 mph? Run a short distance? Do heavy housework? Do moderate sports – golf, dance, doubles tennis?
10 MET	Play competitive sports? Play singles tennis? Ski?

cardiac disease are present. Details about past cardiac events and testing should be requested and reviewed. Past electrocardiograms (ECGs) are critical to obtain in patients found to have an abnormal ECG.

Functional capacity

Functional capacity may be assessed from a careful history in the form of metabolic equivalents. The *metabolic equivalent of task (MET)*, or simply *metabolic equivalent*, is a physiologic concept expressing the energy cost of physical activities as multiples of resting metabolic rate. MET is defined as the ratio of metabolic rate (and therefore the rate of energy consumption) during a specific physical activity to a reference metabolic rate at rest, set by convention to 3.5 ml O₂/kg/min or equivalently, 1 kcal (or 4.184 kJ)/kg/h. By convention, 1 MET is considered the resting metabolic rate obtained during quiet sitting. Patients unable to meet a 4-MET standard are at increased risk for perioperative cardiac risk. Daily activities, such as eating, dressing, walking around the house, and dishwashing, range from 1 to 4 METs. Climbing one flight of stairs, walking on level ground at about 6 km/h, running a short distance, or playing a game of golf range from 4 to 10 METs. Playing tennis, swimming, and playing football exceed 10 METs. This is helpful in assessing cardiac risk and planning preoperative testing (Table 2.1).

The decision to send a patient for further cardiac evaluation is complex and includes consideration of patient comorbidities as well as the level of risk of the planned procedure. The guidelines written by the American College of Cardiology (ACC) and the American Heart Association (AHA) have updated recently and provide excellent algorithms for guidance

in this regard along with various levels of evidence (Table 2.2, Fig. 2.2). Briefly, emergent surgical procedures may not allow further cardiac assessment or treatment. In this case only perioperative medical management and recommendations are required. The patients who are having nonemergency procedures should be evaluated for the presence of active cardiac conditions (Table 2.3). The presence of any of these active cardiac conditions warrants further evaluation prior to procedures of even the lowest risk. If none of these active conditions exists, the patient's functional status should then be assessed.

According to these guidelines, if the patient's functional status is good (>4 MET), even higher-risk procedures (Table 2.4) may be undertaken without further cardiac noninvasive testing. If the functional status is inadequate or cannot be obtained, the presence of five clinical risk factors, as defined by these guidelines, should be ascertained. These clinical risk factors include a history of ischemic cardiac disease, a history of compensated or prior heart failure, diabetes, renal insufficiency, and cerebrovascular disease (Table 2.5). If three or more of these factors are present, and vascular or higher-risk procedures are being contemplated, further cardiac noninvasive testing may be warranted if it is felt this will affect management. Table 2.6 summarizes recommendations for noninvasive stress testing before noncardiac surgery.

Adequate β -blockade should be established perioperatively, if indicated. The recommendations are same for the patients with one or more risk factors going for high-risk vascular or intermediate risk surgery. Patients with no risk factors can proceed with the planned procedure. According to the AHA/ACC guidelines only two groups should be mandated for β -blockade: vascular patients with recent positive provocative cardiac testing (based on Poldermans 1999) and patients already taking β -blockers. Other than that, β blockers are probably recommended for intermediate risk or vascular surgical procedures with the presence of more than one clinical risk factor. Their usefulness is uncertain for patients with no or one risk factor and not already on β blockers. Similarly, patients already receiving calcium channel blockers should continue these medications, including on the day of surgery. Patients taking statins should continue doing so because this has been linked to fewer perioperative cardiac events and improved outcome, presumably by modulating inflammatory pathways. The optimal time for initiation and duration of perioperative statin therapy remains unclear.

There are significant numbers of patients with a history of percutaneous coronary intervention (PCI) in the form

Table 2.2. Levels of evidence

Class I	Class IIa	Class IIb	Class III
Benefit >>> risk Procedure/ treatment should be performed/ administered	Benefit >> risk Additional studies required It is reasonable to perform procedure/ administer treatment	Benefit \geq risk Additional studies required Procedure/ treatment may be considered	Risk \geq benefit No additional studies needed Procedure/ treatment should not be performed/ administered because it is not helpful and may be harmful

Table 2.3. Active cardiac conditions as defined by ACC/AHA 2007 guidelines

Unstable coronary syndromes
 Unstable or severe angina
 May include stable angina in unusually sedentary patients
 Recent myocardial infarction (within 30 d)

Decompensated heart failure, worsening or new-onset heart failure

Significant arrhythmias
 Mobitz II atrioventricular block
 Third-degree atrioventricular block
 Symptomatic ventricular arrhythmias
 Supraventricular arrhythmias with uncontrolled ventricular rate
 Symptomatic bradycardia

Severe valvular disease
 Severe aortic stenosis (mean pressure gradient > 40 mm Hg, aortic valve area < 1.0 cm², or symptomatic)
 Symptomatic mitral stenosis

Table 2.4. Cardiac risk for noncardiac surgery

High risk (>5%)	Intermediate risk (<5%)	Low risk (<1%)
Emergency	Carotid endarterectomy	Endoscopic surgeries
Aortic and major vascular	Head and neck	Superficial procedures
Peripheral vascular	Intraperitoneal and intrathoracic	Cataract surgery
Lengthy procedures with major blood loss or fluid shifts	Orthopedic	Breast procedures
	Prostate	

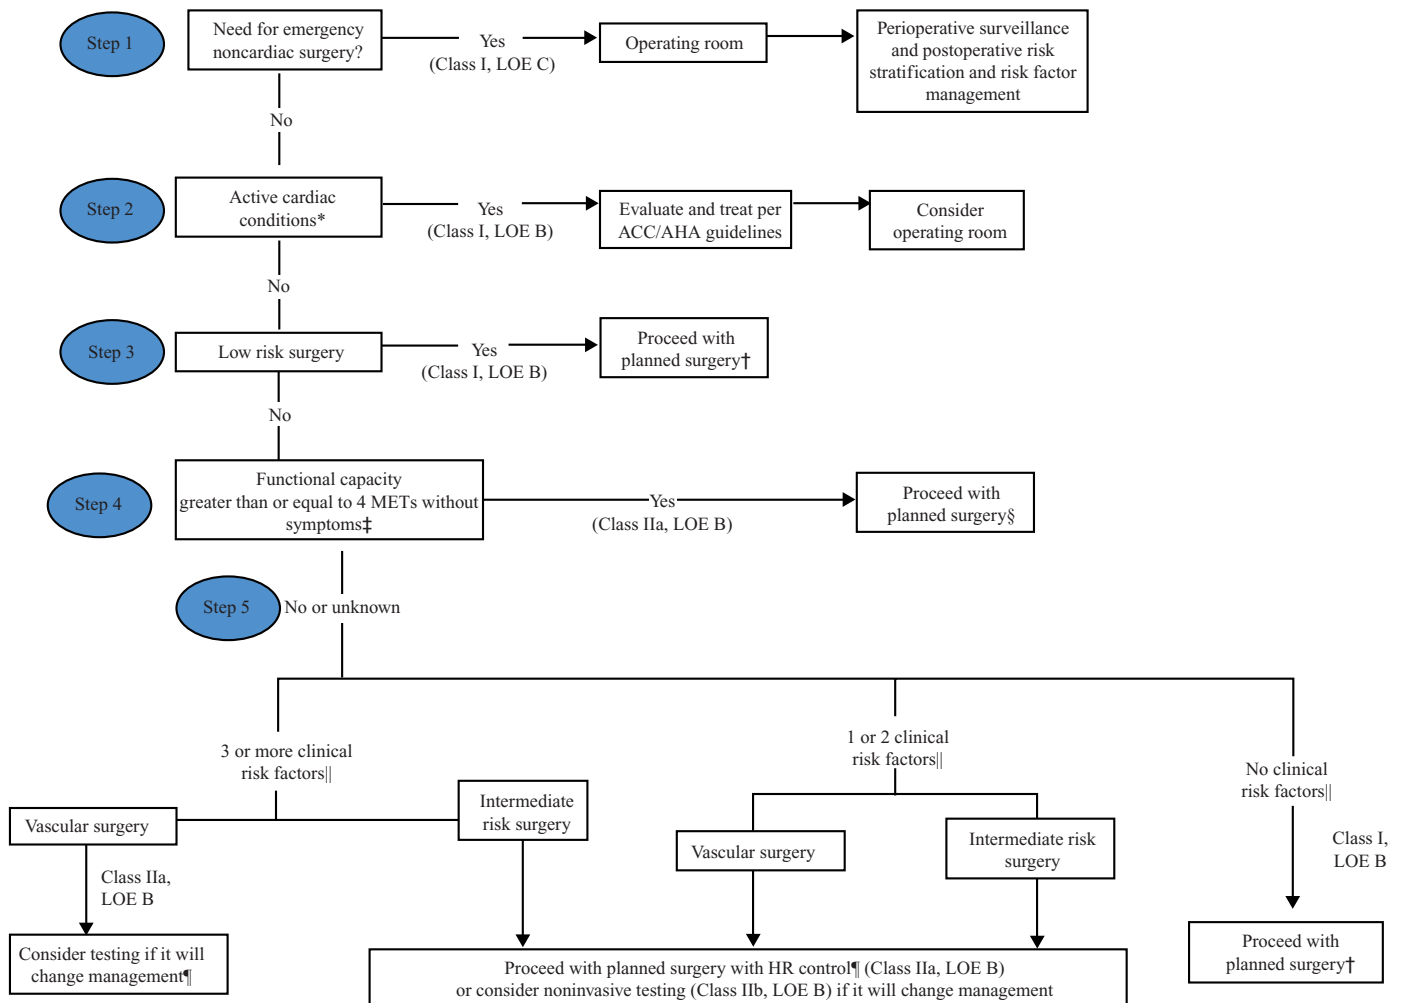

Figure 2.2. Cardiac evaluation and care algorithm for noncardiac surgery based on active clinical conditions, known cardiovascular disease, or cardiac risk factors for patients ≥ 50 years of age. *See Table 2.3 for active clinical conditions. †See class III recommendations in Table 2.6, Noninvasive Stress Testing. ‡See Table 2.1 for estimated MET level equivalent. §Noninvasive testing may be considered before surgery in specific patients with risk factors if it will change management. ||Clinical risk factors include ischemic heart disease, compensated or prior heart failure, diabetes mellitus, renal insufficiency, and cerebrovascular disease. Consider perioperative β-blockade for populations in which this has been shown to reduce cardiac morbidity/mortality. HR, heart rate; LOE, level of evidence. (Modified from Fleisher LA, et al. ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2007; 116:1971–1996.)

Table 2.5. Patient clinical risk predictors

Clinical risk factors (formerly known as intermediate risk factors)	Minor risk predictors (have not been proven to increase perioperative risk independently)
History of ischemic heart disease History of compensated or prior HF Diabetes mellitus Renal insufficiency History of cerebrovascular disease	Advanced age Abnormal ECG <ul style="list-style-type: none"> • LV hypertrophy • Left bundle-branch block • ST-T abnormalities Rhythm other than sinus Uncontrolled systemic hypertension

MI, myocardial ischemia; HF, heart failure.

of balloon angioplasty, bare metal stents (BMS) or drug-eluting stents (DES). These patients require antiplatelet therapy to avoid thrombosis. According to AHA/ACC recommendations at least four weeks of antiplatelet therapy (clopidogrel) is required for patients with BMS and 12 months of dual antiplatelet therapy (aspirin and clopidogrel) is required for patients with DES. Surgeries during this period of antiplatelet therapy pose a serious challenge. Recommendations are to delay the planned surgical procedures for at least 14 days after balloon angioplasty, 30 to 45 days after BMS placement and 365 days after DES placement. After these periods one can proceed to the operating room with continuation of aspirin (Figure 2.3).

A history of hypertension is common, affecting more than 50% of adult Americans. The preoperative assessment in a patient with hypertension should elicit any history of end-organ disease. Ischemia, myocardial infarction, diastolic dysfunction, renal failure, and cerebrovascular disease all may be consequences of untreated hypertension. Although blood pressure should optimally be controlled at the time of the preoperative visit, the literature suggests there are no absolute contraindications based on systolic or diastolic values that necessitate can-

Table 2.6. Recommendations for noninvasive stress testing before noncardiac surgery

Class I	Patients with active cardiac conditions in whom noncardiac surgery is planned should be evaluated and treated per ACC/AHA guidelines before noncardiac surgery
Class IIa	Noninvasive stress testing of patients with 3 or more clinical risk factors and poor functional capacity (less than 4 METs) who require vascular surgery is reasonable if it will change management
Class IIb	Noninvasive stress testing may be considered for patients with at least 1 to 2 clinical risk factors and poor functional capacity (less than 4 METs) who require intermediate-risk or vascular surgery if it will change management.
Class III	<ul style="list-style-type: none"> • Noninvasive testing is not useful for patients with no clinical factors undergoing intermediate-risk noncardiac surgery • Noninvasive testing is not useful for patients undergoing low-risk noncardiac surgery

cellation of an elective procedure. If a patient is seen in the preoperative clinic with poorly controlled hypertension and enough time exists before the procedure, the primary care physician should be contacted to attempt to achieve better medical management.

Pulmonary disease

Chronic pulmonary conditions may increase the risk of post-operative respiratory failure. History taking in patients with chronic obstructive pulmonary disease or asthma should include questions about the type of disease, duration, therapy, and baseline condition. Recent interventions, such as hospitalization, intubation, or changes in medications, such as the addition of steroids or antibiotics, should be documented. Patients may need a steroid pulse prior to surgery, require antibiotics for an acute bacterial process, or they may need arrangements for postoperative chest physiotherapy. Current symptoms may restrict the choice of anesthetic options; for instance, a case

Figure 2.3. Proposed approach to the management of patients with previous percutaneous coronary intervention (PCI) who require non-cardiac surgery. (Modified from Fleisher LA, et al. ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2007; 116:1971–1996.)

generally requiring sedation may necessitate the use of general anesthesia in patients with intractable coughing.

Sleep apnea has been associated with poorer postoperative outcomes and increased incidence of apnea and respiratory failure, especially with the administration of opioids. A history of snoring (confirmed by a partner), hypertension, chronic fatigue, and obesity are all associated with significant sleep apnea. It is becoming increasingly common to refer patients with possible sleep apnea for sleep studies and possible intervention preoperatively, to minimize the risk of postoperative apnea. Patients who wear continuous positive airway pressure masks should be instructed to bring the mask with them on the day of surgery.

Airway history frequently is included as part of the pulmonary assessment. If there has been a prolonged intubation or tracheotomy in the past, it is valuable to elicit information regarding etiology and history (for example, whether trauma or pneumonia was a precipitating factor). Residual damage such as symptomatic tracheal stenosis is important to document because the presence of significant stenosis may influence the choice of anesthetic technique. A history of a difficult intubation should be accompanied by an attempt to retrieve medical records and communicate the issues to the anesthetizing team. During the preoperative interview, it may be necessary to spend extra time with patients explaining the goals and procedures surrounding an awake intubation in simple, reassuring language to allow for informed consent and to reduce anxiety.

Gastrointestinal system

Aspiration may result in devastating complications during anesthesia. A positive history of severe, positional reflux may result in a change in the anesthetic plan. For example, endotracheal intubation may be used in cases in which use of a laryngeal mask airway would have been an option. The history of reflux should be carefully documented, and current symptoms and their severity should be quantified. The frequency of the reflux symptoms, the impact of treatment if prescribed, and the onset of symptoms during the night while the patient is lying flat may help distinguish true reflux from the much more common postprandial.

Obesity increases anesthesia risks. In the obese patient, it is valuable to record recent weight changes, body mass index, intubation challenges in the past, and comorbid conditions such as hypertension, diabetes, and sleep apnea. A further important consideration is the practical impact of the patient's weight. These patients may require special equipment in the operating room, including large blood pressure cuffs, wide stretchers, and larger operating room beds.

Neurologic system

Numerous neurologic conditions may affect anesthetic administration. For any patient with a neurologic condition, the diagnosis, medications, and status of current symptomatology

should be carefully documented. Many neurologic disorders, especially when severe, have an impact on respiratory status. In patients with epilepsy, preoperative assessment should include a description of the seizure type and frequency. Medications should be continued throughout the perioperative period. Many seizure medications are not available as intravenous formulations, so it is necessary to plan for therapy during prolonged periods when the patient is unable to take oral medicines.

Cerebrovascular disease is common, especially in older patients with peripheral vascular disease and diabetes. If a patient had a prior cerebrovascular accident, it is important to document baseline functional and neurologic impairments. Advanced dementia may prevent the clinician from obtaining a medical history or an informed consent. In such case, an arrangement for a family member or health care proxy will be needed to help obtain the preoperative assessment, and their presence may be needed on the day of surgery. Other less common diseases, such as multiple sclerosis, require a brief description of the symptoms during a relapse and residual damage. Some neurologic diseases, such as myasthenia gravis and myotonic dystrophy, carry significant risks from anesthesia; in these instances, clear documentation and recent neurologic evaluation may be valuable adjuncts to the standard preoperative assessment. Spinal cord injury patients often undergo multiple operations and present many anesthetic challenges. At a minimum, the history should include the level of the lesion, residual damage, and the history of hypertensive crises during procedures.

Endocrine system

Diabetes mellitus is the most common endocrinopathy encountered preoperatively and is associated with many comorbid conditions that increase anesthetic risk. In addition to a description of the type of diabetes and the insulin status, a detailed history should be obtained in all diabetic patients to search for occult cardiac disease, renal impairment, or end organ damage. The hemoglobin A_{1c} level can be used to establish the degree of control. Diabetic comas due to diabetic ketoacidosis are rare but represent an important part of the history of the disease, suggesting poor (“brittle”) control and increasing anesthetic challenges. Insulin pumps are becoming more popular for insulin-dependent diabetics. In general, the basal rate of these devices is continued perioperatively, and additional insulin may be added as necessary.

Renal system

Chronic kidney disease affects more than 20 million adults in the United States. Chronic renal failure is a complex systemic disease that may result from many conditions; diabetes mellitus, hypertension, and glomerulonephritis are among the most common causes. For patients on dialysis, the frequency and mode of administration of dialysis should be

documented, including a plan for timing of dialysis perioperatively. Volume control is a critical issue in dialysis patients, and the preoperative history should include documentation of volume overload or dialysis-related problems, such as hypotension.

Hepatic system

Both acute and chronic liver disease may increase the risk of surgery. For patients with liver disease, it is important to document the etiology; for example, whether liver disease is infectious, neoplastic, or alcoholic in origin. End-stage liver disease may manifest with ascites, coagulopathies, and encephalopathy, resulting in significant alterations in drug distribution and metabolism.

Reproductive system

Women of childbearing age should be asked if there is any chance of pregnancy, and the date of their last menstrual period should be documented. The literature suggests that routine pregnancy testing is not warranted in patients who are reliable historians.

Rare diseases

Rare illnesses and conditions may require a more detailed history and communication with the patient's primary physician or specialist. Ideally, these evaluations should be coordinated in advance through the surgeon's office and the preoperative testing clinic. This will provide adequate time for additional studies and communication with the assigned anesthesiologist.

Family history

Malignant hyperthermia is a familial disease, and all preoperative assessment discussions should attempt to rule out any disposition for malignant hyperthermia. Other familial diseases relevant to anesthesia include pseudocholinesterase deficiency, which may be suggested by a history of unexplained prolonged weakness or postoperative intubation in otherwise healthy patients. In the event of a positive history of anesthetic issues, efforts should be made to obtain prior anesthetic records in advance of the surgery.

Anesthetic history

The anesthetic history is a key feature of the preoperative assessment. A patient's prior anesthetic experience is extremely important and will greatly influence the patient's attitude (reduce anxiety) toward the upcoming surgery. The history should include a discussion of prior operations, including the type and approximate dates. A history of difficult intubation, prolonged weakness, or intubation should be clearly documented. Prior postoperative nausea or vomiting may predict future difficulties. Other issues that may arise during the discussion include anxiety regarding poor venous access and various

fears surrounding anesthesia, such as a mask "phobia" or claustrophobia.

Allergies and social habits

Documentation of allergies must include the drug and the reaction. A thorough history can sometimes help distinguish a true allergy from a benign reaction or side effect. The preoperative assessment should include details about alcohol intake, smoking, and illegal drug use. A history of drug abuse and alcoholism may result in increased tolerance to anesthetic agents and the potential for unexpected withdrawal following the surgery.

Medications

A detailed list of medications and dosing schedule is part of the preoperative assessment. It is important to document both prescribed and nonprescribed medications, including vitamins and other supplements. The generic names of drugs should be used and the indications recorded. In general, most medications should be continued until the night before surgery. Although there are no clear data on interactions, most institutions recommend discontinuing all alternative and complementary medication supplements prior to the procedure.

Patients on anticoagulants should not have these medications discontinued without a discussion with the cardiologist or primary care physician prescribing them. In addition, the prescribing physician needs to be made aware of the patient's upcoming procedure so that they can ensure that medication is appropriately restarted postoperatively. On the morning of surgery, patients may be advised to hold diuretic medication and nonessential medications and supplements. Angiotensin-converting enzyme inhibitors may result in significant vasodilatation and hypotension after anesthetic induction; holding these medications on the day of surgery has been previously recommended but is now generally done only prior to cardiac surgery. Short-acting insulin is generally held on the morning of surgery, and long-acting insulin is continued at the usual or a reduced (typically half of usual) dose. Chronic pain medication use may result in significant tolerance and create difficulties with pain management in the postoperative period.

Physical examination

A general assessment of the patient is invaluable. Is the patient healthy looking despite a complicated history? Is the patient frail and cachectic? How anxious is the patient? Is the patient able to give his or her own history? These types of observations can help the anesthesia team prepare for their patient encounter.

The physical examination for a preoperative assessment is a targeted examination focusing on the airway and cardiopulmonary system. Blood pressure, pulse, respiratory rate, height, and weight are recorded. Obtaining resting oxygen

saturation is recommended, especially in patients with a history of cardiopulmonary illness. Auscultation of the heart and lungs should be done to document the presence or absence of murmurs, abnormalities in cardiac rhythm, and abnormal lung sounds. A brief baseline neurologic examination also is recommended. An examination of the back or the proposed site is recommended if a neuraxial or regional technique is contemplated, as scoliosis and kyphosis may be otherwise unappreciated.

The airway examination should include an assessment of the maximal mouth opening, ability to visualize posterior pharyngeal structures, condition of dentition, degree of neck mobility, and submandibular distance. The presence of prominent incisors, loose or missing teeth, full beard, large tongue, facial and neck obesity, cervical disease, and prior tracheal surgery, neck surgery, or radiation may all contribute to difficult airway management.

Preoperative testing

Many studies have demonstrated that preoperative laboratory testing should be directed by the type of surgery planned and the patient's medical status. Routine screening has not been shown to be advantageous and may lead to excessive cost as well as potential morbidity for further investigation of false-positive results.

A hemoglobin or hematocrit test is indicated if the surgery is associated with significant blood loss potential or if the patient has a complex systemic disease resulting in anemia. Elevated hemoglobin from hemoconcentration may suggest a dehydrated patient. Platelet counts are indicated in patients with a history of low platelets or a disease associated with diminished platelets, such as preeclampsia. Bleeding time is usually not performed as a preoperative screening indicator of platelet function. Coagulation studies are indicated in patients with significant liver disease or known coagulopathic conditions. Generally, patients on anticoagulants such as warfarin should have coagulation studies repeated on the morning of the procedure if warfarin has been discontinued so that normal coagulation parameters can be documented.

Healthy ambulatory patients or those with mild to moderate systemic disease such as hypertension do not need routine electrolyte testing. Patients with chronic renal failure should have electrolytes, blood urea nitrogen, and creatinine tested prior to any significant surgery. Renal dialysis patients should have their potassium tested immediately prior to surgery. An electrocardiogram (ECG) should be obtained in patients with cardiac risk factors and a history of cardiac disease. Many institutions use 50 or 60 years as the age at which screening ECGs are required, but there is no definitive recommendation in this regard. A prior ECG within 3 to 6 months of the surgery in the absence of any ongoing symptoms or changes in cardiac status is generally acceptable. Chest radiographs are not recommended preoperatively unless directed by the history or underlying diagnosis.

Table 2.7. ASA Physical status classification system

ASA Physician Status 1	- A normal healthy patient
ASA Physician Status 2	- A patient with mild systemic disease
ASA Physician Status 3	- A patient with severe systemic disease
ASA Physician Status 4	- A patient with severe systemic disease that is a constant threat to life
ASA Physician Status 5	- A moribund patient who is not expected to survive without the operation
ASA Physician Status 6	- A declared brain-dead patient whose organs are being removed for donor purposes

A “type and screen” should be done prior to surgeries with a potential for significant blood loss. The presence of antibodies may make it difficult and time consuming to find compatible products. Patients may choose to provide autologous blood or donor-specific blood products. These patients should be referred to the blood bank in advance of the scheduled surgery to arrange for donation, as several weeks may be necessary to complete these arrangements. Some patients may refuse blood products for religious or personal reasons. In these instances, the reasons and options must be carefully reviewed and alternatives, such as the use of a cell saver and administration of albumin, explicitly discussed and documented.

American Society of Anesthesiologists classification

After the completion of the preoperative assessment, the anesthesiologist assigns an American Society of Anesthesiologists (ASA) classification (Table 2.7). This reflects the patient's condition and underlying disease complexity. Although the classification is not intended as a measure of risk per se, patients with higher ASA classifications often carry independent diagnoses that lead to increased risk from surgery. An E is added to the physical classification to designate a patient in whom surgery is emergent. The ASA physical classification system is a useful way to communicate about patients and is used by health care providers in other disciplines as well.

Consent and instructions

An important part of the preanesthetic interview is the discussion with the patient about potential risks and benefits of the potential anesthetic options, as well as a preliminary plan for the anesthesia. The final choice of anesthetic can be made only by the anesthesia team caring for the patient during the surgery. Patients may become distressed when promised one type of anesthesia prior to surgery and on the day of surgery find a different anesthesia team with an alternative recommendation.

Patients should be given instructions (Table 2.8) regarding medications as well as expectations regarding the day of procedure and postoperative recovery. At minimum, fasting guidelines should be discussed. In many instances, written instructions should be provided, including a contact phone number if issues arise prior to the day of surgery. Similarly,

Table 2.8. Preoperative instructions

Instructions should be clearly written in simple language
 Instructions should be specific, avoiding vague or ambiguous terms such as “maybe”
 Directions to exact location in the hospital
 Recommendations on clothing and belongings
 NPO instructions – written down
 Number to call with change in health

patients should receive clear instructions regarding fasting (Table 2.9) and requirements for discharge, such as transportation home.

Inpatient interviews

The inpatient preoperative interview is now uncommon, and patients who undergo them are usually acutely injured or have complicated medical histories. The routine preoperative history should be supplemented with a thorough review of the inpatient chart, as many patients will not be able to adequately explain their hospital course. Recommendations from consultants in specialties should be sought during the admission, if needed. The most recent laboratory information, including radiologic scans and cardiac testing, should be reviewed. NPO (nothing by mouth) recommendations and recommended medications for the day of surgery should be communicated with the nursing and surgical teams.

Outside facilities

The preoperative assessment of institutionalized patients may be especially challenging. It may be difficult or impractical to require these patients to come to a hospital or facility for a preoperative visit. In these instances, a remote preoperative screen may be conducted. If possible, the facility physician should provide a brief history, physical examination, and the results of any laboratory testing done recently. These may be reviewed by the anesthesiology team, who may decide whether more testing is indicated. The preoperative examination may be completed on the day of surgery. Arrangements for consent from a legal guardian or family member should be made in advance to prevent delays on the day of surgery.

Table 2.9. ASA guidelines for NPO status preoperatively

Substance	Minimum fasting period, h
Clear liquids ^a	2
Breast milk	4
Infant formula	6
Nonhuman milk	6
Light meal	6
Fried or fatty foods, meat	8

^a Include water, fruit juices without pulp, clear tea, carbonated beverages, and black coffee.

Emergency

In extreme cases, it may not be possible to perform more than a very brief preoperative assessment; in these instances, it is important to prioritize the assessment. A few critical facts may be helpful. Is there a family history of anesthetic issues, a history of difficult intubation or tracheotomy, or any allergies? A list of medications may be available, and any laboratory testing should be quickly reviewed.

Cancellations

Sometimes it is necessary to cancel or postpone a procedure based on the results of the preoperative examination, which may cause considerable stress to both the anesthesiologist and the patient. In the event of a cancellation, the anesthesiologist should communicate with the patient and the surgical team and explain why the patient is not ready for surgery and what should be done before the patient is rescheduled. This may mean a cardiology consultation or a recommendation for an adjustment in medications prior to the surgery. Sometimes it is possible for additional tests and consultations to be completed prior to the surgical date, thus avoiding a cancellation. One common cause of day-of-surgery cancellation is a change in the patient's status or a new infection. To prevent these cancellations, patients should be provided with clear guidelines of what to do if they develop an upper respiratory infection or other illness.

Obstructive and restrictive lung disease

Shannon S. McKenna

Introduction

Asthma and chronic obstructive pulmonary disease (COPD) are the two primary obstructive lung diseases that anesthesiologists see on a routine basis. COPD is more common, is more insidious, and poses greater management challenges. Therefore, this chapter focuses on COPD, with only a brief review of asthma.

Restrictive lung disease is fairly uncommon in the operating room setting, but does have specific implications for the anesthesiologist. It is reviewed briefly at the end of the chapter.

Obstructive lung disease

COPD

The significance of COPD

COPD, the most common pulmonary disease encountered in the perioperative setting, afflicts more than 15 million Americans. COPD is now the fourth leading cause of death in the United States. Compared with heart disease, stroke, and cancer, mortality from COPD is increasing rather than decreasing. Tobacco exposure accounts for 85% of all cases.

Definition and classification of COPD

COPD is a chronic disease characterized by airflow limitation that, in contrast to asthma, is not fully reversible. Typically, the airflow limitation progresses over time and is associated with an abnormal inflammatory response in the lung. Classic symptoms include cough, sputum production, dyspnea, and progressive exercise intolerance. Historically, these symptoms were described as either chronic bronchitis or emphysema.

Spirometry is used to confirm the diagnosis and classify the severity of COPD. A postbronchodilator forced expiratory volume in the first second of expiration (FEV_1) $<$ 80% of the predicted value, in the setting of an FEV_1 /forced vital capacity (FVC) $<$ 70%, is an accepted criterion for confirming the presence of COPD. The staging systems currently in use classify the severity of disease based on the percent of predicted FEV_1 alone (Table 3.1). A staging system that incorporates clinical status, spirometry, and radiographic features of the disease would be more clinically useful.

Pathogenesis and pathology of COPD

The pathogenesis of COPD is thought to derive from the combined effects of inflammation, increased oxidative stress, and an imbalance in the activity of proteinases and antiproteinases. Smoking, via particulate inhalation, is a primary trigger for lung inflammation. Genetic factors are thought to account for the fact that not all smokers develop COPD.

Pathologic changes of COPD are present throughout the lung and are progressive over time. In the large central airways, mucous glands are enlarged; there is goblet cell hyperplasia, loss of cilia, and decreased ciliary function. The airway walls are affected by inflammatory cell infiltration, accompanied by increased smooth muscle and connective tissue deposition. Small airways are predominantly affected by chronic inflammation leading to collagen deposition and airway remodeling. Emphysema, which is characterized by enlargement of the airspaces distal to the terminal bronchioles, develops in the parenchyma as a result of the destruction of collagen and elastin in alveolar walls. The pulmonary vasculature also is primarily affected. Initial intimal hyperplasia is followed by inflammation of the vessel wall, smooth muscle deposition, and, ultimately, fibrosis.

Pathophysiology of COPD: the intersection of pathology and function

The pathophysiology of COPD is complex and has a wide-ranging impact on functional status and physiologic reserve. Increased mucus production, with abnormal mucus clearance,

Table 3.1. Global Initiative for Chronic Obstructive Lung Disease staging criteria

Stage	Spirometry
Stage 0 (at risk)	$FEV_1/FVC \geq 70\%$ $FEV_1 \geq 80\%$
Stage 1 (mild)	$FEV_1/FVC < 70\%$ $FEV_1 \geq 80\%$
Stage 2 (moderate)	$FEV_1/FVC < 70\%$ FEV_1 50%–80%
Stage 3 (severe)	$FEV_1/FVC < 70\%$ FEV_1 30%–50%
Stage 4 (very severe)	$FEV_1/FVC < 70\%$ $FEV_1 < 30\%$

Figure 3.1. Flow-volume curve in normal and COPD patients.

results in the chronic cough and sputum production that are often the first clinical symptoms of COPD.

Expiratory airflow limitation is the pivotal pathophysiologic change. Airflow limitation occurs as a result of the convergence of multiple pathologic processes: airway inflammation and edema, mucus accumulation, airway hyperplasia and fibrosis, bronchospasm, and loss of radial traction as collagen and elastin are destroyed. Expiratory flow is markedly reduced throughout expiration, and expiratory time is increased (Fig. 3.1); hyperinflation occurs. Total lung capacity, functional residual capacity

(FRC), and residual volume are all increased (Fig. 3.2). The result is diaphragmatic flattening, elevation of the ribs, and an overall increase in the cross-sectional area of the thorax. This places the lung at a mechanical disadvantage, causing dyspnea, particularly with exertion – the most significant and limiting symptom of COPD.

Gas exchange is impaired via worsened ventilation-perfusion (V/Q) matching. There is an increase in both physiologic dead space and shunt. Varying degrees of hypoxemia and hypercarbia occur in different patients, depending on the specific V/Q distribution and an individual patient's metabolic state.

Chronic hypoxia, combined with direct pathologic changes in the pulmonary vasculature, ultimately results in pulmonary hypertension. Late in COPD, as pulmonary hypertension progresses, patients may develop right ventricular dysfunction and frank cor pulmonale.

Treatment of COPD

Treatment of chronic stable COPD

Smoking cessation is the only intervention that slows the progression of COPD. Yearly influenza vaccination has been shown to significantly reduce morbidity and mortality and is recommended for all patients with COPD. Comprehensive, multidisciplinary pulmonary rehabilitation programs may provide sustained improvement in exercise capacity and quality of life for patients with all stages of COPD.

Pharmacologic management is aimed at symptom relief but does not change the progression of disease. It is approached in a stepwise fashion and is tailored to the individual patient's

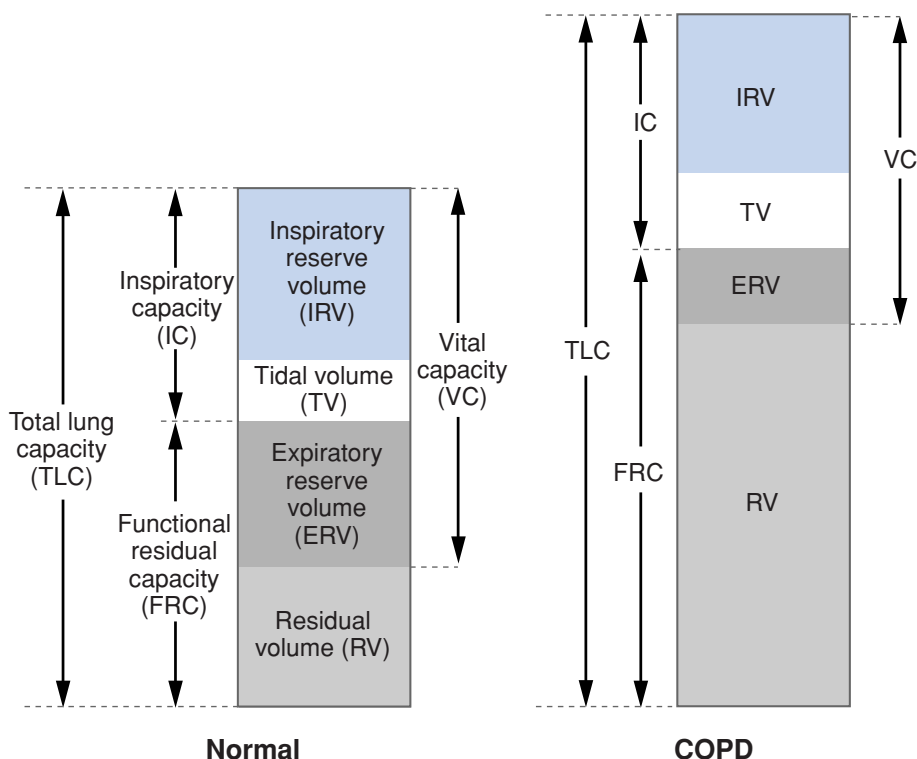

Figure 3.2. Changes in lung volumes and capacities with COPD.

Table 3.2. Commonly used bronchodilator drugs

Drug	Routes	Duration of action, h
β₂ Agonists		
Fenoterol	MDI, Neb	4–6
Albuterol	MDI, Neb, oral	4–6
Levalbuterol	MDI, Neb	4–6

Theophylline	Oral	variable

IV, intravenous; MDI, metered-dose inhaler; Neb, nebulizer.

response (Table 3.2). Short-acting inhaled bronchodilators are used for symptomatic relief in early-stage COPD. For patients with more severe COPD, long-acting inhaled bronchodilators, especially tiotropium, improve lung function, relieve dyspnea, and improve exercise capacity. Inhaled corticosteroids reduce the frequency of exacerbations in patients with severe COPD and may slightly, but not clinically significantly, slow the rate of decline in FEV₁. Use should be limited to patients with frequent acute exacerbations. Recent clinical trials have focused on combination therapy with inhaled long-acting β₂ agonists and inhaled corticosteroids. Combination therapy, in patients with moderate to severe disease, seems to show additive benefits in most trials.

Treatment of acute exacerbations

Acute exacerbations are often triggered by respiratory tract infection. Accompanying symptoms may include worsened dyspnea, wheezing, chest tightness, cough, increased sputum, a change in sputum character, fever, and malaise. Worsened air-flow obstruction, with acute hyperinflation, is thought to be the primary cause of the increased dyspnea. Initial management of acute exacerbations includes escalation of bronchodilator therapy and domiciliary oxygen therapy for patients with hypoxia. Antibiotics should be started if there is evidence of bacterial infection. Systemic corticosteroids shorten the recovery time from acute exacerbations and may be indicated in some patients.

Patients with progressive hypoxemia, hypercarbia, respiratory distress, or evidence of new heart failure require hospital admission. Primary management is the same as in the outpatient setting. The development of progressive hypercarbia and respiratory acidosis is associated with the highest risk of mortality. Noninvasive mechanical ventilation may be particularly effective in treating COPD exacerbations, providing a reduction in both mortality and the need for intubation. Patients with severe acidosis, refractory hypoxemia, or respiratory arrest require intubation and conventional mechanical ventilation.

Treatment of end-stage disease

Treatment options for advanced COPD are limited. They include domiciliary oxygen therapy, lung volume reduction surgery (LVRS), and lung transplantation. Oxygen therapy increases exercise capacity and improves survival in patients with chronic respiratory failure. It is recommended for patients with a PaO₂ <55 mm Hg or an arterial oxygen saturation (SaO₂) <89%. If there is evidence of pulmonary hypertension, oxygen therapy may be provided for patients with a PaO₂ <60 mm Hg.

LVRS is an expensive, high-risk palliative treatment. A recent study sponsored by the National Institutes of Health, identified a small subset of patients who may benefit from LVRS. These patients have upper lobe–predominant emphysema with a low exercise capacity. Several risk factors for poor outcome also were identified. Very few patients with end-stage COPD qualify for LVRS. Lung transplantation is the other treatment option for end-stage disease. Currently, the challenge is to correctly identify the patients with a life expectancy short enough that they would benefit from transplantation.

Perioperative care of the patient with COPD

Risk assessment

Patients with COPD have a 2.7- to 4.7-fold increased risk of perioperative pulmonary complications. The degree of risk correlates with the severity of COPD. The most common pulmonary complications are atelectasis, pneumonia, respiratory failure, and acute exacerbation of underlying chronic pulmonary disease. Age greater than 60 years, American Society of Anesthesiologists (ASA) physical status of II or higher, history of congestive heart failure, and current cigarette smoking are additional risk factors. The type of surgery also is important. The highest risk is associated with aortic, thoracic, and upper abdominal procedures. Neurosurgery, head and neck surgery, emergency surgery, and prolonged surgery (>3 hours) also confer increased risk.

Preoperative assessment should focus on the history and physical examination. Patients with severe COPD can be identified easily on this basis alone. Spirometry does not provide effective risk prediction for individual patients; however, it may be used to predict long-term functional status after major lung resection. Current recommendations are to obtain a chest radiograph for patients older than 50 years undergoing high-risk operations, but it is rare for routine preoperative chest radiographs to influence clinical management.

When patients are found to be at increased risk of postoperative pulmonary complications, the potential benefits of the surgery should be weighed against the risk. There is no true pulmonary contraindication to a potential lifesaving surgery. Even within the specific realm of lung resection surgery, there are very few absolute pulmonary contraindications to surgery.

Preoperative optimization

Smoking cessation is a logical preoperative intervention for patients with COPD. Patients undergoing high-risk surgeries

who have ceased smoking at least 4 weeks prior to surgery seem to have a lower risk of pulmonary complications. Smoking cessation 24 to 48 hours prior to elective surgery normalizes carboxyhemoglobin levels and corrects the left shift of the oxy-hemoglobin dissociation curve, but does not show an improvement in mucociliary function.

Given the significant impact of smoking cessation on the long-term outcome of COPD, all COPD patients should be counseled on smoking cessation, regardless of the type or timing of surgery.

Preoperative optimization of airflow with bronchodilators is thought to decrease perioperative complications. There is no indication, however, for routine preoperative addition of either inhaled or oral corticosteroids. Expert opinion suggests that specific treatment of acute COPD exacerbations preoperatively is beneficial. It may be prudent to delay elective surgery until after full recovery from an acute COPD exacerbation, but there is little evidence available on this issue. The role for routine preoperative pulmonary rehabilitation prior to high-risk surgery is unclear.

Intraoperative management

There is some evidence, of variable quality, available to guide the choice of anesthetic techniques for patients with COPD. One trial of intermediate-acting versus long-acting neuromuscular blockers found a higher rate of residual neuromuscular blockade with the use of long-acting neuromuscular blockers. The rate of postoperative pulmonary complications was three times higher in patients with prolonged blockade. The current recommendation is to use intermediate-acting agents in patients with COPD. There have been several trials comparing neuraxial blockade with general anesthesia and neuraxial analgesia with other postoperative pain relief strategies. Unfortunately, the studies tended to be small and limited by problems with study design or execution; results have been inconsistent. Some of the studies did report lower rates of postoperative pulmonary complications with the use of regional anesthesia and analgesia. Further study is needed; in the interim, it is reasonable to advocate for regional anesthesia and analgesia, when feasible, for patients with significant baseline pulmonary impairment.

Several intraoperative problems may occur during general anesthesia in the setting of underlying COPD. Bronchospasm may cause an abrupt increase in airway resistance and concomitant worsening of airflow obstruction. Acute bronchospasm is best treated with inhaled β_2 agonists or anticholinergics. Increasing the end-tidal concentrations of bronchodilating volatile anesthetics (isoflurane, sevoflurane, halothane, enflurane) also may reverse acute bronchospasm. Rarely, the use of intravenous corticosteroids or low doses of intravenous epinephrine (0.25–0.5 $\mu\text{g}/\text{min}$) via continuous infusion may be necessary to break refractory bronchospasm.

Inspissation of pulmonary secretions may result in acute occlusion of bronchi or even the endotracheal tube itself. Maintaining adequate hydration and humidifying inspiratory gases help prevent desiccation and inspissation of secretions. Use of a large (8.0 mm or larger) endotracheal tube allows for easy endotracheal suctioning and, when necessary, fiberoptic bronchoscopy. On occasion, it may be necessary to instill mucolytics (*N*-acetylcysteine, dornase alfa) through the bronchoscope into an area of mucus plugging.

V/Q matching, which is impaired at baseline in COPD, is even worse during general anesthesia. This leads to widening of the alveolar–arterial oxygen gradient and also the gradient between end-tidal and arterial carbon dioxide. Consideration should be given to arterial blood gas monitoring for patients with significant COPD undergoing major procedures.

Dynamic hyperinflation is one of the major pitfalls of general anesthesia in patients with significant COPD. It occurs when inspiration is initiated prior to the complete exhalation of the previous tidal volume (Fig. 3.3). End-expiratory volumes and pressures (intrinsic positive end-expiratory pressure [PEEP] or auto-PEEP) rise progressively with each subsequent inhalation until a new steady state is reached. As a result, lung compliance decreases, gas exchange is impaired further because of compression of normal lung, barotrauma and alveolar rupture may occur, and venous return is decreased. The decrease in venous return may be profound enough to cause hypotension, decreased cardiac output, and even pulseless electrical activity. Anesthesiologists should be particularly watchful for dynamic hyperinflation during commencement of assisted ventilation,

Figure 3.3. Dynamic hyperinflation during mechanical ventilation.

such as at induction. Judicious hydration helps ameliorate the decrease in venous return. Use of a slow respiratory rate, long expiratory time, and the minimum necessary tidal volume to avoid excessive hypercapnia helps prevent the development of dynamic hyperinflation. Extrinsic PEEP can replace 50% to 75% of intrinsic PEEP. Small airways are held open, and more complete exhalation may occur. Unfortunately, there is no easy way to measure intrinsic PEEP in the operating room, so titration of extrinsic PEEP requires clinical judgment and experience. If severe hypotension is thought to be related to dynamic hyperinflation, the most expedient maneuver is to hold ventilation altogether and allow for unobstructed exhalation.

Timely emergence from general anesthesia may be particularly challenging in patients with severe COPD. Patients with COPD are exquisitely sensitive to the respiratory depressant effects of many commonly used medications, including benzodiazepines, narcotics, barbiturates, propofol, and the volatile anesthetics. The long expiratory time-constant, increased dead space, and widened V/Q distribution typical of severe COPD all result in inefficient clearance of volatile agents. Although there are no good randomized trials of specific anesthetic maintenance techniques in the setting of severe COPD, most experts recommend the use of total intravenous anesthesia (TIVA). TIVA allows for timing of emergence independent of underlying lung function. When short-acting agents (e.g., propofol and remifentanyl) are used in combination with an approach to postoperative analgesia that does not rely heavily on parenteral opioids, postoperative respiratory depression can be minimized.

Postoperative care

Postoperative care should focus on measures that facilitate the patient's rapid return to baseline levels of pulmonary function. This requires the patient to be extubated, awake, and alert and to have adequate pain control. Lung expansion maneuvers such as deep breathing, chest physiotherapy, and incentive spirometry effectively prevent postoperative pulmonary complications. Early ambulation helps restore baseline lung volumes, facilitate clearance of secretions, and prevent venous thromboembolism. Patients should continue their baseline medical therapy

for COPD. Temporary escalation of bronchodilator therapy and use of intravenous corticosteroids or antibiotics may be necessary for patients who experience an acute COPD exacerbation in the perioperative period.

Asthma

Epidemiology of asthma

Asthma is a chronic inflammatory lung disease characterized by the paroxysmal occurrence of cough, wheezing, and/or dyspnea. The prevalence of asthma has increased over the past three decades and is now about 5% in the United States. The annual mortality rate climbed through the mid-1990s but has declined since then. Currently, roughly 4000 people a year die in the United States from asthma.

Pathology and pathophysiology of asthma

Asthma is a chronic inflammatory disease of the airways that results in airflow obstruction. The pathology includes smooth muscle constriction, airway edema, mucus accumulation, airway inflammation, and abnormal deposition of collagen in basement membranes. The airflow obstruction is reversible, in comparison to COPD. Airway hyperresponsiveness is characteristic of asthma. Triggers may include histamine, cold air, viral infections, and a variety of environmental substances.

Treatment of asthma

Asthma treatment focuses on reducing the frequency and severity of symptoms and associated functional limitations. An additional goal is to reduce the occurrence of long-term morbidity, including loss of lung function and medication side effects. The foundation of management is patient education and identification, avoidance of triggers, and regular monitoring, often done with a handheld peak flow meter.

Pharmacologic management is applied in a stepwise fashion based on the severity of disease. A full description of the classification of severity may be found in the 2007 National Asthma Education and Prevention Program Expert Panel Report. The basics of this approach are summarized in [Table 3.3](#). Acute exacerbations often require systemic glucocorticoid use.

Table 3.3. Stepwise approach to baseline asthma treatment

Asthma severity	Typical features	Recommended treatment
Intermittent (step 1)	Sx 2 d/wk or less; normal FEV ₁ at baseline Oral steroids once a year at most	Short-acting inhaled β_2 agonist prn (for step 1 and all other steps)
Mild persistent (step 2)	Sx > 2 d/wk; β agonists use > 2 d/wk; oral steroids twice a year or more	Daily inhaled steroid or alternate controller (leukotriene inhibitor, theophylline, cromoglycates)
Moderate persistent (step 3)	Daily symptoms and β agonist use; some activity limitation; reduced baseline FEV ₁	Daily inhaled steroid (or alternate) plus daily long-acting β_2 agonist
Severe persistent (step 4–6)	Sx throughout day; multiple uses of β agonist each day; extreme activity limitation; FEV ₁ < 60%	Daily long-acting β_2 agonist plus moderate-dose (step 4) or high-dose (step 5) inhaled steroid; standing oral steroids added (step 6)

prn – as needed; Sx – symptoms.

Perioperative care of the patient with asthma

Preoperative assessment and optimization

There are limited data on the rate of perioperative respiratory complications among asthmatic patients undergoing surgery in the modern era. The data that are available suggest a rate of 1% to 2%. Initial assessment should focus on the patient's asthma history. Elements to assess are frequency and severity of symptoms, baseline activity level, degree of compliance with chronic treatment, and the need over the past year for emergency room treatment, hospital admission, or systemic glucocorticoid use. Patients with moderate persistent or severe persistent asthma should be identified, as presumably they are at higher risk for perioperative complications. Lung auscultation may reveal current airflow obstruction if wheezing or a prolonged expiratory phase is present.

Baseline medications should be continued up until the time of surgery. Patients with poor control of their symptoms should have their treatment optimized by their internist or pulmonologist prior to surgery whenever possible. Patients with moderate to severe asthma might benefit from a short course of oral steroids preoperatively, but the data supporting this approach are limited. Patients at risk for adrenal suppression due to chronic treatment should probably receive stress dose steroids perioperatively, though the magnitude of such risk is unknown.

Intraoperative management

Short-acting bronchodilators may be administered prophylactically immediately before anesthesia. Given that endotracheal intubation may be a major stimulus for bronchospasm, it is prudent to avoid general anesthesia when possible. If endotracheal intubation is needed, it is vital to ensure that sufficient depth of anesthesia to suppress airway reflexes is achieved prior to laryngoscopy. There is some evidence that propofol may be associated with less postintubation wheezing than thiopental. Ketamine is the only induction agent that actually produces smooth muscle relaxation. It may be the induction agent of choice in certain cases. Intravenous lidocaine, 1.5 mg/kg, produces smooth muscle relaxation and may be given prior to induction. Intratracheal lidocaine may be given as well, but if the depth of anesthesia is insufficient, it may trigger bronchospasm.

Keys for intraoperative management are to maintain sufficient depth of anesthesia, avoid histamine-releasing drugs, and monitor for and treat bronchospasm if it occurs. See [Table 3.4](#) for signs of intraoperative bronchospasm. If bronchospasm is confirmed, depth of anesthesia should be reassessed and

Table 3.4. Signs of bronchospasm during general anesthesia

Wheezing on auscultation
Increased peak airway pressure with unchanged plateau pressure
Decreased expiratory tidal volumes
Upsloping capnography waveform
Failure of expiratory flow to reach zero (flow vs. time waveform)
Hypotension due to impaired venous return (dynamic hyperinflation)

a short-acting inhaled β_2 agonist should be administered. Dynamic hyperinflation, as described in the COPD section, may occur and should be managed as previously described. Persistent bronchospasm may necessitate repeat dosing of inhaled bronchodilators, administration of intravenous corticosteroids (though onset of action is delayed), or use of a continuous epinephrine infusion at 0.25 to 0.5 $\mu\text{g}/\text{min}$.

Extubation is another high-risk period. Deep extubation is an option for certain patients. When deep extubation is not an option, pretreatment with an inhaled short-acting β_2 agonist and intravenous lidocaine may help prevent bronchospasm on emergence.

Restrictive lung disease

Definition

Restrictive lung disease impairs lung expansion. It is associated with decreased compliance of the pulmonary system and decreased vital capacity. The causative pathology may be located in the lung parenchyma, pleural space, or chest wall. Additionally, neuromuscular diseases may prevent the respiratory muscles from effectively expanding the thoracic cage and functionally cause restriction. Common etiologies of restrictive disease are summarized in [Table 3.5](#).

Pathology and pathophysiology of restrictive disease

The pathology is variable and specific to the underlying disease process. Primary parenchymal diseases often require biopsy for definitive diagnosis. Pulmonary function testing usually shows

Table 3.5. Causes of restrictive pulmonary physiology

Intrinsic to the lung parenchyma
Pulmonary edema
Acute respiratory distress syndrome
Pneumonia
Autoimmune and collagen vascular diseases
Pulmonary fibrosis
Pneumonitis

Pleural space
Tumor (mesothelioma)
Pneumothorax

Anasarca
Pregnancy
Congenital malformations of chest wall/spine
Circumferential burns

Neuromuscular diseases
High spinal cord injury
Muscular dystrophy
Myasthenia gravis and Eaton-Lambert syndrome
Guillain-Barré syndrome
Flail chest

decreased volumes and capacities with a preserved FEV₁/FVC ratio. Clinical symptoms typically include dyspnea and reduced exercise capacity. Other signs and symptoms are specific to the underlying disease process.

Treatment of restrictive diseases

Treatment of restrictive lung disease is specific to the underlying disease. For this reason, it is not unusual to see a patient with restrictive disease present for operative diagnosis. If the disease is localized to the pleural space, operative management may be required.

Perioperative care of the patient with restrictive disease

Appropriate care starts with the recognition that a restrictive process is present. Clues include a restrictive pattern on pulmonary function tests or the presence of a disease or process associated with pulmonary restriction. The next step is to assess severity by evaluating the symptoms and degree of exercise impairment. Oxygen saturation measurement will identify patients with baseline hypoxia. Preoperative exercise testing may be appropriate for a select subset presenting for major pulmonary resection.

Treatable contributors to pulmonary restriction should be addressed preoperatively when possible. These may include pulmonary edema, acute infection, large pleural effusions, or massive ascites. The benefit of specific preoperative treatment of these conditions depends on the operative procedure and the functional reserve of the patient.

Adequate preoxygenation is vital to avoid desaturation during induction, given the decreased FRC. Intraoperative ventilation may require smaller tidal volumes (4–6 ml/kg ideal body weight) at higher rates to avoid excessive inspiratory pressures. Application of PEEP from the beginning of positive pressure ventilation helps maintain FRC and avoid atelectasis. High inspired oxygen concentrations may be needed to avoid hypoxemia. In certain severe cases, use of an intensive care unit ventilator in combination with total intravenous anesthesia may be necessary.

Patients with significant restrictive disease are at increased risk of postoperative respiratory failure. It is important to minimize postoperative respiratory depression, and anesthetic drug choice should be aimed at this goal. Regional anesthesia and analgesia may be quite helpful when the circumstances are amenable. Finally, it is important to remember that many of the parenchymal diseases that cause restrictive pulmonary physiology also are associated with pulmonary hypertension. Care must be taken to avoid worsening pulmonary pressures. In particular, hypoxia, hypercapnia, acidosis, hypothermia, and extreme catecholamine surges should be avoided.

Anesthetic goals in patients with myocardial ischemia and heart failure

Sugantha Sundar, Jason M. Erlich, and Eswar Sundar

According to the 2004 statistics compiled by the American Heart Association (AHA), an estimated 79.4 million American adults have cardiovascular disease. The average annual rate of first cardiac event varies by age group, from seven per 1000 in 35- to 44-year-olds to 68 per 1000 in 85- to 94-year-olds. There are approximately 565,000 new and 300,000 recurrent heart attacks per year. Notably, only 18% of new myocardial infarctions (MIs) are preceded by longstanding angina. These statistics demonstrate a necessity to be aware of the scale of the problem in the United States and to understand the underlying mechanisms of coronary artery disease (CAD) leading to myocardial ischemia and its prevention. The pathophysiology of heart failure and its management are discussed in this chapter. The role of ischemic preconditioning in myocardial protection also are briefly discussed.

Pathophysiology of myocardial ischemia

Myocardial metabolism

The myocardium derives energy from lactate, fatty acids, glucose, pyruvate, and acetate and under special circumstances, such as starvation, from fructose, glycogen, and protein. Myocardial oxygen consumption is one of the highest of any organ at 8 to 10 ml oxygen/100 g myocardium/min. The subendocardial requirement is 20% higher than the epicardium, making it particularly susceptible to ischemia.

Myocardial oxygen supply and demand

Myocardial oxygen demand is determined mainly by heart rate, wall tension, and contractility. Oxygen consumption depends on myocardial wall tension, which in turn is directly proportional to the intracavitary pressure and ventricular radius but inversely related to wall thickness. Thus, decreasing ventricular wall distention can decrease oxygen demand. Basal oxygen requirements determine myocardial oxygen demands.

Oxygen supply to the myocardium is determined by the pressure in the aortic root at the end of diastole and the left ventricular end-diastolic pressure. Coronary artery diameter and the arterial oxygen content determine oxygen supply. Immediately after coronary occlusion, two physiologic

mechanisms occur in an attempt to correct the stoppage of flow:

- “Reactive hyperemia,” in which reperfusion flow increases above preocclusion levels
- “Reactive dilatation,” in which large coronaries dilate in an attempt to relieve the occlusion

These physiologic reactions are limited and do not achieve full coronary flow. At >90% occlusion, reactive physiologic dilation is exhausted and normal flow cannot be maintained, necessitating alternative intervention.

Coronary blood flow is maintained mainly based on perfusion pressure and vascular tone of coronary vessels. Postsynaptic β_1 , β_2 , α_1 , and α_2 receptors are present in myocardium. Presynaptic β_2 activation increases norepinephrine release, which is mediated by postsynaptic β_1 receptors. Postsynaptic β_1 receptors predominate, except in the failing and ischemic heart, in which α_1 receptors serve as reserve and high levels of catecholamines down-regulate β_1 expression. Dopaminergic receptors have not been described in the myocardium.

Coronary plaque rupture with thrombosis is an important etiologic mechanism of perioperative MI (PMI). It is very likely that PMI also results from prolonged ischemia (manifest as ST-segment depression on the electrocardiogram [ECG]) in the presence of severe but stable CAD. Data suggest that the risks for perioperative MI include: (1) poor preoperative cardiac status (CAD, history of congestive heart failure), (2) postoperative hypotension, (3) new (long-duration) intraoperative ST-T changes, and (4) increased intraoperative blood loss and transfusion.

There is growing evidence indicating that patients who have recently undergone percutaneous coronary revascularization and stent implantation may be at increased risk for perioperative in-stent thrombosis and MI. The American College of Cardiology/AHA guidelines recommend a delay of at least 2 weeks and ideally 4 to 6 weeks between implantation of a bare metal stent and noncardiac surgery to reduce the risk of PMI. This allows for 4 full weeks of dual-antiplatelet therapy during stent re-endothelialization and 2 weeks for the antiplatelet effect to dissipate after discontinuation of drug therapy. The risk period for in-stent thrombosis is extended further in patients

receiving a drug-eluting stent, because the drug that prevents neointimal proliferation delays in-stent endothelialization and anti-platelet therapy is therefore recommended for far longer.

Preoperative testing and risk stratification

Preoperative testing and risk stratification of patients undergoing noncardiac surgery have been topics of debate for many years. The decision to recommend further stratification procedures in each patient must take into account the potential benefit versus the potential risk. The risk of myocardial ischemia is related to three important factors: the extent of the patient's disease, the type of surgery, and the degree of hemodynamic stress associated with the procedure. The duration and intensity of coronary and myocardial stressors may be helpful in estimating the likelihood of perioperative cardiac events, particularly for emergency surgery. See [Chapter 2](#) for in-depth discussion of patient evaluation prior to noncardiac surgery, including the latest American College of Cardiology and American Heart Association Guidelines.

Conduct of anesthesia

No one anesthetic is superior to another. There have been no outcome studies to show the superiority of one anesthetic technique over another. It is important to bear in mind that an anesthetic that reduces myocardial oxygen demand and improves coronary blood flow is critical. The choice of anesthetic is determined by the procedure being performed, the clinical condition of the patient, and whether the procedure is an emergency.

The degree of monitoring for ischemia that is warranted is dictated by the clinical situation. Continuous ECG monitoring is the most common method used to detect myocardial ischemia. Monitoring lead V5 can detect up to 82% of ischemic events. Hemodynamic changes, such as hypotension, elevated pulmonary artery pressures, and a decrease in cardiac output are indicators of myocardial ischemia. Regional wall motion abnormalities detected on transesophageal echocardiography may be helpful in determining which coronary artery is involved.

Volatile anesthetics are vasodilators, which could potentially lead to coronary steal in patients with unfavorable anatomy. However, the concern that isoflurane may cause coronary steal has not been validated in human subjects. Reduced serum troponin levels have been documented in cardiac surgical patients receiving volatile anesthetics, possibly reflecting a preconditioning or postconditioning effect. A dose-dependent or class effect of inhalational anesthetics in protecting the myocardium has not been proven in humans.

Neuraxial blockade may be beneficial in certain situations in which sympathectomy is desirable. However, procedures requiring a high dermatomal level of anesthesia may be associated with hemodynamic compromise and may even be detrimental. Use of thoracic epidural anesthesia for postoperative pain control has been associated with fewer pulmonary com-

plications, although the incidence of myocardial infarction or overall mortality is no different.

Monitored anesthesia care was associated with the highest 30-day mortality rate in one large study, possibly because patients who were the sickest were chosen to receive monitored anesthesia care versus general or regional anesthesia. Monitored anesthesia care (MAC) less completely blunts sympathetic nervous system responses to surgical stimulation and hence may be associated with demand ischemia.

Outcome advantages of regional analgesia over patient-controlled analgesia for post-operative pain control have not been documented with sufficient evidence. However, less opioid requirement, better hemodynamic profile, and decreased perioperative hypercoagulable state may be some of the advantages with regional analgesia.

Maintenance of intraoperative normothermia is vital in that patients with core temperatures less than 35°C are at increased risk of developing myocardial ischemia.

Treatment of myocardial ischemia

Treatment of myocardial ischemia is multimodal and depends on the clinical setting.

- In some situations, myocardial ischemia is associated with profound hemodynamic consequences. In this setting, optimizing the blood pressure, reducing the heart rate, and improving preload are crucial.
- Malignant ventricular arrhythmias are not uncommon with severe ischemia. Institution of the Advanced Cardiac Life Support (ACLS) protocols may be necessary when life-threatening arrhythmias occur.
- Nitroglycerin infusion causes coronary vasodilation and improves blood flow to ischemic areas of the myocardium. It also reduces the preload on a failing heart and thus has beneficial effects.
- Calcium channel blockers are given in situations in which coronary vasospasm is suspected.
- Heparin infusion may be indicated to reduce further coronary thrombosis.
- Consideration to stopping surgery and proceeding to the cardiac catheterization laboratory should be given in conjunction with the surgical team. Percutaneous intervention may be necessary with or without the use of thrombolytic therapy. Coronary revascularization may be necessary for a more permanent solution.
- In the interim, placement of an intra-aortic balloon pump (IABP) should be considered to reduce afterload and improve coronary perfusion during diastole.

Ischemic preconditioning and myocardial protection

Ischemic preconditioning (IPC) and myocardial protection have received much attention during the past few years. Ischemic preconditioning is a method by which the target organ

is conditioned prior to the ischemic insult to reduce the extent of injury. IPC may be mechanical or pharmacologic. Several studies have shown the beneficial effects of brief limb ischemia in preconditioning the heart, although this is somewhat impractical in an operating room setting. Pharmacologic IPC may be considered in patients at increased risk for myocardial ischemia. Adenosine, endothelial nitrous oxide, free radicals, kinases, opioids, catecholamines, and adenosine triphosphate (ATP)-sensitive potassium channels have been implicated in remote preconditioning. Adenosine is an extracellular molecule that is both a trigger and a mediator of IPC. Several studies implicated volatile anesthetics to be involved in IPC and to exert a myocardial-protectant effect. Volatile anesthetics reduce the amount of myocardial enzyme leak and reduce the size of an infarct following preconditioning. There is an improvement in ventricular function in patients preconditioned with volatile agents. The precise mechanism by which this works is still unclear, but it appears to be multifactorial. This effect depends, at least in part, on anesthetic-induced opening of ATP-sensitive potassium channels. However, the precise dosing and duration of therapy have not been determined.

Pathophysiology and management of heart failure

Each year, 500,000 cases of heart failure are diagnosed in the United States. Extensive myocardial damage from myocardial ischemia may lead to both systolic and diastolic heart failure. The presence of decompensated heart failure is a major predictor of adverse perioperative outcome, whereas compensated heart failure is an intermediate risk factor for adverse perioperative outcome. Symptoms of dyspnea on exertion, orthopnea, edema of the extremities, and end-organ dysfunction are indicators of heart failure.

Systolic heart function may be measured by calculating the ejection fraction on echocardiography or cardiac MRI. In systolic failure, there is impaired left ventricular contractility, and ejection fraction is a measure of the contractile function of the heart. The ability to increase stroke volume via an increase in preload is reduced, and the Starling curve shifts to the right of the normal curve if afterload and inotropy remain unchanged. As Fig. 4.1 demonstrates, any increase in preload in congestive heart failure due to systolic failure results in a smaller increase in stroke volume than in normal ventricles if inotropy and afterload are kept constant. A decrease in afterload or increase in contractility may improve ventricular performance but will not affect filling pressures. A reduction in preload with an increase in inotropic force, a decrease in afterload, or both yields reductions in ventricular filling pressures and improvement in ventricular performance.

Elevated left ventricular end-diastolic pressure is an indicator of poor systolic function of the heart. Use of inotropes to improve systolic function is the first-line treatment for heart failure, although other types of cardiovascular drugs are also useful (Fig. 4.2).

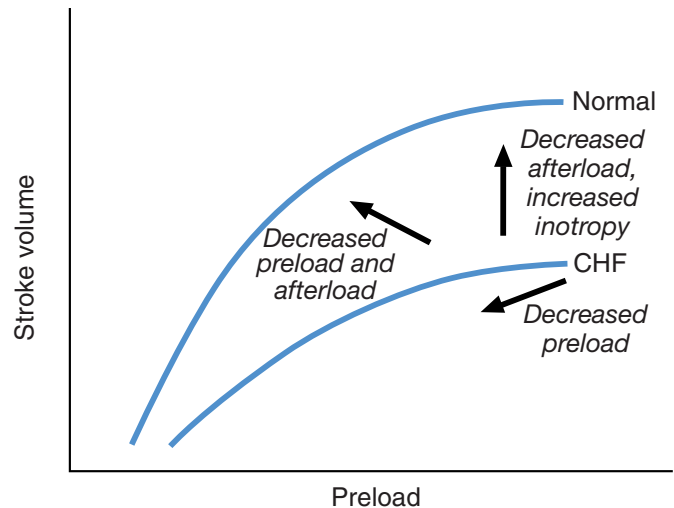

Figure 4.1. Relationship between preload and stroke volume in congestive heart failure. Source: Steele L, Webster NR. Altered cardiac function. *J R Coll Surg Edinb* 2001; 46(1):29–34.

Consideration should be given to the placement of an IABP in the absence of adequate response to inotropic medications and adequate treatment of myocardial ischemia.

The IABP is inserted percutaneously through the femoral artery. The balloon tip is situated distal to the origin of the left subclavian artery and should be above the origin of the renal arteries. X-ray and transesophageal echocardiography may be used to aid in optimal positioning of the balloon tip. The IABP inflation and deflation are usually synchronized with the ECG (the QRS complex) or the arterial pressure waveform (Fig. 4.3). It is vital to time the balloon inflation with the dicrotic notch of the arterial waveform. Deflation should be timed when the arterial pressure waveform reaches the lowest level, indicating that the left ventricle is ready for the next contraction. The initial setup of the balloon pump should be at a 1:2 ratio to accurately time the pump, to be followed by a ratio of 1:1 to obtain optimal

Figure 4.2. Medical management of heart failure.

Figure 4.3. IABP timing: inflation/deflation.

benefits. Some contraindications to placement of an IABP include aortic insufficiency, sepsis, and severe peripheral vascular disease. Cardiovascular effects of the IABP are summarized in Fig. 4.4.

Diastolic heart failure is more challenging to diagnose and manage. It is the inability of the ventricle to adequately relax

between contractions, leading to less filling of the ventricle and atrial hypertension. Chronic hypertension is the most common cause of diastolic dysfunction. It leads to left ventricular hypertrophy and increased connective tissue content, both of which decrease cardiac compliance. Diastolic dysfunction is more common in elderly persons, partly because of increased collagen crosslinking, increased smooth muscle content, and loss of elastic fibers. Patients with diastolic dysfunction are highly sensitive to volume changes and preload. Diagnosis can be made using transthoracic and transesophageal echocardiography. Pulsed-wave Doppler examination across the mitral valve during diastole is one modality used to assess diastolic function. In the normal heart, there is an E wave corresponding to early passive filling of the ventricle, followed by an A wave corresponding to atrial contraction leading to ventricular filling. Milder forms of diastolic heart failure are characterized by impaired relaxation, whereas more advanced forms of diastolic heart failure are characterized by a restrictive pattern. More sophisticated imaging modalities such as tissue Doppler and transmitral flow propagation velocities also may be used to fully evaluate diastolic function. Treatment of diastolic heart failure is equally challenging. Maintaining sinus rhythm is vital in this patient population. Slowing the heart rate allows the ventricle time to fill adequately, and β -Blockers are particularly useful. Angiotensin-converting enzyme inhibitors and angiotensin-converting enzyme receptor blockers may be beneficial in patients with diastolic dysfunction, especially those with hypertension. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers directly affect myocardial relaxation and compliance by inhibiting production of, or blocking angiotensin II receptors, thereby reducing interstitial collagen deposition and fibrosis.

Figure 4.4. IABP effects.

Conduct of Anesthesia

Anesthetic management of patients who are in heart failure is complex and associated with a high mortality (>10%) and morbidity. These factors should be considered before deciding on a plan:

- Underlying pathophysiology of the heart failure
- Surgery or procedure being planned
- What monitoring is required, and how much time is available to optimize the patient

The majority of heart failure results from loss of inotropy (due to ischemia, valvular regurgitations), increased afterload (due to hypertension, aortic stenosis, coarctation), and fluid overload. Some of these conditions require only gentle afterload reduction. This can be achieved by vasodilators such as nitroglycerine or sodium nitroprusside. In patients with severe heart failure, management with inodilators like milrinone, drugs such as dobutamine, or even placement of an IABP may be required.

Occasionally, heart failure can result from an obstruction to the left ventricular outflow tract for example, systolic anterior motion (SAM) of the mitral leaflet. In these conditions drugs such as phenylephrine and β blockers can help stent open the outflow tract and improve symptoms of heart failure.

Preoperative preparation

Before starting anesthesia on patients with heart failure, drugs must be started to treat the heart failure as discussed above. Oxygenation must be maximized using noninvasive means (CPAP) as far as possible. Intubating a patient in heart failure for a procedure is best done in a highly monitored setting like an operating room or an ICU. An IABP may need to be inserted preoperatively, under local anesthesia in some situations.

Choice of anesthetic depends on the procedure being done. Note that spinals and epidurals often impede the ability of the patient to breathe adequately, although the afterload reduction associated with neuraxial anesthesia can be beneficial. However, general anesthesia may be the only option.

Optimal monitoring in the form of arterial lines, pulmonary artery catheters and transesophageal echocardiograms must be considered, and at least an arterial line may have to be inserted preoperatively.

Intraoperative Management

Induction is often accompanied by a precipitous fall in blood pressure and this can be controlled by titrating induction drugs such as etomidate instead of propofol, and titrating vasoconstrictors and inotropes to maintain blood and pulmonary pressures. Intubation often reverses the hypotension but can cause undesired hypertension that can be extremely detrimental to the forward stroke volume. Hence careful titration and timing of induction and hemodynamic support drugs is vital and so is a slick and quick intubation by an experienced person.

The conduct of anesthesia during heart failure requires constant vigilance with regard to the vital signs, pulmonary pressures, echo findings, blood gases, body temperature, blood loss, coagulation and other parameters. Oxygenation should be maximized, ventilation optimized to blood gases and preferably only blood loss should be replaced with blood, thus avoiding unnecessary fluid administration. Serum calcium levels must be checked if blood products are being administered and corrected appropriately as calcium is an excellent inotrope.

Postanesthetic care

Leaving the patient intubated postoperatively may be prudent to allow heart failure to resolve. However, if the patient is deemed to be suitable for emergence and extubation at the end of the procedure, excellent pain control must be in place. If neuraxial anesthesia has been in place, it may be used to provide not only pain relief but also mild afterload reduction to help with heart failure.

Conclusion

Major noncardiac surgery is associated with significant perioperative mortality and morbidity. Most deaths in this setting are related to cardiac complications such as MI. Survivors of in-hospital perioperative ischemic events such as MI, unstable angina, and postoperative ischemia, warrant more aggressive long-term follow-up and treatment than currently are practiced. MI following coronary artery bypass graft surgery is associated with a significant increase in intensive care unit time, hospital length of stay, and overall costs, which contribute to greater hospital and physician service costs.

Anesthetic goals in patients with valvular heart disease

Sugantha Sundar, Devi Mahendran, and Eswar Sundar

Valvular heart disease accounts for a significant proportion of patients requiring cardiac surgery. Rheumatic heart disease as a cause of valvular heart disease has become less common with the aggressive use of penicillin to treat streptococcal infections. However, an increasing proportion of adults with congenital heart disease require operations for recurrent valvular lesions or new lesions related to complications from their original surgical procedure.

The anesthetic management of patients with valvular heart disease undergoing noncardiac surgery requires a clear understanding of the pathophysiology and hemodynamic implications of valvular lesions. A patient's physiologic adaptation to his or her valve disease may be acutely disturbed by perioperative events and anesthetic drugs. Hence, the anesthesiologist must be able to manipulate the patient's hemodynamic status to provide the best possible cardiac output to maintain end-organ perfusion.

This chapter summarizes the anesthetic management of valvular heart disease with particular reference to:

- The preoperative evaluation of the patient with valvular heart disease
- The American Heart Association (AHA) recommendations for endocarditis prophylaxis in valvular heart disease
- Management of anticoagulation regimen in the perioperative period
- The etiology, pathophysiology, pressure–volume loops, hemodynamic goals, and anesthetic considerations for each of the major valvular lesions

Evaluating the patient with valvular heart disease

Preoperative evaluation focuses on determining the severity of the valvular lesion and its hemodynamic significance, residual ventricular function, the presence of concomitant coronary artery disease, and the presence of secondary effects on pulmonary, renal, and hepatic function. [Table 5.1](#) demonstrates points to elicit during history taking. The New York Heart Association (NYHA) grades the clinical severity of heart failure and is a prognostic indicator of outcome ([Table 5.2](#)). Patients with valvular heart disease may have many physical findings;

[Table 5.3](#) outlines the key physical examination findings in these patients.

Preprocedure investigations

Preprocedure investigations must be tailored to the patient and the procedure in question. It is important to exclude active ischemia, heart failure, arrhythmias, and electrolyte imbalances secondary to medications. A coagulation profile may assume importance if a regional anesthetic is being considered in a patient receiving anticoagulants. [Table 5.4](#) outlines the main investigations that may be considered in patients with valvular heart disease.

Premedication

In general, it is recommended that patients receive their usual medications on the morning of surgery. Premedication with standard doses of commonly used drugs such as midazolam or fentanyl is desirable and well tolerated in patients with normal or near-normal ventricular function. However, patients with poor ventricular function may be highly sensitive to opioids, and premedication should be dose-adjusted in accordance with the severity of ventricular impairment and comorbidities.

Endocarditis prophylaxis

The risk of endocarditis varies according to the valvular abnormality, and antibiotic prophylaxis follows AHA guidelines ([Tables 5.5, 5.6, and 5.7](#)).

Prosthetic and mechanical valves

Patients with prosthetic heart valves pose special challenges to the anesthesiologist. The most frequent issue with patients who have a prosthetic valve is the management of systemic anticoagulation in the perioperative period. Prosthetic valves are either bioprosthetic or mechanical. Bioprosthetic valves are usually heterogeneous grafts made from animal tissue and have very low thrombogenic potential. Hence, patients with bioprosthetic valves do not usually need systemic anticoagulation. Aspirin is recommended for all patients with prosthetic heart valves. Aspirin alone is recommended in patients with bioprostheses and no risk factors for thrombosis. However, bioprosthetic

Table 5.1. Points to elicit during history taking

- History of rheumatic fever
- Intravenous drug abuse
- Genetic conditions associated with valvular disease, such as Marfan's syndrome
- Heart surgery in childhood
- Prior valvular surgery, type of prosthetic valve used
- Exercise tolerance
- Fatigability
- Symptoms of dyspnea, orthopnea, dependant edema, chest pain, paroxysmal nocturnal dyspnea, and neurologic symptoms
- A thorough review of medications (e.g., use of digoxin, diuretics, vasodilators, ACE inhibitors, antiarrhythmics, and anticoagulants; if patient is taking digoxin, screen for symptoms of digoxin toxicity)

valves have a shorter lifespan and are therefore more often placed in elderly patients.

On the other hand, mechanical valves are longer lasting, but patients who have a mechanical valve do need lifelong anticoagulation. All patients with mechanical valves require warfarin therapy. Aspirin is usually combined with warfarin in patients with mechanical heart valves and in high-risk patients with bio-prostheses. For high-risk patients who cannot take aspirin, the addition of clopidogrel to warfarin should be considered. Even with the use of warfarin, the risk of thromboembolism is 1% to 2% per year, but the risk is considerably higher without warfarin treatment. Systemic anticoagulation in patients with mechanical valves reduces the risk of thromboembolism by about 75%.

Upon auscultation, patients with mechanical valves may be identified by the high-pitched, crisp opening and closing sounds. Bioprosthetic valves do not have any special auscultatory characteristics. The onset of new murmurs or a change in the quality of murmurs associated with a valve may indicate a problem with the valve or the onset of endocarditis.

Patients presenting for surgery with a prosthetic valve should receive a complete history and physical examination. The anesthesiologist must know what type of valve the patient has and when it was inserted. Preoperatively, transesophageal

Table 5.2. The NYHA functional classification of heart disease

Class	Patient symptoms
Class I (mild)	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitations, or dyspnea.
Class II (mild)	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue, palpitations, or dyspnea.
Class III (moderate)	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes fatigue, palpitations, or dyspnea.
Class IV (severe)	Unable to carry out any physical activity without discomfort. Symptoms of cardiac insufficiency at rest. If any physical activity is undertaken, discomfort is increased.

Table 5.3. Physical findings in valvular heart disease

- Signs of congestive heart failure
 - S₃ gallop
 - Pulmonary rales
 - Elevated jugular venous pressure
 - Hepatojugular reflux
 - Hepatosplenomegaly
 - Pedal edema
- Auscultatory findings specific to individual valvular lesions
- Neurologic deficits secondary to embolic phenomena

echocardiography (TEE) or transthoracic echocardiography can allow excellent visualization of the prosthetic valve and assessment of valvular function. Almost invariably, patients with artificial valves will require perioperative antibiotic prophylaxis for endocarditis.

Patients with mechanical valves taking systemic anticoagulation will require careful management in the perioperative period. The perioperative period is a prothrombotic state, and this danger must be borne in mind when stopping systemic anticoagulation. Intravenous heparin is one method for bridging anticoagulation therapy.

AHA bridging recommendations in patients with mechanical valves who require interruption of warfarin therapy for non-cardiac surgery and invasive procedures are as follows:

- In patients at low risk of thrombosis, defined as those with a bileaflet mechanical aortic valve replacement without risk factors, it is recommended that warfarin be stopped 48 to 72 hours before surgery. This will allow the international normalized ratio (INR) to fall to <1.5; warfarin can then be restarted within 24 hours after the procedure. Heparin is usually unnecessary.
- In patients at high risk for thrombosis, defined as those with a mechanical mitral valve or a mechanical aortic valve with any risk factor, therapeutic doses of unfractionated

Table 5.4. Investigations for patients with valvular heart disease

- ECG for evidence of ischemia, arrhythmias, atrial enlargement, and ventricular hypertrophy
 - Serum electrolytes and renal function (mild–moderate hypokalemia is often seen in patients taking diuretics and can exacerbate digoxin toxicity). Hypomagnesemia may cause perioperative arrhythmias. Hyperkalemia may occur in patients taking potassium-sparing diuretics or ACE inhibitors.
 - Coagulation studies to check for reversal prior to surgery for patients who have been on anticoagulants
 - Arterial blood gases in patients with significant pulmonary symptoms
 - A chest radiograph to assess cardiac size and the presence of pulmonary vascular congestion
- Special studies can provide important diagnostic and prognostic information about valvular lesions:
- Echocardiography with Doppler technology for evaluating valvular heart diseases
 - Cardiac catheterization to identify coexisting coronary artery disease; allows visualization of the cardiac chambers as well as pressure gradients across valves

Table 5.5. AHA recommendations for endocarditis prophylaxis

High- and moderate-risk patients (prophylaxis recommended)	Low-risk patients (prophylaxis not recommended)
<ul style="list-style-type: none"> • Prosthetic valves or history of infective endocarditis • Complex cyanotic congenital heart disease • Surgically constructed systemic-pulmonary shunts or conduits • Congenital cardiac valve malformations, particularly bicuspid aortic valves, and patients with acquired valvular dysfunction (e.g., rheumatic heart disease) • A history of surgical valve repair • Hypertrophic cardiomyopathy with resting or latent obstruction • MVP and auscultatory evidence of valvular regurgitation and/or thickened leaflets on echocardiography 	<ul style="list-style-type: none"> • Isolated secundum ASD • >6 months after successful surgical or percutaneous repair of an ASD, VSD, or PDA. • MVP without MR or thickened leaflets on echocardiography • Physiologic, functional, or innocent heart murmurs, including aortic valve sclerosis • Echocardiographic evidence of physiologic MR in the absence of a murmur and with structurally normal valves • Echocardiographic evidence of physiologic TR and or PR in the absence of a murmur and with structurally normal valves

ASD, atrial septal defect; PDA, patent ductus arteriosus; VSD, ventricular septal defect.

heparin should be started when the INR falls below 2.0 (typically 48 hours before surgery) and stopped 4 to 6 hours before the procedure. Warfarin is then restarted soon after surgery, as determined by the clinical condition of the patient. Heparin is continued until the INR is back within therapeutic range with warfarin therapy. More recently, low molecular weight heparin (LMWH) has been used, although few studies exist to validate the efficacy and safety of either LMWH or unfractionated heparin in this setting.

- Fresh frozen plasma (FFP) may be given to patients with mechanical valves who require interruption of warfarin therapy for emergency surgery or invasive procedures. FFP is preferable to high-dose vitamin K.
- In patients at high risk for thrombosis, therapeutic doses of unfractionated heparin (15,000 units every 12 hours) or LMWH (100 units/kg every 12 hours) may be considered during the period of subtherapeutic INR.

Risk factors for thrombosis include:

- Atrial fibrillation
- Previous thromboembolism
- Left ventricular (LV) dysfunction
- Hypercoagulable conditions
- Older-generation thrombogenic valves
- More than one mechanical valve

Anesthetic considerations

Choice of anesthetic technique/agents to be employed in patients with valvular heart disease depends on the severity of the valvular lesion, its hemodynamic adaptations, and the proposed procedure. Inhalational agents all produce dose-dependent myocardial depression, which may be accentuated in patients with abnormal hemodynamics secondary to valvular disease. Nitrous oxide is less depressant and maintains peripheral vascular resistance. All inhalational agents cause decreases in blood pressure. Isoflurane, sevoflurane, and desflurane are associated with a decrease in systemic vascular resistance with peripheral vasodilation. Desflurane may cause sympathetic activation that could be detrimental to patients with valvular heart disease. Sevoflurane and isoflurane are both considered safe in patients with cardiac disease. Sevoflurane is reported to have a more stable effect on heart rate and cardiac function than other agents.

Table 5.7. Antibiotic regimens for endocarditis prophylaxis**Dental, oral, respiratory tract, or esophageal procedures**

Standard preoperative prophylaxis	Ampicillin	Adults: 2.0 g Children: 50 mg/kg IM/IV

Regional anesthesia may be a consideration for procedures involving extremities, the perineum, and the lower abdomen. Regional anesthetic techniques provide less respiratory and cardiac depression than general anesthesia. However, patients may be very sensitive to the vasodilating effects of spinal and epidural anesthesia. Epidural may be more preferable to spinal anesthesia because of the more gradual onset of sympathetic blockade. A single-shot spinal anesthetic is relatively contraindicated in patients with “fixed” cardiac output states (e.g., critical aortic stenosis [AS]) because these patients are unable to augment their cardiac output in response to the vasodilation and subsequent hypotension that often accompany this technique.

The postoperative management of patients with valvular heart disease should address managing pain control, optimizing fluid therapy, and restarting anticoagulation if necessary. Epidural catheters have been shown to provide excellent postoperative pain relief and should be considered whenever possible in patients with valvular heart disease. Major fluid shifts may occur 48 to 72 hours postoperatively, and patients with severe valvular heart disease require judicious fluid management during this phase, possibly with invasive hemodynamic monitoring. For patients who had been anticoagulated prior to surgery, anticoagulation needs to be restarted, keeping in mind the clinical picture and AHA recommendations.

The anesthetic considerations for valvular heart disease are discussed further in the context of each valvular lesion. Intraoperative monitoring is also tailored to the severity of

the valvular disease and the proposed surgery. In addition to the standard American Society of Anesthesiologists monitors, other monitors may be employed intraoperatively include intra-arterial and pulmonary artery catheters, and TEE. Intra-arterial catheters provide beat-to-beat blood pressure measurement as well as the ability to monitor blood gases periodically. TEE can assess the severity of valvular disease accompanying structural or functional abnormalities and also allows evaluation of valve repair as well as function of artificial valves. Pulmonary artery catheters are used to measure cardiac output, mixed venous saturation, and intracardiac pressures (including pulmonary capillary wedge pressure), which are important indices of ventricular function and filling, and are useful for guiding intra-venous fluid and inotropic therapy.

Left-sided valvular lesions

Mitral stenosis

Mitral stenosis (MS) occurs most commonly secondary to rheumatic fever and typically is functionally significant within two decades. Most patients are female and have combined stenosis and regurgitation (40%) rather than isolated stenosis (25%).

Pathophysiology

MS results from thickening and immobility of the mitral valve leaflets, which causes an obstruction to blood flow from the left atrium to the left ventricle. As a result, there is an increase

in pressure within the left atrium, pulmonary vasculature, and right side of the heart, whereas the left ventricle is underloaded in isolated MS.

There is a significant reduction in preload; hence, a fixed cardiac output state develops. MS markedly affects LV filling, thereby reducing stroke volume and cardiac output. The left atrium undergoes volume overload and stretching, which may result in supraventricular tachycardias, particularly atrial fibrillation, further reducing ventricular filling. Back pressure of blood into the pulmonary circulation causes pulmonary hypertension, leading to right heart failure, hemoptysis, and pulmonary edema. On the systemic side, the reduced cardiac output cannot meet oxygen demands, and organ perfusion is often maintained with a relatively high systemic vascular resistance.

Risk factors for the development of pulmonary edema in MS are:

- Mitral valve area <1.5 cm² (the normal mitral valve area is 4–6 cm²)
- NYHA functional class > II
- Prior adverse cardiac event
- LV ejection fraction (LVEF) < 0.4

Patients with severe MS requiring elective surgery should undergo mitral valvotomy or balloon valvuloplasty prior to their elective procedure, as the presence of pulmonary hypertension is associated with significant morbidity and mortality.

Pressure–volume loop in mitral stenosis

The pressure–volume loop in MS (Fig. 5.1) shows a reduction in end-diastolic, end-systolic, and stroke volume. LV function is normal in most people with MS, but contractility is decreased because of chronic underfilling of the left ventricle.

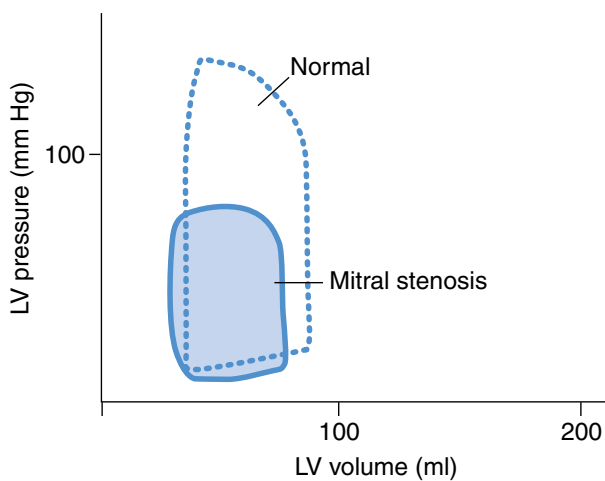

Figure 5.1. Pressure–volume loop in MS.

Table 5.8. Hemodynamic goals for the intraoperative management of valvular heart disease

Lesion	Preload	Systemic vascular resistance	Heart rate	Contractility
Aortic stenosis	↑	↑	↓	→
Hypertrophic cardiomyopathy	↑	↑	↓	↓
Mitral stenosis	↑	→ or ↑	↓	→
Mitral regurgitation	↑	↓	↑	→
Aortic regurgitation	↓	↓	↑	→

Anesthetic considerations in mitral stenosis

The anesthetic considerations in patients with MS are as follows (Table 5.8):

- Maintaining a slightly reduced to normal heart rate facilitates an increase in the time available during diastole, thus improving LV filling.
- Maintaining sinus rhythm facilitates LV filling with the contribution from the atrial kick.
- Maintaining an adequate preload is important to generate an adequate cardiac output. However, fluid therapy should be titrated with care to avoid precipitating pulmonary edema in patients with severe disease.
- Maintaining an adequate afterload is vital to help maintain coronary perfusion.
- Avoiding arterial hypoxemia or hypoventilation that may exacerbate pulmonary hypertension and evoke right ventricular failure is crucial.
- Full hemodynamic monitoring is generally indicated for all major surgical procedures.
- Patients with MS may be very sensitive to the vasodilating effects of spinal and epidural anesthesia.

Mitral regurgitation

Mitral regurgitation (MR) may occur acutely or gradually as a result of several different etiologies. Acute MR may occur in the setting of myocardial ischemia and infarction with papillary muscle dysfunction or chordae tendineae rupture. Chronic MR is usually caused by rheumatic heart disease, ischemia, or mitral valve prolapse (MVP).

Pathophysiology

In MR, a portion of the LV stroke volume is ejected backward into the low-pressure left atrium during systole. As a result, the forward cardiac output into the aorta is less than the left ventricle’s total output (forward flow plus regurgitant volume).

The direct consequences of MR include:

- An elevation of left atrial volume and pressure
- A reduction of cardiac output

- Volume-related stress on the left ventricle because the regurgitant volume returns to the left ventricle in diastole along with normal pulmonary venous return

Factors that affect the volume of regurgitant flow include:

- Mitral valve orifice size
- Time available for regurgitant flow with each systolic contraction
- Transvalvular pressure gradient
- Systemic vascular resistance opposing forward LV blood flow
- Left atrial compliance

In acute MR, left atrial compliance undergoes little immediate change and left atrial pressure increases substantially when exposed to the regurgitant volume. This elevated pressure is transmitted backward to the pulmonary circulation and right heart and may precipitate acute pulmonary edema, right-sided heart failure, and pulmonary hypertension.

In chronic MR, the left atrium dilates and its compliance increases to accommodate a larger volume without a substantial increase in pressure. Both the left ventricle and left atrium show volume overload, leading to increased LV end-diastolic volume with a normal end-diastolic pressure. LV end-systolic volume is normal with a high stroke volume. However, forward cardiac output is substantially impaired because the low-pressure left atrium acts as a “sink” for the LVEF. In chronic MR, the LVEF is usually high because of the low resistance against the regurgitation. An LVEF of 50% may indicate significant LV dysfunction.

Pressure–volume loop in mitral regurgitation

The pressure–volume loop in MR shows an increase in end-diastolic volume with high end-diastolic pressure. End-systolic volume is normal or decreased. In chronic MR (Fig. 5.2), the end-diastolic volume is increased with a normal end-diastolic pressure as a result of the chronic dilatation of the left ventricle. The end-systolic volume is normal because of the markedly increased stroke volume.

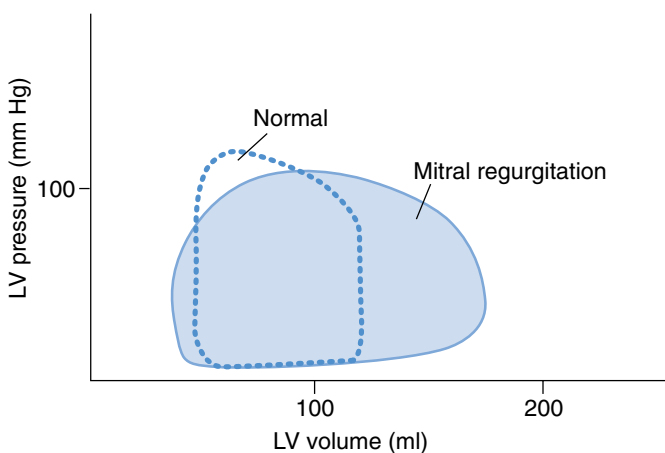

Figure 5.2. Pressure-volume loop in chronic well-compensated mitral regurgitation with normal left ventricular function.

Anesthetic considerations in mitral regurgitation

The main goals are to promote forward cardiac output and minimize regurgitant flow by:

- Medical optimization of MR prior to elective surgery with digoxin, diuretics and vasodilators.
- Maintaining intravascular volume (i.e., an adequate preload) to supply the dilated left ventricle.
- Maintaining normal to high heart rates (80–100 bpm). Higher heart rates promote cardiac emptying and tend to lower LV end-diastolic volume and thus reduce the regurgitant volume during systole. Bradycardia increases the regurgitant volume, decreasing the ejected volume into the aorta.
- Avoiding decreases in contractility. Inotropes with afterload-reducing effects (e.g., milrinone or dobutamine) should be considered.
- Minimizing drug-induced myocardial depression.
- Reducing afterload, because reducing systemic vascular resistance increases forward stroke volume and decreases the regurgitant volume.
- Performing intraoperative monitoring depending on the severity of ventricular dysfunction and the procedure. In patients with severe MR, full hemodynamic monitoring is recommended. Doppler TEE may be used to quantify the severity of the regurgitation and guide therapeutic interventions.
- Noting that patients with mild–moderate MR with well-preserved ventricular function can tolerate most anesthetic techniques without complications. However, patients with higher degrees of MR, especially in the context of atrial fibrillation, may have a high mortality rate.

Mitral valve prolapse

MVP is characterized by an abnormality of the mitral valve support structure that permits prolapse of the valve into the left atrium during contraction of the left ventricle. The estimated prevalence of MVP is 0.6% to 2%. There appears to be an increased incidence of MVP in patients with musculoskeletal abnormalities, including Marfan’s syndrome, pectus excavatum, and kyphoscoliosis.

MVP is the most common valvular cause of chronic MR. Approximately 10% of patients with MVP develop progressive MR and will require mitral valve surgery in their lifetime. However, the natural history of MVP is generally benign, and most patients have a normal lifespan, although serious complications may occur; the most common are infective endocarditis, cerebrovascular accidents (due to embolic phenomena), atrial and ventricular arrhythmias, the need for mitral valve surgery, and, rarely, sudden death. Not all patients with MVP need antibiotic prophylaxis, and these patients must have specific auscultatory or echocardiographic features to justify antibiotic prophylaxis (Table 5.5).

Aortic stenosis

LV outflow tract obstruction may be subvalvular, valvular, or supra-ventricular in nature. The most common etiology of AS is senile calcification and/or fibrosis of a congenital bicuspid valve. In developed countries, rheumatic aortic valvular disease has become very uncommon. However, worldwide, rheumatic fever accounts for a third of all cases of AS.

Pathophysiology

In AS, the narrowed aortic valve creates a resistance to flow and causes a drop in pressure from the left ventricle to the aorta. The pathophysiologic changes in AS are related to the pressure gradient that develops between the left ventricle and aorta. Usually, when the aortic valve opens in systole, there is a minimal gradient between the two chambers. As the stenosis progresses, a resting gradient develops across the aortic valve. As a compensatory mechanism, the left ventricle hypertrophies because of increased wall tension to overcome the stenosis. The increased wall thickness helps normalize wall stress and maintain cardiac output within the normal range. In mild and moderate AS, there is little hemodynamic consequence, and the patient can tolerate this condition for years before the onset of symptoms.

However, with time, LV hypertrophy leads to a decrease in diastolic ventricular compliance (a stiff left ventricle); therefore, end-diastolic pressure must rise to maintain the same end-diastolic volume. The decreased diastolic pressure gradient between the left atrium and left ventricle impairs ventricular filling. The pulmonary capillary bed is usually protected from these diastolic filling abnormalities by a forceful left atrial contraction, which ensures filling of the stiff left ventricle. In AS, the left atrial kick contributes up to 40% (normal, 15%–20%) of ventricular filling. Loss of the atrial kick, as in atrial fibrillation, results in decreased ventricular filling, causing decreased cardiac output or a rise in mean left atrial pressures.

When compensatory LV hypertrophy reaches its limits, muscle degeneration occurs, contractility falls, and the left ventricle dilates to maintain chamber pressure. LV failure ensues, resulting in high pulmonary artery pressures, a low ejection fraction (EF), and reduced cardiac output.

Advanced AS is characterized by a triad of dyspnea on exertion, angina, and orthostatic or exertional syncope. Critical AS is said to exist when the aortic valve orifice is reduced to $<0.7 \text{ cm}^2$ (normal, $2.5\text{--}3.5 \text{ cm}^2$). With severe AS, patients generate a transvalvular gradient $>50 \text{ mm Hg}$ at rest with a normal cardiac output and are unable to increase cardiac output appreciably in response to demand. Intraoperatively, the presence of severe AS is associated with an increased risk of acute myocardial infarction, but not death.

Without surgical treatment, most patients with symptomatic AS die within 2 to 5 years. Percutaneous balloon valvuloplasty is generally used for younger patients with congenital AS and for elderly patients who are considered poor surgical candidates for an aortic valve replacement.

Figure 5.3. Pressure–volume loop in AS.

Pressure–volume loop in aortic stenosis

To generate a normal stroke volume in AS, the intraventricular pressure is high as a result of the pressure gradient across the aortic valve (Fig. 5.3). The end-diastolic pressure is higher than normal in cases of AS because LV hypertrophy leads to reduced LV compliance. High systolic wall tension leads to LV hypertrophy. Initially, LV hypertrophy increases contractility and decreases wall tension during systole. However, in severe AS, the left ventricle stiffens and starts to dilate, resulting in symptoms of LV failure.

Anesthetic considerations in aortic stenosis

Anesthetic considerations in patients with AS are as follows:

- Normal sinus rhythm should be maintained. The ventricle relies on the atrial kick for filling; hence, sinus rhythm is crucial in these patients. Emergent cardioversion is indicated if the patient suffers severe hemodynamic compromise due to arrhythmias.
- Tachycardia or bradycardia should be avoided. Many AS patients behave as though they have a fixed stroke volume, thus cardiac output becomes very rate dependent. High heart rate promotes heart failure by inadequate diastolic filling times and inadequate LV emptying. High heart rate also may aggravate ischemia. Premedication can prevent anxiety-provoked tachycardia. Bradycardia is also poorly tolerated. Heart rates between 60 and 90 bpm are optimal.
- A high normal preload should be maintained because a noncompliant left ventricle requires a high filling pressure to maintain normal end-diastolic volume.
- Sudden decreases in systemic vascular resistance should be avoided. In a normal heart, cardiac output rises when systemic vascular resistance falls; however, in AS, the stenosis limits the rise in cardiac output. Patients with AS are extremely sensitive to vasodilators.

- Myocardial contractility depression should be avoided through prevention of hypercarbia, hypoxia, and acidotic states.
- Concomitant ischemic heart disease worsens an already impaired oxygen delivery system. An adequate aortic diastolic pressure should be maintained using inotropes, vasoconstrictors, and fluid.
- Full hemodynamic monitoring should be considered. TEE can provide useful information for monitoring ischemia, ventricular preload, contractility, valvular function, and the effects of therapeutic interventions.
- Patients with mild to moderate AS may tolerate spinal or epidural anesthesia if it is dosed gradually.
- For general anesthesia, an opioid-based induction technique avoids excessive cardiac depression. Volatile agents should be carefully titrated to avoid excessive vasodilation.

Aortic regurgitation

Aortic regurgitation (AR) may be caused by processes that affect the aortic valve leaflets or the aortic root and valve-supporting structures. Acute AR is most often the result of infective endocarditis, trauma, or an aortic dissection. Chronic AR is usually caused by prior rheumatic valvular heart disease or congenital lesions.

Pathophysiology

Acute AR is characterized by an abrupt regurgitation of blood into a normal left ventricle, leading to a sudden increase in LV volume and a marked elevation of LV end-diastolic pressure. The effective forward stroke volume is reduced because of regurgitant blood flow into the left ventricle during diastole. Systemic arterial blood pressure and systemic vascular resistance are typically low. The decrease in cardiac afterload helps facilitate ventricular ejection. The sudden increase in LV end-diastolic pressure is transmitted to the left atrium and the pulmonary circulation, often producing dyspnea and pulmonary edema. Severe acute AR is an emergency requiring immediate surgery.

In chronic AR, the left ventricle progressively dilates and undergoes eccentric hypertrophy in response to longstanding regurgitation. The dilated left ventricle facilitates the rapid return of blood back to the ventricle during diastole, resulting in a decreased peripheral arterial diastolic pressure. The LV end-diastolic volume and stroke volume gradually increase because the left ventricle receives aortic blood in diastole in addition to blood from left atrium. LV hypertrophy compensates for the increase in LV volume, but over years, decompensation occurs. These changes may ultimately cause arrhythmias, LV impairment, and heart failure.

Most patients with chronic AR remain asymptomatic for 10 to 20 years. For patients with chronic AR, the decision regarding aortic valve replacement surgery is based on the presence of symptoms and should be undertaken before irreversible ventricular dysfunction occurs.

Figure 5.4. Pressure–volume loops in aortic insufficiency.

In chronic AR, aortic valve replacement surgery is indicated for patients with:

- NYHA functional class III to IV symptoms, severe AR, and normal left ventricular systolic function
- NYHA functional class III to IV symptoms with mild to moderate LV dysfunction (EF between 25% and 49%)
- Asymptomatic severe AR with LV dysfunction (EF <50%)
- Severe LV dilation (LV end-systolic volume dimension >55 mm) even in the absence of symptoms

Pressure–volume loop in aortic regurgitation

In acute AR, the end-diastolic volume increases with high end-diastolic pressure (Fig. 5.4). The end-systolic volume is also greater than normal because of regurgitation during isovolumetric relaxation. In chronic AR, the heart may be enormously dilated but the end-diastolic pressure is normal as a result of myocardial remodeling.

Anesthetic considerations in aortic regurgitation

Anesthetic considerations in patients with AR are as follows:

- Preoperative medical therapy should be optimized with digitalis, diuretics, and afterload-reducing agents, particularly angiotensin-converting enzyme (ACE) inhibitors. Decreasing the arterial blood pressure reduces the diastolic gradient for regurgitation.
- Preload should be maintained, but fluids should be titrated carefully to avoid precipitating pulmonary edema.
- Heart rate should be maintained at the upper limit of normal (80–100 bpm). Bradycardia should be avoided because it is associated with increased diastolic filling time, which increases the regurgitant volume. Excessive tachycardia also may contribute to myocardial ischemia.
- A sudden increase in systemic vascular resistance should be avoided because it increases regurgitation.
- Metabolic and drug-induced myocardial depression should be minimized.

- Excessive decreases in diastolic pressure should be avoided so that coronary artery perfusion pressure is maintained.
- Full hemodynamic monitoring may be indicated in patients with acute AR and severe chronic AR.
- Most patients with AR tolerate spinal and epidural anesthesia if intravascular volume is maintained.
- For general anesthesia, the use of isoflurane or desflurane may be beneficial because of its associated vasodilation. In patients with depressed ventricular function, an opioid-based general anesthetic technique should be considered.

Right-sided valvular lesions

Tricuspid stenosis

Tricuspid stenosis is rare and usually coexists with MS, occurring as a sequela of rheumatic heart disease. It is often found in women; it also is seen in association with carcinoid syndrome. The resulting back pressure into the right atrium often results in upper-extremity venous congestion, hepatic enlargement, and ascites. Surgical therapy is usually required (valvuloplasty or valve replacement).

Tricuspid regurgitation

Tricuspid regurgitation (TR) is typically functional rather than structural in that it develops after right ventricular enlargement (e.g., as a result of pressure or volume overload) rather than primary valvular disease. TR also may follow infective endocarditis, rheumatic fever, carcinoid syndrome, or chest trauma or may be a result of Ebstein's anomaly (downward displacement of the tricuspid valve, resulting from abnormal attachment of the valve leaflets). TR is generally well tolerated by most patients in the absence of pulmonary hypertension. Treatment is aimed at the underlying disease process. In moderate to severe TR, tricuspid annuloplasty may be considered.

Pulmonary stenosis

Pulmonary stenosis (PS) is rare and almost always secondary to a congenital deformity of the valve. Severe PS is associated with a peak systolic gradient >80 mm Hg, moderate disease with a gradient of 40 to 80 mm Hg, and mild PS with a transvalvular gradient <40 mm Hg. In moderate to severe PS, transcatheter balloon valvuloplasty should be considered.

Pulmonary regurgitation

Pulmonary regurgitation (PR) refers to diastolic retrograde flow from the pulmonary artery into the right ventricle. Physiologic (trace-to-mild) PR is present in nearly all individuals, particularly in those with advancing age. However, pathologic

conditions that produce excessive and clinically significant regurgitation may result in impairment of right ventricular function and eventually clinical manifestations of right-sided volume overload and heart failure.

Incompetence of the pulmonic valve occurs because of one of three pathologic processes: dilatation of the pulmonic valve annulus, acquired alteration of pulmonic valve cusp morphology, or congenital absence or malformation. Congenital PR and congenital absence of the pulmonic valve are rare conditions. Acquired PR may develop in the setting of severe pulmonary hypertension or dilated cardiomyopathy or after surgical or percutaneous relief of PS following repair of tetralogy of Fallot. Treatment options for PR focus on treating the underlying cause. Pulmonic valve replacement is an option if symptoms and signs of right ventricular dysfunction develop, but outcomes and risks are unclear because the need for replacement is so infrequent.

The perioperative management of obese (body mass index [BMI] ≥ 30 kg/m²) and morbidly obese (BMI ≥ 35 kg/m²) patients presenting for surgery carries a significantly higher risk of morbidity and mortality compared with that of nonobese patients. The obese state elicits a complex physiologic response in a variety of organ systems. The comorbidities associated with obesity present a unique challenge to the anesthesiologist, whose expertise in the perioperative management of this group may have a positive impact on surgical outcome. The number of obese patients presenting for surgery has increased markedly over the past decade. It is well known that perioperative risk, including mortality, is directly related to BMI, with the highest risk in patients with a BMI > 40 kg/m² (Table 6.1).

Obesity as a physiologic state

Obesity is best described as a physiologic state characterized by an imbalance between energy supply and demand. The thermodynamic and physiologic alterations seen in obesity are primarily a result of an excess of stored energy in the form of adipose cells and the effect of this tissue type on overall cellular metabolism and respiration. On the demand side, the energy requirements can be divided into two categories: energy expenditure to maintain homeostasis and energy afforded to match physical activity. This is predicated on the fact that each kilogram of adipose tissue is supplied by a prerequisite number of blood vessels. The overall result is a cardiovascular system characterized by a volume-avid and high cardiac output state (Fig. 6.1).

Preoperative considerations

Cardiovascular system

The preoperative evaluation of the obese patient begins with a detailed evaluation of the cardiopulmonary system and the airway. The obese patient has an increased prevalence of

altered cardiorespiratory mechanics predisposing the patient to ventilation–perfusion mismatch and hypoxemia (Table 6.2). It is thus prudent to pay particular attention to the specific signs and symptoms of any compromised cardiopulmonary reserve. The practitioner may be alerted to the presence or absence of symptoms (resting or exertional fatigue, dyspnea, orthopnea, angina, syncope) and signs of cardiac failure (increased jugular venous distention, adventitious heart or lung sounds, peripheral edema, hepatomegaly). Unfortunately, these symptoms and signs may be obscured by fatty tissue and/or inactivity, necessitating a lower threshold for further cardiac workup.

The electrocardiogram (ECG) may confirm or identify the presence of left or right ventricular hypertrophy, ventricular strain or regional myocardial ischemia, and/or previous myocardial infarction. Chest radiography may reveal signs of pulmonary congestion. The ECG may be invaluable in demonstrating regional wall motion abnormalities, compromised systolic or diastolic function, evidence of ventricular strain or overload, or valvular abnormalities. In fact, the presence of tricuspid regurgitation on echocardiography may be the most useful confirmation of pulmonary hypertension.

Pulmonary system and airway

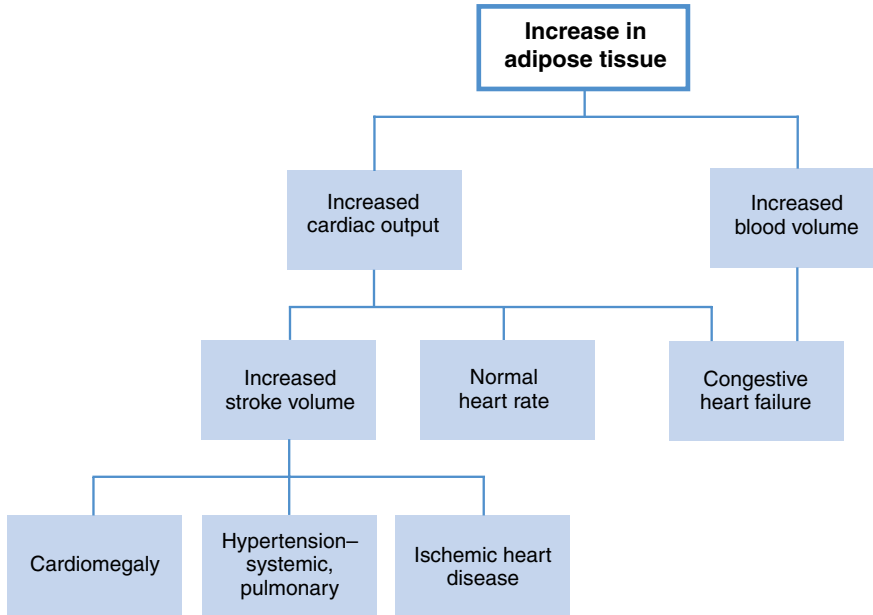

The examination of airway anatomy has been studied, and consequently a relationship between increased neck circumference and difficult intubation has been proposed. A neck circumference >60 cm was associated with a 35% chance of “problematic” intubation in one study. An increase in neck circumference or excess pharyngeal soft tissue may indicate a predisposition to upper airway narrowing or collapse and thus difficult mask ventilation following induction of anesthesia. Resistance to airflow and patency of the airway in these patients depend on pharyngeal muscle tone. Airway obstruction may result during administration of sedatives.

With respect to respiratory mechanics, an excess of adipose tissue in the abdomen and thorax generates a significant reduction in diaphragmatic mobility, with a resultant decrease in functional residual capacity (FRC) and total lung capacity. Lung volumes are reduced further in the supine and anesthetized state. This may be ameliorated somewhat by the application of positive end-expiratory pressure (PEEP; described later), but

Table 6.1. Important indices for diagnosing obesity

BMI	Body weight (kg)/height ² (m)
Waist circumference	>100 cm (males), > 90 cm (females)
Waist–hip ratio	>1.0
IBW (kg)	Height (cm) – 100

Figure 6.1. Cardiovascular changes in obesity.

possibly to the detriment of cardiac output. The plethora of tissue in the chest cavity also decreases respiratory compliance and increases resistance to airflow, all of which worsen in the anesthetized supine patient. Moreover, obesity increases oxygen consumption and carbon dioxide production because of

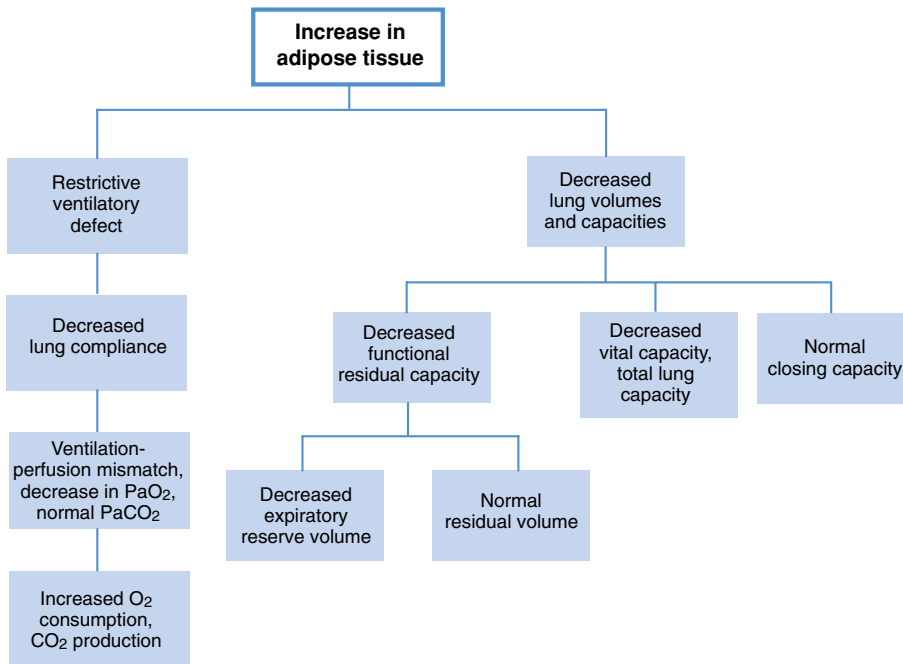

the abundance of metabolically active adipose cells and the increased energy requirement of the obese state. Mean oxygen consumption is increased by as much as 25% in this population; however, this demand is matched by an overall increase in minute ventilation and cardiac output.

Table 6.2. Obesity and associated comorbidities

Organ system	Comorbidity	Anesthetic implications
Cardiovascular	Hypervolemic state High cardiac output state CHF (systolic and diastolic dysfunction) Ischemic heart disease DVT Hypertension Valvular heart disease Peripheral vascular disease	Increased volume of distribution, hypertension Cardiomegaly, CHF Increased risk of perioperative CHF Myocardial infarction, heart failure Perioperative thromboembolism, pulmonary embolism, need for DVT prophylaxis Myocardial ischemia, LV failure Heart failure Reduced blood flow, limb ischemia, poor wound healing
Pulmonary	OSA Pulmonary hypertension Restrictive lung volumes Difficult airway management	Hypercarbia, respiratory acidosis, polycythemia, difficult ventilation Right heart failure Shorter time to hypoxia, difficult oxygenation Difficult ventilation and intubation, pulmonary aspiration
Endocrine	Diabetes and insulin resistance Hypercholesterolemia	Cardiovascular disease, central obesity, perioperative glucose control Systemic cardiovascular disease
Gastrointestinal	Gastroparesis GERD Fatty liver Hepatobiliary disease	Pulmonary aspiration, delayed gastric emptying, PONV? Rapid sequence intubation, risk of pulmonary aspiration Altered liver function Cholelithiasis, biliary obstruction, hepatic insufficiency
Renal	Increased GFR, RBF	Predisposition to renal insufficiency, greater fluid requirements, altered clearance of drugs; consider discontinuation of ACE inhibitors and/or diuretics
CNS	Hypersensitivity to CNS depressants Cerebrovascular disease	Hypersomnolence, central apnea, reduced drug requirement Decreased cerebral blood flow
Hematologic	Polycythemia Thrombosis Poor wound healing	Increased viscosity, poor rheology, platelet aggregation DVT and pulmonary embolus Wound infections

CHF, congestive heart failure; CNS, central nervous system; GERD, gastroesophageal reflux disease; LV, left ventricular.

Figure 6.2. Pulmonary changes in obesity.

The incidence of obstructive sleep apnea (OSA), also termed sleep-disordered breathing, in the morbidly obese may be as high as 90% and may be undiagnosed in most cases. The strong association of severe obesity with OSA, altered lung mechanics, and increased oxygen consumption predispose this patient population to rapid development of hypoxemia during periods of apnea (Fig. 6.2). The presence of OSA may signify a higher likelihood of difficult ventilation and/or intubation.

Apnea, which usually lasts 10 seconds or longer, leads to hypoxemia and hypercapnia. The effects of long-term OSA lead to the development of the “obesity-hypoventilation” or “Pickwickian” syndrome, characterized by obesity, hypoxemia, hypercarbia, daytime hypersomnolence, polycythemia, pulmonary hypertension, and right heart failure. Ischemic heart disease and cerebrovascular disease may be associated. There is evidence to indicate that preoperative continuous positive airway pressure (CPAP) treatment may reduce or even reverse some of the cardiovascular changes observed with severe OSA. There also is emerging evidence for the utility of preoperative polysomnography in select patients to identify the presence and severity of OSA.

Renal system

There is an increase in renal blood flow (RBF), glomerular filtration rate (GFR), and tubular reabsorption in the obese state. Glucose intolerance often presents as proteinuria in obese patients. Measured GFR may be increased as much as 40%. This increased RBF and GFR may be related and proportional to the relative increase in blood volume and cardiac output seen in the obese state. As a result, the clearance of renally excreted drugs may be increased. In the perioperative period,

the obese patient may exhibit an increased susceptibility to hypovolemia and prerenal azotemia, especially in the setting of diuretic, angiotensin-converting enzyme (ACE) inhibitor, or nonsteroidal anti-inflammatory drug (NSAID) therapy and/or the presence of cardiac impairment.

Discontinuation of pharmacologic agents that may reduce GFR and RBF may be warranted to minimize the risk of worsening renal insufficiency or precipitating acute renal failure in the perioperative setting. This highlights the importance of volume loading and maintaining euvolemia in these patients throughout the perioperative period to prevent acute tubular necrosis. It also is important to mention that the intraoperative fluid requirements may be significantly greater than calculated for normal-weight patients. The presence of any systolic or diastolic cardiac dysfunction also may require specific adjustment in fluid administration.

Gastrointestinal system

Based on early studies, obesity was considered a risk factor for gastrointestinal reflux and pulmonary aspiration. This concept has been challenged recently, and the increased incidence of a difficult airway and its management may be a significant contributing factor to the risk of aspiration in this population. Nonetheless, the reverse Trendelenburg position may be used during induction and emergence to minimize cephalad displacement of the diaphragm due to intra-abdominal pressure, thereby reducing aspiration risk and improving lung volumes and respiratory mechanics. The pharmacologic use of H₂ antagonists, proton pump inhibitors, and gastric motility agents has been studied in detail. The administration of these agents may reduce the complications of aspiration but most likely does not reduce the risk.

The presence of hepatobiliary disease in the obese state is clearly increased compared with nonobese patients. In fact, fatty infiltration of the liver and cholelithiasis are common findings in this population. Abnormal cholesterol metabolism may predispose obese patients to hepatic dysfunction and postoperative cholelithiasis.

Induction of anesthesia and airway management

Increasing the preparation time for the management of a potentially difficult airway is a crucial but often overlooked safety factor, particularly during the induction of anesthesia in the obese patient. Several specific maneuvers have been shown to provide optimization during the period of nonhypoxic apnea. During the critical preoxygenation phase of induction, it is recommended that the patient be placed in a 30° reverse Trendelenburg or sitting position, which has been shown to be more effective than preoxygenation in the supine position.

It is important to note that the use of intubating laryngeal mask airway devices has been shown to be as rapid and effective in securing the airway as conventional direct laryngoscopy in obese patients. Early placement of a laryngeal mask airway prior to muscle paralysis may represent an even quicker and more effective modality for establishing adequate ventilation before intubating the trachea. Such devices improve success rates when attempting ventilation prior to securing the airway and should be immediately available during induction. The immediate availability of additional airway adjuncts, such as an Eschmann stylet, bougie, or a fiberoptic bronchoscope, may further improve success rates in the management of the difficult airway.

Adequate prophylaxis of pulmonary aspiration (aim of gastric volume < 25 ml and pH > 2.5), including metoclopramide and H₂ receptor blockers, may be considered. Rapid sequence induction with cricoid pressure may often be selected in the presence of a normal anticipated airway. Difficult venous access and positioning of extremities with adequate padding also should be considered. In addition, regional anesthesia may be technically difficult in obese patients.

Drug administration

The increased cardiac output and relative hypervolemic state in obesity necessitate changes in drug dosing during the induction and maintenance of anesthesia. The volume of distribution of many of the lipophilic anesthetic agents, such as propofol, thiopental, benzodiazepines, and opioids, is observed to be much greater in obese than nonobese patients because of a greater distribution into the extravascular compartment, mainly adipose tissue. Accordingly, recommended induction or loading doses of lipophilic agents are calculated based on total body weight (TBW) and not ideal body weight (IBW) to achieve an effective plasma concentration.

The pharmacokinetics of remifentanyl are similar in obese and lean individuals, and this agent may be an excellent short-acting alternative to other opioids for the obese patient. The

unique and predictable metabolism of remifentanyl also may be exploited in the setting of renal or hepatic dysfunction because of the renal- and hepatic-independent hydrolysis of this ester compound (metabolized by esterases). In summary, the rational basis for the administration of lipophilic induction agents should be based on TBW because of a proportional increase in the volume of distribution with increased body mass.

In contrast, less lipophilic compounds, such as the nondepolarizing neuromuscular blocking agents, display negligible differences in the volume of distribution in obese versus nonobese patients; therefore, loading doses of cisatracurium and rocuronium by IBW are recommended. This is primarily a function of the relatively homogenous distribution of hydrophilic agents into the plasma compartment, with limited drug distribution into the extravascular fat depot. However, the administration of succinylcholine (hydrophilic) deserves particular attention in that the pseudocholinesterase activity is higher in obese patients, necessitating dosages (1–2 mg/kg) based on TBW and not IBW. Conversely, the loading doses of hydrophilic agents such as muscle relaxants, local anesthetics, and antibiotics should be based on IBW, given their relative confinement to the plasma compartment. With respect to repeated administration of both lipophilic and hydrophilic compounds, an assessment of the patient's IBW and overall renal status should determine dosage requirements. Pharmacokinetic parameters of commonly used anesthetic drugs are outlined in [Table 6.3](#).

Drug elimination is determined primarily by clearance mechanisms, with renal excretion being the most dominant. Repeated administrations or infusion doses of a drug must take into account the increase in GFR in obesity, the presence of renal insufficiency, or the possibility of changing renal function during the perioperative period. Repeated administration or infusion of both lipophilic and hydrophilic compounds therefore should be dictated by the patient's overall renal function (taking into account GFR and renal dysfunction) and IBW (not TBW).

The ideal choice of inhalational anesthetic has been studied prospectively in randomized controlled trials. Desflurane and sevoflurane for maintenance anesthesia have been suggested as the inhaled agents of choice because of their rapid and consistent recovery profile, better hemodynamic control, reduced incidence of postoperative nausea and vomiting (PONV), and overall cost-effectiveness and hospital discharge time compared with isoflurane- or propofol-based techniques. A comparison of the recovery profiles of desflurane versus sevoflurane has shown no clinically significant differences in recovery or emergence times.

Intraoperative considerations

Several methods to improve intraoperative oxygenation in obese patients have been evaluated. Specifically, large tidal volume ventilation has been investigated, and studies indicate that volumes >13 ml/kg do not confer any additional benefit in oxygenation or ventilation. In fact, the risk of volutrauma,

Table 6.3. Pharmacokinetic parameters of the main anesthetic drugs given to obese and nonobese subjects

Drug	Volume of distribution (L)		Volume of distribution (L/kg TBW)		Total body clearance (ml/min)		Terminal elimination half-life		Dose recommendations
	Control	Obese	Control	Obese	Control	Obese	Control	Obese	
Thiopental			1.4	4.7**	197.2	416.3*	6.3 h	27.8 h**	LD reduced
Propofol	13.0	17.9	2.09	1.8	28.3	24.3	4.1	4.05	LD and MD based on TBW
Diazepam	90.1	291.9*	1.533	2.81*	1600	2300	40 h	95 h**	LD adjusted to TBW, MD adjusted to IBW
Lorazepam	77	131*	1.23	1.25	4000	6000**	23.9 h	33.5 h**	LD adjusted to TBW, MD adjusted to IBW
Midazolam	114	311**	1.74	2.66**	530	472	2.27 h	5.94 h**	LD adjusted to TBW, MD adjusted to IBW
Atracurium	8.5	8.6	0.141	0.067	404	444	19.8 min	19.7 min	Dose calculated on TBW

Source: Casati A, Putzu M. Anesthesia in the obese patient: pharmacokinetic considerations. *J Clin Anesth* 2005; 17(2):134–145.

with alveolar injury and pulmonary edema, is a risk of high tidal volume ventilation. Vital capacity or recruitment maneuvers represent an important intraoperative strategy in improving oxygenation. The administration of PEEP also has been examined. Levels up to 15 cm H₂O have been shown to improve FRC and oxygenation; therefore, PEEP may be a more effective strategy than high tidal volume ventilation to improve oxygenation. The beneficial effects of PEEP in increasing intra-alveolar pressure also may reduce lung water content and pulmonary edema. However, the hemodynamic effects of PEEP have to be considered, especially in the setting of surgically induced pneumoperitoneum during laparoscopy and the reverse Trendelenburg position. The avoidance of nitrous oxide (or < 50%) during anesthesia may be beneficial in maintaining oxygenation.

During laparoscopy, the effects of intra-abdominal pressure may deleteriously affect respiratory mechanics and the ventilation–perfusion ratio in the obese state. The abundance of abdominal tissue and cephalad displacement of the diaphragm from pneumoperitoneum, surgical retraction, abdominal packing, or the Trendelenburg position may exert a negative effect on FRC and total lung capacity. Ventilation–perfusion mismatch may worsen in this situation because of compromised diaphragmatic excursion, leading to hypercarbia and hypoxemia. Carbon dioxide absorption from intra-abdominal insufflation may further worsen hypercarbia, acidosis, pulmonary vascular resistance, and right ventricular strain.

Postoperative considerations

The increased prevalence of OSA, increased central sensitivity to respiratory depressants, reduced cardiopulmonary reserve,

and risk of thromboembolic complications all may contribute to greater morbidity and mortality in obese patients in the perioperative period. The administration of bilevel positive airway pressure (BiPAP) or CPAP in this patient cohort has proved to be an effective modality to prevent postoperative atelectasis and hypoxia. Early treatment and recognition of postoperative hypoxemia with noninvasive positive pressure ventilation support also may decrease the incidence of respiratory failure, intensive care unit admission, pneumonia, infection, and sepsis.

Obesity is a major risk factor for mortality from acute pulmonary embolism, usually occurring during the postoperative period. The perioperative stress response, as evident by elevated cortisol, antidiuretic hormone, and circulating catecholamines, may further heighten the risk in a group already predisposed to thromboembolism and sudden death, particularly in the setting of immobility. Preoperative administration of heparin subcutaneously and every 12 hours thereafter has been shown to markedly reduce the incidence of deep venous thrombosis (DVT). Low molecular weight heparin at a dosage of 30 mg every 12 hours also has been shown to reduce the incidence of DVT without an increase in bleeding complications.

Postoperative pain management

The physiologic perturbations in obese patients predispose this group to a markedly increased incidence of postoperative cardiopulmonary complications, which has provided the impetus for the generally accepted multimodal and opioid-sparing pain management techniques aimed at minimizing postoperative respiratory depression and improving recovery times.

Consistent with this approach is the administration of NSAIDs, the infiltration of local anesthetics at incision sites, and the use of opioid-free neuraxial epidural analgesia, all of which have been shown to be safe and effective options in reducing opioid requirements and improving pulmonary function postoperatively. More recently, the perioperative administration of pharmacologic adjuncts such as *N*-methyl-*D*-aspartate (NMDA) receptor antagonists (ketamine) or α_2 -agonists (dexmedetomidine) has shown great promise in decreasing overall opioid consumption in the postoperative period when initiated intraoperatively. Collectively, the aforementioned strategies may be used to deliver more effective perioperative pain management in addition to reducing overall cardiopulmonary morbidity and mortality in this high-risk population.

Chronic renal failure

Edward A. Bittner

It is estimated that 8 million Americans have chronic renal failure (CRF), as defined by an estimated glomerular filtration rate (GFR) <60 ml/min/1.73 m² for at least 3 months. Loss of renal function hampers the ability to handle fluids and acid loads, to eliminate potassium and other electrolytes, and to excrete and/or metabolize medications, including anesthetics. Patients with CRF are at high risk for progression of their renal disease in the perioperative period that may be precipitated by otherwise seemingly mild hemodynamic perturbations, nephrotoxins, and hypovolemia. End-stage renal disease (ESRD) is treated by either dialysis or transplantation. A widely used classification divides CRF into stages based on estimated GFR (Fig. 7.1). These stages help facilitate clinical practice guidelines and management approaches.

Etiology

Any disorder that permanently destroys the nephrons may result in chronic renal failure. Common causes of CRF are diabetic nephropathy, hypertensive nephrosclerosis, chronic glomerulonephritis, tubulointerstitial disease, renovascular

disease, and polycystic kidney disease. The cause of the CRF has an impact on management. Patients with primary renal disease (e.g., IgA nephropathy) likely are younger and have good cardiopulmonary reserve. Older patients with CRF due to diabetes mellitus or hypertension also may suffer from diffuse atherosclerosis and heart disease.

Pathophysiology

Azotemia refers to retention of nitrogenous waste products as renal insufficiency develops. *Uremia* refers to more advanced stages of renal insufficiency in which complex, multiorgan system derangements manifest clinically. It results from the inability of the kidney to regulate the volume and composition of extracellular fluid and to excrete waste products. The blood urea nitrogen (BUN) may serve as a marker for uremia but does not cause all the manifestations of the syndrome, and may be elevated independently of renal failure.

Fluid and electrolyte imbalance

Fluid imbalance

Fluid balance in ESRD is difficult to manage because the number of functioning nephrons is too small to either fully concentrate or dilute the urine. A narrow margin for error exists in fluid management, alternating between hypo- and hypervolemia. As little as a positive 500 ml fluid balance may result in hypervolemia. Excessive fluid and sodium intake quickly results in hypervolemia, pulmonary edema, and hypertension.

Metabolic acidosis

Failure to excrete nonvolatile acids (sulfates, phosphates) results in a chronic anion gap metabolic acidosis. In the preoperative period, this metabolic acidosis usually is well compensated (respiratory) but is associated with a markedly diminished buffer base. Minor superimposed acidosis or bicarbonate loss can quickly lead to profound acidemia. Intraoperatively, the metabolic acidosis is unmasked with standard mechanical ventilation. Postoperatively, residual anesthetics and opioids may cause CO₂ retention which will worsen pre-existing acidosis. In addition, opioid-induced narcosis may

Figure 7.1. Classification of chronic kidney disease: normal >90 , mild = 60–89, moderate = 30–59, severe = 15–29, ESRD/dialysis <15 . Values are GFR (glomerular filtration rate) in ml/min/1.73 m².

Table 7.1. Factors contributing to hyperkalemia in CRF

Potassium intake

Constipation
K ⁺ -sparing diuretics
Angiotensin-converting enzyme inhibitors
Heparin

cause CO₂ retention with worsening metabolic acidosis and hyperkalemia.

Electrolyte imbalance

Patients with CRF may present with a wide range of serum K⁺ levels. CRF patients can generally maintain potassium excretion at near-normal levels as long as aldosterone secretion and distal tubule flow are maintained. Acute hyperkalemia suppresses cardiac electrical conduction and may result in asystole. Electrocardiographic (ECG) manifestations of hyperkalemia (prolonged PR interval, widened QRS, peaked T waves) are helpful but often not present. Conditions and drugs that can induce acute hyperkalemia in patients with CRF are summarized in Table 7.1. Hypokalemia, although uncommon in patients with CRF, may occur as a result of the effects of malnutrition and aggressive dialysis. Acute hypokalemia lowers the arrhythmia threshold, and these arrhythmias may be refractory to therapy unless hypokalemia is corrected. Caution regarding potassium repletion is essential in patients with CRF, as acute hyperkalemia easily may result.

Hypermagnesemia may result from inadequate dialysis or ingestion of magnesium-containing antacids or cathartics. It is manifested by skeletal weakness and potentiation of nondepolarizing muscle relaxants. Calcium administration may antagonize the effects of hypermagnesemia.

CRF results in impaired phosphate excretion and decreased vitamin D₃ synthesis, resulting in hyperphosphatemia and hypocalcemia. In response, parathyroid hormone is released, resulting in bone resorption and extracellular calcium release (secondary hyperparathyroidism). Elevation of the calcium phosphate product may result in metastatic calcification (calciophylaxis), especially in blood vessels and skin. *Renal osteodystrophy* refers to the changes in mineral metabolism and bone structure that occur in CRF. It manifests as skeletal and joint deformity, osteomalacia, and spontaneous fractures. Treatment of hyperphosphatemia, hypocalcemia, and renal osteodystrophy consists of administration of vitamin D and calcium,

phosphate binders, and dietary phosphate restriction. Parathyroidectomy with autograft of parathyroid tissue may be used to treat severe secondary hyperparathyroidism.

Cardiovascular disease

Cardiovascular disease is the leading cause of death in patients with CRF. The increased prevalence of coronary artery disease in patients with CRF derives from both traditional and CRF-related risk factors. CRF-related risk factors include chronic volume overload, anemia, hyperparathyroidism, and chronic inflammation. The combination of hypertension and disordered glucose and fat metabolism in patients results in an accelerated form of atherosclerosis. Conduction blocks also may be encountered in patients with CRF as the result of deposition of calcium in the conduction system.

Abnormal cardiac function, secondary to ischemic myocardial disease and/or left ventricular hypertrophy combined with fluid overload and the increased demands imposed by anemia and hypertension, makes these patients particularly prone to congestive heart failure. In addition, a unique form of pulmonary edema may occur in the absence of fluid overload in patients with ESRD. This “low-pressure” pulmonary edema is the result of increased permeability of alveolar capillary membranes, which usually responds well to dialysis.

Pericarditis is a potentially fatal complication that may develop with uremia. It occurs more often in underdialyzed patients than in patients who undergo regular dialysis. The diagnosis should be considered in any patient with advanced CRF who develops unexplained hypotension. Chest pain or ST elevations characteristic of other causes of pericarditis may not be present, and a friction rub may not be audible if a large effusion is present.

Pulmonary function

Patients with CRF have an increased risk of postoperative pulmonary complications. Low oncotic pressure from hypoalbuminemia in the presence of fluid overload may result in pulmonary edema. Decreased muscle mass and decreased surfactant reduce lung volumes and increase the risk of atelectasis. Impaired immune function results in increased susceptibility to pneumonia. Patients with CRF may depend on increased minute ventilation to compensate for metabolic acidosis, resulting in an increased potential for respiratory failure.

Neurologic alterations

Central nervous system dysfunction from uremic encephalopathy may range from subtle personality changes to drowsiness, asterixis, myoclonus, and seizures. Neurologic signs and symptoms depend on the rapidity of progression of uremia rather than on the absolute level of BUN or serum creatinine. Peripheral neuropathy (“stocking-and-glove” distribution) is common and is an indication for hemodialysis. Autonomic neuropathy likely coexists with peripheral neuropathy and manifests as

orthostatic hypotension, impaired circulatory response to anesthesia, potential for silent ischemia, and impaired gastric emptying.

Hematologic alterations

Anemia

CRF frequently is associated with a normochromic, normocytic anemia (hematocrit 25%–28%) due to multiple factors, including decreased erythropoietin production, decreased red cell survival due to dialysis, blood loss via the gastrointestinal (GI) tract, frequent blood sampling, and iron or vitamin deficiencies. Compensatory mechanisms for the chronic anemia include increased cardiac output and a rightward shift of the oxyhemoglobin curve. Treatment of CRF patients with recombinant erythropoietin decreases transfusion requirements, reduces mortality, and improves their quality of life. The anemia of CRF usually is well tolerated for routine/elective surgeries, and the target hemoglobin can be reached through erythropoietin administration and iron supplementation. Transfusion is appropriate for patients with CRF when extensive surgery is planned and there is a potential for excessive blood loss.

Uremic coagulopathy

The pathogenesis of uremic bleeding is multifactorial, but it is caused predominately by alterations in platelet function, including diminished platelet degranulation and reductions in platelet adenosine diphosphate (ADP) and serotonin stores. CRF also results in impaired activation of glycoprotein IIb/IIIa receptors on the platelet membrane, resulting in reduced binding to von Willebrand factor and fibrinogen. Red blood cells improve platelet function through ADP release, inactivation of prostacyclin, and enhancement of platelet–vessel wall interactions. Consequently, anemia is an additional contributor to platelet dysfunction.

The resulting coagulopathy in patients with CRF increases the risk of surgical bleeding and predisposes to GI bleeding, intracerebral hemorrhage, and hemorrhagic pericardial effusion. Diagnosis of uremic coagulopathy may be difficult because the standard coagulation tests – prothrombin time, partial thromboplastin time, and platelet count – usually are normal in patients with CRF. Interventions to reduce bleeding in patients with CRF include a hematocrit goal of 30% for major operations; administration of recombinant erythropoietin, desmopressin acetate (DDAVP), cryoprecipitate, or conjugated estrogens; and intensification of the dialysis regimen using heparin-free or low-dose heparin hemodialysis.

Malnutrition

Malnutrition is prevalent among patients with CRF as a result of multiple factors, including decreased nutritional intake, increased protein catabolism, and dialytic losses. A strong association exists between malnutrition and increased morbidity

and mortality in this population. In addition, nutritional status has a well-established impact on wound healing, infection prevention, and recovery following serious illness. A low BUN level does not necessarily indicate that a patient is well dialyzed but may reflect poor protein intake.

Gastrointestinal dysfunction

Urea acts as a mucosal irritant, and uremic enteropathy may result in inflammation of the entire GI tract. Peptic ulcer disease is prevalent in patients with CRF, and occult GI bleeding may occur. Nausea and vomiting are common in patients with severe uremia and predisposes to an increased risk of regurgitation and aspiration with anesthesia.

Infections

Infections are second to cardiovascular disease as the leading cause of death in patients with CRF. The frequency and severity of infections in this population are the result of leukocyte and immune dysfunction caused by uremia, diabetes mellitus, malnutrition, and the inflammatory response to dialysis. In addition, there is an increased exposure to bacterial pathogens through dialysis grafts and catheters, resulting in increased frequency of sepsis, impaired wound healing, dehiscence, fistulas, and pressure ulcers. The diagnosis of infection may be difficult because many patients with ESRD have baseline hypothermia and bacteremia (which may not be associated with fever). The incidence of hepatitis B and C in patients on chronic dialysis is high because of frequent exposure to blood products. All patients on dialysis should be treated as potentially infected, and medical personnel should take precautions against exposure.

Pharmacologic alterations

The pharmacokinetics of many anesthetic and perioperative drugs are altered in CRF. These alterations may be the result of changes in compartment volumes, electrolytes, pH (acidemia resulting in a higher percentage of nonionized drug), decreased serum protein concentration (resulting in increased bioavailability of protein-bound drugs), impaired biotransformation, and rates of excretion. Lipid-soluble drugs are poorly ionized and undergo metabolism by hepatic transformation to water-soluble forms before elimination by the kidney. Ionized drugs tend to be eliminated unchanged by the kidney, and their duration of action may be prolonged with CRF. Respiratory depression is more common with opioids and sedative agents. An altered pharmacodynamic effect also should be anticipated in patients with CRF.

The duration of action of many drugs administered by bolus or short-term infusion is determined by redistribution not elimination. Consequently, the loading dose does not need to be altered significantly in CRF (unless there is altered pharmacodynamic effect). However, with repeated dosing or long-term infusion, the duration of action depends on elimination; therefore, maintenance doses of drugs with significant renal

Table 7.2. Pharmacologic considerations for commonly used perioperative drugs in patients with CRF

Drug Class	Pharmacokinetics	Considerations
Inhalational Anesthetics Lipid Soluble Benzodiazepines	Eliminated primarily by the lungs Increased free fraction in CRF	Sevoflurane has potentially nephrotoxic metabolite (compound A) Potentiated clinical effect in CRF Certain metabolites are pharmacologically active and accumulate with repeated dosing Exaggerated clinical effect in CRF. Need to reduce induction dose
Barbiturates	Free fraction of induction dose is almost doubled in patients with CRF	Effects are not prolonged in CRF
Propofol	Rapid, extensive hepatic metabolism. Pharmacokinetics unchanged in CRF	CRF does not alter clinical effects CFR does not alter clinical effects
Etomidate	Increased free fraction in CRF	
Ketamine	Redistribution and hepatic metabolism largely responsible for termination of anesthetic effects. Minimal change in free fraction in CRF.	
Opioids	Primarily metabolized in liver	May have increased and prolonged effect in CRF Active metabolites may prolong action with chronic administration: Morphine– 6-glucuronide (morphine) has potent analgesic and sedative effects. Normeperidine (meperidine) has neurotoxic effects. Hydromorphone –3-glucuronide (hydromorphone) can cause cognitive dysfunction and myoclonus. Fentanyl has no active metabolites
Ionized Drugs Muscle Relaxants	Standard dose of succinylcholine raises serum K+ 0.5–0.8 mEq/L which is unchanged in CRF Many nonpolarizing NMBs result in prolonged effects due to reliance on renal excretion	Succinylcholine is not contraindicated in CRF if the serum K+ is not elevated. Cisatracurium, mivacurium, rocuronium are preferable in CRF.
Cholinesterase inhibitors	Decreased elimination in CRF and half life is prolonged	Half life prolongation is similar or greater than the duration of blockade from long acting NMBs so recurarization is rarely seen Increased risk of toxicity in CRF
Digoxin	Excreted in urine	
Vasoactive Drugs Catecholamines		Catecholamines with a-adrenergic effects constrict renal vasculature and may reduce renal blood flow Toxicity from thiocyanate accumulation is more likely in CRF Loading dose is unchanged but maintenance doses are substantially reduced
Sodium nitroprusside	Metabolized by the kidney and excreted as thiocyanate	
Antibiotics	Penicillins, cephalosporins, aminoglycosides, vancomycin are predominantly dependent on renal elimination	

NMB, neuromuscular blocker.

Table 7.3. Preoperative considerations for patients with CRF

History	Goal is to detect comorbid conditions that might adversely impact morbidity and mortality Etiology of renal disease should be elucidated and renal function should be estimated Based of ACC/AHA guidelines, patients with a Cr > 2 mg/dl have at least an intermediate pretest probability of perioperative cardiovascular risk. This warrants detailed CV surveillance before intermediate or high-risk surgery Elective surgery postponed pending resolution of acute processes
Physical Exam	Thorough physical focused on identifying stigmata of CRF, e.g. HTN, elevated JVP, crackles (volume overload), malnutrition, ecchymoses (platelet dysfunction), pallor (anemia)
Labs	ECG and screening lab tests including CBC, electrolytes and coagulation panel
Preoperative Optimization Preoperative Hemodialysis	Elective surgery should be conducted in the setting of optimized acid/base balance, euolemia and k+ management with preoperative dialysis within 24 hours of the procedure. HD should be avoided on the day of surgery due to potential problems with rebound anticoagulation, fluid shifts, hypokalemia, hypoxemia and disequilibrium
Transfusion	Transfusion is appropriate for patients with Hb 8–10 g/dL when extensive surgery is planned and there is a potential for excessive blood loss. Blood transfusion may not be indicated for patients with stable chronic anemia and Hb >= 8 g/dL undergoing minor procedures.
Correction of coagulopathy	Maintain higher Hb (with erythropoietin or transfusion), intensify dialysis regimen, administer DDAVP, cryoprecipitate and conjugated estrogens
Control of hypertension	Blood pressure control may be challenging in patients with CRF. Proceeding with elective surgery with moderate chronic hypertension is acceptable but severe or labile BP should be controlled preoperatively
Treatment of hyperkalemia	Increased risk for patients who present for emergency surgery. Treat with CaCl ₂ , NaCO ₃ , insulin/dextrose, kayexalate, dialysis
Prevention of contrast induced nephropathy	For patients not on HD it may be prudent to postpone major elective surgery for a few days after contrast media exposure. Treatment with NAC and sodium HCO ₃ infusion before contrast administration may prevent contrast induced nephropathy

ACC, American College of Cardiology; AHA, American Heart Association; CBC, complete blood count; CV, cardiovascular; Hb, hemoglobin; JVP, jugular venous pressure.

Table 7.4. Intraoperative considerations for patients with CRF

Premedication	Minimize premedication because of susceptibility to excess sedation and respiratory depression Histamine H ₂ blockers, metoclopramide, citric acid/sodium citrate to reduce gastric acidity and promote emptying
Monitors	ECG, BP cuff, pulse oximeter, capnograph, and thermometer. Invasive monitoring as indicated by comorbid conditions and surgical procedure. No BP cuff on arm with AV fistula or shunt Strict asepsis for all invasive procedures Urinary catheters should not be placed in anuric patients because they may provide a portal for infection
Positioning	Extra care in positioning because these patients are prone to fractures from renal osteodystrophy Patients with sensory neuropathy may not be able to report positional discomfort
Induction	Dose of induction drugs may need to be reduced and rate of administration slowed to avoid hypotension Anticipate hypotension; manage with appropriate preloading of fluid or vasopressors Gastric emptying is delayed in uremic patients; manage as increased risk of aspiration Serum K ⁺ should be checked before administration of succinylcholine
Maintenance	Ideal technique controls BP with minimal effect on cardiac output Sedative and anesthetic doses should be reduced Avoid renally excreted NMBs
Fluids	Intraoperative fluid and blood administration should not be so restrictive as to permit inadequate organ perfusion, even if postoperative dialysis is required Intraoperative dialysis occasionally is required
Ventilation	Consider controlled ventilation because spontaneous ventilation may result in hypercarbia and exacerbate preexisting acidemia and increase K ⁺ concentration
Emergence	Anticipate delayed emergence, aspiration, hypertension, respiratory depression, and pulmonary edema Ensure adequate reversal of neuromuscular reflexes
Regional anesthesia	Regional anesthesia may be used in patients with CRF (e.g., brachial plexus block for AV shunt insertion/revision) Preexisting neuropathies should be determined and documented Coagulopathy, which may be present despite normal clotting studies, should be evaluated prior to regional anesthesia Spinal/epidural anesthesia has been used for renal transplantation. It should be used with caution because patients with autonomic neuropathy have increased risk of hypotension with sympathetic block.

AV, atrioventricular; BP, blood pressure; NMB, neuromuscular blocker.

excretion should be reduced. Pharmacologic considerations for commonly used perioperative drugs in patients with CRF are summarized in Table 7.2.

Perioperative management

Preoperative, intraoperative, and postoperative considerations for patients with CRF are outlined in Tables 7.3, 7.4, and 7.5.

Dialysis and transplantation

Hemodialysis uses an artificial semipermeable membrane that separates the patient's blood from the dialysate and allows exchange of solutes by diffusion. Vascular access and anticoagulation often are required. Blood samples taken immediately after hemodialysis may be inaccurate, because the redistribution of fluid and electrolytes takes about 6 hours. Complications of hemodialysis include arteriovenous fistula infection and thrombosis, hypotension, pericarditis, and hypoxemia. Dialysis "disequilibrium syndrome" may occur if fluid and electrolyte shifts are too rapid. Symptoms are weakness, nausea/vomiting, and, more rarely, convulsions and coma.

Peritoneal dialysis uses the patient's peritoneum as the exchange membrane, with the dialysate infused into the peritoneal cavity via an indwelling catheter. Advantages, compared with hemodialysis, include less hypotension or disequilibrium and no need for anticoagulation. However, peritoneal dialysis is less efficient than hemodialysis. Continuous renal

replacement therapies involve either dialysis (diffusion-based solute removal) or filtration (convection-based solute and water removal) operating in a continuous mode. The major advantage is a slower rate of solute/fluid removal that improves hemodynamic stability compared with hemodialysis. Renal transplantation is the treatment of choice for ESRD. A successful renal transplantation improves the quality of life and survival of patients.

Table 7.5. Postoperative considerations for patients with CRF

Monitoring	Monitor for frequent causes of postoperative morbidity (cardiovascular complications, pulmonary edema, hyperkalemia, etc.)
Fluid management	Should consist of isotonic fluids and dextrose until patient can take by mouth Hypertension is a common postoperative problem exacerbated by fluid overload. For those not on dialysis, diuretics and short-acting antihypertensives are effective. Postoperative dialysis may be needed
Laboratory studies	Check hematocrit, electrolytes, BUN, creatinine, ECG (signs of hyperkalemia, ischemia), and chest radiographs (pulmonary edema) Serum creatinine kinase levels are mildly elevated in the absence of myocardial injury in a substantial number of patients with ESRD, but the myocardial (MB) fraction is usually normal. Troponin I is a specific marker of myocardial injury in ESRD, whereas troponin T should not be used.

Anatomy and physiology

The liver is the largest solid organ in the body, weighing about 1500 g. It has two lobes, the larger right and the smaller left. The right lobe has two additional lobes, the caudate and the quadrate lobes. Blood supply to the liver is about 1500 ml/min (25% of cardiac output), about 75% from the portal vein and the rest from the hepatic artery. However, each blood vessel supplies about 50% of the liver's oxygen requirements. Normal portal vein pressure is about 10 mm Hg, and normal hepatic artery pressure is arterial. The liver is supplied by sympathetic nerve fibers (T6–11), which when stimulated result in vasoconstriction of the hepatic artery, thereby decreasing the hepatic blood flow.

Hepatic blood flow is decreased by any cause that lowers systemic blood pressure and cardiac output. These causes include general and regional anesthesia (spinal/epidural), volatile inhalation agents, positive pressure ventilation (and positive end-expiratory pressure [PEEP]), hypoxemia, β -blockers, and α_1 -agonists. The liver performs several important functions in the body, including metabolic functions (carbohydrate, fat, protein, and drug metabolism), bile secretion, bilirubin excretion, albumin production, ammonia excretion, and synthesis of all the clotting factors, except factor VIII.

Liver cirrhosis

Care of the patient with liver disease undergoing anesthesia and surgery requires awareness that liver disease is, in reality, a multiorgan disorder that causes a variety of pathophysiologic derangements. Causes of chronic liver disease are multifactorial (Table 8.1) but, regardless of the cause, often may progress to cirrhosis. Cirrhosis is characterized by hepatic cell death, fibrosis, and the formation of regenerative nodules.

Cirrhosis is essentially irreversible and leads to important physiologic disturbances. Portal hypertension is common in patients with significant chronic liver disease and results from increased portal blood flow and/or intrahepatic resistance. It is associated with ascites, portosystemic shunts, hepatic encephalopathy, and splenomegaly. Portosystemic shunts most commonly include esophageal varices or hemorrhoids.

Risk stratification of the cirrhotic patient

A basic assessment of the extent of liver failure is necessary to more fully understand its impact on anesthetic and perioperative management, and on patient outcomes from surgery. Two liver failure classification systems exist for assessing prognosis. The Child-Turcotte-Pugh (CTP) classification is based on five variables and stratifies patients by score to determine their disease prognosis (Table 8.2). The greater the CTP score, the worse the prognosis. The Model for End-Stage Liver Disease (MELD) and its pediatric equivalent (PELD) are used for allocating donor livers for transplantation. The MELD is a statistical model based on serum bilirubin, serum creatinine, and the international normalized ratio (INR) to determine the severity of liver disease and the need for transplantation.

Effects of liver disease

Gastrointestinal

Portal hypertension occurs when pressure in the portal vein is greater than 10 mm Hg. The high portal pressure leads to the development of portovenous collaterals (Fig. 8.1a, b), which commonly are found at the following four sites: gastroesophageal, periumbilical, retroperitoneal, and hemorrhoidal.

Table 8.2. Child-Turcotte-Pugh classification of liver failure

	Points (per variable)		
	1	2	3
Serum bilirubin (mg/dl)	<2	2–3	>3
Serum albumin (g/dl)	>3.5	2.8–3.5	<2.8
Prolongation of PT (sec/control) ^a	<4	4–6	6
Ascites	None	Mild	Moderate
Encephalopathy	None	Minimal	Advanced
Interpretation			
Class	Points	Mortality risk, 3 mo–1 y (%)	
A	5–6	4–10	
B	7–9	14–31	
C	10–15	51–76	

^a Nutrition (excellent, good, poor) was replaced with prothrombin time by Pugh’s modification of the Child-Turcotte classification.

Modified from Rowe P, Mandell MS. Perioperative hepatic dysfunction. In: *Anesthesia Secrets*. Philadelphia: Hanley and Belfus; 2002:289–290, and Garg RK. Anesthetic considerations in patients with hepatic failure. *Int Anesthesia Clin* 2005; 45–63.

Ascites is a hallmark of decompensated liver cirrhosis and is caused by alterations in portal blood flow dynamics, activation of the renin–angiotensin–aldosterone system, and reduction in plasma oncotic pressure. The primary treatment for ascites is sodium and water restriction, administration of diuretics, and abdominal paracentesis, which may lead to intravascular fluid depletion.

Esophageal variceal bleeding is a potentially lethal complication of cirrhosis. Treatment includes β -blockers, vasopressin, somatostatin, variceal banding, sclerotherapy, and transjugular portosystemic shunting. However, portosystemic shunting may cause or worsen existing hepatic encephalopathy. Significant portosystemic shunting also decreases steroid hormone clearance because of impaired extraction via enterohepatic circulation of the unbound steroid molecules. These steroids, specifically androgens, undergo peripheral aromatization to estrogen. Elevated circulating estrogen is responsible for the gonadal and pituitary suppression and feminization commonly seen in advanced liver disease.

Patients with liver disease usually have severe metabolic derangements, including hypoglycemia, hypokalemia, hyponatremia, hypomagnesemia, and hypoalbuminemia.

Hemodynamic

Patients with chronic liver dysfunction and cirrhosis commonly have a hyperdynamic circulation (Table 8.3) with a low peripheral vascular resistance and an increased cardiac index. Hyperdynamic circulation and elevated cardiac output are attributed to increased sympathetic nervous system activity, increased blood volume and preload, and reduced systemic vascular resistance. Often cirrhotic patients develop signs of high-output heart failure (also known as “cirrhotic cardiomyopathy”) including impaired cardiac contractility, conduction abnormalities, impaired excitation–contraction coupling, and

(A)

(B)

General circulation

Figure 8.1. (A) The liver in relation to the gallbladder and stomach. (B) The liver in relation to its circulation.

Table 8.3. Hemodynamic derangements in liver cirrhosis

- Decreased systemic vascular resistance
 - Peripheral vasodilation
 - Arteriovenous shunting
- Redirection of blood flow
 - Increased pulmonary, splanchnic, muscle, and skin blood flow
 - Decreased portal vein flow to liver
 - Normal or increased hepatic arterial flow
 - Normal to decreased renal blood flow
- Increased blood volume
 - Decreased serum albumin
 - Decreased plasma oncotic pressure
- Increased cardiac output
 - Apparent cardiomyopathy despite increased output
- Decreased arteriovenous O₂ content difference
 - Increased venous O₂ content
- Decreased responsiveness to catecholamines

decreased β -adrenergic receptor function. Additionally, some patients with a hyperdynamic circulation develop significant left ventricular failure after liver transplantation, possibly as a result of increased peripheral vascular resistance after relief of vasodilation by transplantation. Typical treatment includes inotropes, mechanical ventilation, and supportive care in an intensive care unit.

Hematologic

Hematologic effects include anemia (bone marrow suppression, red cell destruction, blood loss, iron deficiency), thrombocytopenia (splenic sequestration), and coagulopathy. All clotting factors except factor VIII are produced in the liver. Progressive decreasing liver function leads to deficiency of these factors, making patients prone to bleeding. Fresh frozen plasma is used to replace the clotting factors before surgery. A prothrombin time with an INR of <1.4 should be achieved for surgery in these patients. A platelet count of at least $100,000/\text{mm}^3$ is desirable.

Renal

Renal dysfunction is common in patients with liver disease and has at least three major causes: prerenal azotemia, acute tubular necrosis, and hepatorenal syndrome. Prerenal azotemia may result from overuse of diuretics leading to elevated blood urea nitrogen and creatinine, indicative of worsening renal function, and usually responds to reducing the diuretic dose and gentle hydration. Acute tubular necrosis often occurs in the setting of another acute, precipitating factor, such as hypotension, infection, or severe sepsis. Although renal failure commonly develops in the setting of infection in patients with liver disease, renal function tends to recover with the removal of the inciting insult. Hepatorenal syndrome (Table 8.4) is marked by a worsening of renal function as liver disease progresses and does not recover without an improvement in liver function.

Table 8.4. Diagnostic criteria for hepatorenal syndrome^a

Major criteria	
Low glomerular filtration rate, as indicated by serum creatinine	>1.5 mg/dl
Exclusion of shock, ongoing bacterial infection, volume depletion, and use of nephrotoxic drugs	
No improvement in renal function after stopping diuretics and volume repletion with 1.5 L of normal saline	
No proteinuria or evidence of obstructive uropathy or parenchymal renal disease	
Minor criteria	
Urine volume	<500 ml/d
Urine sodium	<10 mEq/L
Urine osmolality	$>$ plasma osmolality
Urine RBC	<50 /high-power field
Serum sodium	<130 mEq/L

^a Only major criteria are needed to establish the diagnosis; minor criteria provide supporting evidence.
RBC, red blood cells.

Pulmonary

Portopulmonary hypertension

Portopulmonary hypertension affects eligibility for liver transplantation and may complicate hepatic resection if it leads to central venous pressure elevation. Portopulmonary hypertension occurs in 2% to 4% of patients with end-stage liver disease and 5% to 10% of patients evaluated for orthotopic liver transplantation. Clinical predictors of pulmonary hypertension in liver transplantation include systemic hypertension, right ventricular dilatation by echocardiography, estimated pulmonary artery systolic pressure ≥ 40 mm Hg by transthoracic echocardiography, right ventricular hypertrophy by echocardiography, and/or a right ventricular heave.

Portopulmonary hypertension is characterized by a mean pulmonary artery pressure >25 mm Hg with a normal pulmonary capillary wedge pressure (i.e., <15 mm Hg) and an elevated pulmonary vascular resistance (i.e., >120 dyne-sec/cm⁵) in the setting of portal hypertension. Factors implicated in the etiology of portopulmonary hypertension include (1) increased pulmonary arterial blood flow secondary to an increase in cardiac index, (2) increased circulating blood volume, and (3) vasoconstriction and progressive pulmonary vascular remodeling due to endothelial and smooth muscle cell proliferation. The most common symptom of portopulmonary hypertension is dyspnea on exertion – fatigue, palpitations, chest pain, and syncope are reported less frequently. Diagnosis of portopulmonary hypertension is by noninvasive transthoracic Doppler echocardiography. Figure 8.2 outlines the diagnostic approach to pulmonary hypertension.

Effective management of portopulmonary hypertension is important because it may facilitate hepatic resection. Pulmonary vasodilator treatment also may allow a marginal patient to receive a liver transplant with reduced mortality. Vasodilators, such as epoprostenol, sildenafil, and nitric oxide, can reduce pulmonary vascular resistance.

Hepatopulmonary syndrome

Hepatopulmonary syndrome is defined by the presence of hepatic dysfunction or portal hypertension, an elevated alveolar-arterial oxygen gradient, and intrapulmonary vasodilation. Patients may present with digital clubbing, spider angiomas, arterial hypoxemia, and dyspnea that worsens upon moving from a recumbent to an upright position (orthodeoxia and platypnea). Hepatopulmonary syndrome may contribute to hypoxemia, even when other cardiopulmonary abnormalities are present (Table 8.3).

The diagnosis of hepatopulmonary syndrome in patients with liver disease is confirmed by arterial desaturation, measured by pulse oximetry and arterial blood gas analysis, and pulmonary vasodilation, assessed by contrast echocardiography, lung perfusion scanning, or pulmonary artery catheterization. Other causes of hypoxia also must be excluded. A flow chart outlining the assessment for hepatopulmonary syndrome is shown in Figure 8.3.

Diagnostic Approach to Pulmonary Hypertension

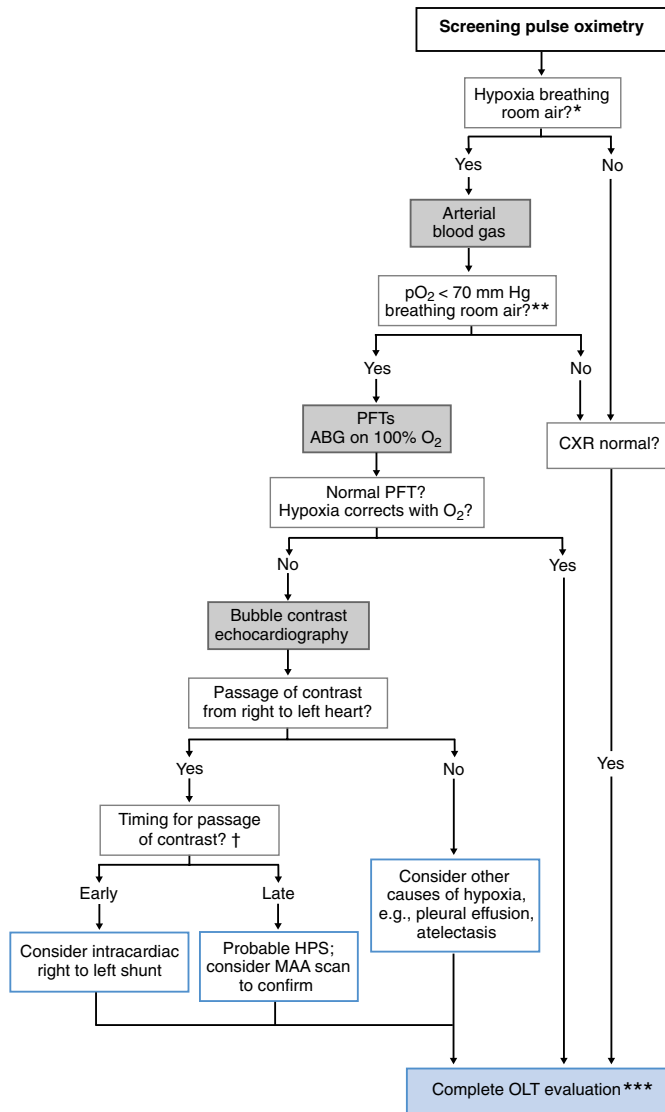

Figure 8.2. Suggested diagnostic paradigm to exclude or monitor pulmonary hypertension. Although there are many variations, it is important to complete the process with a detailed knowledge of the patient’s pulmonary hemodynamics. Normal follow-up: repeat transthoracic echocardiogram or right heart catheterization 1 year after previous test. Elevated risk implies high risk of perioperative mortality. OLT, orthotopic liver transplantation; PA, pulmonary artery.

Diagnostic Approach to Hepatopulmonary Syndrome

* SpO₂ < 90% in standing position while breathing room air

** Performed in standing position

*** Repeat screening pulse oximetry at least annually

† Early = within 1–2 cardiac cycles; late = 3–6 cardiac cycles

Figure 8.3. Diagnostic algorithm for hepatopulmonary syndrome. Some centers extend this algorithm by routinely performing ⁹⁹Tc macroaggregated albumin scanning, which is very sensitive to intrapulmonary shunts, when other possible right-to-left shunts have been excluded. Screening pulse oximetry should be carried out at every clinic visit and at least annually, as development of hepatopulmonary syndrome shortens life expectancy and is accorded additional MELD points when discovered. PFTs, pulmonary function tests; ABG, arterial blood gas; HPS, hepatopulmonary syndrome; MAA, ⁹⁹Tc macroaggregated albumin.

There are no effective medical therapies for hepatopulmonary syndrome, although selective inhibition of nitric oxide production has shown theoretic promise. Among matched cirrhotic patients with and without hepatopulmonary syndrome, liver transplantation was the only therapy shown to increase survival compared with medical therapy alone.

Box 8.1. Major causes of hypoxia in patients with liver disease

- Ventilation–perfusion mismatching
- Premature airway closure
- Pulmonary vasodilation

- Diffusion–perfusion deficit
- Pulmonary emboli
- Compression of lung tissue
- Impaired diaphragmatic function due to ascites
- Pleural effusion
- Pulmonary edema
- Pulmonary manifestations of specific liver disease (e.g., α₁-antitrypsin deficiency)
- Acute exacerbations of intercurrent chronic lung disease

Neurologic

Hepatic encephalopathy

The cause of hepatic encephalopathy is multifactorial. Elevated ammonia levels are often found in patients with hepatic encephalopathy and may play a role in its development. Activation of γ-aminobutyric acid (GABA) receptors in the brain also may contribute to hepatic encephalopathy, and ammonia has been shown to enhance GABAergic currents, which may explain its role in hepatic encephalopathy. Hepatic encephalopathy resembles many other nonfocal neurologic conditions (Table 8.5), from which it must be differentiated. Many of these occur as comorbid conditions in patients with liver failure. The severity of encephalopathy contributes to the CTP system for stratifying severity of hepatic disease.

Autonomic neuropathy

Autonomic neuropathies are found in up to 50% of patients with chronic liver disease and manifest most commonly as impaired cardiovascular function and gastric motility. In addition, patients with autonomic neuropathies experience a higher incidence of hypotension during general anesthesia. More importantly, autonomic neuropathy predicts increased mortality in cirrhotic patients. The development of autonomic neuropathies does not depend on the etiology of the liver disease,

and they generally resolve with the return of normal liver function after transplantation.

Fulminant hepatic failure

Fulminant hepatic failure is severe hepatic dysfunction that occurs most commonly from drug toxicity, most frequently from acetaminophen (Table 8.6), followed by viral hepatitis, and less often by some unidentifiable agent. Acute hepatic encephalopathy is a prominent clinical feature of fulminant hepatic failure and is associated with progressive brain swelling and an increase in intracranial pressure that may result in brain

herniation and death. In patients who are awake and responsive, regular neurologic examinations may be used to exclude dangerous brain swelling.

Treatment of fulminant hepatic failure is supportive, and many patients recover. For those who do not recover, liver transplantation is the treatment of choice. Regardless of the final path to resolution, supportive care aims to reduce the impact of severe encephalopathy and brain swelling. Bacterial infections develop in up to 80% of patients with fulminant hepatic failure and most commonly involve the respiratory and urinary systems. Acute infection may prevent transplantation.

Pharmacologic management in cirrhosis

Cirrhosis and liver failure may affect the distribution, duration of action, elimination, and effect of a variety of drugs by perturbing their normal pharmacokinetics and pharmacodynamics. Cirrhotic patients have a decreased ability to metabolize and clear drugs. Decreases in serum albumin and altered total body water also change the volume of distribution of many drugs. Table 8.7 summarizes these changes. Anesthesiologists need to be cognizant of these changes when administering balanced anesthesia to cirrhotic patients.

Perioperative access and monitoring

Many of the preoperative preparations needed for major surgery in cirrhotic patients are those used for noncirrhotic

Table 8.7. Effect of cirrhosis and liver failure on the administration of drugs used in anesthesia

Drug class	Drug	Effect of liver failure on drug metabolism	Dosing recommendations in cirrhotic patients
Opioids	Morphine	Prolonged half-life	Decrease frequency
	Meperidine		
	Fentanyl	Apparently unchanged	No change for single-dose administration Caution advised for prolonged infusions
Hypnotics	Remifentanyl	Unaffected (metabolism by plasma esterases)	No change
	Methohexital	Unchanged clearance ratio	No change for single-dose administration
	Ketamine	Prolonged half-life due to increased V_d	
	Etomidate		
	Propofol	Unchanged clearance (even with extended infusions)	No change
	Benzodiazepines	Decreased clearance ratio	Reduce preanesthetic dose Contraindicated in hepatic encephalopathy
Neuromuscular blockers	Succinylcholine	Significantly prolonged duration of action (because of decreased synthesis of plasma cholinesterases)	Decrease dose in short surgical procedures
	Mivacurium		
	Vecuronium	Decreased clearance Extended duration of action (except in alcoholic cirrhosis)	Decrease dose
	Rocuronium	Increased V_d	Decrease dose
	Pancuronium	Decreased elimination half-life Extended duration of action	Decrease dose
	Atracurium Cisatracurium	Organ independent Hoffmann elimination	No change
Halogenated volatile anesthetics	Halothane	Causes decreased portal blood flow, and decreased hepatic artery blood flow = decreased hepatic perfusion, which may worsen liver damage	Avoid using entirely
	Isoflurane		
	Sevoflurane Desflurane	Decreased portal blood flow; decreased total hepatic blood flow. Compensatory increase in hepatic artery blood flow	No change

V_d , apparent volume of distribution.

patients. Besides the standard ASA (American Society of Anesthesiologists) monitors, and depending on the planned surgical procedure, additional preparation might include use of warming devices, placement of multiple large-bore peripheral intravenous lines, an arterial line for blood pressure monitoring and obtaining serial blood samples during surgery, central or peripheral venous pressure monitoring, pulmonary artery catheter placement for hemodynamic monitoring (especially in patients with portopulmonary hypertension), and/or intraoperative transesophageal echocardiography.

Postoperative care

Ventilatory management is often the main issue one is concerned about in postoperative cirrhotic patients. Intraoperatively in large abdominal operations, pressure control ventilation (PCV) may be needed to prevent dangerously high peak alveolar pressures and PEEP. PCV with permissive hypercapnia of 60 to 70 mm Hg may be used to prevent alveolar barotrauma or volutrauma. In practice, permissive hypercapnia rarely is needed – modern anesthesia machine ventilators are adequate for the ventilatory needs of cirrhotic patients. Nitric oxide may be used to vasodilate the pulmonary vessels in patients with portopulmonary hypertension.

In procedures with a high transfusion requirement, transfusion-related acute lung injury (TRALI) is always a risk. This type of pulmonary edema may manifest between 1 and 3 days postoperatively or, in severe cases, intraoperatively. After lower-risk smaller procedures, these patients generally initially have a higher F_{iO_2} (fraction of inspired oxygen) requirement stemming from elevated abdominal pressures (i.e., from ascites). Reduced urine output from transient renal insufficiency may occur and is fairly common, occurring in as many as one-third of cirrhotic patients.

Pain management requires special attention in cirrhotic patients with encephalopathy, as opioids may cause undesirable and pronounced sedation. Neuraxial epidural anesthesia may be used as an alternative anesthetic and analgesic method; however, coagulopathy may prevent initial placement, delay catheter removal, and place the patient at increased risk for epidural hematoma and from exposure to foreign blood products if correction of a coagulopathy is necessary to remove a

catheter. As such, patient-controlled intravenous analgesia usually is a safer method of postoperative pain control but requires careful attention.

Diabetes mellitus and perioperative glucose control

Ruma R. Bose and Balachundhar Subramaniam

According to the Centers for Disease Control and Prevention, diabetes mellitus (DM) is present in 24 million people (7% of the US population; www.cdc.gov/medicalpressure/2008/r080624.htm, 2008). The prevalence of hyperglycemia in hospitalized patients is 26%, of whom 12% have previously unrecognized diabetes or hospital-related DM. A high blood glucose level predisposes patients to organ morbidity and increased mortality. Hyperglycemia in the intraoperative and perioperative settings has been seen not only in diabetics but also in nondiabetics. This condition is associated with poor outcome, increased hospital mortality, infection, sepsis, poor wound healing, and ischemic events. In the intensive care unit (ICU), hyperglycemia has been correlated with prolonged mechanical ventilation, sepsis, renal insufficiency, and neurologic deficits. Therefore, knowledge of the optimal intraoperative blood glucose level, which is still a topic of contention, is of utmost importance to the anesthesiologist.

The American Diabetes Association (ADA) Expert Committee on the Diagnosis and Classification of Diabetes Mellitus describes in-hospital hyperglycemia as follows:

- Medical history of diabetes – DM previously diagnosed and acknowledged by the patient's treating physician
- Unrecognized diabetes – hyperglycemia (fasting blood glucose ≥ 126 mg/dl or random blood glucose ≥ 200 mg/dl) occurring during hospitalization and confirmed as diabetes after hospitalization by standard diagnostic criteria, but unrecognized as diabetes by the treating physician during hospitalization
- Hospital-related hyperglycemia – hyperglycemia (fasting blood glucose ≥ 126 mg/dl or random blood glucose ≥ 200 mg/dl) occurring during hospitalization and reverting to normal after hospital discharge.

Types of diabetes mellitus

Type 1 diabetes

Different types of diabetes mellitus are listed in Fig. 9.1. Type 1 involves 5% to 10% of patients with diabetes. The β -cells of the pancreas are affected by an autoimmune process, leading to

decreased production of insulin. Patients with type 1 DM are prone to develop ketoacidosis.

Type 2 diabetes

Type 2 is present in 90% to 95% of diabetic patients. Insulin resistance is stated as the primary cause of diabetes. Hence, there is hyperglycemia despite high or normal circulating levels of insulin. This level eventually falls as a result of feedback inhibition of insulin production by the pancreas. Patients with type 2 DM are less likely to develop ketoacidosis but are prone to develop a hyperglycemic, hyperosmolar, nonketotic state.

Gestational diabetes

Gestational diabetes manifests during pregnancy and is more common in patients with a family history of diabetes. Twenty percent to 50% of patients diagnosed with gestational diabetes go on to develop type 2 diabetes within the next 5 to 10 years.

Stress-related diabetes

During stressful events such as surgery and hospitalization, hyperglycemia occurs as a result of multiple factors that lead to an increase in concentration of blood glucose, a decrease in production of insulin, and insulin resistance (Fig. 9.1). The stress of surgery leads to the production of corticosteroids and stress hormones such as glucagon, growth hormone, epinephrine, and norepinephrine. These substances cause an increase in gluconeogenesis and glycogenolysis by the liver, ultimately leading to an increase in glucose production. In addition, the catabolic hormones cause insulin resistance, which decreases glucose uptake by muscle and fat. Epinephrine and norepinephrine inhibit insulin release by their action on α -adrenergic receptors. The net result is an increase in blood glucose concentration, eventually leading to an increase in insulin secretion by β -cells of the pancreas. Normally, because it is an anabolic hormone, insulin decreases the production of glucose by inhibiting gluconeogenesis and glycogenolysis and enhances its uptake peripherally. However, in stressful situations the blood glucose level remains elevated because of the reasons mentioned earlier.

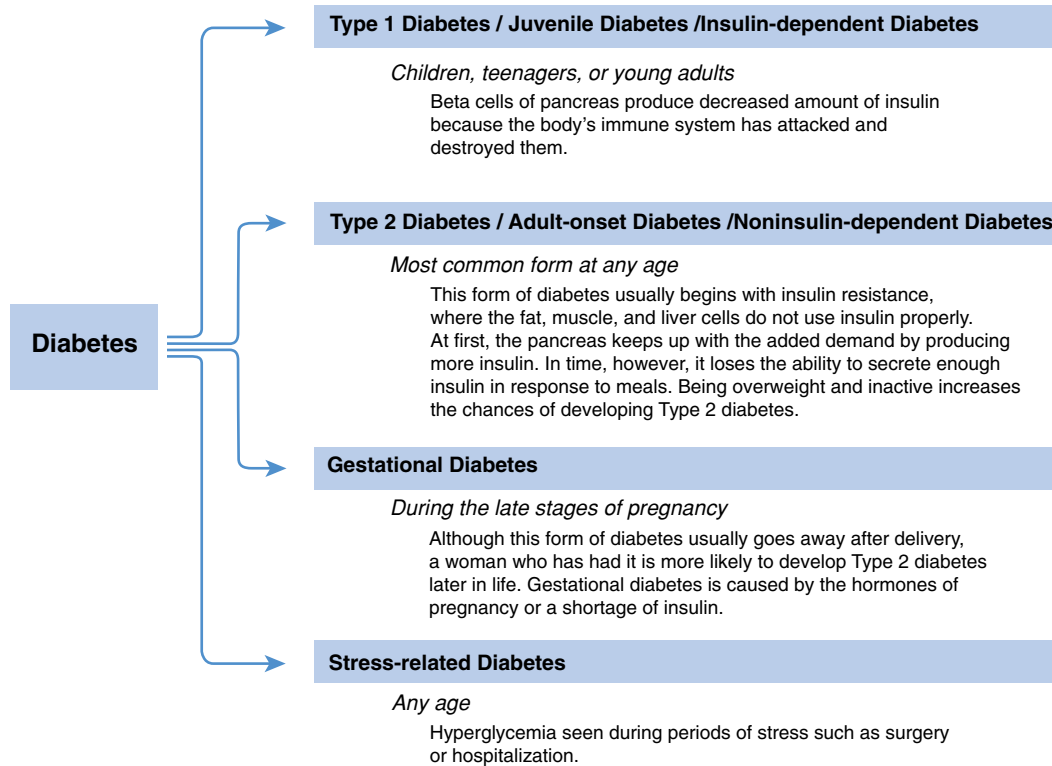

Figure 9.1. Classification of DM.

Adverse effects of hyperglycemia

Complications related to diabetes can be classified into acute and chronic. Acute complications are diabetic ketoacidosis, nonketotic hyperosmolar state, and hypoglycemia. Long-term effects are seen in virtually all the organ systems and include retinopathy, cataract, coronary artery disease, peripheral vascular disease, and renal insufficiency, to name a few.

In the perioperative setting, hyperglycemia is associated with an increase in overall hospital mortality. There is an increase in the incidence of pneumonia, wound infection, and sepsis. In acute myocardial infarction (MI), hyperglycemia is associated with increased mortality, congestive heart failure, and cardiogenic shock. In cardiac surgery patients, there is an increase in sternal wound infection, in-hospital mortality, postoperative renal failure, delayed stroke, and length of hospital stay. In ICU patients, hyperglycemia is associated with poor neurologic outcome, prolonged mechanical ventilation, sepsis, and renal failure.

Endothelial function

Hyperglycemia alters the integrity of the endothelium by inhibiting nitric oxide, which leads to an increase in cellular permeability, inflammation, angiogenesis, and thrombogenesis.

Thrombosis

Animal and human studies have demonstrated an increase in thrombosis associated with hyperglycemia, which is the result

of an increase in the production of thromboxane and von Willebrand factor, coupled with the inhibition of plasminogen activator. As a result, there is platelet activation and aggregation, which in the setting of shear stress, as seen during hemodynamic fluctuations in the perioperative period, increases the incidence of thrombus formation.

Wound infection

Hyperglycemia has been associated with an increased incidence of postoperative wound infection, which may be explained by microvascular changes in the tissues that limit blood supply to the tissue. Another contributing factor is the decrease in phagocytosis and chemotaxis of the polymorphonuclear cells. A marked reduction in phagocytic and cytotoxic activity of the polymorphonuclear cells was observed in patients with poorly controlled blood glucose levels. A decrease in the incidence of sternal wound infections in diabetic patients after coronary artery bypass grafting was seen in those with a blood glucose level <200 mg/dl in the immediate postoperative period. The effect of perioperative hyperglycemia and hyperinsulinemia on monocytes was studied, and a decrease in HLA-DR expression was seen, which correlated with infectious complications and mortality.

Wound healing

Glycemic control in the perioperative period improves wound healing by increasing granulation tissue formation, fibroblast

proliferation, and collagen synthesis. Hyperglycemia may cause nonenzymatic glycosylation with the production of abnormal proteins that decrease elastance and tensile strength, which are an essential part of the wound healing process. Diminishing insulin activity also decreases capillary proliferation, which worsens the tissue healing process.

Hyperglycemia and outcomes in critically ill patients

Glucose homeostasis is altered in critically ill patients, leading to increased glucose production and insulin resistance. Hyperglycemia in ICU patients has been associated with a higher incidence of MI, congestive heart failure, and cardiogenic shock. It also has been associated with a prolonged length of stay in the ICU as well as a prolonged duration of mechanical ventilation. A significant correlation has been found with stroke, neurologic injury, polyneuropathy, and renal insufficiency in these patients. In a landmark study, Van Den Berghe et al. in 2001 showed a reduction in mortality from 8% to 4.6% in ICU patients who maintained their blood glucose concentrations between 80 and 110 mg/dl. The largest reduction was seen in multiple organ failure due to sepsis. There was a decrease in in-hospital mortality, bloodstream infection rate, and acute renal failure requiring dialysis. There also was a decrease in the median number of blood transfusions, polyneuropathy, and the need for prolonged mechanical ventilation.

Neurologic injury

Supranormal blood sugar levels at the time of cerebral insult, be it traumatic head injury, subarachnoid hemorrhage, intracerebral hemorrhage, cerebrovascular accident, or stroke, are associated with a worsened neurologic outcome. Evidence suggests a profound benefit of blood glucose control in patients with global central nervous system ischemia. Glucose acts as a substrate for anaerobic metabolism, increasing lactate levels, worsening intracellular acidosis, and disrupting normal intracellular homeostasis. There is a correlation of poor functional recovery in stroke patients with hyperglycemia. The tissue most vulnerable to ischemia is the penumbra or the area surrounding the area of primary insult, and the progression of stroke depends on the viability of this region. Hyperglycemia has been associated with irreversible damage to this vulnerable region of the brain.

Myocardial infarction

Type 2 diabetes has been referred to as a “cardiovascular disease associated with hyperglycemia.” Patients with diabetes tend to suffer painless MI, which makes timely detection and treatment difficult. The size of the infarct is larger and recovery is poor compared with the general population. During an MI, there is an increased production of stress hormones, which, in conjunction with preexisting insulin resistance, leads to a decrease in the utilization of glucose by the myocardium. The energy

Table 9.1. Signs and symptoms of autonomic imbalance

| • Gastroparesis | • Asymptomatic hypoglycemia |

requirements are fulfilled by fatty acid metabolism, which utilizes more oxygen, increasing the myocardial oxygen requirement and widening the demand–supply gap, thereby worsening ischemia.

Some of the other mechanisms that cause poor outcomes with hyperglycemia are worsening of ischemic preconditioning, a decrease in the formation of collateral blood supply, accelerated myocyte death, and worsening of reperfusion injury. The DIGAMI (Diabetes Mellitus Insulin-Glucose Infusion in Acute Myocardial Infarction) trial showed the beneficial effects of blood glucose control in patients with acute MI. A continuous insulin infusion was used to control blood sugar during acute MI, followed by intensive subcutaneous insulin therapy for 3 months. This regimen improved long-term survival and caused an absolute reduction in mortality by 11%. A moderate perioperative target range of 100 to 150 mg/dl in vascular surgical patients has the potential to reduce perioperative MI rates.

Autonomic imbalance

Patients with diabetes have a 10% to 50% incidence of autonomic neuropathy. Some of the signs and symptoms are listed in [Table 9.1](#).

Patients with autonomic neuropathy lack the compensatory mechanisms to deal with hemodynamic fluctuations and hypoxia and are therefore more prone to sudden cardiac death, arrhythmias, and postoperative MI. Additionally, they are more likely to aspirate due to gastroparesis.

Ketoacidosis

Diabetic ketoacidosis usually occurs in type 1 diabetics but may also occur in type 2 diabetics. It is a life-threatening condition resulting from lack of insulin and highly elevated blood glucose levels (up to 500 mg/dl). There is accumulation of ketone bodies (acetoacetate and β -hydroxybutyrate). The resulting anion gap metabolic acidosis leads to dyspnea, nausea and vomiting, thirst (hypovolemia), abdominal pain, constant urination (diuretic effect of glucose), agitation, and confusion. If the blood glucose levels are not corrected coma may result.

Diabetic ketoacidosis is treated with aggressive hydration, insulin drip (10 units/h or 0.1 units/kg/h to decrease blood glucose levels at a rate of not more than 100 mg/dl/h), and replacement of electrolytes (especially potassium; insulin carries glucose and potassium into the cell). When the blood

Figure 9.2. Complications of DM.

glucose reaches 250 mg/dl, an infusion of 5% dextrose in water is started to prevent hypoglycemia. Patients are actively monitored with repeated measurements of blood glucose, urine output, and vital signs.

Intraoperative blood glucose management

Preoperative evaluation

Preoperative evaluation of diabetic patients should include assessment of glycemic control; early detection and treatment of electrolyte disturbances, hypoglycemia, and ketoacidosis; and determination of the extent of end-organ disease. The American College of Cardiology/American Heart Association guidelines state that a patient's risk for cardiac complications is a function of the patient's medical history, current functional status, and the specific surgical procedure. DM is considered an intermediate risk factor for postoperative cardiac morbidity. Complications of DM are shown in Fig. 9.2.

Cardiovascular disease is the most common cause of morbidity in diabetic patients. A thorough history and physical examination should be performed and a baseline electrocardiogram (ECG) obtained in every patient. The presence of arrhythmias, Q waves, left ventricular hypertrophy, or ST changes have been correlated with increased cardiac morbidity. Noninvasive and invasive cardiac testing may be warranted in high-risk patients undergoing major or intermediate-risk surgical procedures. Asymptomatic patients with diabetes have shown significant perfusion defects during thallium testing.

Signs and symptoms of autonomic neuropathy should be elicited. The tilt test is an easy method for assessing orthostatic hypotension (a positive test is a decrease in blood pressure of approximately 30 mm Hg in the upright position). A pulse rate variability of ≤ 5 bpm during deep inspiration and expiration (normal being 15 bpm) also is an indicator of autonomic imbalance. Renal insufficiency is a common complication associated with diabetes and requires further evaluation.

The type of diabetes and its management with regard to insulin regimen or oral hypoglycemic agents should be determined. Patients should be asked about the occurrence and frequency of hypoglycemic episodes. Type 2 diabetic patients who are on oral hypoglycemics may need to be started on an insulin regimen perioperatively to ensure adequate control of blood sugar in the setting of stress, fasting, and change in nutritional regimen while in the hospital. However, well-controlled type 2 diabetic patients undergoing same-day surgery may not require insulin.

Airway examination

Patients with a history of longstanding diabetes may demonstrate the "prayer sign," which is difficulty in approximating the metacarpophalangeal joints of the two hands. These patients also may have restricted neck extension, which may cause problems during airway management. The restricted neck extension is a result of atlanto-occipital joint fusion. Patients showing the prayer sign have a greater incidence of microvascular disease.

Laboratory tests

In addition to routine laboratory tests, blood glucose, ECG, blood urea nitrogen, creatinine, and plasma electrolyte levels should be evaluated. Twenty-four-hour creatinine clearance is recommended in some patients with renal insufficiency. Urine should be checked for ketones and albumin. The hemoglobin A_{1c} level (an indicator of glycosylated hemoglobin) may be checked to determine the adequacy of blood sugar control during the previous 4 to 6 weeks.

Medications

Whenever possible, the surgery should be scheduled in the morning to minimize the catabolic state and hypoglycemia. If the patient is on metformin, some have advocated stopping it

Figure 9.3. Preoperative management of blood sugar in patients with DM.

at least 24 hours before surgery because of its rare propensity to cause lactic acidosis, but this is no longer widely accepted. Sulfonylureas and thiazolidinediones may be stopped the day before surgery. Preoperative blood sugar should always be checked; the goal is to maintain an optimum glucose level and prevent hypoglycemia. One has to be cognizant of the fact that intraoperatively and immediately postoperatively, all the signs and symptoms of hypoglycemia may be masked; therefore, frequent blood sugar measurements are advised.

Insulin pumps deliver a continuous infusion of short-acting insulin, and the rate of infusion is controlled by the patient based on periodic blood sugar measurements. The insulin pump delivers baseline insulin, and it is important to maintain this infusion rate in insulin-dependent diabetics. However, some experts advocate substituting intravenous insulin infusions for the subcutaneous pump because of concerns for altered cutaneous blood flow during surgery. Rhodes and Ferrari in 2005 laid out practice guidelines for the preoperative management of pediatric patients with diabetes, and these

*Correction factor (CF) = 1500/ [Total daily dose (TDD) of insulin]
 Example: If TDD is 50 U, CF = 1500/50 = 30 U
 1 U of regular insulin will decrease the blood sugar by 30 mg/dl. Blood sugar is maintained between 100 and 150 mg/dl.

Figure 9.4. Insulin regimen to manage hyperglycemia.

Table 9.2. Insulin time chart

Type of insulin	Start of action	Peak of action, h	Duration of action, h
Humalog (rapid)	15 min	1.5–2	4
Regular (short)	30 min	2–3	5
NPH (intermediate)	1–2 h	4–8	14–20
Lente (intermediate)	2–3 h	8–12	16–24
Ultralente (long)	2–4 h	8–14	18–24
Lantus (long)	1–2 h	6	18–26

may be applied to adults as well. Preoperative management of diabetic patients based on these guidelines is summarized in Figs. 9.3 and 9.4, and Tables 9.2 and 9.3.

Intraoperative management

It is universally accepted that intraoperative hyperglycemia is deleterious to patient outcome, but there is continuing debate regarding the ideal target blood glucose level. Earlier studies suggested a more generous margin for blood glucose levels; for example, Pomposelli et al. in 1998 showed a benefit in outcome if the limit was 220 mg/dl. Later studies lowered this limit to anywhere between 100 and 120 mg/dl. Van Den Berghe’s study in ICU patients showed a difference in outcome when blood glucose was maintained at <110 mg/dl. The major concern with dropping the safe level of blood glucose is the risk of hypoglycemia, with its attendant life-threatening complications. The recent NICE-SUGAR (Normoglycemia in Intensive

Table 9.3. Insulin regimen for patients who require continuous IV infusion.

- Continuous background infusion of 10% dextrose and 1/2 NS is required
- Insulin infusion is piggybacked (1U for 3g dextrose)
- Blood glucose is maintained at 100–500 mg/dl
- Subsequent dose adjustment of insulin is based on the current insulin infusion rate and the rate of decline of blood glucose levels

Source: Adapted from figure 7; Rhodes RT, Ferrari LR. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005; 101:986–999.

Care Evaluation – Survival Using Glucose Algorithm Regulation) study seriously challenged the tight glucose target range. A moderate target of 100 to 150 mg/dl seems to have more benefits than risks.

In 2004, the American College of Endocrinology set up a taskforce whose recommendation for the target blood glucose level was 110 mg/dl in ICU patients and a maximum of 180 mg/ml in non-ICU patients. The goal at our institution is to maintain the intraoperative blood glucose level between 100 and 150 mg/dl in all patients with diabetes. Blood glucose should be measured immediately preoperatively and every hour intraoperatively and during the immediate postoperative period. There are many insulin regimens for managing intraoperative hyperglycemia. A background glucose infusion is recommended to prevent hypoglycemia, ketosis, and protein breakdown, especially when using continuous insulin infusion. Potassium levels should be measured periodically. Insulin and epinephrine stimulate potassium uptake by the cells, whereas hyperosmolality and acidosis translocate potassium out of the cells.

If intraoperative blood glucose measurements warrant insulin administration, the bolus dose is calculated as follows: For insulin-dependent diabetic patients, the daily insulin requirement is divided by 24, and that is the initial dose (approximately 0.1 units/kg body weight); in patients who are insulin naïve the dose is 0.02 units/kg intravenously (IV). Repeat doses are calculated by the rapidity of change in blood glucose level and incorporation of a correction factor. If the surgery is emergent, preoperative assessment and optimization of metabolic status and adequate volume replacement should be the goal. Surgery should be delayed if possible to achieve metabolic control. If surgery cannot be delayed, adequate fluid replacement and timely correction of electrolyte imbalance, especially potassium levels, will decrease the occurrence of arrhythmias and hypotension.

Postoperative management

Postoperative management includes measurement of blood glucose levels and continuation of the IV or a subcutaneous insulin regimen until the patient can resume caloric intake. Nausea and vomiting should be treated aggressively. Adequate pain control is important to minimize the release of catabolic hormones that increase blood glucose levels. Renal dysfunction

should be kept in mind when prescribing analgesics. Patients should be monitored closely for signs of hypoglycemia, respiratory depression, and hemodynamic instability. A postoperative ECG should be obtained to monitor for ischemic changes. With regard to patients receiving an insulin infusion, consideration for continuing it should be given in postoperative patients discharged from the ICU, those on corticosteroids, and those who have had an organ transplant or stroke.

Common blood disorders

Jonathan D. Bloom and Edward A. Bittner

Erythrocyte disorders

Anemia

Anemia is defined as a deficiency in the concentration of functional red blood cells (RBCs) in the circulation. It should be noted that a change in reported hemoglobin (Hb) or hematocrit (Hct) does not necessarily indicate a change in erythrocyte mass, as dehydration may falsely elevate a normal value whereas hemodilution may falsely lower it. Conversely, the Hb/Hct may be reported as normal in the setting of acute bleeding, prior to fluid resuscitation and re-equilibration.

Clinical considerations

Perioperative concerns about the anemic patient are based on the physiologic expectation that anesthesia, surgery, and the postoperative period commonly increase a patient's oxygen demand in the setting of an already limited oxygen reserve. Despite this, evidence that blood product transfusions are associated with adverse outcomes (e.g., transfusion-related acute lung injury, transfusion reactions) have altered perioperative transfusion practices, prompting the physician to weigh the benefit of the acute increase in transfused product against the risks of transfusion.

Knowledge of the clinical consequences and physiologic responses to anemia is essential for providing appropriate perioperative care. Basic compensatory responses to anemia involve central, regional, and microcirculatory alterations in blood flow, as well as a shift of the oxyhemoglobin dissociation curve to the right. Acute normovolemic anemia results in increased cardiac output resulting from both increased venous return and decreased afterload. This is further augmented by decreased blood viscosity and increased inotropy from sympathetic stimulation. Regional blood flow is altered by redistribution from nonvital to vital organs (e.g., from skeletal muscle to the heart and brain). Microcirculatory changes enable increased tissue oxygen extraction via capillary recruitment. Finally, anemia results in increased 2,3-diphosphoglycerate concentrations in RBCs, which shift the oxyhemoglobin curve to the right, favoring oxygen unloading. Oxygen delivery remains essentially unchanged until hemoglobin concentration falls below 7 g/dl.

The increase in cardiac output in response to acute normovolemic anemia differs between awake and anesthetized patients.

Increased cardiac output in awake patients is the result of an increase in stroke volume and heart rate, whereas increased cardiac output in anesthetized patients primarily is the result of an increase in stroke volume alone. Consequently, tachycardia in the anesthetized patient in the setting of acute anemia most likely is a sign of hypovolemia and should be treated with crystalloids or colloids.

Causes of anemia

The three major causes for anemia are (1) blood loss, (2) decreased RBC production, and (3) increased RBC destruction. The diagnosis for most causes of anemia can be determined from a thorough history and physical examination. Symptoms of anemia are variable and depend on a patient's coexisting diseases. For example, in a healthy patient, symptoms of anemia may not develop until the Hb level decreases below 7 g/dl. Laboratory tests that may be helpful in distinguishing the cause(s) of the anemia include a peripheral smear (for erythrocyte size and shape), mean cell volume, and reticulocyte count. The reticulocyte count typically is elevated in anemia caused by RBC destruction and is inappropriately low in anemia caused by a failure of RBC production. Other tests that may be useful include serum iron and ferritin levels; vitamin B₁₂/folate levels; serum bilirubin, lactate dehydrogenase, and haptoglobin levels; and the direct antiglobulin test (direct Coombs).

Types of Anemia

Anemias can be classified into two categories, primary and secondary. The former results from a structural abnormality of the hemoglobin molecule or of the erythrocyte membrane. The second category is more common, having multiple etiologies, which are described briefly later.

Megaloblastic anemias are caused by impaired DNA synthesis and are most commonly a result of deficiency of folic acid (the most common vitamin deficiency, commonly seen in severely ill patients, alcoholics, and parturients because of dietary deficiencies) and/or vitamin B₁₂. In the general surgical population, megaloblastic anemia commonly is caused by disease or partial resection of the gastrointestinal tract. Signs and symptoms, in addition to anemia, may include glossitis, tachycardia, flow murmurs, splenomegaly, and neurologic disorders (mainly in B₁₂ deficiency) such as ataxia, loss of deep

tendon reflexes, loss of posterior column sensations, confabulation, dyspnea, headache, fatigue, diarrhea, and other gastrointestinal symptoms. Management, as with all causes of anemia, is focused on maintenance of adequate oxygen delivery to the tissues. Long-term exposure to nitrous oxide has been shown to produce a megaloblastic anemia with neurologic changes and may exacerbate the effects of preexisting vitamin B₁₂ deficiency. Preexisting neurologic deficits should be documented and may preclude use of regional anesthetic techniques.

Iron deficiency anemia results from insufficient iron intake or a rapid turnover of cells (e.g., chronic blood loss or hemolysis). The finding of a microcytic, hypochromic anemia, together with a low serum ferritin level, is a rapid and effective method of making the diagnosis.

Anemia of chronic disease, the second most common cause of anemia after iron deficiency, occurs in patients with acute or chronic immune activation. Abnormal uptake and accumulation of iron within the cells of the reticuloendothelial system result in impaired erythropoiesis and blunted response to erythropoietin. The diagnosis is largely one of exclusion. Laboratory evaluation reveals a mild normochromic, normocytic anemia with a low reticulocyte count and normal total body iron (ferritin) stores. Treatment currently centers on managing the underlying disease.

Sickle cell disease

Sickle cell disease (SCD) is an inherited blood disorder stemming from production of the abnormal hemoglobin molecule HbS. A single amino acid substitution (glutamic acid to valine at the sixth position of the hemoglobin β -chain) results in a loss of negative charge, which allows for neighboring HbS molecules to associate and polymerize upon deoxygenation, resulting in the distorted, sickled erythrocyte shape. Even when fully oxygenated, a fraction of erythrocytes remains dense, dehydrated, and sickled, resulting in the vaso-occlusive manifestations. Injury to a sickled erythrocyte cell membrane as a result of polymerization causes adherence to vascular endothelial cells, resulting in reduced blood flow, which initiates the vicious cycle of ischemia, hypoxia, and further polymerization and sickling (Fig. 10.1).

Complications of SCD are hemolysis, anemia, aplastic crisis (sudden cessation of bone marrow activity), painful crisis, splenic atrophy (with associated increased infection risk to encapsulated bacteria), hypercoagulability, stroke, pulmonary embolism, asthma, hepatopathy, renal insufficiency/failure (from repeated infarcts), acute chest syndrome (the most common cause of death in adults with SCD), and secondary pulmonary hypertension. The various clinical manifestations of SCD are listed in Table 10.1.

Treatment of SCD consists of supportive regimens (folate, magnesium, zinc), pneumococcal vaccine, prophylactic penicillin, hydroxyurea (increases HbF levels, which interfere with HbS polymerization), anhydration agents, transfusion (for aplastic crisis or sequestration), pain therapy for painful crisis, and (rarely) bone marrow transplantation.

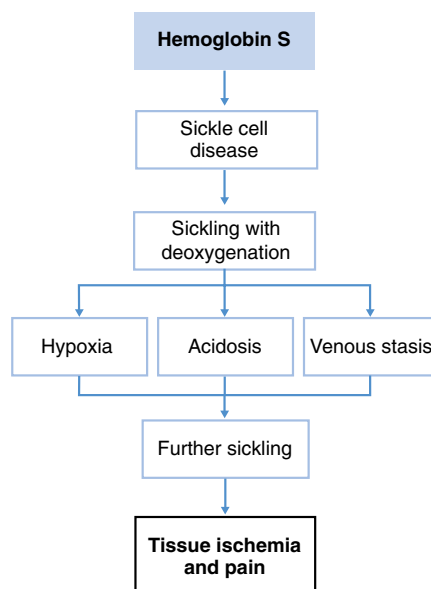

Figure 10.1. Factors precipitating sickling.

Preoperative assessment should include evaluation for infection, dehydration, vaso-occlusion, and end-organ damage. Intraoperatively, the patient should avoid sickling triggers, such as hypothermia, hypoxemia, hypovolemia, acidosis, and hypotension. In addition, fluid replacement should be selected over vasoconstrictors when possible. The use of tourniquets should be minimized, as they produce local stasis and acidosis. If a tourniquet is unavoidable, the limb should be carefully exsanguinated and the cuff duration minimized.

Perioperative prophylactic transfusion frequently is used in surgical patients with SCD, but no consensus exists regarding the best regimen. Prophylactic red blood exchange has not been shown to be superior to simple RBC transfusion in the preoperative setting. Regional techniques may be used, but epinephrine should be avoided. Acute chest syndrome, especially common the first 48 to 72 hours postoperatively, is characterized by chest pain, cough, progressive anemia, hypoxemia, and the presence of new pulmonary infiltrates on chest radiograph.

Table 10.1. Clinical manifestations of SCD

System	Complications
Neurologic	Pain crisis, stroke, retinopathy, neuropathy, chronic pain syndrome
Pulmonary	Acute chest syndrome, airway hyperreactivity, restrictive lung disease
Genitourinary	Hyposthenuria, chronic renal insufficiency, urinary tract infection, priapism, increased obstetric complications
Gastrointestinal	Cholelithiasis, liver disease, dyspepsia
Hematologic	Hemolytic anemia, acute aplastic anemia, splenic enlargement/fibrosis
Orthopedic	Osteonecrosis, osteomyelitis, dactylitis
Vascular	Leg ulcers
Immunologic	Immune dysfunction, erythrocyte auto/alloimmunization

Less common causes of anemia

Thalassemias are a group of inherited disorders characterized by decreased rates of production or failure to synthesize normal globin chains. Clinical features of thalassemia include anemia, hemolysis, and bone marrow hyperplasia. Treatment is based on the severity of the anemia. Bone marrow transplantation for patients with severe anemia may be curative. Regular transfusion may be required if the thalassemia is severe.

Hereditary spherocytosis is a rare anemia caused by an inherited RBC cytoskeletal abnormality. A defect of the spectrin protein in the cell membrane results in a more rounded and fragile RBC. Anemia typically results from splenic destruction of the abnormal cells. Cholelithiasis secondary to chronic hemolysis and elevated serum bilirubin concentrations are common. Hemolytic crises, triggered by folate deficiency or infection may worsen the anemia. Treatment of hereditary spherocytosis is splenectomy.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common inherited RBC enzyme disorder, affecting 400 million people worldwide. Chronic hemolytic anemia is the most common manifestation. Drugs that form peroxides by interactions with oxyhemoglobin can trigger hemolysis in patients with G6PD deficiency. These agents include antimalarial drugs, nitrofurantoin, probenecid, phenacetin, vitamin K, quinidine, and nitroprusside. There is considerable variability in the hemolytic response to drugs. Hemolysis typically begins 2 to 5 days after the offending drug's administration. Bacterial infections also may trigger hemolytic episodes. Patients with G6PD deficiency cannot reduce methemoglobin; therefore, drugs such as nitroprusside and prilocaine should not be used in these patients. Anesthetic drugs have not been incriminated as triggering agents.

Immune hemolytic anemias are characterized by antibody formation against the RBC membrane. These antibodies may be acquired through drug exposure, disease, or erythrocyte sensitization. Immune hemolytic anemias can be divided into (1) autoimmune hemolysis, (2) drug-induced hemolysis, and (3) alloimmune hemolysis. Autoimmune hemolytic anemia includes warm and cold antibody hemolytic anemia, according to the optimal temperature at which the antibodies act to destroy RBCs. Cold hemolytic anemias are of special concern in the perioperative setting, because the cold operating room environment and hypothermia during cardiopulmonary bypass may precipitate a hemolytic crisis. Maintaining a warm environment is essential; in rare instances, plasmapheresis may be required to reduce cold antibody titer before hypothermic procedures. Of note, clinically insignificant cold-reacting RBC autoantibodies often are detected incidentally in the blood bank laboratory. Only the rare examples of cold autoantibodies that cause hemolysis in vivo require special measures in the operating room.

Several clinical entities, including neoplasia, infection, and collagen vascular diseases, may result in immune hemolytic anemias. Immune hemolytic anemias also may be drug induced from several commonly administered drugs,

including acetaminophen, cephalosporins, hydralazine, and hydrochlorothiazide. Alloimmune hemolytic anemia most commonly manifests as hemolytic disease of the newborn, in which maternal antibodies against fetal RBCs with incompatible Rh or ABO blood groups are produced and cross the placenta.

Polycythemia

In contrast to the previously mentioned erythrocyte disorders, polycythemia is defined by an elevated hemoglobin concentration and increased hematocrit. It can be divided pathophysiologically into primary polycythemias (those not caused by increased erythropoietin) and secondary polycythemias (those caused by increased erythropoietin production). Polycythemia vera, the most common type of primary polycythemia, is a neoplastic stem cell disorder. Untreated polycythemia vera may result in an increased risk of thrombosis as well as hemorrhage. Possible clinical manifestations of thrombosis include myocardial infarction (MI), ischemic stroke, pulmonary embolism, peripheral arterial thrombosis, and deep venous thrombosis.

Secondary polycythemias result from increased erythropoietin production in response to chronic tissue hypoxia (e.g., as occurs with ascent to high altitude or with cardiopulmonary disease), tumors that secrete erythropoietin (e.g., kidney tumors), or inherited conditions that result in overproduction or exaggerated response of erythropoietin. The main goal in treating polycythemia is to correct the condition responsible for the increased cell mass, if possible. Phlebotomy is used to lower the hematocrit and prevent hyperviscosity while the primary condition is being corrected. Treatment of polycythemia vera additionally involves myelosuppressive drugs such as hydroxyurea.

Coagulation disorders

Coagulation is a complex process, occurring in response to an injury, in which the blood forms clot or thrombus. Injury usually occurs to the endothelial lining of the blood vessel, which initiates a coagulation cascade leading to hemostasis (cessation of blood loss from the damaged vessel).

Coagulation of blood involves two important processes, formation of a platelet plug (primary hemostasis) and formation of fibrin strands to strengthen the platelet plug (secondary hemostasis). The latter occurs via proteins known as clotting/coagulation factors. Spontaneous thrombus formation in normal endothelium is prevented by proteins and factors such as heparan proteoglycans, prostacyclin, nitric oxide, and tissue plasminogen activator. However, when the endothelium is damaged, these anticoagulant proteins are down-regulated and other proteins (procoagulants) are up-regulated.

Once the endothelial lining is damaged, it exposes collagen to which circulating platelets bind (primary hemostasis). This adhesion is facilitated by von Willebrand factor (vWF), causing the platelets to become activated. Activated platelets release

Figure 10.2. The coagulation cascade.

humoral factors such as adenosine diphosphate (ADP), platelet activating factor, and thromboxane, which in turn activate the platelets. Activated platelets contain an increased amount of calcium, which activates protein kinase C, which in turn modifies the membrane protein “integrin,” increasing its affinity to bind fibrinogen.

Secondary hemostasis consists of the coagulation cascade, which is a series of reactions, to form fibrin. The coagulation cascade consists of two initial pathways (Fig. 10.2): the tissue factor (extrinsic) pathway and the contact activation (intrinsic) pathway. These two initial pathways converge into a common pathway leading to the formation of thrombin and fibrin.

The coagulation cascade consists of various clotting/coagulation factors, all of which are serine proteases or glycoproteins. The various coagulation factors are listed in Table 10.2. All factors, except factors III, IV, and VIII, are synthesized in the liver. Factors II, VII, IX, and X (plus proteins C and S) are vitamin K dependent for their synthesis. Proper functioning of the coagulation cascade requires cofactors such as phospholipids and vitamin K. Regulators of the coagulation cascade include protein C, antithrombin, tissue factor pathway inhibitor, plasmin, and prostacyclin. Common laboratory tests of hemostasis are listed in Table 10.3.

Coagulation disorders can be broadly divided into disorders of hemostasis or thrombosis, with an intermediate group

Table 10.2. Coagulation factors

Factor	Name	Plasma concentration, $\mu\text{g/ml}$	% of normal required for hemostasis
I	Fibrinogen	3000	30
II	Prothrombin	100	40
III	Tissue factor	–	–
IV	Calcium	–	–
V	Proaccelerin	10	10–15
VII	Proconvertin	0.5	5–10
VIII	Antihemophilic	0.1	10–40
IX	Thromboplastin	5	10–40
X	Stuart	10	10–15
XI	Prethromboplastin	5	20–30
XII	Hageman	30	0
XIII	Fibrin stabilizing	30	1–5

that includes both disorders. They are classified further by the hemostatic component involved, that is, platelet or clotting factors.

Platelet disorders

Thrombocytopenia

Platelet disorders are subdivided into disorders of platelet number and platelet function. *Thrombocytopenia* is defined

Table 10.3. Common laboratory tests for hemostasis

Class	Test	Normal value
Platelet function	Platelet count	100,000–400,000 cells/ μl
	Bleeding time	< 10 min
Coagulation studies	Platelet function and aggregation analysis	
	PT–tissue pathway	Normal, 11–14 sec; prolonged with low levels of factor I, II, V, VII, or X, or liver disease. INR standardizes results across laboratories.
	PTT–contact activation pathway	Normal, 24–35 sec; prolonged with low levels of factor I, II, V, VIII, IX, X, XI, or XII. Heparin prolongs PTT.
	Thrombin time	Normal, 22–32 sec; prolonged with low levels of factor I or II
	ACT	Normal, 80–180 sec. Monitor heparin therapy with large doses in the operating room.
	Thromboelastography	Measure of time to initial clot formation, time to clot formation, clot strength, clot lysis
Fibrinolysis tests	D-dimer levels	When plasmin cleaves cross-linked fibrin (fibrinolytic states)
	Fibrin degradation products	Excessive activity of plasmin, which degrades fibrin (DIC)

INR, international normalized ratio.

as a platelet count $<150,000/\mu\text{l}$. Major causes of thrombocytopenia include decreased production, increased destruction/consumption, sequestration, and dilution. Common causes of decreased production of platelets include drug effects, infections, chemotherapy or radiation therapy, alcohol toxicity, and certain vitamin deficiencies (B_{12} /folate). Increased platelet destruction and consumption occur in several conditions, including disseminated intravascular coagulation (DIC), drug exposure, autoimmune states (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura/hemolytic uremic syndrome, antiphospholipid antibody syndrome), HELLP syndrome (hemolytic anemia, elevated liver enzymes, and low platelet count), physical destruction (cardiopulmonary bypass, giant hemangiomas, large aortic aneurysms, large tissue wounds), and adherence to grafts. Dilution typically occurs after massive resuscitation/transfusion. Splenic sequestration is found in patients with portal hypertension.

Some forms of thrombocytopenia are associated with thrombotic risk (e.g., heparin-induced thrombocytopenia and antiphospholipid syndrome) rather than bleeding. Surgical bleeding due to thrombocytopenia does not typically occur until the platelet count falls below $50,000/\mu\text{l}$, and spontaneous bleeding is not typically seen unless the platelet count falls below 5000 to $10,000/\mu\text{l}$. Dilutional thrombocytopenia is the most common cause of intraoperative coagulopathy. Assuming the preoperative platelet count is normal, as much as 80% of the circulating blood volume may have to be replaced before clinically significant thrombocytopenia occurs. Rapid diagnosis is important to minimize bleeding or thrombotic risk through appropriate therapy.

There are multiple causes of *qualitative platelet abnormalities*. Inherited causes stem from abnormalities of the platelet membrane (e.g., Bernard-Soulier syndrome, Glanzmann disease) or granule abnormalities. The former typically are associated with more significant bleeding than the latter. Inherited conditions are rare and usually are diagnosed in childhood. The most common causes of acquired platelet dysfunction are the various antiplatelet agents used to prevent thrombosis and decrease the risk of MI, stroke, and other thrombotic complications. Platelet transfusion may be necessary to support surgery. The major offending classes are cyclooxygenase inhibitors, phosphodiesterase inhibitors (dipyridamole), ADP receptor antagonists (ticlopidine and clopidogrel), and glycoprotein IIb/IIIa antagonists (abciximab, tirofiban, eptifibatid).

Perioperative risk of hemorrhage in patients taking antiplatelet agents varies with the agent used and the surgical procedure. In general, bleeding risk increases when a patient receives two or more agents or when the agent is combined with another anticoagulant medication. Risks of perioperative bleeding must be weighed against the risk of thrombosis by withholding agents. It is important to note that several commonly used herbal supplements, including garlic, ginkgo, ginseng, and vitamin E, also are inhibitors of platelet function and should be discontinued at least 1 week prior to surgery. Qualitative platelet disorders also may be seen in various

Table 10.4. Classification and treatment of vWD

Type	Mechanism of disease	Treatment of choice
1	Partial quantitative deficiency of vWF (and factor VIII)	Desmopressin
2	Qualitative defects of vWF

systemic conditions, including uremia, liver disease, myelodysplastic syndromes, and DIC. Finally, the reversible qualitative platelet dysfunction caused by cardiopulmonary bypass is a major cause of nonsurgical bleeding in cardiac surgery.

von Willebrand disease

von Willebrand disease (vWD) deserves special attention as it is relatively common, present in 1% to 2% of the general population. vWD arises from a qualitative or quantitative deficiency of vWF. This multimeric protein acts as an adhesive link between platelets and the injured blood vessel wall, as well as a carrier for factor VIII. Acquired forms of vWD are associated with lymphoproliferative disease, tumors, autoimmune disease, hypothyroidism, cardiac and valvular defects, and medications (e.g., valproic acid). The most common symptom is mucocutaneous bleeding, such as easy bruising, epistaxis, gingival bleeding, and menorrhagia. vWD should be considered in any patient with a history of unexplained postoperative bleeding. If vWD is suspected in a patient about to undergo an elective procedure, the case should be canceled until a proper hematologic workup is obtained. The mechanisms behind the various types of vWD, as well as their treatments, are shown in [Table 10.4](#).

Clotting disorders

Inherited coagulation disorders

Hemophilias

The most common examples of an inherited coagulation disorder are the hemophilias, characterized by a partial or complete

deficiency of a coagulant factor. The two most common are deficiencies in factors VIII and IX, corresponding to hemophilia A and B, respectively. Both diseases have X-linked recessive inheritance; therefore, males are far more commonly affected than females. Up to 50% of hemophilia cases appear *de novo* as a result of new mutations. Female carriers may actually behave as mild cases, as some have significantly reduced coagulation factors themselves, and obstetric anesthesiologists, in particular, should be aware of these.

Preoperatively, unexplained bruising or bleeding in young males or a positive family history usually indicates referral to a hematologist. Patients with hemophilia A or B usually demonstrate an isolated prolongation of activated partial thromboplastin time (aPTT), that is, normal prothrombin time (PT), thrombin clotting time, fibrinogen level, and platelet count. However, very mild cases may actually demonstrate a normal aPTT, and direct factor level measurements become necessary for diagnosis. Bleeding may occur anywhere, but the most common sites are into joints (80%) and muscles, as well as from the gastrointestinal tract. Bleeding severity relates to the degree of factor deficiency. For example, spontaneous bleeds occur in severe cases (<1% coagulant factor), whereas patients with moderate (1%–5%) and mild (>5%) factor deficiencies may bleed excessively only after trauma or surgery.

Treatment is aimed toward replacement of the specific coagulation factor. Historically, the use of plasma-derived coagulation factor concentrates tragically caused HIV and hepatitis C virus infections among thousands of hemophilia patients. Recombinant factor replacement is now available to minimize infectious disease exposure. Moreover, all coagulation factor concentrates are now required to undergo viral inactivation steps during manufacturing. Like products such as albumin, factor concentrates currently are considered to have zero risk of viral transmission.

Up to 30% of patients with severe hemophilia A may develop alloantibody inhibitors to factor VIII. In most cases, these patients cannot be treated using factor concentrates and must be managed using “bypass” agents, such as recombinant factor VIIa. Close consultation with a hematologist is mandatory.

Acquired coagulation disorders

Acquired inhibitors of coagulant factors

Another class of closely related bleeding disorders consists of the acquired inhibitors of coagulant factors, typically associated with autoimmune disorders, drug reactions, or the postpartum period. Elective surgery should be postponed until inhibitor formation is suppressed.

Vitamin K deficiency

A more common form of acquired bleeding disorder is deficiency of vitamin K, a compound necessary for the synthesis of factors II, VII, IX, and X, as well as the anticoagulant proteins C and S. Vitamin K consists of two subunits: vitamin K₁, found in green leafy vegetables, and vitamin K₂, synthesized by intestinal

bacteria. Patients therefore can acquire vitamin K deficiencies by poor diet and/or by taking antibiotics that destroy intestinal bacteria. Biliary obstruction, malabsorption, cystic fibrosis, and resection of the small intestine also may contribute to vitamin K deficiency. The PT usually is prolonged first, as factor VII typically is depleted relatively early. Urgent treatment of vitamin K deficiency requires intravenous vitamin K, administered slowly to prevent hypotension. Improvement in coagulopathy usually is apparent 6 to 8 hours after administration.

Medications

A few commonly used medications act on the coagulation cascade in a similar manner. These systemic anticoagulants are used to prevent or treat thromboembolic complications and are recommended for an increasing number of medical conditions, including mechanical heart valves, atrial fibrillation, venous thromboembolism, acute MI, and stroke. A typical example is warfarin, which works by inhibiting vitamin K epoxide reductase, preventing vitamin K synthesis. Because warfarin is a highly protein-bound compound in the plasma, unintentional increases in anticoagulation may occur when warfarin is displaced by other protein-bound drugs.

Other drug interactions occur by medications inhibiting or activating the cytochrome P-450 system, as it is metabolized almost entirely by the liver. Rapid reversal can be accomplished by administration of fresh frozen plasma (FFP) and vitamin K. In urgent cases (e.g., intracerebral hemorrhage on warfarin), the infusion of prothrombin complex concentrate (PCC) should be considered. PCCs contain factors II, VII, IX, and X, and thus provide immediate replacement of factors that are deficient from warfarin therapy.

Unfractionated heparin acts by binding reversibly to antithrombin III, accelerating its inhibition of coagulation factors XII, XI, X, IX, plasmin, and thrombin. This effect can be reversed by administering protamine, although stopping the heparin infusion usually is adequate during a short period, as the half-life of heparin is <1 hour. Low molecular weight heparin (LMWH) also acts via antithrombin III but has a greater ability to inhibit factor Xa than thrombin. The half-life, in contrast, is longer, as LMWH can be given once daily as a maintenance dose. Two additional classes of anticoagulant medications are direct thrombin inhibitors, such as argatroban, and direct factor Xa inhibitors, such as fondaparinux.

Disorders of fibrinolysis

The typical example of a disorder of fibrinolysis is DIC, a consumptive coagulopathy characterized by inappropriate and widespread systemic activation of coagulation and excessive fibrinolysis, resulting in small vessel thrombosis and generalized bleeding. DIC also is associated with thrombocytopenia, elevated fibrin split products, and elevated D-dimers. Various triggers of DIC are shown in Fig. 10.3. Treatment primarily is supportive and aimed toward correcting the underlying cause.

Figure 10.3. Conditions associated with DIC.

Theoretically, a key strategy to managing DIC is interruption of the coagulation process. Very rarely, the use of heparin is considered for this purpose – particularly for patients with overt thromboembolism or extensive deposition of fibrin. Treatment with FFP (to replace coagulation factors), cryoprecipitate (to replace fibrinogen), and platelet concentrates may be of value in the setting of diffuse bleeding.

Disorders of thrombosis

Most, if not all, cases of thromboembolism result from a convergence of underlying genetic predisposition and acquired precipitating events. Virchow's triad, consisting of altered blood flow (stasis), vascular endothelial injury, and altered blood constituents (inherited or acquired hypercoagulable states), provides a simplified model for venous thromboembolism.

Inherited hypercoagulable states are associated with venous rather than arterial thrombosis. These may be the result of increased prothrombotic protein activity or quantity (factor V Leiden, prothrombin gene mutation G20210A, or increased levels of factor VII, VIII, IX, or XI, or vWF) or from decreased activity or quantity of antithrombotic proteins (protein C, protein S, and antithrombin). Coagulation and anticoagulation proteins are consumed acutely during a thrombotic event, so testing should take place 2 to 3 weeks after the thrombotic event. Hypercoagulable laboratory workup typically includes a complete blood count, PT, partial thromboplastin time (PTT), fibrinogen, protein C assay, protein S antigen, anticardiolipin antibody, factor V Leiden assay, lupus anticoagulant panel, homocysteine assay, and functional antithrombin assay. Patients with suspected or documented hypercoagulable states are treated with warfarin for 6 months or until they are

thrombosis-free for 2 months. Patients who develop a second thrombotic event or have other risk factors require long-term anticoagulation.

Acquired hypercoagulable states also are possible. The perioperative setting itself is associated with increased risk of thrombosis secondary to both an increased prothrombotic state and inhibition of fibrinolytic pathways. This is especially true for orthopedic, major vascular, neurosurgical, and oncologic procedures. Additional risk factors among surgical patients include age, previous thrombotic event, malignancy, thrombophilia longer surgery and immobilization times.

An additional acquired hypercoagulable state the clinician should be aware of is heparin-induced thrombocytopenia (HIT), a transient antibody-mediated, prothrombotic disorder initiated by exposure to heparin. Diagnosis is made when HIT antibody formation is accompanied by an otherwise unexplained fall in platelet count (usually >50%) and/or by other clinical sequelae, such as thrombosis, skin lesions, or acute systemic reaction. Treatment for patients with suspected or confirmed HIT is cessation of heparin and initiation of non-heparin anticoagulants, such as direct thrombin inhibitors, to prevent thrombotic complications. LMWHs should be avoided, as they cross-react with HIT antibodies. Vigilance should be maintained in identifying and eliminating sources of heparin exposure, including heparin-coated lines and line and port flushes.

Autoimmune hypercoagulable states may be inherited or acquired. The two typical examples, anticardiolipin antibody and lupus anticoagulant, may result in venous or arterial thromboses, thrombocytopenia, and recurrent fetal losses. These autoantibodies usually occur in association with other autoimmune diseases but can occur independently. Patients with these disorders are at increased risk for developing ischemic and valvular heart disease, as well as recurrent cerebral infarcts, headaches, and visual disturbances. As such, these patients commonly receive chronic anticoagulation. Additional perioperative measures to decrease thrombotic risk include the use of elastic stockings and maintenance of normovolemia and normothermia. Additionally, because the autoantibodies inhibit phospholipid-dependent coagulation in vitro, heparin monitoring should be performed using whole-blood coagulation tests only (e.g., activated clotting time [ACT]).

The elderly patient

Ruma R. Bose and Sheila R. Barnett

The term *geriatric/elderly* generally is reserved for patients 65 years and older; however, this definition combines a large group of individuals with a wide range of abilities. Aging is an inevitable process producing measurable changes in the structure and function of tissues and organ systems. One of the main problems encountered by anesthesiologists when dealing with elderly patients is distinguishing the impact of age versus the effect of disease on organ function. The anesthesiologist is faced with the challenge of estimating the reserve capacity of vital organ systems and predicting the ability of the individual to deal with the stress of anesthesia and surgery.

Risk factors and the elderly

Although chronologic age per se is not a contraindication for surgery or anesthesia, elderly patients are at increased risk for adverse events following surgery. Certain factors are known to increase the risk associated with surgery in older patients. These include:

- Operative site: intra-abdominal and intrathoracic procedures are less well tolerated.
- Physical status at the time of surgery: preoperative stabilization is important. The presence of congestive heart failure, renal failure, or ischemic heart disease carries a higher risk of morbidity and mortality.
- Emergency surgery: this carries a poor prognosis.

Guidelines for treating geriatric patients

Elderly patients may be challenging to care for because of the tremendous heterogeneity within this age group. However, a few common themes arise that can help guide the care of the elderly patient:

- Clinical presentation of disease frequently is atypical, leading to delays and errors in diagnosis. This may result in a later presentation to the operating room, a more advanced disease condition, and greater likelihood of instability.
- Individuals over age 65 years have, on average, three or four medical diseases, often limiting function and increasing morbidity.

- Polypharmacy is a major issue in this population. Many older patients are on multiple medications that may affect the administration of anesthesia.
- Diminished organ reserve may be unpredictable, and even significant limitations may become apparent only during stressful events.
- The impact of extrinsic factors such as smoking, environmental factors, and socioeconomic status on physiologic age is difficult to quantify.
- Significant interindividual variability and heterogeneity exist in the aged population, making responses difficult to predict based on age alone.
- A disproportionate increase in perioperative risk may occur without adequate preoperative optimization, and adverse events are more frequent when cases are done on an emergent basis.
- Meticulous attention to detail may help avoid minor complications, which in elderly patients may rapidly escalate into major adverse events.

Aging and major organ systems

Cardiovascular system

Cardiovascular complications represent the primary source of perioperative complications in elderly patients. Preexisting cardiac conditions, such as coronary artery disease, hypertension, and abnormal left ventricular function, put the patient at risk for a postoperative cardiac event (Fig. 11.1).

The combined effects of these aging changes result in a decrease in compensatory response of the cardiovascular system to stress and hypotension. Elderly patients cannot compensate for hemodynamic fluctuations by altering heart rate, stroke volume, cardiac output, and oxygen delivery to the same extent as younger individuals, rendering them vulnerable to the side effects of anesthetic agents that alter hemodynamics and the consequences of surgery.

Pulmonary system

Perioperative pulmonary morbidity and mortality increase with age. There is a gradual decrease in pulmonary reserve, and it may be difficult to separate age-related changes from those

secondary to disease and environmental factors. The influences of prior smoking and environmental exposures are particularly difficult to distinguish from senescence (Table 11.1).

These mechanical changes are exacerbated by an aging central nervous system with diminished responsiveness to hypoxemia as well as to hypocapnia and hypercapnia. In addition, older patients exhibit increased sensitivity to opioid-induced blunting of the normal ventilatory response to hypercarbia. Residual anesthetic agents may further suppress these reflexes. Thus, older patients are more susceptible to developing hypoxia, making them unable to respond appropriately to hypoxemia and hypercarbia. In general, supplemental oxygen and close monitoring are required, especially in the immediate postoperative setting.

Central nervous system

There is continual neuronal loss with aging, which is more prominent in gray matter versus white. There is a gradual decline in cerebral metabolic rate, oxygen consumption, and cerebral blood flow. Decreases in neurotransmitter action of

acetylcholine, dopamine, and serotonin may predispose older patients to delirium and increased sensitivity to effects of centrally acting medications. Simple pain thresholds rise with age, reflecting a reduction in end-organ pain neurons and peripheral deafferentation. However, central processing of pain and thalamic amplification probably remain normal.

Peripheral nervous system

Sensory changes occur and may lead to decreased visual acuity and increases in dark adaptation. Diminished hearing, particularly at the high frequencies above 10 kHz, has been observed. Attrition of taste buds, diminished ability to detect smell, and diminished thirst sensation have been noted and may lead to dehydration and orthostatic hypotension. Joint perception and vibration sense are compromised, contributing to an increased risk of falls. The risk of falls is exacerbated by the changes in the peripheral nervous system as well. Electrical conduction falls in both sensory and motor nerve pathways by about 2% to 3% per decade after adulthood, or approximately 0.15 m/sec/year. Peripheral neurogenic atrophy is common, resulting in decreased muscle strength and fine motor control. Aging also is accompanied by a progressive predominance of type 1 (slow-twitch) over type 2 (fast-twitch) muscle fibers.

These changes may lead to increased difficulty with balance and coordination following surgery, especially if the surgery involves a limb. Postoperatively, regional blockade may further distort the older patient's ability to balance or use crutches or walking aids. These may be important considerations when choosing the surgical setting (inpatient versus ambulatory) and the type of anesthesia (regional versus general).

Postoperative delirium, cognitive dysfunction, and stroke

Postoperative mental status changes are one of the events about which elderly patients are most concerned. Common postoperative mental status changes result from delirium, cognitive dysfunction, or perioperative stroke.

Delirium is an acute confusional state associated with fluctuating mental status and disorientation (Chapter 55). It may be accompanied by agitation or combative behavior. The incidence of postoperative delirium ranges from 5% to 50% and has been linked to numerous preexisting conditions and medications (Table 11.2). Delirium may manifest as postoperative agitation, and confusion may occur unexpectedly, usually appearing 1 to 4 days following surgery and often after an initial lucid period. Certain medications are associated with an increased incidence of delirium, including meperidine, benzodiazepines (especially lorazepam and diazepam), and medications with anticholinergic effects (diphenhydramine and atropine).

Initial management of delirium is supportive, addressing the ABCs: airway, breathing, and circulation. Once hemodynamic stability is assured, the next step is to search for an etiology. This requires a search for a physical illness, infection, or drug toxicity. Untreated pain is a common cause of agitation

Table 11.2. Causes of delirium

and confusion in the postoperative period and may go unrecognized in demented patients with communication problems. Opioids should be considered early in treatment, and haloperidol, in small doses, may be useful in treating acutely agitated elderly patients. Supportive measures include safety precautions such as rails and close supervision. The use of simple measures, such as provision of clocks, good daytime lighting, familiar photos, and personal objects, may help reorient older people facing a new environment and may improve their ability to cope. Postoperative delirium is associated with significant increases in length of stay, nursing home admission, and morbidity and mortality.

Postoperative cognitive dysfunction (POCD), in contrast to delirium, refers to subtle cognitive changes usually detected on neuropsychological testing after surgery. Early POCD is related to increasing age, increasing duration of anesthesia, a low level of education, a second operation, postoperative infection, and respiratory complications. Prolonged POCD (3 months) is associated only with increasing age. Patients with POCD at discharge have a higher mortality at 1 year after surgery. POCD continues to be investigated, and the role of anesthesia in the development of POCD is not yet fully understood. Potential mechanisms currently under investigation include, but are not limited to, exaggerated decline in central cholinergic function, perioperative hypoxia and hypotension, genetic predisposition, and abnormal stress response with prolonged hypercortisolemia.

Postoperative stroke is also a significant cause of altered mental status and morbidity following surgery. In general, the dramatic increase in cerebral arteriosclerosis observed with advanced age is associated with an increase in the incidence of stroke. The overall incidence of stroke is 1.5 times higher in individuals 65 to 74 years old, twice as high in patients 75 to 84 years old, and three times as high in patients aged 85 years or older compared with younger age groups. Perioperative stroke risk increases from 0.2% in patients less than 65 years of age to 3.4% in patients older than 80 years.

Renal system

As many as 30% of elderly patients have renal impairment prior to surgery, which predisposes them to acute tubular necrosis postoperatively (Table 11.3). Acute renal failure accounts for

Table 11.3. Renal changes in the elderly

Decrease in renal blood flow (mainly in cortex)
Variable decline in glomerular filtration rate
Decline in ADH response
Decrease in total body water
Decreased ability to conserve sodium
Diminished urine-concentrating ability (urine osmolarity declines from 1200 mOsm/kg at age 30 y to 900 mOsm/kg by age 80 y)
Decline in renin–aldosterone levels
Decreased thirst perception (dehydration)

ADH, antidiuretic hormone.

one-fifth of the postoperative deaths in the elderly. A steady decrease in glomerular filtration rate is accompanied by a decline in lean body mass. Thus, creatinine production declines, and seemingly normal creatinine values may not accurately reflect true renal function. Measuring creatinine clearance gives a more accurate idea of renal function.

Hepatic system

Aging is associated with a loss of functioning mass of hepatocytes. The decrease in drug metabolism parallels the loss of functional mass, but there is significant interindividual variation. Hepatic blood flow diminishes, leading to decreased clearance of drugs. Albumin production declines with age and is reduced further by malnutrition and chronic and acute diseases, which may result in an increase in the free portion of protein-bound drugs. Phase II metabolism appears to be unaltered.

Pharmacokinetic and pharmacodynamic changes

The administration of medications in the elderly is especially challenging. Older patients exhibit increased sensitivity to medications such as opioids and inhalational agents, and the effects may be prolonged because of delayed clearance and excretion (Table 11.4). In general, it is important to reduce the initial doses and increase the interval between repeated doses in older patients.

As a person ages, there is a decrease in total body water and an increase in fat reservoirs, leading to a decrease in the initial volume of distribution of water-soluble medications. A delay in intercompartmental clearance further affects the initial redistribution of drugs, potentially leading to a higher initial plasma concentration of medications such as propofol. Albumin levels tend to decrease with age; in addition, the quality of protein

Table 11.4. Elimination half-life of drugs

Drug	Young people	Older people
Fentanyl	4 h	15 h
Alfentanil	1.5 h	2 h
Diazepam	24 h	72 h
Midazolam	2.8 h	4.3 h
Vecuronium	16 min	45 min

binding deteriorates with advanced age. The decrease in plasma albumin increases the free fraction of the drugs, increasing the available concentration at the receptor site and causing a more profound effect. This becomes more important in drugs that are highly protein bound, such as barbiturates, benzodiazepines, and opioids. Reductions in liver blood flow and renal function lead to a prolonged duration of action of the drugs and their metabolites. The increase in body fat may act as a reservoir for lipid-soluble drugs, leading to prolonged duration and elimination half-life of lipophilic drugs, such as morphine.

In older patients, these changes may result in an increased potential to manifest adverse effects associated with medications. For instance, hypotension associated with propofol administration may be prolonged and increase the risk of ischemia in patients with underlying cardiac or cerebrovascular disease. Adverse events may be increased by polypharmacy, and in older patients it is advisable to minimize the number of different agents used when possible.

Anesthetic management

There is no “best” anesthetic for an elderly patient. In contrast to pediatric patients, in whom it is possible to make assumptions about anesthetic requirements based on age-specific physiologic changes, elderly patients are a heterogeneous population and chronologic age may not reflect the physiologic age. Older patients require a careful preoperative assessment for the presence of concomitant disease, medication use, and functional status, all of which will influence the choice of anesthesia.

Preoperative examination

The preoperative evaluation is critical for the safe administration of anesthesia to elderly patients. The goal of a preoperative assessment is to establish the baseline health and functional status of the patient, identify comorbid conditions, and determine whether further evaluation and optimization are required. Elderly patients have an average of three diseases after the age of 65 and are frequently on multiple medications, making the preoperative assessment especially challenging. Chronic pain, agitation, and dementia may prohibit the patient from lying still during the procedure, making a plan for deep sedation unfeasible, even if the procedure is minor. The early identification of patients requiring further investigation or those with special issues may help with advance planning and room scheduling.

The preoperative evaluation of patients with extensive medical histories may be very difficult in those with baseline dementia and memory loss, and every effort should be made to obtain prior medical records. A mental status examination should be considered for all geriatric surgical patients. Preoperative depression and alcohol abuse are relatively common and not always admitted by the patient or family, but these will increase the risk of delirium in the postoperative period. Frail older patients frequently need assistance postoperatively, and the plan for postoperative care should be discussed in advance with the patient and relevant relatives or caretakers.

As with all preoperative testing, requests for laboratory studies or further investigations should be directed by the history and a physical examination that includes a functional assessment. A baseline electrocardiogram (ECG) generally is indicated in women over the age of 55 years and men over 45 years. Further testing beyond the history and physical is determined by an assessment of the surgical procedure and the baseline comorbidities of the patient. For instance, a patient with significant cardiac morbidity about to undergo cataract surgery may not need further investigation, whereas a patient with fewer cardiac risk factors coming in for high-risk surgery will need a comprehensive cardiac evaluation.

Polypharmacy is a common occurrence in elderly patients, and a complete list of medications, including over-the-counter and alternative treatments, should be included in the preoperative assessment. It may be helpful to ask patients to bring all their medications to the preoperative clinic or on the day of surgery to lessen confusion regarding multiple prescriptions.

Intraoperative management

Premedication

A general principle when treating the geriatric patient is to avoid any unnecessary medications. Premedication should be administered carefully because of increased sensitivity to the drugs and a higher incidence of postoperative delirium. Midazolam is a popular benzodiazepine administered in the preoperative period. Older patients are more sensitive to the effects of midazolam; therefore, the starting dose may need to be reduced and the interval between supplemental doses increased. Anticholinergic agents such as diphenhydramine and scopolamine should be avoided because of increased incidence of delirium.

Induction

Profound hypotension may occur following the induction of general anesthesia in older patients. Several factors contribute to the development of hypotension, including a decreased volume of distribution for induction agents, leading to a more pronounced effect for the same dose. Hypovolemia also exaggerates this effect, especially in patients who are fasting, hypertensive, or on diuretics and those who have had bowel preparations.

Aging results in a diminished capacity to respond to hypotension because of blunting of the baroreceptor reflex, leading to a reduction in heart rate increases. This may be exacerbated by medications that further reduce the ability to respond to hypotension, such as β -blockers and angiotensin-converting enzyme inhibitors. Therefore, the dose of induction agent may need to be decreased, vasopressors should be readily available, and the interval between doses of repeated medications should be lengthened as necessary.

Drug administration

Benzodiazepines

Elderly patients exhibit increased central nervous system sensitivity to midazolam; therefore, a lower starting dose is recommended. Reduced hepatic microsomal oxidation and clearance result in an elimination half-life roughly twice that in younger patients. Longer-acting benzodiazepines, such as lorazepam and diazepam, have significantly prolonged action in the elderly and may lead to delirium and confusion; therefore, they should probably be avoided in this population.

Propofol

In the elderly, propofol has a smaller volume of distribution and initial target organ levels are higher, which may result in a greater degree of hypotension compared with other agents, because of vasodilatory effects. The initial redistribution likely also is slowed in the older patient, so dosing intervals should be increased; this is particularly true in patients with reduced cardiac output. The short duration of action and minimal side effects associated with propofol are advantageous in the older patient with baseline cognitive dysfunction and multiple comorbidities, provided the hypotension is tolerable. In general, the induction dose of propofol may need to be reduced by 25% to 50% and titrated slowly to effect.

Thiopental

Thiopental has a slower onset of action and causes a reduction in cardiac output in older patients. The dosage generally should be reduced 25% to 50% in the elderly. The elimination half-life is prolonged to almost 25 hours in older individuals, compared with 12 hours in younger patients. Thiopental should be used with caution in frail elderly patients with cardiac or renal disease.

Etomidate

Etomidate is a short-acting agent metabolized by ester hydrolysis. A rapid recovery and minimal cardiac depressant effects make it a useful agent in the elderly patient with multiple comorbidities, especially in the presence of hypovolemia. The 11- β -hydroxylase blockade caused by a single bolus of etomidate should be considered. Drug clearance is hepatic flow dependent and may be prolonged; thus the overall dose may need to be reduced.

Opioids

Aging is associated with increased sensitivity to opioid medications, resulting in a predisposition to respiratory depression and apnea. Hepatic metabolism is reduced, the volume of distribution generally is increased, and renal clearance of metabolites is reduced. As with other medications for the elderly, the dose of opioids should be reduced and the interval between doses prolonged.

Remifentanyl, metabolized by plasma and tissue esterases, has an extremely short half-life. Its noncumulative nature offers advantages in the elderly patient, particularly in cases requiring sedation and in those with intense short periods of pain and stimulation. The clinician should be aware of the potential bradycardia associated with remifentanyl administration, particularly in patients who already are β -blocked. Fentanyl has minimal cardiac side effects, although older patients exhibit increased sensitivity. In general, the dose should be reduced 50% and titrated slowly to effect. Morphine is longer acting, with active metabolites; thus, there may be increased risk of respiratory depression, as with all long-acting opioids.

Inhalational agents

The minimum alveolar concentration (MAC) of inhalational agents declines 4% every decade over age 40. By the age of 70 years, the MAC is reduced 20% to 30% compared with that of a younger subject. This may reflect an age-related loss of central nervous system reserve and a decrease in neurotransmitter levels. Cardiac effects of these agents, such as reduced myocardial contractility, are exaggerated in most elderly patients, especially those with already compromised cardiac function. Shorter-acting agents such as desflurane offer some advantages in the elderly, but there are no consistent data to support the use of one short-acting inhalational agent over another.

Muscle relaxants

Aging results in a decrease in muscle mass and strength, as well as a slowing in time and rate of relaxation, likely as the result of decreased rate and maximal speed of calcium uptake in the endoplasmic reticulum. The duration of action of nondepolarizing muscle relaxants is prolonged in the elderly because of slower hepatic metabolism and decreased renal clearance; however, this generally has little effect on the clinical administration of the medications. Agents that undergo Hoffman's degradation, such as atracurium and cisatracurium, are not affected by aging. Mivacurium, which is metabolized by plasma cholinesterase, can demonstrate a prolonged duration of action because of a decrease in the level of cholinesterase in frail elderly patients. The pharmacokinetics of depolarizing muscle relaxants are not affected by aging. Complete reversal of neuromuscular blockade is important to prevent adverse events associated with prolonged weakness in the recovery area. Tachycardia associated with anticholinergic medications such as glycopyrrolate may not be well tolerated in patients with underlying ischemic disease. Reducing the dosage or administration of short-acting β -blockers such as esmolol may offset the tachycardia.

Airway management

Elderly patients have diminished pharyngeal sensitivity and a loss of protective laryngeal reflexes, and are at increased risk from silent passive aspiration. Sedation and residual anesthetic

drug effects may compound this risk. Establishment of an airway may be difficult in elderly patients. The factors that may complicate airway management include limited neck extension, advanced arthritis, increased vertebral insufficiency worsened by neck extension, and reduced mouth opening. Although the edentulous state can make intubation easier, it also can make mask ventilation much more difficult, and an oral airway may be required to achieve an adequate mask fit. Sympathetic response to laryngoscopy is exaggerated in elderly patients, and the resulting hypertension and tachycardia may be poorly tolerated by patients with underlying cardiac disease.

Regional anesthesia

Although anecdotal evidence suggests there may be significant advantages to spinal or epidural anesthesia over general anesthesia, there are few data to support a clear advantage in the elderly patient. Certain advantages that have been shown in patients undergoing epidural or spinal anesthesia include a reduction in the incidence of postoperative thrombosis, blood transfusion, and blood loss during orthopedic procedures. Age-related decreases in the clearance of local anesthetics and subsequent accumulation may predispose the older patient to toxicity. Lower doses of local anesthetics may be needed because nerve size and conduction are reduced with aging. The quantity of myelinated fibers is diminished in older patients, and by age 90, one third of myelinated fibers have disappeared.

Placement of regional techniques may be more difficult secondary to arthritis and calcification of spinal ligaments. Other comorbidities and chronic pain may restrict optimal positioning. Local anesthetics in the epidural and subarachnoid space ultimately are absorbed into the circulation, and the plasma concentration depends on their absorption, distribution, and elimination. With age there is a decrease in the size and compliance of the epidural space, and equivalent doses of local anesthetics may cause a higher level of sensory blockade in the elderly than in the younger individual. Elderly patients also tend to exhibit more dramatic decreases in blood pressure, and vasopressors should be immediately at hand to treat hypotension. Postdural puncture headaches are less common in elderly patients.

Positioning

Many elderly patients have characteristics that predispose them to accidental injury from seemingly benign positions. These factors include accelerated loss of subcutaneous and intramuscular fat, resulting in bony prominences requiring extra padding; demineralized long bones susceptible to fractures; atrophied skin tissues, leading to skin tears after tape and intravenous line placement; and, in general, slow healing. Vertebral insufficiency may predispose older patients to unexpected cerebral ischemia with neck extension during airway manipulation or positioning for surgery. Osteoarthritis and ankylosing spondylitis may limit optimal positioning during intubation and during placement of central neuraxial blockade.

Monitoring

Older patients need careful monitoring during and after anesthesia. The significant incidence of cardiovascular disease requires careful vigilance for ischemia and arrhythmias, and a five-lead ECG may offer more information than a basic three-lead ECG monitor. Similarly, elderly patients are at increased risk for hypoxemia, and continuous monitoring of oxygen saturation should be accompanied by end-tidal CO₂ monitoring for ventilation, even during simple monitored anesthesia cases. The ability to compensate for hemodynamic fluctuations is impaired in older patients, and an arterial line may be very useful for continuous monitoring. In general, more aggressive use of invasive monitoring should be considered.

Thermoregulation

Hypothermia is both more common and less well tolerated in the older frail patient. The normal thermoregulatory response to cold stress involves peripheral vasoconstriction, shivering, and eventual activation of brown fat metabolism. These mechanisms may be impaired in the elderly. The major age-related changes that predispose the elderly patient to hypothermia are a steady decline in basal metabolic rate, leading to reduced heat production, and a parallel increase in heat loss. Adverse effects from hypothermia include an increase in blood loss from platelet dysfunction and coagulopathies, myocardial ischemia, and poor wound healing. Active warming of the older patient should be performed both within the operating room and in the postoperative period.

Postoperative recovery

Some of the common problems facing the elderly during recovery are respiratory depression, delayed awakening from anesthesia, postoperative delirium, and inadequate pain management. Postoperative respiratory insufficiency is a common problem seen in the elderly and frequently is the result of residual effects of medications used intraoperatively. With advanced age, the respiratory response to hypoxia and hypercarbia is decreased, and this is exaggerated further by intraoperative use of opioids. Respiratory effort frequently is insufficient in frail older patients with weakened thoracic musculature, and the ability to cough and clear secretions is diminished. This predisposes patients to aspiration, atelectasis, and pneumonia. Lingering effects of anesthetics also increase postoperative respiratory insufficiency.

The accurate assessment of pain in the elderly may be difficult because of sedation, dementia, confusion, and delirium, which may result in under-treatment of pain. Regional techniques may be advantageous, minimizing the need for parenteral opioids. Nonopioid pain medications, such as the

α_2 -agonists (gabapentin) and acetaminophen, may be useful adjuncts and help reduce the dose of opioids. When opioids are used, careful monitoring and potentially reduced dosing should be considered. Patient-controlled analgesia offers significant advantages in the cognitively intact elderly patient. In more impaired patients, continual pain assessment and treatment are important.

Neurologic diseases and anesthesia

Spiro G. Spanakis, John Lin, and Pankaj K. Sikka

Patients with neurologic disease require special consideration and preparation in the perioperative period. Preoperatively, the current status of the patient's disease must be assessed and optimized, if possible. Medications should be reviewed and a plan established for their administration or discontinuation in the perioperative period. Regional anesthesia may be used in patients with certain neurologic diseases, but in others it may exacerbate their disease or be contraindicated. Consent for surgery and anesthesia may need to be obtained from a health care proxy if associated cognitive impairment is present.

Intraoperatively, a plan for neuromuscular blockade for endotracheal intubation and maintenance must be established. Patients with neurologic disease may exhibit an atypical response to nondepolarizing and depolarizing muscular blockers. Outward manifestations of neurologic disease may include motor and sensory deficits, but autonomic dysfunction also may be present.

Postoperatively, patients may exhibit impaired respiratory function leading to respiratory insufficiency in the recovery room, an exacerbation of their sensory or motor symptoms, or impaired cognitive function that may interfere with recovery from anesthesia.

Cerebrovascular disease

Cerebrovascular disease is usually manifested as transient ischemic attacks (TIAs) or stroke. TIAs are defined as facial or extremity weakness and speech problems lasting <24 hours. Patients with TIAs should undergo further neurologic evaluation, because they are prone to developing stroke. Presence of a carotid bruit may or may not be associated with significant carotid disease. Following a stroke, elective surgery should be deferred for at least 2 to 3 months, to allow resolution of regional blood flow abnormalities and CO₂ responsiveness.

Preoperatively, patients with stroke should undergo detailed neurologic and cardiac evaluation. Strokes may be thrombotic, embolic, or hemorrhagic. Thrombotic strokes usually occur in elderly patients with coronary artery disease (atherosclerosis), hypertension, or diabetes mellitus. Embolic (air, calcium debris, fat, fibrin) strokes usually are associated with valvular heart surgery. Hemorrhagic strokes are the result of intracranial hemorrhage due to hypertension, cerebral aneurysm rupture, or arteriovenous malformation. Patients (except those with

hemorrhagic strokes) are usually on warfarin, aspirin, or dipyridamole therapy. These drugs may need to be stopped preoperatively.

Intraoperatively, patients with stroke should have a smooth induction with avoidance of succinylcholine, as denervation of the muscles may lead to a hyperkalemic response. Blood pressure should be maintained at a level higher than normal because of the rightward shift of cerebral autoregulation. Neuromuscular blockade should be monitored on the normal extremity, as the affected extremity may show an exaggerated response to nerve stimuli and thus an underestimation of the degree of blockade.

Use of shorter-acting anesthetic agents may be beneficial for faster recovery and assessment of neurologic function postoperatively. Adequate pain and blood pressure control and avoidance of hyperglycemia should be the goal. Risk of postoperative stroke for nonneurologic surgery is estimated to be about 0.25%. Risk of stroke is higher in patients undergoing neurologic and cardiovascular surgery and those with prolonged hypotension or hypertension. Hypotension may result in cerebral hypoperfusion, which may cause thrombosis and infarction. Sustained hypertension may disrupt the blood-brain barrier and cause intracranial hemorrhage.

Seizure disorders

Seizures are either idiopathic or the result of a central nervous system disorder. Recurrent paroxysmal seizures are termed *epilepsy*. Seizures occur because of abnormal brain electrical activity and may result from decreased inhibitory neurotransmitter activity (γ -aminobutyric acid), increased excitatory neurotransmitter activity (glutamic acid), or increased neuronal firing.

Seizure activity may be focal or generalized in the brain. Seizures may be classified as generalized (grand mal or tonic-clonic), petit mal (staring or repeated blinking of the eyes), or partial (simple or complex to varying degrees). Tonic-clonic seizures are characterized by tonic motor activity (30 seconds), followed by a clonic (jerking) phase, with or without loss of consciousness. When accompanied with loss of consciousness, they are termed *grand mal seizures*. *Status epilepticus* is defined as two consecutive tonic-clonic seizures without regaining consciousness, or seizure activity for 30 minutes or longer.

Patients presenting for surgery with a history of seizures should be asked about the type of seizures they have, medications they are taking, and the frequency of seizures. Seizures, if not idiopathic, may occur as a result of head injury, stroke, cranial tumors, metabolic abnormalities (hypoglycemia, uremia), or drug toxicity. Antiseizure medications should be continued until surgery, and may even have to be supplemented intraoperatively.

Intraoperatively, antiseizure medications decrease the duration of neuromuscular blockade. Antiseizure medications cause hepatic microsomal enzyme induction. Potentially epileptogenic medications such as enflurane, methohexital, and ketamine should be avoided. It is important to remember that atracurium is metabolized to laudanosine, and meperidine to normeperidine, which have epileptogenic potential.

Postoperatively, antiseizure medications should be restarted as soon as possible. Seizures are more likely to occur during the postoperative period. Grand mal seizures should be treated aggressively. Management includes maintaining the airway to prevent hypoxia and administering intravenous drugs such as midazolam (2–5 mg), diazepam (5–10 mg), thiopental (75–125 mg), or propofol (50–75 mg) to control the seizure. Phenytoin (500–1000 mg) is often administered for prevention of additional seizures.

Autonomic dysfunction

Autonomic dysfunction is usually seen in disorders of the central or peripheral nervous system, such as diabetes mellitus, chronic alcoholism, multiple sclerosis, syringomyelia, and spinal cord injury. Common manifestations of autonomic dysfunction are summarized in [Table 12.1](#).

Intraoperatively, these patients manifest hypotension, which may cause coronary and cerebral hypoperfusion. Vasodilatory effects of general anesthetic agents and epidural and spinal anesthesia are poorly tolerated. Patients with severe hemodynamic instability should be observed with invasive arterial blood pressure monitoring. These patients are usually hypovolemic and tolerate blood loss poorly. Management consists of treatment of hypotension, preferably with direct-acting vasopressors; fluid administration; and maintenance of normothermia.

Alzheimer's disease

Alzheimer's disease is characterized by irreversible impairment of cognitive function, memory disturbances, and difficulty maintaining and sustaining attention. Progressive

degeneration of cholinergic neurons in the cortex, amygdala, and hippocampus results in marked cortical atrophy. Patients also may experience gait and motor disturbances, seizures, or myoclonus, eventually leading to apraxia and aphasia later in the disease course.

Outpatient pharmacologic therapy of the disease is aimed at slowing disease progression and delaying the onset of symptoms and apraxia. Tacrine, donepezil, and rivastigmine are cholinesterase inhibitors used to treat the disease and should be continued in the perioperative period. Tacrine induces down-regulation of postsynaptic acetylcholine receptors, and patients may exhibit altered responses to nondepolarizing blocking agents. Donepezil blocks acetylcholine hydrolysis and therefore exaggerate depolarizing blockade by succinylcholine. Anticholinergics (except glycopyrrolate, which does not cross the blood–brain barrier) may exacerbate symptoms in the postoperative period, giving rise to confusion and cognitive dysfunction.

Preoperatively, patients may be disoriented and uncooperative, so a health care proxy should give consent for all procedures. Regional anesthesia may be used only if the patient can remain cooperative. Premedication should be minimized and short-acting agents used when possible for sedation and analgesia.

Recent research shows that general anesthetics induce long-lasting neurotoxicity (at the molecular level) and cognitive dysfunction in animal models. For example, desflurane increases β -amyloid production in human neuroglioma cells. β -amyloid plaques have been implicated in the pathogenesis of Alzheimer's disease; however, the implications of these studies for clinical practice have yet to be determined.

Parkinson's disease

Parkinson's disease affects individuals between the ages of 50 and 70 years and is an important cause of perioperative morbidity. Apoptosis of the dopaminergic neurons in the substantia nigra of the basal ganglia gives rise to thalamic and brainstem nuclei inhibition, resulting in suppression of the motor cortex. Excessive thalamic inhibition results in suppression of the cortical motor system, leading to akinesia, cogwheel rigidity, and tremor, whereas inhibition of brainstem locomotor areas contributes to abnormalities of posture and gait. Intellectual function is preserved early in the disease course.

Three classes of drugs are used to treat Parkinson's disease; they provide symptomatic relief because no cure exists. Dopamine agonists include bromocriptine, pergolide, ropinirole, pramipexole, and cabergoline. Levodopa (a metabolic precursor of dopamine) administered with carbidopa (which inhibits peripheral breakdown of dopamine) also is commonly used. Early use may be associated with a quicker onset of bradykinesia, so therapy sometimes is delayed in the disease course. The type B monoamine oxidase inhibitor selegiline, which prolongs the action of dopamine in the striatum, also may be used.

Table 12.1. Common manifestations of autonomic dysfunction

Orthostatic hypotension
Bladder dysfunction
Gastrointestinal dysfunction
Lacrimation and salivation
Decreased sweating

Autonomic instability manifesting as hypotension or hypertension may be related to treatment with levodopa or may be a result of the disease process itself. Other side effects of levodopa therapy include orthostatic hypotension, cardiac irritability, and nausea and vomiting. Dopamine agonists also may precipitate hypotension. Drug interactions with meperidine, serotonergic drugs, and catecholamines also must be considered in any patient on monoamine oxidase inhibitors. Anticholinergic drugs and antihistamines may be used during acute exacerbation of symptoms.

Preoperatively, a thorough history and physical examination should be performed, focusing on specific areas commonly affected by Parkinson's disease. A history of orthostatic hypotension, cardiac arrhythmias, hypotension, hypertension, autonomic dysfunction, and impaired temperature regulation should be identified. Existing respiratory impairment should be assessed, along with a history of pharyngeal muscle dysfunction and dysphagia and the degree of muscle rigidity. History of gastrointestinal reflux and nutritional and mental status also should be assessed (Table 12.2).

Medications should be continued until the day of surgery, but the side effects must be appreciated during the administration of anesthesia. Because the half-life of levodopa is short (1–3 hours), interruption of therapy may result in severe muscle rigidity that interferes with ventilation or in the development of parkinsonism hyperpyrexia syndrome, which is the result of an acute suppression of central dopaminergic activity. Intravenous levodopa has been used during the perioperative period, although it may result in side effects such as hypertension, hypotension, and dysrhythmias. Also, a rapid sequence induction may be indicated in patients with delayed gastric emptying, who are at increased risk for pulmonary aspiration.

Table 12.2. Assessment of the patient with Parkinson's disease

System	Assessment by history
Head and neck	Pharyngeal muscle dysfunction Dysphagia Sialorrhea Blepharospasm
Respiratory	Respiratory impairment from rigidity or bradykinesia
Cardiovascular	Orthostatic hypotension Cardiac arrhythmias Hypertension Hypovolemia Autonomic dysfunction
Gastrointestinal	Weight loss Poor nutrition Susceptibility to reflux
Urologic	Difficulty in micturition
Endocrine	Abnormal glucose metabolism (selegiline)
Central nervous system	Muscle rigidity, akinesia, tremor, confusion, depression, hallucination, speech impairment

Adapted from Rudra A, Rudra P, Chatterjee S. Parkinson's disease and anaesthesia. *Indian J Anaesth* 2007; 51(5):382–388.

Table 12.3. Neurologic disease and neuromuscular blocking agents

Disease	Depolarizing neuromuscular blockade	Nondepolarizing neuromuscular blockade
Alzheimer's disease	No disease-related contraindication	Prolonged effect in patients on donepezil receiving atracurium
Parkinson's disease	Single case report of hyperkalemia	No disease-related contraindication or altered response
Huntington's disease	Decreased plasma cholinesterase may lead to prolonged response	Increased sensitivity
ALS	Vulnerable to hyperkalemia after administration	Prolonged response
MS	Avoid if paresis or paralysis is present	Prolonged response possible
GBS	Contraindicated	Prolonged response possible
Neurofibromatosis	Increased sensitivity	Increased sensitivity

Dopamine antagonists such as metoclopramide, phenothiazines, and butyrophenones should not be given, because they may cause extrapyramidal symptoms. Because Parkinson's disease may result in autonomic insufficiency, hemodynamic instability and altered response to vasopressors sometimes are seen during anesthesia. Patients with Parkinson's disease exhibit a normal response to nondepolarizing muscle blockade. There is only an isolated report in the literature of hyperkalemia following succinylcholine administration, although other factors probably contributed to the incident. Alterations in the response to neuromuscular blocking agents in neurologic diseases are summarized in Table 12.3.

There are no reports of adverse responses to modern inhalational gases such as isoflurane, sevoflurane, and desflurane. Ketamine has been reported to potentiate sympathomimetic properties of levodopa, whereas morphine, alfentanil, and fentanyl have been reported to exacerbate muscle rigidity. Regional anesthesia may have some potential advantages over general anesthesia, such as avoidance of neuromuscular blockers and manipulation of the airway. No data from randomized controlled trials exist that can point to the best anesthetic technique. During the postoperative period, these patients are susceptible to symptom exacerbation, aspiration, respiratory failure, and mental confusion.

Huntington's disease

Huntington's disease is an autosomal dominant disease characterized by the triad of choreiform movements, progressive dementia, and personality changes, with an onset age of 35 to 40 years. The mechanism of the disease involves marked atrophy of the basal ganglia, particularly the caudate nucleus and globus pallidus.

There is no cure for the disease, and treatment is symptomatic. Haloperidol is used to decrease choreoathetoid movements by nonselectively antagonizing dopamine receptors. Fluphenazine also may relieve chorea, hallucinations, and delusions.

Preoperatively, the history and physical examination should focus on symptoms of dysphagia, because pharyngeal muscle dysfunction, common in this disease, increases the risk of aspiration in the perioperative period. Dysphagia also leads to malnutrition and cachexia.

Sodium thiopental has been implicated in prolonged apnea in afflicted patients if used at dosages >3 to 5 mg/kg. Decreased plasma cholinesterase levels may lead to a prolonged response after succinylcholine administration. These patients also may exhibit prolonged responses to nondepolarizing muscle relaxants.

Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS) is a degenerative disease of the motor ganglia in the anterior horn of the spinal cord and the spinal pyramidal tracts, resulting in upper and lower motor neuron dysfunction. Weakness and atrophy of respiratory muscles eventually result in respiratory failure and death.

Preoperatively, the severity of the disease may be assessed by spirometry. Patients with ALS exhibit reduced vital capacity with adequate gas exchange until late in the course of the disease. These effects are exacerbated further by general anesthesia. Successful epidural analgesia has been described in these patients, whereas there have been reports of neurologic sequelae in patients receiving spinal anesthesia.

Patients with ALS exhibit a prolonged response to nondepolarizing muscular blockade. Depolarizing agents induce hyperkalemia and therefore should be avoided. Bulbar involvement may occur, with resulting dysphagia and increased risk of pulmonary aspiration. Autonomic dysfunction also may be present, giving rise to orthostatic hypotension and a resting tachycardia.

Multiple sclerosis

Multiple sclerosis (MS) is an autoimmune disorder characterized by a progressive demyelination of the brain and spinal cord. Women are affected twice as often as men, with an onset of disease between the ages of 20 and 40 years. There are several categories of the disease, the most common being relapsing–remitting MS, eventually resulting in gradual neurologic deterioration.

Exacerbations of MS are characterized by paresthesias, visual problems, and motor weakness. Visual disturbances result from optic neuritis and diplopia. Only symptomatic treatment is available with a variety of drug classes, including corticosteroids, used for acute relapses. History of steroid use should be obtained in the preoperative evaluation, because patients may have received high doses for an extended period, resulting in adrenal insufficiency later. Other drugs used in-

clude interferon- β , glatiramer acetate, intravenous immunoglobulin, methotrexate, and cyclophosphamide.

Patients with MS exhibit varied responses to general anesthesia. An exacerbation of their symptoms may be expected in the postoperative period in general. When indicated, peripheral nerve blocks and epidural anesthesia may be used, spinal anesthesia is somewhat controversial, with limited evidence of either safety or harm. Autonomic dysfunction also may be present late in the disease. If paresis or paralysis is present, depolarizing muscle blockade should be avoided. Patients with MS may exhibit a prolonged response to depolarizing neuromuscular blockade and should be monitored if these drugs are administered to them. Intraoperatively, hyperthermia should be avoided because it may exacerbate symptoms.

Guillain-Barré syndrome

Guillain-Barré syndrome (GBS), an acute demyelinating polyneuropathy, usually occurs after a viral illness, resulting in ascending motor paralysis. Bulbar involvement may occur, resulting in respiratory failure requiring ventilatory support in an otherwise healthy person. GBS also may present in pregnancy.

GBS associated with pregnancy results in an increased need for ventilatory support and an increased risk of maternal mortality. Regional anesthesia has been used for labor but may exacerbate neurologic symptoms. This risk must be weighed against the risks of general anesthesia in pregnant patients.

Neurofibromatosis

Neurofibromatosis is a progressive autosomal dominant disorder involving multiple organ systems. The airway may be compromised if neurofibromas are present in the cervical, laryngeal, or mediastinal regions. Intracranial tumors may be the presenting diagnosis in the perioperative period. Intellectual function also is compromised with disease progression. The endocrine system may be involved, and patients may present with pheochromocytomas, carcinoid tumors, medullary thyroid carcinoma, or hyperparathyroidism. Spinal neurofibromas may complicate or contraindicate spinal anesthesia.

Syringomyelia

Syringomyelia is thought to occur as the result of obstruction of the cerebrospinal fluid outflow from the fourth ventricle. The increased pressure causes dilation and cavitation of the spinal cord, leading to neurologic symptoms. Most commonly, the cervical spine is affected, causing sensory and motor deficits in the upper extremities. Associated craniovertebral anomalies, including Arnold-Chiari malformation and thoracic scoliosis, are common.

These patients typically present to the operating room for decompressive procedures, including ventricular–peritoneal shunting. Respiratory function should be assessed preoperatively and any neurologic deficits documented. Patients may

have increased sensitivity to neuromuscular blocking drugs because of the presence of muscle wasting.

Autonomic hyperreflexia

Autonomic hyperreflexia is a reaction caused by hyperstimulation of the autonomic nervous system. In the United States, the reported prevalence of this syndrome in individuals with spinal cord injuries at the T6 level and above is 48% to 90%. Although it commonly occurs in patients with spinal cord injuries above T6, patients with a spinal cord injury at T6 through T10 also may be susceptible. Autonomic hyperreflexia syndrome is manifested by systemic hypertension, bradycardia, sweating, and flushing of the skin. If not treated promptly, it may lead to seizures, stroke, myocardial infarction, and death.

Causes and triggering factors

The most common cause of autonomic hyperreflexia is spinal cord injury above the T6 level. Other causes include effects of cocaine and amphetamines, GBS, and severe head trauma.

Distention of a hollow viscus such as the rectum or bladder is the most common triggering stimulus (Table 12.4). However, the reflex may occur from any endogenous or exogenous stimulus occurring below the level of the cord lesion. Tactile or thermal skin stimulation, decubitus ulcers, labor contractions, and urinary tract infections also have been reported precipitants of this syndrome. Although most incidences occur in the operating room, it is important for the anesthesiologist to consider other causes in the postoperative period following recovery from regional or general anesthesia. The differential diagnosis of autonomic hyperreflexia also includes carcinoid syndrome, thyroid storm, neuroleptic malignant syndrome, pheochromocytoma, and toxemia of pregnancy.

Symptoms and signs

Autonomic hyperreflexia is seen only after resolution of spinal shock (loss of sensation and reflexes below the level of injury, flaccid paralysis) and return of spinal cord reflexes. This period of “postacute spinal cord injury” begins approximately 1 to 3 weeks after initial injury and remains for the duration of the patient’s life. Symptoms of autonomic hyperreflexia often are divided between symptoms seen above versus below the level of spinal cord transection (Table 12.5).

In addition, some patients may experience difficulty breathing, changes in body temperature, and muscle spasms.

Table 12.4. Triggering factors of autonomic hyperreflexia – below the level of injury

Bladder distention (most common) – blockage of urinary catheter, infection, stones
Bowel distention – constipation, gas, digital stimulation, anal fissures
Pregnancy – labor and delivery
Miscellaneous – skin irritants, wounds, burns, appendicitis and other infections

Table 12.5. Symptoms and signs of autonomic hyperreflexia

Above the lesion	Below the lesion
Bradycardia (vagal stimulation)	Hypertension (severe)
Nasal stuffiness	Mesenteric ischemia, abdominal pain
Cutaneous flushing	Cold skin, vasoconstriction
Headache, blurred vision, seizures, aphasia	Acute renal failure
Cerebral and retinal hemorrhage	
Dysrhythmias, pulmonary edema	

Associated morbidity includes cerebral and subarachnoid hemorrhage, retinal hemorrhage, seizures, and pulmonary edema secondary to left ventricular failure. Spinal cord lesions at or above T6 generally result in intense manifestation of the syndrome, whereas lesions between T6 and T10 result in mildly elevated blood pressure with few other associated symptoms. Lesions below T10 generally do not result in hypertensive changes with compensatory reflex responses. Systolic blood pressure elevations >15 to 20 mm Hg above baseline in adults or children with spinal cord injuries may be significant enough to warrant consideration of autonomic hyperreflexia syndrome.

Pathophysiology of the reflex

Cutaneous sensory endings, as well as mucosal and muscle afferent pathways of hollow organs, ascend in the spinothalamic tracts and dorsal columns. Motor outflow reflexes occur via sympathetic inputs in the spinal cord lateral horns, which target blood vessels and viscera. In patients without spinal cord injury, this reflex is normally inhibited by outflow from higher central nervous system centers. However, in the presence of spinal cord transection, this inhibitory outflow fails to reach back to the effector organs innervated by spinal cord roots below the level of transection. Essentially, the sympathetic nervous system below the level of spinal cord injury becomes functionally isolated from all inhibiting (parasympathetic) influences of the brainstem and hypothalamus (Fig. 12.1).

Stimulation below the level of spinal cord injury elicits a vasoconstrictive response in the splanchnic sympathetic outflow (T5–L2). The carotid and aortic arch sinus baroreceptors detect this intense hypertension. As expected, a reflex bradycardia via the intact cranial nerve X (vagus) pathway ensues. In addition, the stimulation of afferent pathways (sympathetic) from these receptors to the vasomotor center in the medulla results in vasodilation (parasympathetic) above the level of cord injury. This vasodilation may help to correct the hypertension elicited by the sympathetic outflow; but in patients exhibiting autonomic hyperreflexia, this compensatory response is inadequate and systemic hypertension with associated symptoms persists.

Prevention and treatment

Preventive measurements are important considerations in managing patients with the potential for developing autonomic hyperreflexia. Application of topical anesthesia to the bladder

Figure 12.1. The autonomic reflex arc.

or rectal mucosa may be helpful in patients undergoing bladder or rectal instrumentation. Unfortunately, this technique is unreliable because the underlying muscular layer proprioceptors are not anesthetized. Spinal anesthesia (preferable) or epidural anesthesia is a reliable technique for preventing autonomic hyperreflexia during surgical operations of the lower abdomen, pelvis, and lower extremities. Alternatively, general anesthesia may be used if spinal or epidural anesthesia is not indicated, to prevent autonomic hyperactivity in these types of surgeries. It is important to remember that administration of succinylcholine ≥ 24 hours after spinal cord transection may

cause hyperkalemia. Injuries to the phrenic nerve or diaphragmatic innervation (C3–5) may require endotracheal intubation and ventilatory support. Maintenance of body temperature is of primary importance in patients with spinal cord transection. Because of immobility, patients with chronic spinal cord transection may develop muscle atrophy, decubitus ulcers, osteoporosis, deep vein thrombosis, or chronic urinary tract infections, with renal failure being the most common cause of death.

Among pregnant patients with spinal cord lesions above T6, the risk of developing autonomic hyperreflexia is about 80% to 90%, especially during labor. Autonomic hyperreflexia can be prevented in pregnant patients during childbirth by using spinal or epidural anesthesia. It is important to differentiate autonomic hyperreflexia (hypertension may occur with uterine contractions) from preeclampsia of pregnancy.

Removal of the inciting stimulus is important in terminating the reflex. This may be all that is needed for the reflex to subside. If the suspected cause is urinary blockage, the catheter should be checked for any kinks or blockage. Pharmacologic treatment of hypertension includes drugs such as sodium nitroprusside, nitroglycerin, nifedipine, hydralazine, and prazosin or clonidine for recurrent or chronic episodes. Bradycardia may be treated with anticholinergics. Men with spinal cord injuries and erectile dysfunction should be questioned about the use of sildenafil, as profound hypotension may occur with the administration of nitrates.

Anesthetic considerations in psychiatric diseases

Houman Amirfarzan and Pankaj K. Sikka

Each year, about 44 million people in the United States experience a mood or psychological disorder ranging from mild to severe mental illness. Patients on medications often present for surgery; therefore, it is important for the anesthesiologist to be aware of any drug interactions that may occur perioperatively.

Mood disorders

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), divides mood disorders into the following categories: major depression, bipolar I, bipolar II, dysthymic, cyclothymic, disorders due to general medical conditions, those due to substance abuse, and depressive, bipolar, and mood disorders not otherwise specified.

Depression

Depression is characterized by persistent depressed mood, loss of interest, sleep disorder, fatigue, difficulty concentrating, and recurrent thoughts of death or suicide. Symptoms should cause significant impairment and not be the result of substances or bereavement. The exact mechanism of depression is not known but is believed to be the result of deficiency of catecholamines (dopamine [D₂], serotonin, or norepinephrine [NE]) in the brain. Therefore, pharmacologic treatment is directed toward increasing the concentrations of these catecholamines in the brain (Fig. 13.1). Electroconvulsive therapy (discussed in Chapter 96) is reserved for severe depression, refractory cases, or depression with suicidal ideation.

Brain catecholamine concentration may be increased by inhibiting (1) the reuptake of the catecholamines back into the cell (reuptake inhibitors) or (2) catecholamine metabolism, by inhibiting the enzyme monoamine oxidase. Commonly used drugs are the selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and miscellaneous other drugs.

The first line of treatment for major depressive disorder is a regimen consisting of antidepressant drugs, with four main categories: TCAs, MAOIs, serotonin–NE reuptake inhibitors, and one heterogeneous group not otherwise classified. Mood stabilizers often are also part of the drug regimen. Because MAO is an enzyme promoting the breakdown of NE, MAOIs indirectly

Figure 13.1. Mechanism of action of antidepressants.

Table 13.1. Side effects of SSRIs

Agitation	Anxiety, sweating
Headache	Nausea
Insomnia	Restlessness
Appetite suppression	Inhibition of cytochrome P-450

increase NE in the brain. Similarly, SSRIs indirectly increase brain serotonin levels. Mood is critically dependent on the neurotransmitters NE, D₂, and serotonin. Trials with antidepressants may take more than 3 to 4 weeks to identify the drug with the best results, but reliable predictors for its success are not available.

Selective serotonin reuptake inhibitors

Fluoxetine was the first SSRI released in the United States. Between 1987 and 1994, it was prescribed for more than 10 million people, making it the second most widely prescribed medication in the United States. SSRI agents currently available include fluoxetine (Prozac; Eli Lilly, Indianapolis, IN), paroxetine (Paxil; Pfizer, New York, NY), sertraline (Zoloft; Pfizer), citalopram (Celexa; Forest Pharmaceuticals, St. Louis, MO), and fluvoxamine (Luvox; Jazz Pharmaceuticals, Palo Alto, CA). Their relatively mild side effect profile and once-daily dosing schedule make them a safe and convenient alternative to the TCAs and MAOIs. SSRIs have low sedative and anticholinergic properties, do not cause postural hypotension or cardiac conduction defects, and have a very low risk of death from overdose compared with the TCAs. SSRIs are activating (stimulating) and therefore are taken during the day. Their side effects are listed in [Table 13.1](#).

Fluoxetine and paroxetine may inhibit the activity of the cytochrome P-450 enzyme and so have a greater potential than other SSRIs for interaction with other drugs. Sertraline and citalopram only mildly inhibit this enzyme and hence have a lower likelihood of interactions with coadministered medications. In addition, paroxetine has a mild affinity for muscarinic receptors and may cause more anticholinergic side effects than other SSRIs (although much less than the TCAs).

Tricyclic antidepressants

TCAs are used to treat depression and chronic pain syndromes. They inhibit the reuptake of catecholamines in general, thus increasing their concentration in the nerve synapses and brain. Commonly used TCAs include amitriptyline (Elavil; AstraZeneca, Wilmington, DE, and Laroxyl; Roche, Nutley, NJ), doxepin (Sinequan; Pfizer), desipramine, nortriptyline (Aventyl; Eli Lilly), and imipramine (Tofranil; Mallinckrodt Inc., Hazelwood, MO). It is important to remember that an increase in catecholamine activity may increase the minimum alveolar concentration (MAC) of inhalation anesthetics.

The most common side effects of TCAs are anticholinergic effects, as listed in [Table 13.2](#). Amitriptyline has the most marked anticholinergic effects, whereas doxepin has the fewest

Table 13.2. Side effects of TCAs

Anticholinergic – dry mouth, blurred vision, constipation, urinary retention, tachycardia, confusion, delirium	Cardiac – prolonged PR and QT intervals, wide QRS complexes, arrhythmias, sudden cardiac death
Sedation (decreases MAC), weight gain	Postural hypotension
Hypertensive response	Sexual dysfunction

cardiac effects. The elderly are particularly susceptible to memory impairment, confusion, and hallucinations. Sedation and weight gain may result from concomitant blockade of histamine H₁ receptors, and orthostatic hypotension may occur from blockade of α_1 -receptors. Atropine and glycopyrrolate have been noted to have increased muscarinic activity in the presence of TCAs.

Compared with normal patients, a decrease in intraoperative core temperature and an increased incidence of shivering have been observed in patients taking TCAs. The most important interaction between anesthetic agents and TCAs is an exaggerated response to indirect-acting vasopressors and sympathetic stimulation (hypertensive crisis). Administration of ketamine, meperidine, pancuronium, ephedrine, or epinephrine-containing local anesthetic solutions should be done with caution. Management consists of treating the hypertension emergently with a drug such as phentolamine or nitroprusside.

Monoamine oxidase inhibitors

Catecholamines are metabolized by the enzyme MAO. Hence, MAO inhibitors increase the availability of catecholamines in the nerve synapses. Two common isoforms of the MAO enzyme are the type A (selective for serotonin, NE) and type B (selective for phenylethylamine) isoforms. MAOIs often are not used for treatment because of their potential to precipitate enhanced sympathetic activity and severe hypertension (hypertensive crisis) with the concomitant ingestion of tyramine-containing foods (aged cheeses, beer, champagne, soy sauce, avocados, bananas, overripe or spoiled food, and any fermented, smoked, or aged fish or meat). The hypertensive reaction is dose-dependent and may be exacerbated if the patient is also taking a sympathomimetic drug. In the past, it was suggested that MAOIs be discontinued 2 to 3 weeks before any elective procedure involving general anesthesia. This precaution is no longer encouraged or practical for many procedures, because discontinuation of the drug may acutely place the patients at a greater risk for depression or suicide. MAOIs for clinical use include phenelzine, isocarboxazid, and tranylcypromine.

Miscellaneous drugs

Venlafaxine (Effexor; Pfizer), bupropion (Wellbutrin; Glaxo-SmithKline, Research Triangle Park, NC), and duloxetine (Cymbalta; Eli Lilly) have been shown to reduce neuropathic pain; therefore, they are preferred in treating depressed patients

Table 13.3. Potential interaction with drugs used in anesthesia

Class	Interacting drugs	Response
TCAs and MAOIs	Ephedrine, NE, epinephrine	Exaggerated pressor responses
	Halothane Meperidine	Cardiac arrhythmias Hyperthermia, coma, seizures
Lithium carbonate	Atropine, scopolamine Neuromuscular blocking drugs	Mental confusion Prolonged action

with chronic pain, to alleviate both the pain symptoms and treat the underlying depression. These drugs also are used to treat depression in patients who do not respond to typical antidepressant drugs. St. John's wort is an herbal product used for treating depression. Studies in the United States do not support its efficacy in the treatment of severe depression. The side effect profile of St. John's wort is extensive, but the main concern for anesthesiologists is the similarity this drug bears to the MAOIs in their potential for precipitating hypertension and hyperpyrexia. Concomitant use with SSRIs may lead to a form of "serotonin syndrome," characterized by agitation, hyperthermia, diaphoresis, tachycardia, and neuromuscular rigidity. In summary, detailed information on antidepressant drugs is important because they are widely prescribed and have interactions with drugs used in anesthesia. Table 13.3 shows potential interactions of antidepressant drugs with drugs used in anesthesia.

Bipolar disorder

The true prevalence of bipolar disorder (alternate periods of mania [elation] and depression) is uncertain; the diagnosis likely is missed when patients are seen for depression but are not asked specifically about symptoms suggesting prior episodes of mania or hypomania. Bipolar disorders are divided into types I and II, the former characterized by at least one manic or mixed episode, the latter by at least one hypomanic episode (lower severity than mania) and major depressive episodes. A mixed episode is defined as one that fits the criteria for both major depressive and manic episodes for 1 week. Mania is treated most effectively by administration of lithium (orally), carbamazepine (especially in lithium-refractory patients), and atypical antipsychotics.

Lithium

Despite its efficacy in the treatment of mania, lithium has a very narrow therapeutic index. The plasma level of lithium must be monitored routinely and perioperatively. A serum concentration of 0.6 to 0.8 mEq/L is considered therapeutic for the treatment of stable mania. Slightly higher levels, up to 1.2 mEq/L, are acceptable for treating acute episodes. Levels >2.0 mEq/L are considered toxic and require withdrawal of the drug and aggressive hydration with sodium-containing solutions or administration of osmotic diuretics, such as mannitol. Lithium

Table 13.4. Manifestations of lithium toxicity

System	Effects
Central nervous	Confusion, sedation (decreases MAC), muscle weakness (prolongs muscular blockade), ataxia, tremors, slurred speech, seizures
Cardiovascular	Widening of QRS complexes, AV heart block, hypotension
Endocrine	Hypothyroidism
Hematologic	Leukocytosis, aplastic anemia
Renal	Nephrogenic diabetes insipidus, tubular acidosis
Gastrointestinal	Nausea, vomiting, abdominal pain

AV, atrioventricular.

alters sodium transport across cell membranes by inhibiting the sodium–potassium pump, thus inhibiting the intracellular formation of cyclic adenosine monophosphate. Lithium toxicity (Table 13.4) is compounded by sodium depletion, and concurrent use of diuretics that inhibit the uptake of sodium in the renal tubule (loop diuretics and thiazides) is hazardous and should be avoided. Lithium also inhibits the action of antidiuretic hormone on the distal renal tubule, leading to nephrogenic diabetes insipidus in severe cases of lithium toxicity. Lithium can prolong the action of neuromuscular blocking agents.

Atypical antipsychotics

The term *atypical* refers to an antipsychotic medication that produces minimal extrapyramidal side effects (sustained contraction of muscle groups [neck, jaw, tongue, eyes], restlessness, agitation), has a low propensity to cause tardive dyskinesia (repetitive, purposeless involuntary movements – grimacing, tongue protrusion, lip smacking) with long-term treatment, and treats both positive and negative signs and symptoms of schizophrenia as well as bipolar disorders. A systematic review and meta-analysis found that the efficacy of atypical antipsychotics was comparable with that of mood stabilizers in treating acute mania but that a combination of antipsychotic and mood-stabilizing agents was more effective than mood stabilizers alone.

In addition to lower D₂-receptor potency and occupancy at therapeutic doses, atypical agents selectively antagonize mesolimbic D₂ receptors more than those in the nigrostriatum and prefrontal cortex. As a result, side effects attributable to nigrostriatal D₂ blockade (extrapyramidal symptoms) occur less frequently, as do side effects attributable to prefrontal D₂ blockade (neurocognitive impairment). Serotonin–D₂ antagonism is the reason atypical antipsychotics may be given in smaller doses, producing fewer extrapyramidal side effects while maintaining clinical efficacy.

Atypical agents currently available include clozapine, risperidone (Risperdal; Janssen, Titusville, NJ), olanzapine (Zyprexa; Eli Lilly), quetiapine (Seroquel; AstraZeneca), and ziprasidone (Geodon; Pfizer). Although each agent has different affinities for specific receptors, most drugs fall into one of two groups. The first group consists of clozapine, olanzapine,

Table 13.5. Side effects of antipsychotic drugs

System	Effects
Central nervous	Extrapyramidal symptoms, seizures (especially clozapine), sedation, cognitive dysfunction
Autonomic nervous	Orthostatic hypotension, anticholinergic effects (tachycardia, dry mouth, urinary retention)
Cardiovascular	Prolonged QT interval, torsades de pointes
Respiratory	Laryngospasm, dyskinesia
Hematologic	Leukopenia, pancytopenia
Endocrine	Weight gain, sexual dysfunction, galactorrhea
Gastrointestinal	Constipation, jaundice

and quetiapine, all of which demonstrate multiple receptor antagonism (α_1 , H_1 , and muscarinic₁). The second group consists of risperidone and ziprasidone, which demonstrate only α_1 -adrenergic receptor antagonism.

Schizophrenia

Schizophrenia, the most common psychotic disorder, is thought to occur as the result of hyperactivity of the dopaminergic system. Symptoms include delusions, hallucinations, agitation, social incompatibility, withdrawal, and lack of hygiene. Schizophrenia may be associated with depression or mania. Commonly used antipsychotic drugs used to treat schizophrenia include phenothiazines (chlorpromazine, thioridazine), butyrophenones (haloperidol), loxapine (Loxapac; Wyeth-Ayerst, Radnor, PA), clozapine, and risperidone. Side effects of antipsychotic drugs are listed in Table 13.5.

Agitation

Safety is the first consideration with any psychiatric patient. When confronted with an agitated patient, physical restraint, including room seclusion, should be applied only as necessary to maintain the safety of the patient and staff or to avoid destruction of property.

Among the neurotransmitters, serotonin plays a major inhibitory role in aggressive behavior. Atypical antipsychotic medications, which affect both serotonin and D_2 activity, may have primary antihostility properties, which the traditional antipsychotic medications lack. Patients requiring injectable antipsychotics may be given olanzapine, ziprasidone, aripiprazole, or haloperidol. Additionally, for patients who agree to take oral medication but whose cooperation is marginal, risperidone and olanzapine are available as tablets that disintegrate in the mouth and therefore do not allow the patient to conceal a pill and surreptitiously discard it. The tablets are absorbed through the gastrointestinal tract at the same rate as standard pills (i.e., those not absorbed transmucosally). Oral and injectable preparations appear to be comparable in efficacy in acutely agitated patients.

Agitated patients also may benefit from a benzodiazepine. Lorazepam (Ativan; Pfizer) has the advantages of compatibility with antipsychotics, evidence of efficacy, and availability in oral, intramuscular, and intravenous formulations. Lorazepam, 0.5

to 2 mg, may be administered at the same time and by the same route as the antipsychotic.

Neuroleptic malignant syndrome

Perhaps the most feared complication of neuroleptics is neuroleptic malignant syndrome (NMS). NMS may be caused by antipsychotics, meperidine, or metoclopramide. Higher dosages or a rapid and large increase in dosage also may trigger the development of NMS. The first symptom to develop is usually muscular rigidity, followed by high fever and changes in cognitive functions. Other symptoms may vary but include unstable blood pressure, confusion, coma, delirium, and muscle tremors. The creatine phosphokinase plasma concentration will be elevated as a result of increased muscular activity. Patients may be hypertensive and usually have a metabolic acidosis, with mortality rates around 20% to 30%.

Treatment requires withdrawal of the offending agent, initiation of bromocriptine or dantrolene therapy, and supportive care. Anesthesia personnel must be aware of the similarity of NMS and malignant hyperthermia (MH), and especially vigilant when providing care to persons with a documented history of either. A primary defect in skeletal muscle has been suggested in view of similarities in the clinical presentations of NMS and anesthetic-induced MH, although NMS is associated with a normal muscle biopsy (unlike MH). Patients with neuroleptic-induced parkinsonism may develop intercurrent fever caused by infections or dehydration and be mistaken for cases of NMS. Although NMS has been reported before and after surgery, it appears unlikely to develop intraoperatively, in contrast to MH. Among differential diagnoses, serotonin syndrome should be mentioned because in its most severe form, which is associated with MAOIs, it presents as an NMS-like hypermetabolic state (although it usually presents with milder and more transient symptoms indicative of an agitated delirium).

Substance abuse and anesthesia

Thomas J. Graetz and Lisa R. Leffert

Recreational drugs are substances used without medical justification, causing changes in consciousness, habituation, and, in some cases, addiction (Table 14.1). The illicit use of these substances, which include alcohol, cocaine, amphetamines, marijuana, and opioids, is common; it is estimated that almost 10% of the US population >12 years of age have ingested recreational drugs in the past month. Acute and chronic substance abuse affect anesthetic care through the associated physiologic derangements and interactions with perioperative medications.

The following discussion highlights the epidemiologic, pharmacologic, and anesthetic implications of recreational drug use; in addition, the effects on pregnant women and their developing fetuses are highlighted.

Optimal care of the substance-abusing patient includes knowledge of which drugs he or she has ingested. The anesthesia consultation should contain detailed questions about the patient's use of recreational drugs, asked in a private and non-judgmental fashion. Because patients tend to underreport their recreational drug use, it is important to recognize the relevant signs, symptoms, and comorbidities and to use drug testing when feasible. The most common specimen tested is urine (Table 14.2), although bioassays are available to test blood, hair, fetal meconium, and umbilical cord tissue.

Tobacco

General considerations

Tobacco use is common; more than 72 million Americans over 12 years of age (approximately 30% of the population) have used a tobacco product in recent months. Tobacco-containing products include cigarettes, the focus of this discussion. Other use includes chewing and pipe tobacco, snuff, and cigars.

Tobacco smoke contains more than 3000 active substances, including carbon monoxide and nicotine. Carbon monoxide decreases available oxygen for delivery to cells by avidly binding to hemoglobin to form carboxyhemoglobin and shifting the hemoglobin dissociation curve to the left. Inhaled nicotine acts on nicotinic (cholinergic) receptors in the brain and the periphery immediately upon exposure, causing sympathetic stimulation. Nicotine is metabolized by the liver to cotinine prior to being excreted in the urine.

Inhalation of tobacco smoke has diverse systemic effects, including increases in heart rate, blood pressure, and myocardial contractility. Smoking tobacco increases the rate of cardiovascular disease, and also affects the lungs, changing the quality and quantity of mucus production, decreasing mucociliary clearance, and predisposing patients to bronchitis and chronic obstructive pulmonary disease (COPD). Tobacco is addictive; cessation of smoking may lead to withdrawal symptoms including cravings, insomnia, and headaches. Some patients use nicotine replacement therapies such as gum, patches, or inhalers to facilitate cessation; the American College of Obstetricians and Gynecologists recommends they be used in pregnant patients only when nonpharmacologic interventions have failed.

Anesthetic implications

Smokers are at increased risk for perioperative complications, including pneumonia, respiratory failure, decreased wound healing, and unanticipated intensive care unit admission. Smoking cessation should be encouraged preoperatively, as oxygen delivery and exercise capacity have been shown to improve even after only a few hours. Longer duration of cessation (up to 6 months) may be required to confer additional benefits in terms of decreasing perioperative pulmonary complications.

Anesthetic management of a smoker should include a thorough investigation of frequently associated comorbidities, including cardiovascular and pulmonary disease. Of particular concern is the propensity for increased secretions, decreased ciliary motility, and impairment of gas exchange. Airway "irritability" associated with general anesthesia is thought to occur in smokers, although the published data are not entirely supportive of this concept. When feasible, neuraxial and peripheral regional techniques may be beneficial in these patients as their use can minimize airway manipulation.

Alcohol (ethanol)

General considerations

Ingestion of alcohol as beer, wine, or distilled liquor is common; 51% of Americans over 12 years of age report current drinking, whereas 23% of the population 12 years or older report binge drinking. Acute ethanol exposure places the individual at risk

Table 14.1. Recreational drugs

Substances	Drug properties	Systemic effects	Anesthetic implications
Tobacco	Nicotine – works via nicotinic cholinergic receptors in a variety of complex neurotransmitter systems, including peripheral autonomic effects. Metabolized to cotinine. Carbon monoxide – interacts with hemoglobin to form carboxyhemoglobin, which decreases the available oxygen for cells and increases the affinity of oxygen for red blood cells	Increased heart rate Increased blood pressure Increased myocardial contractility Decreased tissue oxygen levels Increased mucus production Decreased mucociliary clearance Small airway dysfunction	Increased risk for pulmonary complications Potential for airway “irritability” and bronchospasm Regional technique allows airway manipulation to potentially be avoided Cessation should be encouraged
Ethanol	Absorbed rapidly from GI tract Metabolized by alcohol dehydrogenase	<i>Acute</i> Impaired cognition Increased gastric acidity Hypovolemia <i>Chronic</i> Hypertension Anemia Peripheral neuropathy Cardiomyopathy Liver cirrhosis Pancreatitis Malnutrition Cancer Metabolic derangements Withdrawal Tremor Hypertension Tachycardia Nausea and vomiting Agitation Potential for delirium tremens	<i>Acute</i> Potential for uncooperative patient Impaired airway reflexes Decreased MAC <i>Chronic</i> Manifestations of comorbid diseases Altered drug metabolism Empirically increasing anesthetic doses is <i>not</i> recommended (conflicting data) Withdrawal Altered hemodynamics Potential for seizures
Cocaine	Reuptake inhibitor of presynaptic sympathomimetic neurotransmitters. Metabolized by serum and liver esterases	Local anesthetic properties CNS stimulation Cardiovascular complications including arrhythmias, hypertension, myocardial ischemia Seizures Proteinuria	Potentially uncooperative patient Altered pain perception Delayed gastric emptying β -Blockers may lead to unopposed alpha stimulation Resistance to ephedrine Reports of increased risk of thrombocytopenia (conflicting data)
Amphetamines	Indirect sympathomimetics that stimulate the CNS	Dose-dependent CNS stimulation Cardiovascular complications including arrhythmias, hypertension, myocardial ischemia Seizures Proteinuria	Toxic effects potentiated when combined with ethanol Potentially uncooperative patient Altered pain perception Resistance to ephedrine β -Blockers may lead to unopposed alpha stimulation
Marijuana	Smoked or ingested (slower onset)	Tachycardia Mucociliary dysfunction Elevated carboxyhemoglobin Biphasic effects Lower doses leading to increased sympathetic activity and decreased parasympathetic activity Higher doses leading to increased parasympathetic activity including bradycardia and potentially hypotension	Likely use of other drugs concomitantly Arrhythmias Potential for pulmonary complications
Opioids	Variable route of administration	<i>Acute</i> Decreased ventilatory drive Dysphoria Unconsciousness Miotic pupils <i>Withdrawal</i> Occurs 4–6 h after opioid intake and peaks at 48–73 h Agitation	Potential for acute withdrawal syndrome if opioid antagonists or agonist–antagonists given to chronic users Clonidine can ameliorate some withdrawal symptoms To treat acute pain in chronic user: Develop care plan with patient Multimodal therapy (including NSAIDs, regional techniques) is recommended

(continued)

Table 14.1. (continued)

Substances	Drug properties	Systemic effects	Anesthetic implications
Hallucinogens (LSD)	Complex mechanisms of action with agonist, partial agonist, and antagonist effects at various serotonin, dopaminergic, and adrenergic receptors Effects begin in 15–45 min and last 4–6 h, with metabolism by the liver	Tachycardia Hypertension Insomnia Lacrimation Rhinorrhea Yawning Diarrhea Mild sympathetic effects relative to cocaine, amphetamines, or ecstasy Euphoria Anxiety Paranoia Visual and auditory hallucinations	Maintain baseline opioid requirements Anticipate increased acute analgesic needs (30%–100% or more than in opioid-naïve patients) Agitation may be treated with benzodiazepines Supportive therapy, with resolution of symptoms usually within 12 h Avoid use of neuroleptic drugs because these may worsen symptoms Patients may have an exaggerated response to sympathomimetics
Solvents	Diverse group of substances Specific properties vary by specific substance	Euphoria, excitement, and feeling of invulnerability Sympathetic stimulation Hypotension Cardiomyopathy Renal failure	Tachyarrhythmias Hypoxia from respiratory depression, aspiration Formation of carboxy- and methemoglobin, airway edema

GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

for antegrade amnesia and impaired judgment: a blood alcohol level of 50 mg/dl leads to impairment of some skilled tasks, and 80 mg/dl is the legal limit for driving in many states. Ethanol is metabolized by alcohol dehydrogenase, aldehyde dehydrogenase, and cytochrome P-450, leading to elevated levels of cellular NADH, which results in metabolic derangement.

Acute intoxication from ethanol ingestion increases gastric acidity. Chronic use may lead to myriad medical problems, including hypertension, cardiomyopathy, anemia, gastritis, hepatic cirrhosis, and/or chronic pancreatitis. Cognitive motor deficits and peripheral neuropathy also may ensue. Withdrawal from ethanol in a chronic abuser may occur 6 to 48 hours after consumption and usually manifests as tremor, hypertension, tachycardia, nausea, vomiting, and hallucinations. Benzodiazepines and α_2 -agonists are the mainstays of treatment for withdrawal. Delirium tremens, with its attendant autonomic instability, is a potential complication of untreated withdrawal and may be fatal if left untreated.

Anesthetic implications

Whether or not they have eaten recently, acutely alcohol-intoxicated patients are at increased risk for aspiration because of delayed gastric emptying, increased gastric acid secretion, and impaired airway reflexes. As such, pretreatment with a non-particulate antacid and histamine (H_2) blocker should be instituted. For general anesthesia, a rapid sequence induction should be performed unless a difficult intubation is anticipated. Intoxicated patients may be hypoglycemic or volume depleted secondary to vomiting, poor fluid intake, and/or diuresis.

Classic teaching has been that acute alcohol intoxication decreases patients' anesthetic needs, partly because of the additive effect of alcohol and other central nervous system (CNS)

depressants. The notion that chronic alcoholics have a higher anesthetic requirement than their non-alcohol-using counterparts seems based originally on an abstract published by Han in 1969, which described an alteration in mean minimum alveolar concentration (MAC) values of halothane in six chronic alcoholic patients compared to six "normal healthy adult subjects." Of note, a subsequent study showed that thiopental pharmacodynamics and pharmacokinetics were not statistically significantly different in 11 chronic alcohol users compared with nine controls. Additionally, a small study from 1993 looking at propofol induction doses in humans showed a slightly higher dose of propofol was needed at induction of general anesthesia. Given the presence of additional vulnerabilities in this patient population, such as decreased nutritional status and increased cardiac comorbidities, empirically increasing anesthetic dosing should be done with caution.

Table 14.2. Drug detection in urine

Drug	Analyte	Detection window via urine, days
Tobacco	Cotinine	2–4
Cocaine	Benzoyllecgonine	~2–3
Amphetamines	Methamphetamine	~3–6
Ecstasy	MDMA	~2
Marijuana	THC	~1–2
	THCCOOH	~4
LSD	LSD	~1–2
	2-Oxo-3OH-LSD	~4
Opioids (heroin)	Morphine	~1–3

THCCOOH, 11-Nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid.

Data from Haufroid and Lison 1998; Wallach 2000; Verstraete AG. Detection times of drugs of abuse in blood, urine, and oral fluid. *Ther Drug Monit* 2004; 26(2):200–205.

Peripheral and neuraxial anesthesia may be used safely in these patients in appropriate surgical circumstances, provided that (1) the patient is cooperative (benzodiazepines may be beneficial), (2) coagulopathy (due to associated liver disease) has been ruled out, (3) the patient is euolemic, and (4) baseline neurologic deficits (e.g., peripheral neuropathy) are taken into consideration.

Cocaine

General considerations

Approximately 15% of the population over 12 years of age have used cocaine. An alkaloid derived from the *Erythroxylon coca* plant, cocaine commonly is prepared as a water-soluble hydrochloride salt that can be snorted, injected intravenously, or absorbed intrarectally or intravaginally. Cocaine also may be modified using ether and ammonia or sodium bicarbonate to form “free-base” or “crack” cocaine, respectively. Both free-base and crack can be smoked.

Cocaine has a biologic half-life of 0.5 to 1.5 hours and is metabolized primarily by plasma and liver esterases to ecgonine methyl ester and benzoylecgonine. Patients who are homozygotes for atypical plasma cholinesterase have impaired in vitro ability to metabolize cocaine in addition to succinylcholine. Acquired deficiencies in the quantity of plasma cholinesterase secondary to liver disease, pregnancy, plasmapheresis, hypothyroidism, and malnutrition also may alter cocaine metabolism, although these may or may not have a clinically significant effect. If cocaine is metabolized in the presence of ethanol, cocaethylene, which has a longer half-life than cocaine and amplified physiologic effects, is formed.

Cocaine exerts its pharmacologic action by preventing reuptake of dopamine, norepinephrine, and serotonin. Increased CNS levels of dopamine lead to feelings of euphoria and contribute to the addictive nature of cocaine. Repeated exposure to cocaine may cause dopamine depletion and anhedonia. Cocaine is unique in that it also functions as a local anesthetic with inherent vasoconstrictive properties.

Anesthetic implications

The anesthetic implications of cocaine use relate to its multi-organ system effects and to the frequent concomitant use of other recreational drugs. Cardiovascular sequelae of acute and chronically elevated catecholamine levels include hypertension, dysrhythmias, and conduction disturbances, in addition to an increased risk of developing myocardial ischemia, dilated cardiomyopathy, valvular disease, and aortic dissection.

Some authors advocate pretreatment with benzodiazepines and antihypertensive agents prior to induction of general anesthesia to attenuate the adrenergic effects of cocaine. Recommended therapy for severe cocaine-induced hypertension includes hydralazine, nitroprusside, nitroglycerin, or phentolamine. β -Blockers are relatively contraindicated because of the risk of unopposed alpha activity, leading to a further increase in

blood pressure and coronary vasoconstriction. Labetalol, with its concomitant (albeit weak) alpha effects, may be less problematic. Given the variable effects of cocaine on myocyte calcium metabolism, some authors have cautioned against the use of calcium channel blockers in cocaine-intoxicated patients, although others advocate its use.

Treatment for cocaine-induced hypotension should begin with intravenous (IV) fluids and a search for underlying causes. If a vasopressor is needed, direct-acting vasoconstrictors such as phenylephrine may be advisable because ephedrine may be associated with an exaggerated or attenuated response depending on levels of circulating catecholamines. Cardiac arrhythmias should be treated according to Advanced Cardiac Life Support (ACLS) protocol, using cardioversion or defibrillation if indicated. Use of volatile anesthetics during general anesthesia, most notably halothane, may increase the risk of cardiac arrhythmias. Of note, an animal study published in 1988 by Hayashi showed that epinephrine-exposed dogs had fewer ventricular arrhythmias when exposed to isoflurane than to sevoflurane. Finally, the use of ketamine is relatively contraindicated in patients with acute cocaine intoxication as it may provoke an exaggerated hemodynamic response.

Patients who abuse cocaine also may suffer neurologic consequences including headache, agitation (may respond to benzodiazepines), depression, seizures, psychosis, stroke, and cerebral atrophy. Additionally, opioid receptor modulation secondary to chronic cocaine use may lead to breakthrough pain during spinal or epidural anesthesia as well as postoperatively, despite an adequate sensory level. The MAC of halothane has been shown to be increased during acute cocaine intoxication in animals.

Pulmonary comorbidities associated with cocaine use occur primarily in the setting of inhalation. As is the case for tobacco smokers, these patients have an increased risk of asthma, chronic cough, and diffusion abnormalities. Other related complications include pneumothorax and pulmonary edema. Because individuals who smoke cocaine are at risk for upper airway burns, extra care must be taken if intubation is planned. Snorting cocaine may lead to nasal septal injury, which precludes insertion of airway, temperature, and nasogastric devices through the nares.

Gastric emptying is delayed by cocaine ingestion, so pretreatment with a nonparticulate antacid and H_2 blocker should be instituted. For general anesthesia, a rapid sequence induction should be performed, unless a difficult intubation is anticipated.

Although cocaine has been shown to cause increased platelet activation and aggregation, the presence of cocaine-induced thrombocytopenia is both supported and refuted in the literature. If feasible, the platelet count should be checked in these patients prior to placing a regional anesthetic. In addition, for those who have end-stage liver disease, it is prudent to assess coagulation status.

Finally, patients who inject cocaine or any other illicit drugs are more likely to have infectious complications (including HIV and viral hepatitis) and difficult intravenous access.

Amphetamines

General considerations

Amphetamines cause the release of catecholamines from pre-synaptic nerves, leading to CNS stimulation with feelings of euphoria. Six percent of the population have used amphetamines at some point during their lives; methamphetamines are the most commonly used drugs in this class. 3,4-Methylenedioxymethamphetamine (MDMA or “ecstasy”) is chemically related to methamphetamines and also has hallucinogenic properties (see Hallucinogens).

Metabolism of amphetamines is variable; up to 30% of the drug is excreted unchanged in urine. The plasma half-life varies from 5 to 30 hours, depending on urine output and pH (increased pH leading to decreased excretion). Amphetamines frequently are taken in combination with other drugs; for example, ethanol plus methamphetamines is known to provide more pleasurable sensations for the user and also to be more demanding on the cardiovascular system than either substance alone.

Anesthetic implications

The signs, symptoms, and anesthetic considerations of amphetamine intoxication are generally similar to those of cocaine, and therapy should be directed accordingly: benzodiazepines to blunt the excitatory effects of amphetamines and nitrates, hydralazine and phentolamine for treatment of severe hypertension. Hypotension in a chronic amphetamine user likely is the result of catecholamine depletion and possibly down-regulation of α - and β -adrenergic receptors; as such, phenylephrine may be a more effective corrective therapy than an indirect agent such as ephedrine.

Regional or general anesthetic techniques may be used in amphetamine-intoxicated patients, depending on the overall clinical picture. Of note, chronic use of methamphetamines is associated with severe tooth decay (“meth mouth”), which puts these patients at risk for having teeth dislodged during intubation. In addition, the results of animal studies suggest that MAC for volatile anesthetics is decreased in the setting of chronic amphetamine use and increased in the setting of acute ingestion. Because MDMA intoxication may lead to hyperpyrexia, core body temperature should be measured in these patients and active warming devices used with caution.

Marijuana (cannabis)

General considerations

Marijuana was used recreationally by about 16% of the population 18 to 25 years old and 8% of those over 12 years old in 2006. Derived from the *Cannabis sativa* or *C. indica* plant, marijuana contains over 400 different compounds, including over 60 cannabinoids. The most potent and studied cannabinoid in marijuana is Δ^9 -tetrahydrocannabinol (THC). Marijuana is frequently smoked, although it can be orally ingested.

Cannabinoids, which are metabolized by the liver and eliminated in the urine, have complex effects mediated by endogenous receptors. Marijuana users experience anxiolysis, sedation, intoxication, and analgesia; dysphoria and paranoia also may occur. A biphasic effect on the autonomic nervous system occurs: low to moderate doses lead to sympathetic stimulation, tachycardia, and hypertension, whereas high doses lead to sympathetic inhibition with resultant bradycardia and hypotension. Life-threatening arrhythmias in patients without preexisting cardiac disease are rare, although ectopy may occur.

Smoking three to four cannabis cigarettes per day has been estimated to result in the same degree of bronchopulmonary damage as smoking 20 cigarettes a day. The cannabinoids are lipid-soluble substances, leading to their long elimination half-life (about 7 days). Withdrawal from chronic marijuana use reportedly is associated with headache, restlessness, tremor, and anxiety.

Anesthetic implications

Because marijuana cigarettes contain many of the compounds in tobacco (excluding nicotine), inhalation may lead to mucociliary dysfunction, bronchial irritation, and decreased tissue levels of oxygen secondary to increased carboxyhemoglobin. As is the case with tobacco, use of peripheral or neuraxial regional anesthetics may enable the anesthesiologist to avoid instrumenting the airway. Caution should be taken when administering anticholinergics and other vagolytic medications (e.g., pancuronium), as these medications may worsen the tachycardia frequently seen with marijuana. Marijuana also may potentiate the sedative effects of other medications.

Opioids

General considerations

The opioid class of medications includes “opiates” derived from the poppy plant (e.g., morphine and codeine) and other semisynthetic or synthetic formulations, such as heroin, oxycodone, and methadone. These drugs frequently are injected intravenously but also may be injected subcutaneously or ingested orally. The prevalence of heroin abuse in the population over 12 years of age is 1.5%, and that of nonmedical use of pain relievers (e.g., oxycodone) is estimated at 14%. Heroin, an acetylated morphine, is highly addictive and reaches the brain in <10 seconds when injected intravenously; it is metabolized in the liver prior to excretion by the kidneys and has an elimination half-life of 1 to 2 hours.

Oxycodone is a popular opioid of abuse because of its high oral bioavailability and potency.

Methadone is a synthetic opioid used recreationally and in medical practice as substitution therapy for heroin addicts and to treat chronic pain. Its peak concentration after oral administration occurs at 4 hours; its elimination half-life is highly variable and prolonged (15–40 hours). Opioid intoxication leads to decreased ventilatory drive and decreased

airway reflexes. Withdrawal symptoms include agitation, tachycardia, hypertension, insomnia, lacrimation, rhinorrhea, and yawning.

Anesthetic implications

When caring for a patient who chronically uses opioids, it is essential to communicate effectively, to maintain the patient's baseline opioid requirements, and to anticipate acute additional analgesic needs. Tolerance to opioids and abnormal pain sensitivity in these patients make achieving optimal pain control more challenging; they are more likely to report breakthrough pain intraoperatively when regional anesthesia is used and postoperatively regardless of the mode of anesthesia. As such, multimodal therapy including nonsteroidal medications, peripheral and neuraxial techniques, and adequate doses of opioids (30%–100% above what is expected in opioid-naïve patients) is indicated. Medical therapy is enhanced when coupled with a detailed conversation outlining the care plan. Withholding necessary opioids for fear of relapse in a formerly addicted patient is not medically justified.

Patients on chronic methadone maintenance should continue receiving their baseline-dosing regimen. Opioid antagonists (e.g., naloxone) and mixed agonists–antagonists (e.g., nalbuphine) are relatively contraindicated in chronic opioid users, unless they have overdosed or are undergoing medically supervised detoxification. Withdrawal symptoms can be ameliorated by α_2 -agonists (e.g., clonidine) or by careful reintroduction of opioids. IV abuse of opioids and other recreational drugs frequently is associated with subsequent difficult IV access and infectious complications including cellulitis, viral hepatitis, HIV, and endocarditis.

Hallucinogens

General considerations

Five percent of the population over the age of 12 years have used hallucinogens (e.g., lysergic acid diethylamide [LSD], phencyclidine [PCP], psilocybin, or mescaline) during their lifetime. Hallucinogens have complex mechanisms of action, including agonist, partial agonist, and antagonist effects at serotonin, dopamine, and adrenergic receptors; ingestion typically produces mind-altering CNS stimulation, including visual, auditory, and tactile hallucinations, and mild adrenergic stimulation compared with cocaine and amphetamines. These effects typically occur approximately 1 hour after ingestion and may last up to 12 hours. No specific withdrawal syndrome is associated with abrupt discontinuation of these substances, although psychological dependence frequently occurs.

Anesthetic implications

Management of the hallucinogen-intoxicated patient typically is supportive and noninterventional. As such, the choice of regional versus general anesthesia depends primarily on the clinical situation. If necessary, agitation can be treated with

benzodiazepines. Neuroleptic agents should be avoided because they may potentiate the undesirable effects of these compounds. Hallucinogens may cause arrhythmias and hypertension, which can be managed in the usual fashion. As these patients may have an inadequate response to ephedrine, phenylephrine may be more effective in the treatment of hypotension.

Solvents

General principles

Solvents are popular substances of abuse because they are readily available and inexpensive. Approximately 9% of the population over 12 years of age have used inhalants during their lifetime. Solvents may be ingested orally or inhaled because they readily vaporize at room temperature. The primary effect of these recreational drugs is on the CNS, causing a “rush” of excitement and disinhibition. These effects, typically of short duration, may be prolonged by sequential inhalations. Solvent abuse may lead to irritation of mucous membranes, epistaxis, rhinorrhea, aspiration, fatal arrhythmias, burns, and accidental death. Chronic use may result in multiorgan system pathology, including renal failure, leukemia, aplastic anemia, hepatocellular carcinoma, cardiomyopathy, and brain atrophy.

Anesthetic implications

A careful neurologic examination is important in order to document preexisting sensory and motor deficits. Solvent intoxication may lead to hypoxemia as a result of suffocation and/or methemoglobinemia. The drug user's airway also may be injured by the inhalation process, leading to mucosal injury and edema. Repeated use of nitrates may lead to syncope, hypotension, and the potential for methemoglobinemia. Care should be used with epinephrine-containing medications, as the inhalational agents may sensitize the myocardium. Respiratory and neurologic abnormalities should be specifically evaluated. Additionally, electrolyte abnormalities may occur and should be identified and corrected, if present.

Pregnant patients and their developing fetuses

An estimated 17% of pregnant women smoke cigarettes. Smoking tobacco leads to in utero exposure to carcinogens and toxic metabolites of tobacco, as well as to hypoxia from placental vasoconstriction and increased levels of carboxyhemoglobin. Smoking places pregnant women at risk for complications such as intrauterine growth restriction (IUGR), placental abruption, premature rupture of membranes, low birth weight, and perinatal mortality. A negative association between smoking and preeclampsia has been reported in the literature.

Approximately 12% of pregnant women report alcohol use. Fetal alcohol syndrome (FAS) secondary to in utero ethanol exposure is the leading cause of preventable birth defects and developmental abnormalities. Key features of the diagnosis of

FAS are facial dysmorphism (smooth philtrum, thin vermilion border, and small palpebral fissure) and neurologic and developmental abnormalities. No level of alcohol exposure has been identified as “safe” for use during pregnancy.

Cocaine use may lead to placental abruption, preterm labor, spontaneous abortion, IUGR, preterm delivery, stillbirth, and neonatal abstinence syndrome. Pregnant women who abuse cocaine are at higher risk for needing cesarean delivery for fetal distress. Cocaine-exposed infants weigh less, are shorter, and have an increased incidence of infections, particularly those that are sexually transmitted. Early reports suggested that in utero cocaine exposure is associated with congenital anatomic defects, although more recent data have not supported this observation.

Amphetamine use during pregnancy has been implicated in some fetal anomalies in animal studies (e.g., cardiac abnormalities and cleft lip) as well as in IUGR. Additionally, prematurity, placental abruption, and fetal distress have been associated with amphetamine use in pregnancy.

Marijuana use during pregnancy allows the potent metabolite THC to readily cross the placenta. Although THC is not an established teratogen, chronic use may lead to IUGR, uteroplacental insufficiency, and low birth weight.

Specific concerns regarding the fetus associated with chronic opioid use include decreased birth weight, longer and more frequent hospital stays, increased fetal mortality, and neonatal abstinence syndrome (NAS). The latter is a withdrawal syndrome seen in neonates exposed to opioids in utero and is characterized by gastrointestinal, respiratory, and nervous system dysfunction manifesting as irritability, high-pitched cry, tremors, hypertonicity, vomiting, diarrhea, and tachypnea. When maternal abstinence is not feasible, methadone maintenance therapy (MMT) is used as replacement/maintenance therapy for heroin addiction. MMT has been shown to increase prenatal medical care, decrease NAS, and reduce maternal illicit drug use at delivery.

There is conflicting evidence as to whether prenatal PCP exposure has negative effects on the developing fetus. PCP use

during pregnancy has been associated with smaller and more premature infants.

Solvent abuse in pregnancy has been associated with an increased incidence of IUGR, preterm labor, and prenatal death. Toluene may contribute to FAS with concomitant use of alcohol.

Anatomy of the human airway

William H. Rosenblatt, editor

Sarah H. Wiser

Understanding the anatomy of the human airway is critical to safe and efficient airway management. The upper airway consists of the passages from the nose and mouth to the larynx. The lower airway includes structures distal to the glottis (Fig. 15.1).

Nasal cavity

The nasal cavity provides for the passage, filtration, humidification, and warming of inhaled air. Its anatomic borders are the cribriform plate superiorly, the hard palate inferiorly, and the turbinates laterally. It is divided in the midsagittal plane by the septum. From the nares anteriorly, the nasal passage extends posteriorly and slightly caudad to reach the nasopharynx.

General sensation to the mucous membranes of the nasal cavity is derived from the trigeminal nerve (Table 15.1). The anterior lateral wall and anterior septum are supplied by the anterior ethmoid nerves (V1), whereas the sphenopalatine nerves (V2) provide sensation to these structures posteriorly. The floor of the nasal cavity (or hard and soft palates) is supplied by the infraorbital and greater palatine nerves (V2) anteriorly and posteriorly, respectively. The nasal cavity has a rich and redundant blood supply from the ophthalmic, maxillary, and facial arteries.

Oral cavity

The mouth includes the dentition, anterior two-thirds of the tongue, floor of the mouth, and undersurface of the hard and soft palates. The division between the oral cavity and the oropharynx is marked by the anterior tonsillar pillars or palatoglossal folds. The tongue is attached to the mandible anteriorly and laterally; posteriorly it is attached to the stylohyoid process and the hyoid bone. The tongue continues posteriorly into the pharynx and is attached to the epiglottis by mucosa. This mucosa creates the glossoepiglottic fold (medially) and the pharyngoglottic folds (laterally). The vallecula is the fossa formed by these folds.

General sensation to the tongue is supplied by three cranial nerve branches: the lingual branch of the trigeminal nerve (anterior two-thirds), the glossopharyngeal nerve (posterior one-third), and a small component derived from the vagus nerve (Table 15.1). The primary blood supply to the oral cavity is from a branch from the external carotid artery.

Figure 15.1. Anatomy of the upper human airway.

The mandible is the primary bony structural support of the mouth. It is a horseshoe-shaped structure with two vertical rami that articulate with the temporal bones of the cranium. The temporomandibular joint provides for two types of movement: rotation and translation. These movements allow for opening of the mouth. The space between the horizontal rami of the mandible is called the mandibular space.

Pharynx

The pharynx is a U-shaped fibromuscular tube that, anatomically and functionally, is divided into three areas: the

Table 15.1. Sensory innervation of the airway

Nerve	Sensory distribution
Trigeminal nerve (CN V)	Mucous membranes of the anterior nasal cavity
V1 anterior ethmoidal nerve	Mucous membranes of the posterior nasal cavity
V2 sphenopalatine nerves	Hard and soft palate
V2 palatine nerves	Roof of the nasopharynx
V2 pharyngeal branch	General sensation to the anterior two-thirds of the tongue
V3 lingual nerve	
Facial nerve (CN VII)	Taste to the anterior two-thirds of the tongue
Glossopharyngeal nerve (CN IX)	General sensation and taste to the posterior third of the tongue Nasopharynx (except the roof – supplied by V) Oropharynx Tonsils Laryngopharynx, pharyngeal surface of the epiglottis
Vagus nerve (CN X)	Contributes to the glossopharyngeal nerve for sensation to the oropharynx and laryngopharynx
Internal laryngeal nerve	Sensation of the pyriform recesses
Recurrent laryngeal nerve	Laryngeal surface of the epiglottis, and laryngeal structures to the vocal cords Sensation below the vocal cords and distal airways

CN, cranial nerve.

nasopharynx, oropharynx, and hypopharynx. The nasopharynx, as discussed earlier, is posterior to the nasal cavity and serves as an air conduit. The oropharynx is the main passage of the aerodigestive tract. The palatoglossal folds separate the oropharynx from the oral cavity anteriorly. The hypopharynx, the continuation of the aerodigestive tract, extends from the epiglottis to the lower border of the cricoid cartilage; it is contiguous with the esophagus. The larynx bulges posteriorly into the hypopharynx, thus creating lateral recesses on either side, called the pyriform recesses.

General sensation to the pharynx is supplied by the trigeminal, glossopharyngeal, and vagus nerves (Table 15.1). The trigeminal nerve supplies sensory innervation to the roof of the nasopharynx, and the glossopharyngeal nerve supplies sensory innervation to the remainder of the nasopharynx. The glossopharyngeal and vagus nerves both contribute sensory innervation of the oropharynx, including the posterior third of the tongue. The blood supply to the pharynx is derived from the external carotid artery.

Larynx

The larynx lies at the level of the third to sixth cervical vertebrae, anterior to the hypopharynx. Functionally, the larynx is the organ of phonation and the passageway for air into the trachea and lungs. The epiglottis acts to protect the lower airways from contamination from the alimentary tract. The larynx

**Figure 15.2.** The cartilaginous skeleton of the larynx.

consists of a cartilaginous skeleton bound by ligaments, membranes, and muscles.

The cartilaginous skeleton of the larynx consists of three unpaired cartilages – the epiglottis, thyroid, and cricoid, and three paired cartilages – the arytenoid, cuneiform, and corniculate (Fig. 15.2). The epiglottis is the functional division between the oropharynx and larynx. The thyroid cartilage houses the glottic opening and is attached to the hyoid bone by the thyrohyoid membrane superiorly and to the cricoid cartilage inferiorly by the cricothyroid membrane. The cricoid cartilage is signet ring-shaped and is the only complete cartilaginous ring in the airway. The cricothyroid ligament continues posteriorly behind the thyroid cartilage to form the anterior commissure and subsequently to create the true vocal cords, which attach and continue between the arytenoids medially to meet in the midline. The arytenoids are attached to the epiglottis laterally

Table 15.2. Motor innervation of the larynx

Superior laryngeal nerve (external branch) (CN X)	Cricothyroid muscle
Recurrent laryngeal nerve (CN X)	All other muscles of the larynx

CN, cranial nerve.

Table 15.3. Clinical manifestations of motor nerve injury

Nerve	Subtypes of Injury	Clinical manifestation	Cord position/appearance
Superior laryngeal nerve (external branch)	Unilateral injury <ul style="list-style-type: none"> • Acute • Chronic 	Hoarseness Generally has minimal effect (the other vocal cord compensates), but there may be residual dysphonia	Aryepiglottic fold shortened on the affected side and lengthened on the normal side; affected cord appears wavy
Recurrent laryngeal nerve	Bilateral injury Unilateral injury Bilateral injury <ul style="list-style-type: none"> • Acute • Chronic 	Hoarseness, tiring of voice Hoarseness	Cords appear wavy Affected cord – adducted to the paramedian position
Vagus nerve (prior to branching of the nerve)	Unilateral injury Bilateral injury	Stridor, respiratory distress Aphonia Hoarseness Aphonia	Cords nearly closed Cords are paramedian Affected cord – midline Midway between abduction and adduction (cadaveric position)

by the aryepiglottic ligaments and have articular facets inferiorly with the cricoid cartilage.

The branches of the vagus nerve supply all the motor and sensory innervation to the larynx (Tables 15.1 and 15.2) via its branches, the superior and recurrent laryngeal nerves. The superior laryngeal nerve divides into the internal laryngeal (sensory) and the external laryngeal (motor) nerves before entering the larynx. The internal laryngeal nerve pierces the lateral edge of the thyrohyoid membrane, inferior to the greater cornu of the hyoid bone, and travels superficially in the pyriform recess to enter the larynx. The internal laryngeal nerve supplies sensation to the base of the tongue, laryngeal surface of the epiglottis, and larynx to the vocal cords. The left recurrent laryngeal nerve loops around the aortic arch and the right loops around the right subclavian artery. Both then travel to supply sensory innervation to the vocal cords, trachea, carina, and distal airways.

The larynx is designed for phonation and protection of the airway. The muscles that perform these functions are divided into external and internal groups. The external group allows for position and movement of the entire larynx, whereas the internal group provides for delicate movements that affect glottic opening. The exception to this is the cricothyroid muscle, which lies external to the larynx and acts to provide tension to the vocal cords (adductor). The recurrent laryngeal nerve supplies all motor function to the internal laryngeal muscles (Table 15.2), whereas the cricothyroid muscle is supplied by the external branch of the superior laryngeal nerve. Laryngeal blood supply is derived from the carotid and subclavian arteries. Occasionally, a small cricothyroid artery crosses the superior portion of the cricothyroid membrane. Clinical manifestations of motor nerve injury are summarized in Table 15.3.

Trachea

The trachea is a tubular structure that begins at the inferior border of the cricoid cartilage at the level of the sixth cervical vertebra. It consists of 16 to 20 C-shaped hyaline cartilaginous rings connected posteriorly by the membranous trachea. The adult trachea is approximately 12 mm in diameter and 9 to 15 cm in length and bifurcates into the left and right mainstem bronchi at the carina. The carina is at the level of the sternal angle, which corresponds to the junction of the fourth and fifth thoracic vertebrae. The right mainstem bronchus is 1 to 2 cm in length and divides into upper, middle, and lower lobes, whereas the left mainstem bronchus is 4 to 5 cm in length and divides into upper and lower lobes. Air continues through the bronchioles to reach the alveoli, where gas exchange occurs.

Airway assessment

Rahul Koka and B. Scott Segal

The preoperative evaluation of the airway and the ability to predict difficulty in airway management are essential components of preparing the patient for surgery. American Society of Anesthesiologists (ASA) Closed Claims Project analysis of adverse outcomes associated with anesthesia reveals that the most common cause of serious injury during anesthesia is inadequate ventilation. More often than not, this is secondary to problems with laryngoscopy and/or mask ventilation, that is, the “difficult airway.” Being able to predict the difficult airway is an essential tool that allows the anesthesiologist to select appropriate airway devices, techniques, and procedures.

Patient history

Preoperative airway management must include a focused and detailed history of diseases or symptoms related to the airway as well as a review of prior airway management events. There are recognized associations between a variety of congenital, acquired, and traumatic disease states and problems with airway management (Table 16.1). These diseases are usually associated with specific findings on physical examination that correlate with difficult laryngoscopy or ventilation.

In addition, there are other factors that may compromise airway functionality, including edema, burns, smoke inhalation, and history of oral or nasal bleeding. Tracheal/esophageal stenosis may occur after prior tracheostomy or prolonged intubation. Snoring may suggest obstructive sleep apnea, difficulty with mask ventilation, and problems during emergence and extubation.

A history of prior attempts at intubation and ventilation also should be reviewed and may be the best predictor of difficulty with future events. A history of a difficult intubation, mask ventilation, or supraglottic airway placement may be a significant warning sign of future difficulties. If an anesthesiologist encounters airway problems, it is important to document such information and advise the patient. To date, there is no national searchable database of difficult airway patients in the United States; however, such databases have been started in Austria and the United Kingdom.

Physical examination

Examination of the airway should start with an evaluation of issues that would present problems during mask ventilation, intubation, supraglottic device placement, or tracheostomy. These components of the physical examination are listed in Table 16.2.

Prediction of difficult airway management

Fortunately, true difficult airways are uncommon. In anesthetic practice, not only are most patients easy to ventilate and intubate, most of those who are predicted to be difficult are not.

Prediction of difficult mask ventilation

According to the ASA Task Force on Management of the Difficult Airway (2003), difficult bag–mask ventilation occurs when the anesthesiologist cannot provide adequate ventilation because of an inadequate mask seal, excessive gas leak, or excessive resistance to the entry or exit of gas. The incidence of this difficulty is small (only 1%–5% for difficult and 0.01%–0.14% for impossible mask ventilation). Risk factors for difficult ventilation are shown in Table 16.3.

Other risk factors suggested, but not proven, to cause difficulty include lack of teeth, limited mandibular protrusion, macroglossia, massive jaw or heavy jaw muscles, and abnormal neck anatomy. Additional factors that should be considered are facial dressings or burns, skin sensitivity, and pharyngeal pathology such as the lingual tonsil, lingual tonsillar hypertrophy, and a thyroglossal cyst.

Prediction of difficult intubation

Direct laryngoscopy with a rigid laryngoscope is the historical tool used for orotracheal intubation. In addition to patient characteristics, the most important factor in determining the success or failure of airway management is the skill of the personnel managing the airway and their ability to recognize and react to the difficult airway. If direct laryngoscopy is predicted to be difficult on preoperative assessment of the patient, other approaches should be considered.

Table 16.1. Conditions associated with difficult endotracheal intubation

Syndrome/pathology	Description/difficulty
Congenital syndromes	
Down's	Large tongue, small mouth make laryngoscopy difficult; small subglottic diameter is possible; laryngospasm is common
Klippel-Feil	Neck rigidity because of cervical vertebral fusion
Pierre Robin	Small mouth, large tongue, mandibular anomaly; awake intubation essential in neonate
Treacher Collins Turner's	Direct laryngoscopy is difficult High likelihood of difficult direct laryngoscopy
Acquired disease states	
Angioedema	Obstructive swelling renders ventilation and intubation difficult
Ankylosing spondylitis	Fusion of cervical spine may render direct laryngoscopy impossible
Diabetes mellitus	May have reduced mobility of atlanto-occipital joint
Hypothyroidism	Large tongue and abnormal soft tissue (myxedema) make ventilation and intubation difficult
Laryngeal edema (postintubation)	Irritable airway, narrowed laryngeal inlet
Obesity	Upper airway obstruction with loss of consciousness; tissue mass makes mask ventilation difficult
Papillomatosis	Airway obstruction
Radiation therapy	Fibrosis may distort airway or make manipulations difficult
Rheumatoid arthritis	Mandibular hypoplasia, temporomandibular joint arthritis, immobile cervical spine, laryngeal rotation, and cricoarytenoid arthritis make intubation difficult
Sarcoidosis	Airway obstruction (lymphoid tissue)
Scleroderma	Tight skin and temporomandibular joint involvement make mouth opening difficult
Soft tissue, neck injury (edema, bleeding, emphysema)	Anatomic distortion of airway, obstruction
Temporomandibular joint syndrome	Severe impairment of mouth opening
Tetanus	Trismus renders oral intubation impossible
Infection	
Abscess (submandibular, retropharyngeal, Ludwig's angina)	Distortion of airway may render mask ventilation or intubation extremely difficult
Croup, bronchitis, pneumonia (current or recent)	Airway irritability with tendency for cough, laryngospasm, bronchospasm
Epiglottitis	Laryngoscopy may worsen obstruction
Trauma	
Basilar skull fracture	Nasal intubation attempts may result in intracranial trauma
Cervical spine injury	Neck manipulation may traumatize spinal cord
Maxillary or mandibular injury	Airway obstruction, difficult mask ventilation and intubation; cricothyroidotomy may be necessary with combined injuries

Adapted from Miller RD. *Miller's Anesthesia* 2000: 5th edition; Tables 42–2 and 42–3.

Table 16.2. Components of the airway physical examination

Parameter	Factors for consideration
General appearance	Level of consciousness; evidence of respiratory distress, stridor, or cyanosis; body habitus; cervical collar or evidence of external trauma; pregnancy and body jewelry
Face	Beard or obvious facial abnormalities that might prevent adequate seal during mask ventilation
Nares Temporomandibular joint	Patency, masses, evidence of trauma Interincisor distance (≥ 4 cm or 2 fingerbreadths is desirable), ability to prognath the mandibular teeth anterior to the maxillary teeth
Palate	High arched palate or a long narrow mouth may present difficulty
Tongue	Piercings or large tongue may cause difficulty
Submental space Dentition	Thyromental distance ≥ 7 cm is desirable Dentures, loose teeth, prominent upper incisors or canines, with or without overbite
Neck	Short thick neck is associated with difficult intubation, decreased neck mobility, or inability to sniff

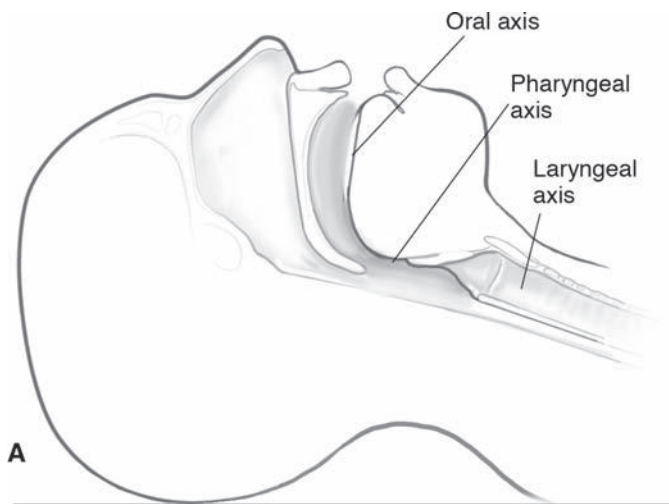

Atlanto-occipital joint extension

Direct laryngoscopy typically is performed with the patient supine and the operator standing at the head of the bed. The goal of laryngoscopy is to visualize the laryngeal opening. Therefore, the operator attempts to position the patient in such a way as to create a straight line between the observer and the larynx. The three-axis alignment theory describes the airway as consisting of the oral and pharyngeal anatomic axes, leading the laryngoscopist to the opening of the laryngotracheal axes (Fig. 16.1). According to the theory, two former lines need to be in alignment for visualization of the vocal cords. Elevation of the head (about 10 cm) with pads below the occiput and the shoulders remaining on the table helps align the laryngeal and pharyngeal axes. In addition, head extension at the atlanto-occipital joint creates the shortest distance (almost a straight line) from the incisors to the glottic opening. Therefore, risk factors for difficult intubation include those that prevent alignment of this axis or anatomic structures that block direct visualization.

The “sniffing position” (Fig. 16.2), originally suggested by Magill to help align a patient's head during tracheal intubation, requires some degree of neck mobility (actually Magill suggested an “elderly gentleman sniffing the early morning air” or “draining a pint of beer”). Reduced atlanto-occipital joint

extension is a predictor of difficult intubation based on measurements made of the cervical spine, mandible, and upper jaw in patients considered to be difficult to intubate. In general, neck extension $<35^\circ$ is associated with difficulty in intubation; the average neck extension is 54° to 64° . Therefore, the range of motion of the neck plays a large part in the prediction of difficult intubation.

Mallampati classification

In 1983, Mallampati suggested and tested the following hypothesis: “If the base of the tongue is disproportionately large, it overshadows the larynx, rendering exposure of the latter by direct laryngoscopy poor or difficult.” From this premise, a rating system was devised comparing tongue size to pharyngeal size. The Mallampati classification system, later modified by

Figure 16.2. Sniffing position for optimizing the airway position for ventilation or endotracheal intubation.

Samsoon and Young (1987), has since become a standard practice in airway assessment (Fig. 16.3). The test is done as the patient sits with the head in a neutral position, the mouth open, and the tongue protruding to its limit. The airway is assessed and classified according to the pharyngeal structures seen. The patient is not asked to phonate during this maneuver, as it raises the soft palate and, on average, the view of the pharynx. In addition, the test should be repeated twice to avoid false positives and negatives. The Mallampati classification is as follows:

- Class I – soft palate, pharyngeal wall, entire uvula, and pillars
- Class II – soft palate, pharyngeal wall, portion of uvula
- Class III – soft palate, base of uvula or no uvula
- Class IV – hard palate only

The Mallampati examination is the most commonly used test in airway assessment. It is relatively easy to perform, with no need for extra equipment. However, it has a sensitivity of only about 50% for predicting difficult intubation, with a high false-positive rate. The results of the test depend a great deal on patient cooperation and proper positioning, two factors that have been shown to be difficult to replicate.

Figure 16.3. The modified Mallampati classification system.

Mouth opening and mandibular space

In addition to the Mallampati classification, other screening tests include measuring the mouth opening using interincisor distance and measuring mandibular space using the thyromental distance. The former is reflected in the Mallampati examination, and although it is assessed often, it has not been shown to be an independent predictor of difficult tracheal intubation. Normal interincisor distance is about 4 cm.

Thyromental distance is defined as the distance from the chin (mentum) to the thyroid cartilage notch with the patient's neck in an extended position. Normal distance is 6.5 to 7.0 cm. Distances of 6.0 to 6.5 cm have been associated with difficult laryngoscopy and those <6.0 cm with difficult intubation. The combination of Mallampati score and thyromental distance is one of the best overall predictors of difficult intubation.

Dentition

Although injury to a patient's teeth during intubation is unusual, it still is one of the most common complications of anesthesia. In addition, prominent teeth may hinder direct laryngoscopy by limiting the alignment of the oral and pharyngeal axis during laryngoscopy. Risk factors for dental injury and difficult laryngoscopy include prominent upper incisors or canines or an overbite. An edentulous state can help with direct laryngoscopy (oral axis alignment) but may cause hypopharyngeal obstruction by the tongue during bag-mask ventilation.

Prediction of difficult supraglottic device insertion

Supraglottic devices often are the first rescue devices used in the "cannot intubate, cannot ventilate" scenario. Placement of the laryngeal mask airway (LMA) is not always easy, and seating above the vocal cords rarely is not possible. The rate of failure to place an LMA is 0.24%, and studies correlating the ease of LMA insertion with Mallampati classification are controversial at best.

Prediction of difficult surgical airway

The emergent surgical airway is a situation of last resort for most anesthesiologists. It is a rare event, thus there are limited data on the prediction of difficult tracheostomy. Obese patients, particularly those with obstructive sleep apnea, may pose a problem because excess skin and redundant tissue may impair the operation. Tracheostomy placement also may be difficult in infants and children because of their relatively short necks.

Perioperative airway management

Sibinka Bajic and Sarah H. Wisner

Airway management is fundamental to the practice of anesthesia. To provide safe and effective airway management, the anesthesiologist must be knowledgeable in both airway techniques and equipment. In addition, knowledge of basic airway anatomy and an understanding of the patient's characteristics will help determine the appropriate approach to the patient's airway in clinical practice.

A general approach to airway management is outlined in Fig. 17.1. This represents an effective preoperative exercise to help guide perioperative airway management and the path to be followed through the American Society of Anesthesiologists (ASA) difficult airway algorithm.

Noninvasive airway maintenance techniques

The noninvasive airway maintenance technique is suitable for procedures that allow for a local or regional anesthetic, supplemented with sedation and oxygen, when general anesthesia is not required. The patient needs to be cooperative and

to understand that light sedation may not make him or her unaware of the surgical procedure. Furthermore, the patient should be informed that a general anesthetic may be necessary in the event of an inadequate block or a surgical/anesthetic complication.

Nasal cannula

Supplemental oxygen may be delivered either by nasal cannula or a simple face mask. A nasal cannula can be placed rapidly and comfortably in most patients. The continuous flow of oxygen causes nearly 80% of the gas to be wasted during expiration. During quiet respiration, the fraction of inspired oxygen content (FiO_2) increases by 1% to 2% (above 21%) per each liter of oxygen flow. The maximal level of FiO_2 that can be achieved with a nasal cannula is 40% to 50% at oxygen flows >10 L/min. Flows >5 L/min create gas jetting into the nasal cavity, with subsequent drying and crusting of the nasal mucosa, leading to patient discomfort. In situations in which a higher FiO_2 is required, a face mask is a better alternative. Pooling of oxygen beneath drapes has been a factor in operating room fires, and caution must be exercised whenever the surgical site is proximal to the airway or oxygen source.

Face masks

The nonreservoir simple face mask is suitable for patients who require a moderately increased level of oxygen therapy for short periods (e.g., during an operation, medical transport, care in the postanesthesia recovery or emergency room). The FiO_2 received depends on the mask volume, pattern of ventilation, and oxygen flow rate. At low flows, exhaled carbon dioxide is retained in the mask, resulting in rebreathing; thus the minimal flow rate should be 5 L/min. One should expect an FiO_2 of 30% to 60% with flows of 5 to 10 L/min, respectively.

Two types of reservoir masks are commonly available for use: the partial rebreathing mask and the nonrebreathing mask. The partial rebreathing mask, a simple mask with a reservoir bag, is considered a low-flow system. At flow rates of 6 to 10 L/min, the system can provide an FiO_2 of 40% to 70%. The nonrebreathing mask is similar to the partial rebreathing mask, except that it has a series of one-way valves between the bag and mask. These valves prevent exhaled air from returning to the

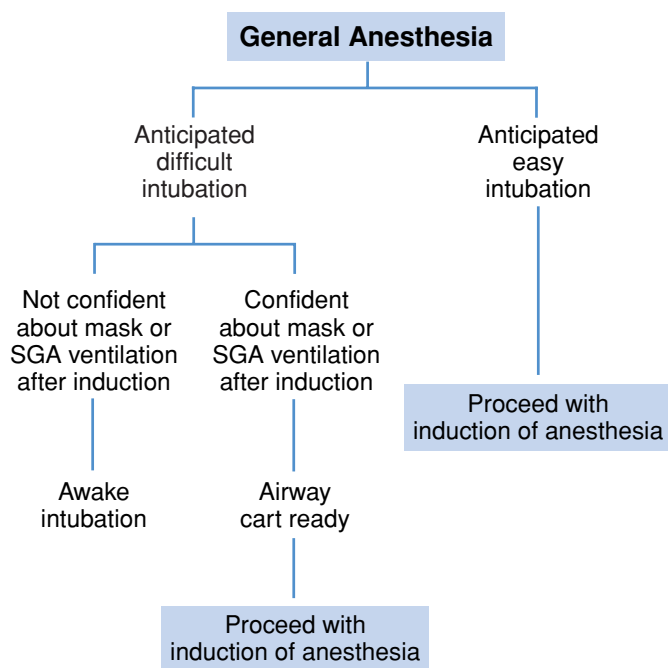

Figure 17.1. A general approach to airway management.

Figure 17.2. Artificial airways: oropharyngeal, Ovassapian intubating airway, and nasopharyngeal airways.

bag, thereby preventing rebreathing. Because a nonbreathing mask coupled with high oxygen flow (15 L/min) may provide an FiO_2 of nearly 100%, it is commonly used in intensive care settings as a preoxygenation device prior to intubation.

During sedation with spontaneous respiration, the oxygen saturation, pattern of breathing, and end-tidal CO_2 should be monitored continuously. The clinician should be vigilant for potential airway compromise secondary to excessive sedation. Partial airway compromise often manifests with airway “noises.” Inspiratory noises of snoring occur as a result of loss of pharyngeal muscle tone due to central nervous system depression. This loss of pharyngeal muscle tone can be corrected by airway maneuvers such as a head tilt/chin lift and/or a jaw thrust, or by placement of an artificial (nasal or oral) airway (Fig. 17.2). Inspiratory noises of stridor or “crowing” may indicate serious and impeding laryngeal obstruction or laryngospasm, which should be recognized rapidly and treated with positive pressure ventilation and/or removal of airway secretions. This may require deeper anesthesia and airway control if not resolved quickly. The total lack of respiratory noises combined with ongoing inspiratory effort (e.g., suprasternal and costal retractions) occurs in the setting of total airway collapse and must be treated immediately.

Oro- and nasopharyngeal airway

The oropharyngeal airway may be used for airway patency or as a bite block (Fig. 17.2). It is a hollow, rigid structure with a proximal flange, bite block, and curvature that mimics the contour of the airway. It is contraindicated if pharyngeal and laryngeal reflexes are intact, as it may lead to gagging with regurgitation or laryngospasm. Other potential complications include airway trauma during insertion and airway obstruction.

Alternatively, the nasopharyngeal airway is used to maintain upper airway patency and is better tolerated in sedated or

lightly anesthetized patients, even if pharyngeal and laryngeal reflexes are intact (Fig. 17.2). It is a curved cylinder made of one of several pliable materials, with a proximal flange to prevent overinsertion into the airway, and is beveled on one side to minimize mucosal trauma. Contraindications to nasopharyngeal airway use include nasal airway obstruction, nasal and basilar skull fractures, a markedly deviated septum, coagulopathy, and cerebrospinal fluid rhinorrhea. Complications include epistaxis, nasopharyngeal submucosal tunneling, and pressure sores.

Invasive airway maintenance techniques

Bag–mask ventilation

Bag–mask ventilation is minimally invasive and remains the mainstay to assist or control ventilation in the peri-induction/emergence period of a general anesthetic, for the delivery of an anesthetic, and during resuscitation. The most important aspect of effective mask ventilation is achieving a good mask seal. An adequate mask seal requires proper handling of the mask and often placement of the patient’s head and neck in the “sniffing” position. The sniffing position is flexion of the neck at the lower cervical vertebrae with extension at the atlanto-axial joint. In the supine patient, the sniffing position can be achieved easily by placing a small ring or folded blanket under the patient’s head to flex the neck and tilt the head backward.

There are two techniques for holding a mask, the one-handed and two-handed/two-person techniques. The one-handed technique involves placement of the mask onto the patient’s face with the thumb and index fingers around the circuit connector of the mask, down-placing the mask onto the face with concurrent upward displacement of the mandible with the remainder of the fingers, known as a “jaw thrust” (Fig. 17.3). This technique frees the other hand for delivery of positive pressure breaths by squeezing the reservoir bag. Difficulty with mask ventilation is encountered in elderly, obese, edentulous,

Figure 17.3. Proper finger/hand position during one-handed bag–mask ventilation.

Figure 17.4. Disposable LMA (left) and ProSeal LMA (right).

or bearded patients, as well as in patients with a history of obstructive sleep apnea. In such instances, a two-handed/two-person technique may be required to deliver adequate ventilation. Here, the primary operator acts to ensure a good seal between the mask and the patient's face while performing a bilateral jaw thrust and mask seal with both hands; the second operator ventilates the patient by squeezing the reservoir bag. One should be cautious not to cause trauma to the eyes or branches of the facial and trigeminal nerves while providing mask ventilation.

Whenever mask ventilation is used, no more than 15 to 20 mm Hg of positive pressure should be required, unless pulmonary pathology or obesity is present. Applying higher pressure may lead to gastric insufflation, compromise of oxygenation, regurgitation, and/or aspiration. If greater pressure is required or difficult ventilation is present, the clinician should adjust the mask fit, try a two-handed technique, and consider placement of oro/nasopharyngeal airway devices. If initial troubleshooting is unsuccessful, more "invasive" methods should be considered.

Supraglottic devices

Supraglottic devices are designed to keep the airway patent without entering the larynx. Several types of supraglottic devices are available; the one most commonly used is the Laryngeal Mask Airway (LMA). Recently, many new supraglottic devices became available that vary by material composition, shape, and, in some instances, functionality. The Combitube has been used largely in rescue/emergency airway situations. Another device, the King laryngeal tube (King LT;

King Systems, Noblesville, IN), has been used increasingly for standard anesthetic procedures. The latter two devices are promoted as conferring some protection against aspiration, although randomized controlled trials are lacking to confirm this potential benefit. In general, supraglottic devices are indicated for nonemergent anesthetic cases, in healthy patients without the risk of aspiration, and for routine, short procedures. Outside these indications, they may be used for rescue when tracheal intubation fails or is not available.

Laryngeal Mask Airway

The LMA (Fig. 17.4) is composed of an airway tube with a standard 15-mm anesthetic connector at the proximal end and an inflatable mask at the distal end. As with cuffed endotracheal tubes (ETTs), inflation is controlled by a pilot balloon system. The opening of the airway tube is covered by two bars to prevent the epiglottis from being trapped in the airway tube, which might cause obstruction of airflow. Once inserted, the LMA sits in the hypopharynx with the opening overlying the laryngeal entrance and the tip of the mask within the upper esophageal sphincter. The LMA, an alternative to mask ventilation and tracheal intubation, is used in 35% of all general anesthetic cases in the United States. In addition, the LMA is a useful tool in the ASA difficult airway algorithm as a rescue device in patients with unexpected difficult airways or as a conduit for intubation.

When correctly placed, the LMA can seal the hypopharyngeal space and allow for spontaneous or positive pressure ventilation of up to 20 cm H₂O pressure. Although the LMA will protect the larynx from oropharyngeal secretions, it was

Figure 17.5. LMA insertion technique.

not designed to protect the airway from regurgitated contents. However, reports of aspiration are rare. The LMA is best suited for nonemergent, short procedures in supine ASA I or ASA II patients with no risk of aspiration. However, the LMA has been used for airway management in a wide variety of cases, including transesophageal echocardiography, cardioversions, head and neck operations, pulmonary procedures, surgery in patients in a nonsupine position, and laparoscopic cholecystectomies. Contraindications for elective LMA placement include patients who have not fasted; laboring women; and any patient with risk of pulmonary aspiration, hiatal hernia with significant

positional gastroesophageal reflux disease (GERD), oropharyngeal, glottic or subglottic airway obstruction; poor pulmonary compliance; or a limited mouth opening.

Multiple techniques for placing an LMA have been described. However, to ensure proper placement of the LMA, the recommended technique is the one described by its inventor, Dr. Archie Brain (Fig. 17.5). This technique involves the following:

- Completely deflating and lubricating the mask (however, some trials have shown greater success with partial cuff inflation)

- Holding the LMA with the dominant hand, with the index finger between the airway tube and the mask
- Placing the patient's head and neck in the sniffing position and widening the oropharyngeal angle by placing the nondominant hand at the vertex of the head to open the mouth, allowing for visualization of the hard palate
- Inserting the LMA by flattening the mask against the hard palate and advancing the LMA posteriorly with the index finger while maintaining cranial pressure
- Removing the index finger of the dominant hand
- Inflating the mask, upon which the LMA lifts out by 1 to 2 cm and the cricoid cartilage moves forward. Once the LMA is inflated, the anesthesia circuit can be connected for conformation of adequate ventilation, with either spontaneous or controlled ventilation (with or without muscle relaxation).

Several LMA types and sizes are available (made by LMA Inc., San Diego, CA), including LMA Classic and its disposable version (LMA Unique); LMA ProSeal, which has a separate port used to verify its position and can accommodate a tube for gastric suctioning, and its disposable version (the LMA Supreme); LMA Fastrach, or intubating LMA, designed to facilitate blind or fiber-optically guided endotracheal intubation; and the LMA CTrach, which adds video capability to the Fastrach. A variety of adult and pediatric sizes are available, and appropriate size selection and cuff inflation is vital for a successful LMA seal (Table 17.1). With proper use, the incidence of gastric content aspiration with an LMA is equal to that of the tracheal tube.

Finally, it is important to be aware of complications of LMA insertion, including sore throat, vascular compression due to an overinflated and improperly positioned device, mucosal injury, and neurapraxias. The lingual, hypoglossal, and recurrent laryngeal nerves are the three most commonly involved in LMA-related nerve injury.

Combitube

The Combitube is a double-cuffed, double-lumen tube that allows ventilation and oxygenation with either tracheal or esophageal intubation. It is used occasionally for routine anesthesia, emergency airway control (during cardiopulmonary resuscitation), and difficult airway management (massive upper

Table 17.1. Recommended LMA size according to various patient weights

LMA size	Weight, kg

1½	5–10
2	10–20
2½	20–30
3	30–50
4	50–70
5	70–100
6	>100

Figure 17.6. Cross-section of the Combitube.

gastrointestinal bleed, massive regurgitation, or unanticipated difficult intubations). Distally, the “pharyngeal” lumen is blind and has eight perforations at the level between the cuffs. The second lumen is “tracheoesophageal” and is open distally. The proximal balloon (oropharyngeal) is located at the middle portion of the Combitube, and the distal cuff (tracheoesophageal) is located at the distal end (Fig. 17.6). A unique tube design allows ventilation both when the Combitube is inserted into the esophagus (via the perforations of the pharyngeal lumen) and when it is inserted into the trachea, through the opened distal end of the tracheoesophageal lumen. In either case, the proximal or oropharyngeal balloon seals the oral and nasal cavity after inflation, and the distal conventional tracheal tube cuff isolates the respiratory from the gastrointestinal tract. It is important to remember that the oropharyngeal balloon is made of latex. When it is inserted, the teeth or alveolar ridge should fall between the two black rings printed on the proximal end of the double-lumen tube indicating the limit of insertion.

The Combitube is available in two sizes: 37F fits patients who are 4 to 6.5 feet tall, and 41F fits those taller than 6 feet, with some overlap. It is inserted “blindly,” with 90% of Combitube placements resulting in an esophageal position, and ventilation is carried out via the perforations of the pharyngeal lumen. Advantages of the Combitube include rapid airway control and protection from aspiration, no requirement for

Figure 17.7. King LT in proper position. The bigger balloon is the pharyngeal balloon; the smaller one is the esophageal balloon.

visualization of the larynx, and the ability to maintain the neck in neutral position. Contraindications include the presence of esophageal obstruction or other pathology, upper airway foreign body, intact gag reflex, lower airway obstruction, patients with latex allergy, and patients <4 feet tall. Reported complications include laceration of the esophageal wall and pyriform sinus, as well as complications similar to those of the LMA.

King laryngeal tube

The King LT consists of a silicon airway tube and two (distal and proximal) low-pressure cuffs (Fig. 17.7). The airway tube is short and J-shaped (with approximately a 130° midshaft angle) and has a blind tip. The King LT has two ventilation outlets located on the ventral aspect of the tube, between the two cuffs. When the tube is inserted correctly, the proximal cuff lies in the pharynx and the distal cuff in the upper esophagus; both cuffs inflate simultaneously via a single inflation line. The King LT is designed for use during spontaneous or controlled ventilation. Spontaneous or positive pressure ventilation occurs via the midcuff openings. It is reusable (a disposable version also is available) and can be inserted “blindly” or with the aid of the laryngoscope. Inadvertent tracheal intubation occurs rarely. Six sizes are available, and size selection is based on the patient’s weight (sizes 0–2) and height (sizes 3–5). The King LT is not appropriate for patients with an increased risk of aspiration, poor lung compliance, increased airway resistance, or lesions of the oropharynx or epiglottis.

Laryngeal tube suction (LTS; King Systems) is similar to the King LT but incorporates a second, posterior esophageal lumen. This esophageal lumen represents a release valve for increases in gastric pressure and permits gastric suctioning.

Endotracheal intubation

Perioperative endotracheal intubation provides a means for airway patency and protection, mechanical ventilation, and the ability to remove tracheobronchial secretions in the anesthetized patient. Primary surgical indications for endotracheal intubation are prevention of loss of the airway, complicated cases (requiring a significant proportion of time to be focused on nonairway tasks), unusual positioning for surgery, cases in which high airway pressures may occur, and those in which gas exchange is likely to be impaired. Primary patient indications for endotracheal intubation include airway protection, the need for close control of end-tidal CO₂, and postoperative intubation. A secondary need for tracheal intubation arises when surgical or anesthetic complications occur, such as high spinal, massive blood loss; malignant hyperthermia; or inadequate regional anesthesia.

Orotracheal intubation is the commonest route of intubation for general anesthesia and cardiopulmonary resuscitation (Fig. 17.8). The nasotracheal approach is reserved for surgical procedures requiring free access to the oropharynx or for patients with limited access to the oral cavity. Standard ETTs are made of polyvinyl chloride and shaped to follow the contour of the airway. However, the shape and rigidity of the ETT may be altered by inserting a stylet through the tube. It is important to note that the proximal end of the stylet should not protrude from the ETT, as it may cause trauma to the airway. ETTs usually have a lateral opening at the proximal end (Murphy’s eye) to prevent occlusion. Besides the standard ETTs, wire-reinforced flexible tubes (armored) and preshaped tubes (oral and nasal) are available. Armored tubes are resistant to kinking and occlusion and therefore are preferable for use in head and neck and prone-position surgeries.

To ensure a proper seal in the trachea, cuffed ETTs are available. Cuffed ETTs consist of a balloon at the proximal end, which can be inflated via a pilot cuff. These cuffs may be high pressure (low volume) or low pressure (high volume). High-pressure cuffs may cause tracheal mucosal ischemia, especially if tracheal intubation is continued for lengthy cases. Low-pressure (high-volume) cuffs may cause sore throat (large surface area) and provide an improper seal to guard against aspiration.

Selecting the proper ETT size is important. Larger tubes provide better airway gas flow, whereas smaller ones cause less airway trauma. For an adult male, about a size 8.0 (internal diameter in millimeters) is preferable, whereas about a size 7.0 is preferred for an adult female. In children, ETT size can be calculated by the formula $4 + \text{age}/4$. For example, in an 8-year-old child, one can use a 6.0 ETT. Uncuffed ETTs generally are used for children <5 years old.

Standard intubation technique utilizes direct laryngoscopy. There are many types of laryngoscopes and blades available, but the two in most widespread use are the Macintosh (curved) blade and Miller (straight) blade. Other available blades have different angles of curvature, lengths, optical components, and even movable parts.

Figure 17.8. (A) Orotracheal intubation. (B) Nasotracheal intubation.

The Macintosh blade is designed to be advanced into the vallecula (space between the base of the tongue and the lingual surface of the epiglottis), and its blade displaces the tongue and soft tissues forward, exposing the larynx. Advantages of the Macintosh blade include less trauma to the teeth, more space in the oro- and hypopharynx for passage of the ETT, and less bruising and damage to the epiglottis. The Miller straight blade is designed to lift the epiglottis to expose the vocal cords. The Miller blade may produce a better view of the glottic opening compared with curved-type blades. However, its blade flattens tissue with less displacement, thus providing less space for passage of the tube. The Miller blade is more advantageous in patients with a small mandibular space, large incisors, or a large epiglottis, whereas the Macintosh blade may be better for patients with a small mouth (Fig. 17.9).

Preparation for general anesthesia and tracheal intubation should include appropriate airway equipment checked for proper function, an oxygen source, suction, and a flowing intravenous line; anesthetics and muscle relaxants of choice; proper patient positioning; and preoxygenation. The latter also is termed *denitrogenation* and involves replacement of the lung's nitrogen volume with oxygen, so an oxygen reservoir is present after the onset of apnea. Preoxygenation is performed by placing a tightly fitting face mask and delivering 100% oxygen for 5 minutes to a spontaneously breathing patient. Without preoxygenation, arterial desaturation may occur after 1.5 to 2 minutes of apnea, whereas a healthy preoxygenated patient will not develop desaturation until after about 7 or more minutes of apnea. An alternative method that is less time-consuming is to ask the patient to take eight vital capacity breaths of 100% oxygen.

Successful laryngoscopy requires proper positioning of the patient to gain adequate visualization from the lips to the glottis. The most frequently used position for intubation is the sniffing position (described earlier). This position creates maximal

alignment of the axes of the airway, allowing direct visualization of the glottis. The typical technique for laryngoscopy includes the following steps: (1) The laryngoscope is held in the left hand. (2) The mouth is opened with a scissoring motion of the right thumb and index finger on the teeth or gingiva. (3) The laryngoscope is inserted into the right side of patient's mouth and advanced toward the epiglottis while sweeping the tongue to the left. (4) With the wrist held straight, the laryngoscopist's arm and shoulder lift the tongue and pharyngeal soft tissue in an anterior and caudal direction to expose the glottic opening.

Figure 17.9. Miller blades (left 3) and Macintosh (right 2).

Figure 17.10. View of the vocal cords. Grade I: the entire glottic opening is visualized. Grade II: only the posterior aspect of the glottic opening is visualized. Grade III: only the tip of the epiglottis is visualized. Grade IV: only the soft palate is visualized.

(5) The ETT is passed through the glottic opening from the right-hand side to avoid obstruction of the glottic view during insertion. The laryngoscopist should never use the blade as a lever, as this may cause significant damage to the teeth or gingiva.

The view of the larynx and vocal cords may be complete, partial, or impossible. Four grades of laryngeal views were described by Cormack and Lehane (Fig. 17.10).

If a good laryngeal view is not achieved during laryngoscopy, external laryngeal manipulation of the cricoid cartilage may improve the view. Furthermore, many types of intubation guides and stylets have been designed and are useful during difficult laryngoscopy. Intubation using an introducer known as a bougie is an essential adjunct to direct laryngoscopy. Many of the available bougies have a curved distal tip that allows for intubation into the trachea, even with suboptimal views (grade II or III). The bougie is “hooked” beneath the

epiglottis and advanced into the trachea. A tactile click may be sensed as the tip moves over the tracheal rings; if the tactile sensation is smooth, the bougie likely has passed into the esophagus and should be repositioned. Once the bougie is in the trachea, the ETT can be placed over the bougie.

Nasotracheal intubation (Fig. 17.8b) typically is reserved for surgical procedures requiring free access to the oropharynx (e.g., maxillofacial surgery) and when there is limited access to the oral cavity. An ETT 0.5 to 1 mm smaller than that planned for oral intubation is selected. If a difficult airway is not anticipated, the naris is prepared with a vasoconstrictor (phenylephrine drops), and a lubricated ETT is passed through the nose after induction. A laryngoscope (direct, fiberoptic, or video) often is used to advance the tube under visual guidance. Manipulation of the head position, larynx, or ETT with Magill’s forceps may be needed to guide the ETT into the larynx.

Figure 17.11. Various endotracheal tubes. From left to right: armored, regular, nasal RAE, and oral RAE tubes.

Relative contraindications of nasotracheal intubation include basal skull fractures, coagulopathy, planned systemic anticoagulation or thrombolysis, and elevated intracranial pressure. Complications include epistaxis (seen with inadequate topical vasoconstriction, large tube size, and anatomic abnormalities), retropharyngeal laceration/abscess, turbinectomy, and paranasal sinusitis (with prolonged nasotracheal intubation).

Proper placement of the ETT can be verified by a variety of methods. The gold standard techniques include visualization of the ETT passing between cords, bronchoscopy, and sustained detection of the end-tidal CO₂. Other techniques of confirmation include auscultation of both lung fields and the stomach, chest expansion, condensation in the ETT during exhalation, palpation of the cuff in the suprasternal notch, expansion of a self-inflating bulb applied to the ETT, and chest radiography. If breath sounds are heard unilaterally, a mainstem bronchial intubation should be suspected, and the ETT should be withdrawn until breath sounds are auscultated bilaterally. Additional complications of laryngoscopy and endotracheal intubation include (1) airway trauma (damage to teeth, lips, tongue, pharynx, vocal cords, arytenoid cartilages, or trachea), (2) physiologic responses to airway manipulation (hypertension, tachycardia, increase in ocular or intracranial pressure, laryngospasm), (3) tube malposition (esophageal or endobronchial placement, unintentional extubation), and (4) tube malfunction (cuff perforation, ignition, and obstruction).

Airway injury remains a common anesthetic complication. Approximately 6% of all recent anesthesia-related injury claims were for airway injury, with the most frequent sites of injury being the larynx (33%), pharynx (19%), and esophagus (18%). According to Closed Claims Project data, injuries to the esophagus and trachea were more frequently associated with difficult intubation, whereas injuries to the temporomandibular joint and larynx were more frequently associated with non-difficult intubation. The incidence of dental injuries during airway manipulation is approximately one per 2073 patients, with maxillary incisors being the most frequently injured teeth. Compared with patients with normal teeth, those with poor dentition are three times more likely to have dental injuries if they are easy to intubate and a 20 times more likely if they are moderate to difficult to intubate.

Rapid sequence induction

In the rapid sequence induction (RSI) of anesthesia, after adequate preoxygenation, intravenous administration of an induction agent is quickly followed by a rapidly acting neuromuscular blocking agent with the application of constant cricoid pressure (Sellick's maneuver, 30-40N) prior to the loss of consciousness. Cricoid pressure causes the downward displacement of the cricoid cartilage (a complete signet-shaped ring) against vertebral bodies so that the esophagus or hypopharynx lumen is compressed. Direct laryngoscopy and endotracheal intubation are performed following the onset of muscle relaxation. This technique minimizes the time between loss

of consciousness and intubation and theoretically confers increased protection against pulmonary aspiration. It is indicated in patients undergoing general anesthesia with a high risk of aspiration of gastric contents (full stomach, impaired gastroesophageal sphincters, delayed gastric emptying, loss of protective airway reflexes). Patients at risk include those who are in labor, morbidly obese, or diabetic; patients with positional GERD; and those undergoing emergency procedures. However, the effectiveness of cricoid pressure has been questioned recently. MRI studies revealed that the esophagus is displaced laterally relative to the cricoid in more than 50% of normal patients without cricoid pressure and that this proportion reaches 90% when cricoid pressure is applied.

Classic RSI precludes the ability to "test" the airway with mask ventilation. In theory, a muscle-relaxed patient who cannot be intubated or mask ventilated might be encountered. If such a situation arises, the clinician should follow the ASA difficult airway algorithm emergency pathway sequence. Many leaders in the field are now questioning the necessity of not ventilating RSI patients prior to intubation. A review of the literature has shown that the reason for omitting ventilation during RSI is based on marginal, anecdotal evidence.

Extubation

The time of emergence and tracheal extubation may be a vulnerable period for patients. The ASA Task Force on Management of the Difficult Airway commented that since their publication of the original guidelines in 1993, there has been little change in extubation-related claims. During extubation, there is risk of aspiration, laryngospasm, bronchospasm, airway obstruction, vocal cord paralysis, hypertension, or hypoventilation. Extubation criteria include return of consciousness and spontaneous respiration, ability to follow simple commands, intact gag reflex, sustained head lift for 5 seconds (the resolution of neuromuscular blockade), adequate pain control, and stable vital signs. Objective extubation criteria include respiratory rate <30/min, tidal volumes >5 ml/kg, vital capacity >10 ml/kg, peak negative inspiratory force of -20 cm H₂O, dead space/tidal volume ratio of <0.6, PaO₂ >70 mm Hg, and PaCO₂ <55 mm Hg on an FiO₂ of 40%. The patient is asked to open his or her mouth, and secretions and/or blood are removed with a suction catheter. The ETT is removed after the cuff is deflated. Because of the risk of hypoxia due to hypoventilation and diffusion hypoxia, it is essential to have an oxygen source available at the time of extubation. Patients who presented with a difficult airway at the induction of anesthesia should be considered at risk for extubation failure. Preparation for extubation includes performance of the leak test (air escape when the ETT is cuff deflated), pre-extubation oxygenation, full neuromuscular blocking agent reversal, and verification of the patient's ability to follow commands. In cases of prolonged intubation or suspected airway edema, a leak test may be performed to detect air escape when the ETT cuff is deflated. If there is any anticipation of difficulty, advanced airway rescue equipment should

be available. An airway exchange catheter (a hollow-lumen tube placed in the trachea via the ETT) may be used if there is suspicion of extubation failure. On ETT removal, the catheter may be left in place for minutes to hours and facilitates a “Seldinger-like” reintubation or is used for oxygen insufflation.

Management of the difficult airway

Essi M. Vulli and Wariya Sukhupragarn

Management of a difficult airway is one of the more challenging tasks for an anesthesiologist. It necessitates dexterity with various airway devices and techniques as well as the ability to adapt rapidly to complex and evolving situations involving diverse patient factors and clinical scenarios. Competency in dealing with a difficult airway is expected of all anesthesiologists and is of critical importance, for it can have a profound impact on patient outcome (death, brain injury, cardiopulmonary arrest, unnecessary tracheostomy, and airway trauma). The American Society of Anesthesiologists (ASA) Closed Claims Project database demonstrates that difficult intubation is the second most frequent primary damaging event leading to anesthesia malpractice claims.

Definition

In 2003, the ASA Task Force on Management of the Difficult Airway published an updated report that defined the difficult airway as “the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with face mask ventilation of the upper airway, difficulty with tracheal intubation, or both.” This publication includes a revised difficult airway algorithm (DAA), which is a simple yet invaluable tool to guide the practitioner in these situations (Fig. 18.1). As stated in *Current Anaesthesia and Critical Care* journal, an alternative and often-used definition of a difficult airway is a “an intubation requiring more than three attempts at laryngoscopy or taking longer than ten minutes.”

Preoperative evaluation of the airway is of paramount importance. It allows the practitioner to anticipate problems with mask ventilation and/or intubation. This evaluation includes a concise medical history, review of previous anesthesia documents when available, and a focused physical examination. Such an evaluation should be performed whenever possible prior to induction of anesthesia.

Difficult airway algorithm

A practitioner enters the DAA by first examining the airway and making a premanagement decision of awake intubation (entrance point A) or airway control after the induction of general anesthesia (entrance point B). In doing so, the practitioner either anticipates difficulty with airway manipulation or feels that no difficulty should be encountered. In this context,

“airway manipulation” should be interpreted as meaning supraglottic airway (SGA) ventilation (mask ventilation, laryngeal mask airway [LMA], or other SGA device) and/or endotracheal intubation. The importance of this distinction is to stress that it is not only anticipated intubation but also anticipated difficulty with ventilation that should drive a practitioner to proceed with caution and to perhaps choose option A.

Alternative airway devices and techniques

This section discusses the many devices and techniques available to assist the practitioner when a difficult airway is encountered. They may be of particular use in situations involving unsuccessful initial intubation attempts after induction of general anesthesia (i.e., most commonly, failed conventional direct laryngoscopy) or when conventional mask ventilation is difficult, or both.

If the clinician encounters the cannot-intubate/cannot-ventilate situation, it is imperative to consider (1) calling for help, (2) returning to spontaneous ventilation, and/or (3) awakening the patient. The following devices and techniques are helpful in these critical situations, but calling for help early is critical.

Laryngeal Mask Airway (LMA)

As discussed in Chapter 17, the LMA was developed by Archie Brain and first introduced into clinical practice in Great Britain in the mid-1980s; it was approved for use in the United States by the US Food and Drug Administration in 1991. The LMA is recognized by the ASA as a critical tool for the difficult airway patient. It appears in the 2003 iteration of the DAA as the third recommended strategy after failed “laryngoscopy/face mask ventilation.” Although each of the three mentioned techniques – laryngoscopy, mask ventilation, and LMA – is expected to fail in one to three in 1,000 patients, unanticipated failure of all methods is expected to occur in fewer than one in 500,000 cases. The LMA ProSeal (LMA Inc., San Diego, CA) may add to this resuscitation potential by allowing the rescuer to empty the stomach.

The LMA Fastrach (LMA Inc.), also known as intubating LMA (ILMA), was developed by Brain and introduced into clinical practice in 1997 (Fig. 18.2). The Fastrach has been used for patients with normal and anticipated difficult airways,

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:

- A. Difficult Ventilation
- B. Difficult Intubation
- C. Difficulty with Patient Cooperation or Consent
- D. Difficult Tracheostomy

2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management

3. Consider the relative merits and feasibility of basic management choices:

4. Develop primary and alternative strategies:

* Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO₂

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

Figure 18.1. The difficult airway algorithm (*Anesthesiology*, Vol. 98, #5, May 2003, Page 1273).

Figure 18.2. LMA Fastrach.

immobilized cervical spines, and airways distorted by tumors, surgery, or radiation therapy and for patients wearing stereotactic frames. It was designed for use as a tool for blind endotracheal intubation. It consists of an anatomically curved steel tube and handle that allows for easy insertion, following the palate (as will all laryngeal masks) without the need to insert fingers into the oral cavity or move the patient's cervical spine. Furthermore, the steel handle allows the clinician to direct the aperture of the LMA during intubating attempts. The ILMA can be used to introduce an endotracheal tube (ETT) up to 8.5 mm in diameter.

During Fastrach insertion, the head and neck are kept in the neutral position with the device handle parallel to the patient's chest. With the cuff fully deflated, the Fastrach distal tip is placed against the palate and rotated along the palate and posterior pharyngeal wall until resistance is met. The cuff is inflated to a pressure of not more than 60 cm H₂O.

Once in situ, the Fastrach is used as a ventilation device. It is advised that the operator continually support the handle during ventilation and subsequent intubation attempts. One recommended technique consists of two separate movements used to optimize both Fastrach ventilation and blind intubation. The first step involves using the handle to rotate the Fastrach in the

sagittal plane until the best ventilation is obtained. The second movement involves lifting the Fastrach slightly from the posterior pharynx using the handle. These two steps allow for easy placement of the ETT through the device. Once the position has been optimized, a lubricated ETT is blindly placed via the Fastrach. If intubation fails, the up-down maneuver (whereby the Fastrach is rotated out by 6 cm and then back into the airway with the cuff inflated) reseats the epiglottis. A new-generation Fastrach, the LMA CTrach includes a handle-mounted monitor that allows the operator to view the glottis during intubation.

Once endotracheal intubation is done successfully, the next step is to remove the ILMA. This should be done with extreme caution so as not to extubate the patient. The ETT adapter is removed, and the cuff is deflated. A stylet is used to push the ETT down while gently pulling the LMA out. The adapter is then put back in the ETT, the cuff is inflated, and ventilation is checked for end-tidal CO₂ (ETCO₂). Some have advocated leaving both the ETT and the LMA in place, particularly when this technique has been used in a difficult airway. As with all new devices, it is strongly advised that the operator use the Fastrach and CTrach on normal patients prior to applying them to difficult airway scenarios.

Endotracheal tube guides

Numerous ETT guides are available. These devices serve as "Seldinger-like" conduits over which an ETT may be passed into the trachea and/or one endotracheal tube may be exchanged for another. One of the most commonly used tube guides is the gum elastic bougie with a coude tip (angled up). During a direct laryngoscopy with a poor laryngeal view, the bougie is threaded under the epiglottis and passed blindly into the trachea. As the coude tip gently moves across the anterior tracheal wall, the practitioner can appreciate the cartilaginous tracheal rings. Failure to appreciate the rings means probable esophageal placement, and the bougie is repositioned. ETT guides are capable of traumatizing and even perforating the airway or esophagus. Care should be taken not to advance the guide beyond the carina. During advancement of the ETT over the guide, the use of jaw thrust, laryngoscopy, and/or a rotating movement (90° counterclockwise) of the ETT may decrease the risk of entrapping glottic structures.

The Aintree AEC ET Guide (Cook Critical Care, Bloomington, IN) is designed to be used in conjunction with a flexible fiberoptic bronchoscope (FOB) (Fig. 18.3). This guide is a 19F hollow polyethylene tube through which a pediatric-sized FOB may be passed. It is supplied with Rapi-Fit adapters for attachment to a ventilation circuit or high-pressure oxygen source. An Aintree guide/FOB technique may be used for placing an ETT after airway rescue with an LMA or other SGA.

Lighted stylets

Lighted stylets serve to transilluminate the soft tissue structures of the anterior neck to direct the ETT into the trachea. As the

Figure 18.3. Aintree Airway Exchange Catheter.

stylet enters the glottic opening, this transillumination is seen as a distinct glow immediately below the thyroid prominence. A more diffuse glow is seen if the stylet tip is located in the esophagus. The Trachlight (Laerdal Medical Corp. Armonk, NY; Fig. 18.4) has a reusable handle, a flexible disposable wand, and a stiff retractable stylet. This device has an improved light source compared with older models. The stylet allows the ETT to be molded to a 90° angle for better transillumination and then easily advanced into the trachea as the stylet is retracted. Rigid and semirigid fiberoptic stylets are now available with or without video-assisted technology. Examples of these include the Seeing Optical Stylet (SOS; Clarus Medical, Golden Valley, MN), Bonfils Retromolar Intubation Fiberscope (Karl Storz GmbH, Tuttlingen, Germany), Weiss video-optical intubation stylet, and Nanoscope (Nanoptics, Inc., Gainesville, Florida).

Lighted stylets such as the Trachlight may be inappropriate for patients with known airway abnormalities such as tumors,

Figure 18.4. Trachlight.

infections/abscesses, foreign bodies, and trauma. They are relatively contraindicated in obese patients and those with limited neck extension (transillumination may prove difficult).

Indirect fiberoptic laryngoscopes

New laryngoscopic devices have all but abandoned the concept of direct laryngoscopy in favor of indirect visualization of the larynx. The earliest of these modern devices is the Bullard laryngoscope (Circon Corp., Stamford, CT; Fig. 18.5). The Bullard

Figure 18.5. The Bullard laryngoscope.

Figure 18.6. Video Macintosh intubating laryngoscope system (used with permission).

incorporates an anatomically curved blade that facilitates visualization of the larynx without the need for a wide-mouth opening or neck extension. A fiber-optic bundle runs along the posterior aspect of the blade and ends near the distal aspect. Light can be supplied from a standard battery laryngoscope handle or via a fiberoptic cable from a high-intensity light source. The eyepiece can be used directly or with a camera that transmits the image to a video screen. A working channel located on the posterior aspect of the blade can be used for suction, insufflation of oxygen, or administration of saline flush or local anesthetics. The Bullard has a detachable stylet (one stylet version is hollow for passage of an ETT exchange catheter). As with any airway device, proficiency comes only with practice in nonchallenging airway situations.

Newer video-laryngoscopes incorporate image technology into the distal aspect of the blade, eliminating the need for fragile and expensive fiberoptic bundles. The video Macintosh intubating laryngoscope system (VMS) was designed using a standard Macintosh blade and laryngoscope handle (Fig. 18.6). The GlideScope (Verathon Medical, Bothell, WA) has more acute distal angulation (60°) of the laryngoscope blade, so the operator need not displace the tongue for optimal laryngeal viewing on a remote screen. The McGrath laryngoscope includes the acute angulation blade but is highly portable, incorporating the image screen onto the laryngoscope handle itself.

Flexible fiberoptic intubation

Flexible fiberoptic bronchoscopy is arguably the most important alternative airway technique with which one must have proficiency. The flexible FOB may be used in a myriad of clinical situations; it may be used in the awake or the anesthetized patient (orally or nasally) who has or is suspected of having a difficult-to-manage airway. It is useful for the intubation of patients with upper or lower airway abnormalities and unstable or immobile cervical spines. It also may be used as a means to confirm proper ETT placement, to aid in the placement

of double-lumen tracheal tubes, or for performing pulmonary lavage or toilet.

Unlike many other tools available to the airway manager, use of the FOB requires the development of a sophisticated plan and skill set. The following are essential steps in the preparation and proper use of the bronchoscope:

- Assess the shaft of the FOB by holding the handle and allowing the objective end to hang freely. If the insertion shaft shows excessive bends or curvatures, there may be damage to the nonglass elements.
- Check proper functioning of the control lever. The distal 1 to 2 cm should move smoothly in the sagittal plane, typically 90° or more from midline.
- Ensure that the working channel is clear by attaching suction or an oxygen source. A “clogged” channel may indicate poor cleaning or damage.
- Check the fiber bundle by focusing on text a few millimeters from the lens. The inability to produce a clear image may indicate poor cleaning of the lens or moisture within the sealed elements. Note the number of black dots in the visual field. These represent individual broken fibers, and too many may make the FOB unusable. You may want to document the number of broken fibers before and after use.

When using the FOB for intubation, the following steps may improve technique:

- The handle of the FOB is held in the nondominant hand, with the thumb over the control lever and first finger positioned over the valve of the working channel. Oxygen or suction should be attached for clearing secretions and lens defogging.
- The objective end is held as close to the patient as possible; the insertion cord should always be kept straight. Turning of the objective during advancement is accomplished with both hands in a coordinated fashion.
- As one enters the airway, identifiable structures should always be visible, such as tracheal rings and the carina (Fig. 18.7). Using a device such as the Ovassapian intubating oral airway (in both awake and induced patients) facilitates the creation of a visible path and protects the scope from biting.
- Using the smallest clinically adequate tracheal tube or turning the bevel 90° counterclockwise facilitates ETT entrance into the larynx.
- Prior to anesthetic induction (after awake intubation), the operator should strive to see the tracheal carina and ETT simultaneously to confirm successful intubation.

Minimally invasive techniques

Approach to the airway via the extrathoracic trachea and larynx presents the airway manager with a completely new access to the airway. This may be vital if airway management from above has failed or is likely to fail. Unfortunately, the Closed Claims

database has shown that when the anesthesiologist chooses to use an invasive technique, it may be successful but usually is done too late to affect the outcome.

The technique of *retrograde guided intubation* has historical importance for the airway manager. Prior to the advent of many of the current supraglottic and video-assisted devices, retrograde intubation was a mainstay of difficult airway teaching. The basic technique involves the retrograde passage, via a large-bore needle, of a catheter, suture, or wire through the cricothyroid membrane, up through the larynx, pharynx, and mouth or nose. The wire, suture, or catheter is recovered and is used to pass a tracheal tube in the antegrade direction through the larynx. In the opinion of the current authors, this technique may be considered useful but not “essential,” and the reader is referred to other sources for details.

Transtacheal jet ventilation (TTJV) is a percutaneous emergency airway option included in the DAA. It is a relatively simple procedure, and although it may be lifesaving, it may be fraught with complications. A large-bore (12- to 16-gauge) nonkinking needle-catheter is inserted at a 90° angle to all planes in the midline of the cricothyroid membrane with the patient supine and the neck extended (unless contraindicated). The right-handed practitioner should stand to the right of the patient and use the nondominant hand to stabilize the laryngeal cartilages. A Luer-Lok syringe should be attached to the needle-catheter and continuous aspiration performed once the skin is punctured. Once air is aspirated, the needle and catheter are advanced slightly, then the catheter is advanced alone into the airway (in the direction of the carina) and the needle is removed. Several devices currently are available for jet ventilation once the catheter is in position. Low-pressure systems such as an Ambu bag or anesthesia circuit cannot provide sufficient pressure for oxygenation and ventilation during TTJV. Several nonkinking catheters are available and should be used in place of an angiocatheter (e.g., the Cook transtacheal jet ventilation catheter; Cook Critical Care).

Complications of TTJV may be life threatening (e.g., subcutaneous emphysema, pneumomediastinum, pneumothorax, esophageal puncture), and most can be avoided by using careful air aspiration during the needle placement, beginning the insufflation process with low pressure (e.g., 10–15 cm H₂O), and maintaining an open upper airway with an oral airway or SGA. It is important that a regulated oxygen injector, such as the Manujet III (VBM, Sulz, Germany), be used to prevent accidental overpressurization. Inflation pressure should be increased to a maximum of 50 cm H₂O, using chest movement as a guide. TTJV may be especially dangerous if there is outlet obstruction. In these cases, surgical cricothyrotomy may be a better choice of airway.

Cricothyrotomy and *emergency tracheostomy* are invasive, lifesaving procedures performed for the “cannot-intubate/cannot-ventilate” clinical scenario, in which awakening the patient is not an option. They are especially useful when total upper airway obstruction is known or suspected, a situation

in which TTJV likely would be ineffective. Surgical cricothyrotomy and tracheostomy procedures are usually performed by an experienced surgical team. Percutaneous cricothyrotomy systems are available and may be more appropriate for the occasional user. The Melker Emergency Cricothyrotomy Kit (Cook Critical Care) uses a Seldinger catheter over-the-wire technique. A 2-cm skin incision is made over the cricothyroid membrane and a needle is inserted via the cricothyroid membrane until air is aspirated. A guidewire is passed through the needle, which is then removed. A catheter/dilator (3.4, 4, or 6 mm internal diameter) is inserted over the wire and into the airway. The catheter is available in cuffed and uncuffed versions. Complications are similar to those listed for TTJV. This technique is not recommended for children under 5 years of age. Damage to the cricoid cartilage may lead to life threatening airway collapse.

Awake intubation

If difficulty with airway management is anticipated, awake intubation (box A of the DAA) may be the most prudent choice. This is especially true if the practitioner expects difficulty with ventilation as well as intubation and/or there is a significant aspiration risk. The awake state provides several advantages over an anesthetized state: spontaneous ventilation is maintained, the size and patency of the pharynx and retropalatal spaces are increased, the tone of both the upper and lower esophageal sphincters is maintained, and important airway reflexes, including cough and gag, are preserved.

Successful awake intubation requires patience on behalf of the practitioner and methodical preparation of the patient. Adequate preparation of the patient includes not only the use of topical and intravenous medications, but also psychological guidance. The mature patient should be informed of the rationale for the decision to proceed with awake intubation and be reassured that once the airway is prepared, discomfort will be minimal. The use of medications to decrease anxiety may be considered but should be used with discretion. Benzodiazepines such as midazolam may be administered in small amounts to decrease anxiety, and opioid agonists such as fentanyl also may be used for their analgesic, sedative, and antitussive properties.

Ketamine and the α_2 -agonist dexmedetomidine are becoming increasingly popular agents for sedation for awake intubation, as they have fewer respiratory depressive effects. However, the operator must be cognizant that anxiolytic agents can produce airway obstruction, especially in patients prone to obstructive sleep apnea or when multiple agents are combined, therefore leading to loss of airway control. Furthermore, an overly sedated patient may no longer be capable of cooperating with procedures or protecting his or her own airway.

An antisialagogue such as glycopyrrolate (0.2–0.4 mg intravenously/intramuscularly) is an important component of awake intubation. Antisialagogues increase the effectiveness of topical anesthetics and make the use of fiber-optic devices easier

by minimizing secretions on lenses. If nasal intubation is to be performed, a vasoconstrictor such as oxymetazoline, phenylephrine, or cocaine should be applied to the nasal mucosa to prevent bleeding.

Local anesthetics may be applied topically by numerous methods or injected as part of a regional anesthetic technique. Anesthesiologists should be knowledgeable of each agent's toxicities, toxic doses, and acceptable doses. Lidocaine, an amide local anesthetic, is a commonly used agent. It is available in many different preparations (solution, viscous, ointment) and concentrations (0.5%–5%). Cocaine, available as a 4% solution, also is commonly used because it is both an effective local anesthetic and a potent vasoconstrictor; therefore it commonly is used for nasal airway preparation. Its use is contraindicated in patients with ischemic heart disease, hypertension, tachyarrhythmias, or preeclampsia or in those taking monoamine oxidase inhibitors. Other local anesthetics used for airway topicalization include tetracaine and benzocaine. Tetracaine has a relatively long duration of action but a narrow therapeutic window. Benzocaine has the advantage of rapid onset and short duration of action but may produce methemoglobinemia.

All anesthesiologists must have a thorough knowledge of the airway anatomy, including its sensory and motor innervations, to provide adequate airway anesthesia for awake airway manipulation. For practical purposes, there are three general anatomic areas of importance: the nasal cavity/nasopharynx, oropharynx, and hypopharynx/larynx/trachea.

Techniques for topicalization are as follows:

1. Non-needle technique

- A noninvasive method of anesthetizing all three anatomic areas at once involves nebulized lidocaine and a face mask. Nebulization results in high levels of drug absorption and blunts all airway reflexes. This technique should not be used in patients at risk for aspiration of gastric contents.
- Nasal passage/nasopharynx: Local anesthetic-soaked cotton swabs are advanced slowly into the nasal passage up toward the sphenoid bone over a period of a few minutes, or cotton pledgets may be placed with bayonet forceps.
- Base of tongue/posterior oropharyngeal wall: Local anesthetic-soaked swabs are placed at the base of the

palatoglossal arch (bilateral), where the glossopharyngeal nerve travels, and are applied for 5 minutes.

- Hypopharynx/larynx/trachea: The tip of the patient's tongue is wrapped with unfolded gauze while the tongue is extended maximally to prevent the patient from swallowing the local anesthetic. The local anesthetic solution is dripped on the tongue base slowly via a 5-ml syringe fitted with a plastic catheter. This procedure should take 1 to 2 minutes and is accompanied by coughing as the agent is aspirated. The patient should be reassured that this spontaneous coughing is desirable.

2. Needle technique

- Sphenopalatine nerve block may be performed by injection of local anesthetic through the greater palatine foramen, which is located between the second and third maxillary molars, 1 cm medial to the palatogingival margin. This block will cover the nasal turbinates and posterior two thirds of the nasal septum.
- Glossopharyngeal nerve block (blocks gag reflex and decreases the hemodynamic response during laryngoscopy): There are two approaches. The landmark for the anterior approach (palatoglossal fold) is the end of the gutter between the tongue and teeth at the base of the palatoglossal arch. The posterior approach (palatopharyngeal fold) requires a tonsillar needle to inject local anesthetic from behind the palatoglossal arch at its midpoint.
- Superior laryngeal nerve block (inhibits sensation of the larynx above the vocal cords): The external approach can be performed with three different landmarks: the hyoid cornu, thyroid cornu, and upper border of thyroid cartilage 2 cm from the thyroid notch.
- The translaryngeal block (transtracheal technique) anesthetizes the tracheal mucosa, which is innervated by the recurrent laryngeal nerve. Local anesthetic is injected via an angiocatheter passed through the cricothyroid membrane. Coughing during injection may spread local anesthetic to the inferior and superior surfaces of the vocal cords.

Figure 18.7. Fiber-optic view of the (A) vocal cords and (B) carina.

Once adequate patient preparation and airway topicalization are achieved, the clinician may choose from many different methods for placing an ETT in an awake patient. For example, one may choose to use an FOB (Fig. 18.7), perform direct laryngoscopy or video-laryngoscopy, or even perform blind nasotracheal intubation. As long as the patient can cooperate and has been rendered analgesic, the operator has many options from which to choose. Awake fiberoptic intubation using a flexible bronchoscope is the most commonly used method. As soon as the ETT is advanced, the carina visualized, and ET CO_2 detected, anesthesia can be safely induced.

Although uncommon, there are a few contraindications to awake intubation, including patient refusal or inability to cooperate or a true allergy to local anesthetics. Patients in whom the clinician should use caution include those with ischemic heart disease, who likely would not tolerate significant cardiovascular stimulation; those with poorly controlled bronchospasm; and those in whom one wishes to avoid raising intracranial or intraocular pressures.

Medical gas supply, vacuum, and scavenging

Yasodananda Kumar Areti, editor

Jesse M. Ehrenfeld and Yasodananda Kumar Areti

If anything can go wrong, it will (Fig. 19.1). Although infrequent, several accidents and mishaps have been reported with the use of medical gases. Adequate safety precautions therefore must be taken to ensure that accidents are minimized and adequate backup measures are in place. In the United States, the Department of Transportation has published requirements for manufacturing, labeling, filling, transportation, storage, handling, and maintenance of medical gas cylinders and containers. The Department of Labor and the Occupational Safety and Health Administration (OSHA) regulate matters affecting the safety and health of employees in all industries.

Medical-grade gas is supplied to the operating room via two delivery mechanisms – a central supply and portable cylinders. Most anesthetizing locations have access to a central supply of the three most commonly used medical gases – oxygen, nitrous oxide (N₂O), and air. These and all other gases also may be supplied via gas cylinders – most commonly “E”-size cylinders – mounted on anesthesia machines. A waste anesthetic gas scavenging system and a medical suction system for surgical and anesthetic use also are provided centrally.

Physical principles

Medical gases are stored in cylinders either as compressed gases (oxygen, air) or liquefied gases (oxygen, N₂O, carbon dioxide). Table 19.1 depicts the relationships among gas volume, pressure, and temperature.

Pressure

Anesthesiologists make pressure measurements in both patients and machines, and hence should have a good understanding of pressure and its units of measurement. Pressure is expressed as force per unit area. Although the SI unit is the pascal, this represents a tiny pressure; therefore, the kilopascal (kPa) is used more commonly. The other units commonly used are presented in Table 19.2.

Critical temperature and critical pressure

Critical temperature is defined as the temperature above which gases cannot be liquefied by applying pressure. *Critical pressure* is the pressure at which a gas can be liquefied at its critical temperature. The critical temperature of N₂O is 36.5°C, hence

Table 19.1. Common gas laws

Law	Relationship	Formula
Boyle's	Pressure and volume	$P_1V_1 = P_2V_2$
Charles's	Volume and temperature	$V_1/T_1 = V_2/T_2$
Gay-Lussac's	Temperature and pressure	$P_1/T_1 = P_2/T_2$
Ideal gas	Pressure, volume, and temperature	$PV = nRT$

P, absolute pressure; V, volume; T, absolute temperature; n, number of moles; R, universal gas constant.

N₂O is supplied as a liquefied gas in the cylinders at room temperature. The critical temperature of oxygen is –118°C, hence at room temperature oxygen cannot be liquefied, and exists as compressed gas. Liquid oxygen (LOX) can be obtained only if the oxygen is cooled below its critical temperature and pressurized. To maintain this temperature, special insulated and refrigerated containers are required for supply of LOX.

Avogadro's hypothesis

Equal volumes of gases at the same temperature and pressure contain an equal number of molecules. This number of particles is 6.022×10^{23} and is known as Avogadro's number. One mole of any gas occupies 22.4 L at standard temperature and pressure (0°C, 1 atm) and 24 L at room temperature and pressure (RTP; 20°C, 1 atm). This principle is used to calculate the contents of a cylinder containing liquefied gas and the amount of vapor that can be generated from a given amount of volatile liquid.

Medical gases and supply

Oxygen

Medical-grade oxygen (99% pure or greater) is a necessity in any operating room. Oxygen is synthesized commercially by first

Table 19.2. Units of pressure

kPa	Kilopascal
cm H ₂ O	Centimeters of water
psi	Pounds per square inch
mm Hg	Millimeters of mercury
101 kPa = 760 mm Hg = 1030 cm H ₂ O = 14.7 psi = 1 atm at sea level	
1 kPa = 7.5 mm Hg	
1 mm Hg = 1.35 cm H ₂ O	

Figure 19.1. University of Alabama LOX spill. Eight thousand gallons of LOX escaped, making it temporarily impossible to assess either the primary tank or secondary reserve tank. Efficient implementation of predetermined protocol ensured that there was no adverse patient outcome despite peak use at the time of the incident. (Reproduced with permission from Schumacher SD, Brockwell RC, Andrews JJ, Ogles D. Bulk liquid oxygen supply failure. *Anesthesiology* 2004; 100:186–189.)

liquefying compressed air. Oxygen is separated from liquid air by using the difference in the boiling points of oxygen and nitrogen (fractional distillation). Nitrogen evaporates first, leaving liquid oxygen, which is then evaporated. Dried and purified oxygen is supplied as compressed gas in cylinders at ambient temperature. It also may be supplied in cryogenic containers containing liquid oxygen.

Liquid oxygen

Oxygen often is stored as a liquid, although it is used primarily as a gas. Liquid storage is less bulky and less costly than the equivalent capacity of high-pressure gaseous storage. Physical properties of oxygen are shown in [Table 19.3](#).

Because the temperature difference between the product and the surrounding environment is substantial, even in the winter, keeping LOX insulated from the surrounding heat is essential. The product also requires special equipment for handling and storage. A typical storage system consists of a cryogenic storage tank, one or more vaporizers, a pressure control system, and piping necessary for the fill, vaporization, and supply functions. The cryogenic tank is constructed, in principle, like a thermos bottle. There is an inner vessel surrounded by an outer vessel. Between the vessels is an annular space that contains an insulating medium, from which all the air has been removed. This space keeps heat away from the LOX held in the inner vessel. Vaporizers convert the LOX into a gaseous state. A pressure control manifold then controls the pressure of the gas fed to the pipelines. A backup system may comprise another smaller-sized LOX container or manifold of oxygen cylinders. The backup system should have a separate feed line to the pipeline network to lessen the risk of interrupted supply.

Oxygen concentrator

Oxygen concentrators are devices that can be used as a primary source of oxygen to feed pipelines in remote locations. Oxygen is generated onsite using pressure swing adsorber technology. Oxygen in the atmospheric air is concentrated by adsorption of nitrogen by a molecular sieve (a zeolite). Oxygen produced by this method has a concentration of $93\% \pm 3\%$. Pressurized air passes through a bed of zeolite usually contained in two containers. As one container adsorbs nitrogen, the other is purged of adsorbed nitrogen and the zeolite is regenerated. The adsorbent has a high affinity for water; hence, the design should include adequate purges, low dead space, and heat exchangers. The beds should be sealed so that atmospheric moisture cannot seep into the zeolite. The output concentration of oxygen should be monitored carefully to ensure delivery of adequate oxygen to the pipelines. The size of the adsorption beds determines the output. They must always have a pressurized reservoir large enough to cope with peak flows. Portable oxygen concentrators also are available and are quite popular for home oxygen therapy.

Nitrous oxide

N_2O often is provided for use as an anesthetic gas. It is synthesized commercially by heating ammonium nitrate and is stored

Table 19.3. Physical properties of oxygen

- Boiling point at 1 atm: -183.0°C (90°K)
- Critical temperature: -118.4°C
- Critical pressure: 729.1 psia (49.6 atm)
- Expansion ratio, liquid to gas, boiling point to 20°C : 1:860

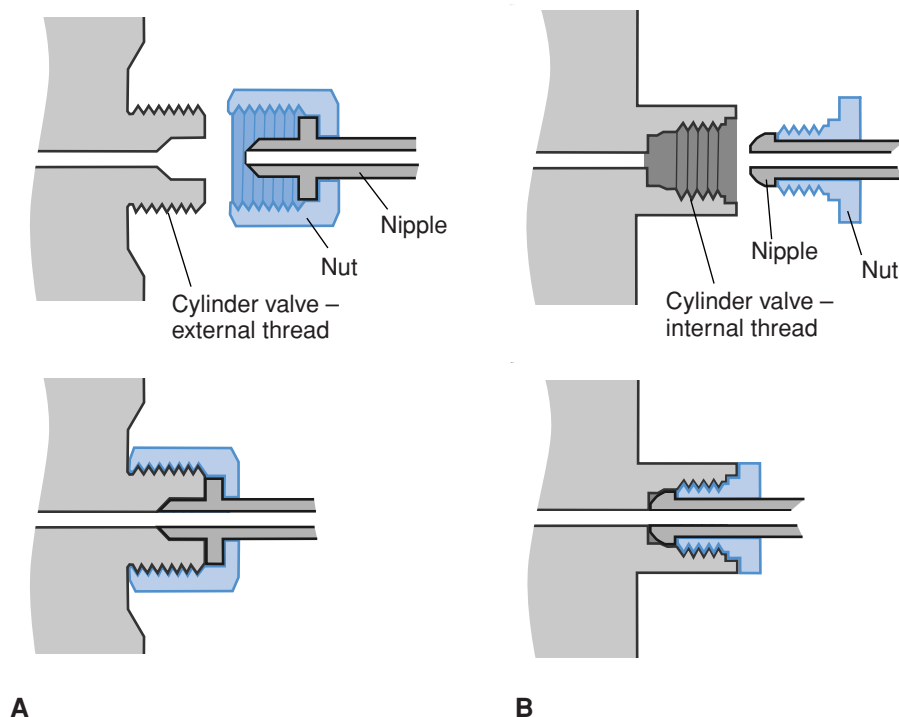

Figure 19.2. Valve outlet connections for large cylinders. The threads of the valve outlet must match those on the nut. When the nut is tightened, the nipple seats against the valve outlet. **(A)** The threads are on the outside of the cylinder valve outlet and the nut screws over the valve outlet. **(B)** The valve outlet thread is internal so that the nut screws into the outlet.

as a liquid at room temperature because the critical temperature of this gas is 36.5°C. N₂O usually is stored in large H-cylinders that are cross-connected via an auto-switching manifold. The banks usually have a smaller number of cylinders compared with an oxygen supply because of the higher content of liquefied gas and lower consumption of N₂O. As N₂O becomes vaporized from a liquid to a gas, heat is absorbed from the surrounding atmosphere, which may lead to the formation of frost on the outside of a gas cylinder.

Medical air

Air is the natural atmosphere of the earth – a nonflammable, colorless, odorless gas that consists of a mixture of gaseous elements (nitrogen, oxygen, water vapor, a small amount of carbon dioxide, and traces of many other constituents). Medical air may be provided by a manifold of cylinders or a central compressor plant. Usually two compressors are used; these may run alternately or concurrently depending on the demand. This also ensures that during servicing or repairing, the supply is not interrupted. Air from the intake to the compressors is drawn through a filter and silencer. There usually is an air cooler to cool the compressed air. The air then passes through a non-return valve into a large reservoir to maintain a constant air pressure. After leaving the reservoir, the air is cleaned by passing it through baffled separators and filters to remove particulate impurities such as oil droplets. The air is then passed through two driers containing a desiccant to remove any excess

humidity. Finally, the air is passed through a bacterial filter to ensure removal of any contaminants.

Medical gas cylinders

Medical gases are stored in metal cylinders of various sizes. Table 19.4 indicates the color codes, state in cylinders, and pressure for different medical gases. Cylinders are made of aluminum or steel alloys; each is tested by visual inspection and with a hydraulic stretch test to ensure its integrity when subjected to test pressures 1.66 times the service pressure. Each cylinder is permanently stamped on its shoulder to indicate the contents, service pressure, serial number, manufacturer's symbol, owner's symbol, test date (original test date and retest date), and mark of the testing facility.

Valves

The bulk cylinders supplying the pipelines (type H) are fitted with bullnose valves with a non-interchangeable screw-thread system (Fig. 19.2), which is different from the Diameter Index Safety System (DISS), discussed later. The type E or smaller cylinders that serve as backups on anesthesia machines are fitted with a pin-indexed valve (Fig. 19.3).

Filling

The pressure inside a cylinder may vary with ambient temperature. To prevent buildup of excessive pressure, a cylinder should not be filled above the service pressure stamped on the cylinder

Table 19.4. Medical gas cylinders

Gas	Formula	Color (US)	Color (international)	psi at 21°C	State in cylinder	E-cylinder capacity, L
Oxygen	O ₂	Green	White	1900–2200	Gas	660
Carbon dioxide	CO ₂	Gray	Gray	838	Gas and liquid <31°C	1590
Nitrous oxide	N ₂ O	Blue	Blue	745	Gas and liquid <37°C	1600
Helium	He	Brown	Brown	1600–2000	Gas	500
Nitrogen	N ₂	Black	Black	1800–2200	Gas	660
Air		Yellow	White and black	1800	Gas	600

for compressed gases. The filling limit on cylinders containing liquefied gases is based on the filling ratio or filling density, which is the percent ratio of weight of a gas in the cylinder to the weight of water the cylinder would hold at 60°F. The filling density of N₂O and carbon dioxide is 68%.

Safety pressure release

Every cylinder is fitted with a safety pressure release device to vent the contents into the atmosphere if the inside pressure increases to a dangerous level. The venting orifice is closed with a disk that ruptures at a given pressure, a fusible plug (Wood's metal) that melts at high temperatures, or a spring-loaded pressure relief valve. In pin-indexed valves, this device is present just below the conical depression for the screw clamp; hence, care should be taken to prevent any inadvertent damage while mounting the cylinder on the anesthesia machine.

Devices to open or close the cylinder

Large cylinders are fitted with a “hand wheel” to open and close the valve. Small cylinders come with a spindle valve, and the spindle can be opened or closed with a wrench or handle. A wrench usually is fixed to the anesthesia machine to prevent misplacement. While using these wrenches, one must be careful not to handle the hexagonal gland nut that fixes the spindle valve to the cylinder.

Contents of the cylinder

The contents of a cylinder containing compressed gases such as oxygen can be calculated using Boyle's law, using the pressure inside the cylinder and the water capacity of the cylinder:

$$P_1 \times V_1 = P_2 \times V_2$$

$$V_1 = \frac{P_2 \times V_2}{P_1},$$

where P₁ is the atmospheric pressure, V₁ is the volume of oxygen available at atmospheric pressure, P₂ is the pressure in the cylinder, and V₂ is the water capacity of the cylinder or volume of oxygen in the compressed state.

For example, in a type E cylinder with a water capacity of 4.7 L, if the pressure gauge reads 100 atm (1470 pounds per square inch gauge [psig]), the approximate amount of oxygen available (V₁) to be used at 1 atm will be

$$V_1 = \frac{100 \text{ atm} \times 4.7 \text{ L}}{1 \text{ atm}} = 470 \text{ L}$$

The water capacity of a type H bulk cylinder is 47.2 L. For all practical purposes, if one learns to read the pressure in the cylinder in atmospheric pressures (the number labeled as kPa × 100), then multiplying this by 4.7 (or even with 5 for approximate values) will give an estimate of the contents of the type E cylinder for compressed gases.

The contents of a cylinder containing liquefied gases (N₂O and carbon dioxide) cannot be estimated by measuring the pressure inside the cylinder, because the pressure remains nearly constant until all the liquid is evaporated. However, they can be estimated using Avogadro's principle. The molecular weight of N₂O and carbon dioxide is the same: 44 g/mole. According to Avogadro's hypothesis, 44 g would occupy a volume of 24 L at RTP (20°C, 1 atm). Hence, a liter of N₂O weighs about 1.8 g. The actual weight of the gas in the cylinder should be estimated by the difference between the actual weight and the tare (empty) weight of the cylinder. This weight in grams divided by 1.8 (one may use 2 for approximation and ease of calculation) gives us an estimate of the contents of the cylinder. This aspect is particularly useful for laparoscopic surgeons and their teams to have an idea of the contents of carbon dioxide cylinders prior to starting the surgery.

Manifold and pipeline network

Normally, the main gas supply to the anesthesia machine is the hospital pipeline system, delivered at approximately 50 to 55

Figure 19.3. Pin-index safety system for different gases. Two pins in the hanger yoke of the anesthesia machine are aligned with two corresponding holes on the cylinder head to prevent mounting of a wrong cylinder.

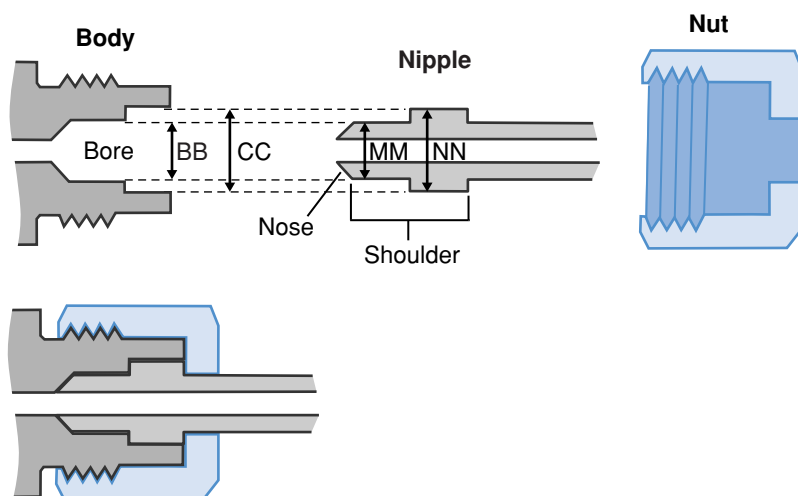

Figure 19.4. DISS – see text for details.

psig. The gas supply to the pipeline supply may be from one of the following sources:

1. Primary LOX tank with a smaller, secondary LOX tank as a backup
2. Primary LOX tank with a manifold of compressed gas cylinders as a backup
3. Two banks of compressed gas cylinders with a smaller bank of compressed gas cylinders as a backup

The capacity of the primary supply depends on the demand of the hospital. It should be more than enough for 2 days' consumption, and the backup should be enough for at least 1 day's consumption. The high-pressure source is connected to the pipeline through a two-stage pressure regulator. If a manifold of cylinders is used, only one of the two banks supplies the pipeline at any time. When this bank reaches exhaustion, the second bank automatically begins supplying gas. The status of the banks is indicated by visual indicators at the source, as well as at a manned control station, to enable a prompt change of empty cylinders.

The supply and manifolds usually are located outside the hospital. From the manifold, the gases are carried to various points of care through a network of pipelines made of copper. These networks consist of risers and branches to individual areas of the hospital. Each area should have pressure monitors and shutoff valves so that repairs and maintenance can be performed without having to shut down the entire system. The network should not result in a decrease in pressure of >5 psig from the source to the outlet. The pipelines should be clearly labeled as to the contents by letters, color-coded bands, and the direction of gas flow at periodic intervals.

Outlets

The pipelines end in terminal wall outlets with color-coded plates. These outlets may be either non-interchangeable quick-coupling outlets or DISS outlets.

Quick connectors

Quick connectors (automatic quick-coupler valves, quick connects, quick-connect fittings, quick couplers) allow apparatus (e.g., hoses, flow meters) to be connected or disconnected by a single action using one or both hands, without the use of tools or undue force. Quick connectors are more convenient than DISS fittings but tend to leak more. Each quick connector consists of a pair of gas-specific male and female components. A releasable spring mechanism locks the components together. Hoses and other equipment are prevented from being inserted into an incorrect outlet by using different shapes and different spacing of the mating portions.

The Diameter Index Safety System

The DISS was developed to provide non-interchangeable connections for medical gas lines at pressures ≤ 1380 kPa (200 psi). Each DISS connector consists of a body, nipple, and nut combination (Fig. 19.4). There are two concentric and specific bores in the body and two concentric and specific shoulders on the nipple. The small bore (BB) mates with the small shoulder (MM), and the large bore (CC) mates with the large shoulder (NN). To achieve non-interchangeability between different connectors, the two diameters on each part vary in opposite directions so that as one diameter increases, the other decreases. These dimensions are unique for each gas, and only properly mated parts will fit together and allow the threads of the nut and body of the valve to engage.

Safe use of cylinders

To prevent injury, gas cylinders must always be properly secured and stored in a cool environment protected from fire and open flame. Care should be taken to ensure that cylinders are never dropped, because damage to a pressurized cylinder may lead to the creation of a fatal projectile. The personnel handling the

cylinders should be trained adequately. The cylinders should be kept closed at all times, except when they are in use. A cylinder should always be opened slowly, to prevent a rapid rise in temperature due to adiabatic expansion.

Other medical gases of interest to anesthesiologists

Entonox

Entonox (BOC, Manchester, UK) is a mixture of 50% oxygen and 50% N_2O stored in cylinders at a pressure around 2000 psig. Although the critical temperature of N_2O is $36.5^\circ C$, in a mixture of gases such as Entonox, it remains in gaseous phase. However, at a temperature below $-5.5^\circ C$, a liquid phase containing 20% oxygen and 80% N_2O may form below the gas; this sometimes is referred to as pseudo-critical temperature. To prevent delivery of a hypoxic mixture, it is recommended that Entonox cylinders be stored at temperatures $>10^\circ C$. Entonox is used mostly for obstetric and dental analgesia; it also is used for wound dressing changes and during transport of patients with long bone fractures but no other injuries. It usually is self-administered under the supervision of medical or paramedical personnel through a two-stage pressure regulator and a demand valve.

Nitric oxide

The role of inhaled nitric oxide (iNO) for clinical use has increased remarkably during the past decade. The discovery of iNO's role in pulmonary vascular tone led to a flood of research from basic science to large randomized clinical trials in patients of all ages, resulting in thousands of publications. In 1992, the journal *Science* named nitric oxide the "Molecule of the Year." Several researchers received a Nobel Prize in medicine and physiology for their work with nitric oxide in 1998. The only US Food and Drug Administration–approved indication for iNO is the treatment of term neonates with hypoxic respiratory failure associated with pulmonary hypertension, as a means to improve oxygenation.

Nitric oxide is supplied as a gaseous blend of nitric oxide (800 ppm) and nitrogen in a nonliquefied form at a cylinder

pressure of 2000 psig at $21^\circ C$. Cylinders are constructed of an aluminum or steel alloy. Nitric oxide is administered into the ventilator breathing circuit through a monitoring unit (NOx box, NOdomo unit [Dräger, Lübeck, Germany], INOvent [INO Therapeutics, Clinton, NJ]), which operates at 55 to 60 psig. The most commonly used initial dose is 5 to 20 ppm by inhalation. Monitoring the levels of inspired nitric oxide, nitrogen dioxide, and methemoglobin is essential. Weaning should be achieved gradually in decrements of 5 ppm over 6 to 8 hours.

Heliox

Helium and oxygen mixtures (heliox) have been used for medicinal purposes since 1934. Heliox has been reported to be effective in a variety of respiratory conditions, such as upper airway obstruction, status asthmaticus, decompression sickness, post-extubation stridor, bronchiolitis, and acute respiratory distress syndrome. Helium, an inert gas, is odorless and tasteless and does not support combustion or react with biologic membranes. Helium is 86% less dense (0.179 g/L) than room air (1.293 g/L). It is seven times lighter than nitrogen and eight times less dense than oxygen. The lower density of helium reduces the Reynolds number associated with flow through the airways, favoring laminar over turbulent flow. Hence, heliox mixtures have the potential to decrease the work of breathing in patients with increased airway resistance. Heliox also increases the deposition of inhaled particles to the distal airways in patients with severe asthma.

Heliox is commercially available and supplied at the point of care as compressed medical gas cylinders in sizes H, G, and E. Helium and oxygen typically are blended to percentage concentrations of 80/20, 70/30, and 60/40. Gas regulators manufactured specifically for helium must be used to deliver the gas safely and accurately. The mixture can be administered to the patient via either an endotracheal tube or a face mask with a reservoir bag.

Vacuum

A vacuum is a volume of space that is essentially empty of matter, such that its gaseous pressure is much less than atmospheric pressure (negative pressure). Vacuums commonly are

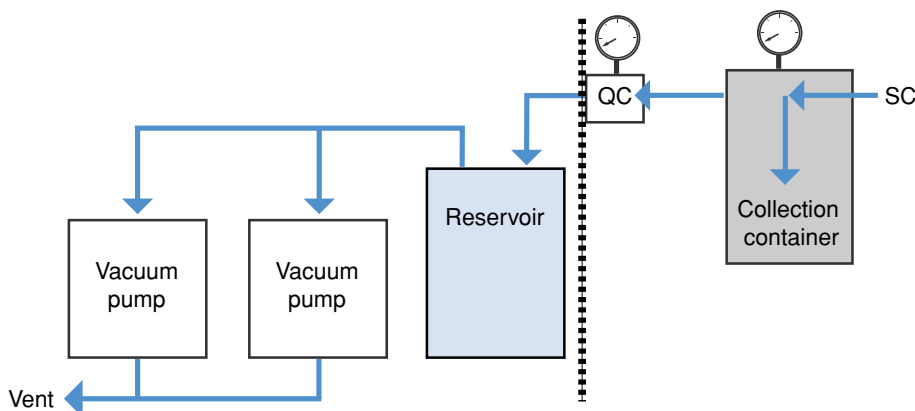

Figure 19.5. Complete suction system. Normally, liquids and solids do not move any further than the collection container. SC, suction catheter; QC, quick coupler at the wall.

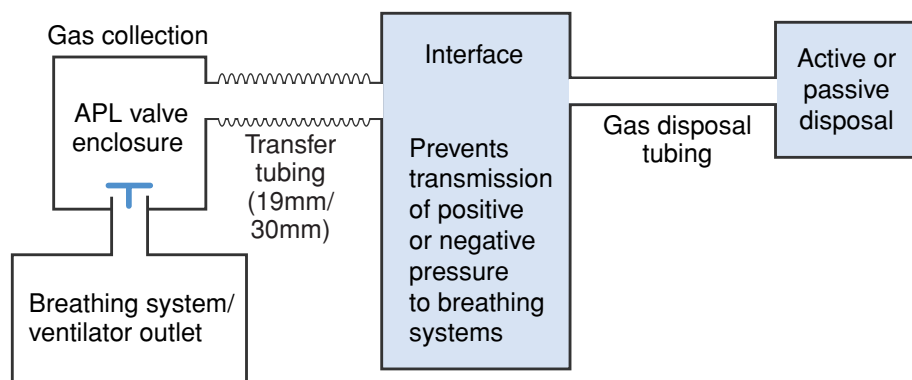

Figure 19.6. Schematic representation of the components of a scavenging system.

used to produce suction. Suctioning is an important part of anesthesia practice to remove and/or collect solids, gases, and liquids from the patient, airway devices, and the patient's environment.

The most common source of vacuum in health care facilities is the pipeline system (Fig. 19.5). The system must be capable of maintaining a vacuum of approximately 40 kPa (300 mm Hg) at the user end. The suctioning apparatus is connected to a wall inlet through a non-interchangeable coupler similar to those used for medical gas pipelines. The pipelines are connected to a central vacuum source. These pipelines are constructed of copper and are slightly larger than the medical gas pipelines. Vacuum is created by two pumps connected in parallel. These pumps are essentially air compressors mounted in reverse to create a partial vacuum. There is a reservoir between the pumps and the pipeline to even out the vacuum and collect any fluids or debris that may enter the system.

Scavenging systems

The anesthetic gases and vapors that leak into the surrounding room during medical procedures are considered waste anesthetic gases. It is estimated that more than 250,000 health care professionals in the United States who work in hospitals, operating rooms, dental offices, and veterinary clinics potentially are exposed to waste anesthetic gases. The relationship between exposure to trace concentrations of waste anesthetic gases in the operating room and the possible development of adverse health effects has concerned health care professionals for many years. Some potential effects of exposure to waste anesthetic gases are nausea, dizziness, headaches, fatigue, and irritability, as well as sterility, miscarriages, birth defects, cancer, and liver and kidney disease, among operating room staff and their spouses (in the case of miscarriages and birth defects). The reports on the effects of exposure to waste anesthetic gases are controversial. However, scavenging of waste anesthetic gases is recommended for all areas, as are work practices to reduce contamination. In addition, there should be a program for management of waste anesthetic gases, with a documented maintenance schedule for all anesthesia machines and the ventilation system in the operating room and postanesthesia care units.

Factors contributing to operating room pollution include:

1. Use of breathing systems with high-flow techniques
2. Poorly fitting masks
3. Failure to turn off gases at the end of anesthesia
4. Filling of anesthetic vaporizers without key systems
5. Liquid agent spills
6. Leaks in the machine and breathing systems
7. Improper scavenging

The components of a scavenging system are shown in Fig. 19.6. The waste gases are collected by suitable modification of adjustable pressure-limiting valves and ventilator relief valves and are transferred via special tubing to the scavenging interface. These tubes are of different sizes and appearances to prevent misconnection or direct connection to breathing systems (19 mm/30 mm; corrugated tubes used in breathing systems are 22 mm). The interface protects the breathing systems from excessive positive or negative pressure. From the interface, the gases are conducted through collapse-proof tubing to the gas disposal assembly, which eliminates excess waste gas.

There are two types of gas disposal systems:

1. *Active:* This is the most common system and uses central vacuum. It provides for high flows but only slight negative pressure.
2. *Passive:* The pressure of the waste gas itself produces flow through the system, and no vacuum is used.

Occlusion of scavenging systems may produce high levels of positive pressure in the breathing systems, leading to barotrauma. In active systems, failure of the interface may transmit excess negative pressures to the patient.

From Morton to Zeus

Since the first demonstration of ether anesthesia by William T. G. Morton in 1846, the apparatus to administer anesthesia evolved from a simple Morton inhaler to the present-day sophisticated anesthesia workstations care stations (Fig. 20.1). The 20th century saw anesthesia machines built around the prototype of Henry Edmund Gaskin Boyle in 1917 (1875–1941). Dräger (Telford, PA) adopted the name *Zeus* for its latest brand of anesthesia workstations. Zeus, according to Greek mythology, is the king of all gods and is all powerful. The name *Zeus* is supposed to indicate the power packed into these machines. They incorporate safe systems for target controlled inhalational anesthesia, total intravenous anesthesia, sophisticated ventilators matching intensive care unit ventilators, extensive monitoring capability, and data networking capabilities.

This chapter covers the principles of anesthesia machines used to deliver inhalational anesthesia. In the United States, the two major manufacturers of anesthesia machines are GE Datex-Ohmeda and Dräger Medical. Anesthetic mishaps due to machines are becoming a rarity thanks to the safety features incorporated in these machines, as recommended by the American Society of Testing and Materials (ASTM) International. However, one of the common reasons for adverse outcomes related to anesthesia equipment is lack of familiarity with the equipment, as well as inadequate pre-use checking. Hence, it is advisable for all users to familiarize themselves with the machine and safety documents that come with it before using any equipment.

Structure of the anesthesia machine

The machine itself can be divided into three sections (Fig. 20.2):

1. **High pressure:** This part of the machine is exposed to the high pressures in the cylinders (yoke, pressure gauge, and pressure regulators).
2. **Intermediate pressure:** This part of the machine is exposed to the pressures in the pipelines (pipeline connections, oxygen failsafe devices, oxygen flush, ventilator gas outlets, pressure gauge, and flow meter needle valves).
3. **Low pressure:** This part of the machine lies from the needle valves of the flow meters to the common gas outlet

(rotameters, vaporizers, back bar, pressure-relief valve).

This section should not be confused with the breathing systems, which are also referred to as low-pressure systems.

Components of the machine

Power supply

The electrical and pneumatic components of most modern machines are powered by electricity, and the master switch should be turned on before using the machines. The master switch activates the flow of gases into the intermediate-pressure pneumatic circuit of the machine. The emergency oxygen flush can be activated even when the power is off. The machines also come with a backup battery system, which keeps charging when the machine is plugged in, even if the master switch is in the off position. Once the power is turned on, there is always a “minimum assured flow” of oxygen at 200 ml/min, and the machines perform self-checks. In an emergency situation, the operator can bypass these checks. Some machines limit the number of consecutive times this bypass can be used. The machines are also equipped with visual and/or audible alarms to indicate loss of power.

Medical gas inlets

The medical gases (oxygen, nitrous oxide [N₂O], and air) are supplied through pipelines, which are connected to the machine through non-interchangeable connections (Fig. 20.3). The ASTM standards for anesthesia workstations require that every anesthesia machine have a Diameter Index Safety System (DISS) fitting for each pipeline inlet to prevent incorrect connections (DISS is discussed in Chapter 19).

All piped supplies have a backup cylinder supply (one or two E-type cylinders). The outlet port of the cylinder is aligned with the gas inlet nipple. A Bodok seal is placed between the cylinder and the yoke to ensure leak-free fitting. The assembly has a pin-indexed safety system to prevent incorrect connection of gases. The two pins on the machine should be aligned with the corresponding holes in the cylinder head. Before mounting the cylinder, it should be opened gently (cracked) to blow away any dust in the port, then closed. The cylinder is securely mounted with a screw clamp. Presence of leaks in this area can be detected

by applying soapy water to the junction and observing for any bubble formation.

Pressure gauge

All machines are equipped with Bourdon pressure gauges (patented in 1849) to monitor the pressure in the cylinders and pipelines (Fig. 20.4). A flexible tube within this gauge straightens when exposed to gas pressure. This motion is transmitted to a pointer through a gearing mechanism. In modern machines, these gauges are located at the front panel. The dials carry two types of units of measurement of pressure (psi and $\text{kPa} \times 100$). Monitoring the pressure will ensure an adequate gas supply at all times, and the pressure in the oxygen cylinder gives a clue as to

the quantity of oxygen backup. The gauges on the N_2O cylinder do not give any indication of the amount of N_2O in the cylinder, because N_2O exists as a liquid (see Chapter 19).

Pressure regulator

Each gas supplied from the cylinders to the machine must have a pressure regulator (Fig. 20.5). Pressure regulators not only reduce the pressure of gases from the cylinders, but also provide gases at a nearly constant reduced pressure to the flow meters, despite the changing pressures in the cylinders. Because pressure is defined as force per unit area, a high pressure acting on a small area may be balanced by a low pressure acting on a large area (large diaphragm in the regulator). A simple pressure-reducing valve constructed using this principle, however, results in decreasing reduced pressure as the cylinder contents empty. To smooth the flow and keep the reduced pressure nearly constant, a set of high-force springs was added to the modern

Figure 20.4. Pressure gauge for pipeline and cylinder supply.

P: Cylinder pressure

Figure 20.5. Basic principle of the pressure regulator: $P \times a = p \times A$ (high pressure acting on a small area is balanced by low pressure acting on a large area diaphragm).

regulator. The pressure regulators on anesthesia machines are factory preset to reduce the high pressure in the cylinders to 300 to 350 kPa (45–50 psi). The pipeline pressures are supplied at a pressure of 350–400 kPa (50–55 psi) to ensure that the pipeline supply is used preferentially even if the cylinder is left open unintentionally. Some machines have second-stage regulators in the intermediate-pressure section before the flow meters and oxygen flush. The second regulator reduces the oxygen pressure further to approximately 20 psi gauge (psig) for oxygen and 38 psig for N₂O. This ensures lower pressure at oxygen flush; minimizes pressure fluctuation to the flow meter, thereby maintaining constant flow; and decreases the wear and tear of needle valves of the flow meters. Two-stage regulators are also used in the demand-flow Entonox (BOC, Manchester, UK) apparatus.

Check valves

Check valves are present on the yoke after the fresh gas entry port to prevent leaks during the change of cylinders and to prevent filling of the cylinders from pipelines or the second backup cylinder, even if the cylinders are inadvertently left open. These valves are also present at the entry of pipelines to prevent backflow into the pipeline in the event pressures fall in the pipeline while the backup cylinder is being used. A check valve is also present downstream of the vaporizer bank to ensure that back pressure is not transmitted to the vaporizers, particularly when oxygen flush is activated.

Safety devices to prevent administration of a hypoxic gas mixture

A devastating complication of administering anesthesia is delivering a hypoxic gas mixture. The incorporation of ASTM-recommended standards in the anesthesia work station and its components has made this occurrence much rarer than in the past. Color coding of cylinders and pipelines, non-interchangeable threaded connections to the regulators of bulk cylinders, a pin-indexed safety system for cylinders mounted on the anesthesia machine, non-interchangeable quick couplers, and DISS for pipelines have all improved safety. Appropriate calibration and monitoring of the oxygen concentration delivered by the machine and inspired by the patient is another important advance in the standard of care. The following

devices incorporated in the anesthesia machine itself are additional measures to prevent accidental administration of hypoxic gas mixtures.

Oxygen failsafe device

In Datex-Ohmeda machines, N₂O is always connected to its flow meter through an oxygen failsafe device. This device has a spring-loaded valve (Fig. 20.6). Oxygen pressure acts against the force of the spring and keeps this valve open so that N₂O can flow to its flow meter. Once oxygen pressure drops below 30 psig (205 kPa), the unopposed force of the spring closes the valve and N₂O can no longer be administered.

In some machines, air supply also flows through a failsafe device. However, some manufacturers allow air to be delivered directly to the flow meter, which enables the anesthesiologist to administer air in the event of oxygen failure. Modern machines incorporate an electronic switch that will not allow air and N₂O to be used at the same time.

Oxygen failure protection device

The oxygen failure protection device (OFPD), used in Dräger machines, proportionately decreases the N₂O pressure based on the oxygen pressure. In oxygen failsafe devices, the flow is “all or none.” In the OFPD, the flow is proportional and variable and maintains a desired level of fraction of inspired oxygen (FiO₂). Only at extremely low oxygen pressure is the N₂O flow is entirely stopped.

Proportioning systems

Newer machines are equipped with proportioning devices that ensure a minimum FiO₂ at all times.

Datex-Ohmeda Link 25

The flow meter control valves of oxygen and N₂O are mechanically linked to each other with chains. Normally, both knobs can be operated independently. Whenever the proportion of oxygen approaches 25%, the gear engages and both control knobs move simultaneously. This mechanical system is supported by a pneumatic system in which both flow meters operate at different pressures because of the differential setting in the respective second-stage pressure regulators. The resulting combination ensures a minimum FiO₂ of 0.25.

Dräger oxygen ratio monitor controller

Oxygen and N₂O are interlocked pneumatically to ensure a fresh gas oxygen concentration of at least 25% ± 3%. The pressures downstream of the flow control valves of N₂O and oxygen and upstream of the resistors before the flow meter tubes are linked through pressure transducers. This system controls the slave control valve, which controls the N₂O inlet pressure.

Oxygen low-pressure alarm

The low-pressure or oxygen supply failure alarm will sound when there is a significant increase or decrease in oxygen supply pressure. This occurs when there is a sudden loss of cylinder or pipeline pressure or when the anesthesia machine is turned on or off. A commonly used mechanism uses a pressurized canister that is filled with oxygen when the anesthesia machine is turned on. The stream of oxygen that enters the canister passes through a whistle, and a sound can be heard when the machine is turned on. If the oxygen pressure then falls below a certain value, this canister will empty and direct a reversed stream of oxygen through the whistle. This alarm may not be heard if the oxygen supply pressure drops very gradually over a long period. Some machines have a visual alarm as well. The audible alarm should be activated within a few seconds after oxygen pressure drops below 200 kPa, and has a minimum noise level of 60 dB at 1 m. The alarm can be switched off only by restoring the oxygen supply.

Flow meters

A needle valve controls the flow of individual gases into the flow meter (Fig. 20.7). A needle valve has a relatively small orifice with a long, tapered, conical seat. As the control knob is turned, the plunger is retracted and gases flow between the seat and plunger. Because it takes many turns of the fine-threaded screw to retract the plunger, precise regulation of the flow rate is possible. To avoid damage to the seat and prevent the stem from disengaging from the body, there are stops at the “off” and “maximum” flow positions. The control knobs are labeled clearly, color coded, and tactilely distinguishable. The oxygen control knob is larger and has a fluted profile. Electronic, solenoid-controlled flow devices are used in new machines.

The actual flow is measured by cylindrical tubes with varying internal diameters (Thorpe tubes). The flow meters on anesthesia machines are traditionally called *rotameters* (a trade name adopted by the British Oxygen Company). They are variable-orifice, fixed-pressure difference devices. As the flow increases, the rotating bobbin rises in the flow meter and the annular orifice around the cylindrical bobbin increases. The calibration is either etched on the flow meter or written immediately to the right of the tube. One reads the flow at the top of a cylindrical bobbin or the center of a spherical bobbin.

At low flows, the flow meters are calibrated in milliliters per minute (or in decimal fractions of liters per minute), whereas at high flows they are calibrated in liters per minute. To facilitate accuracy at low flows, two tubes may be used to measure

Figure 20.7. Needle valve.

flows for a single gas. One tube measures up to 1 L/min, and the higher flows are measured in the second tube. However, there is only one control knob and the flow meter tubes are connected in a series.

Flow tubes are equipped with float stops at the top and bottom of the tube. The upper stop prevents the float from ascending to the top of the tube and plugging the outlet. It also ensures that the float is visible at maximum flows instead of being hidden in the manifold. The bottom float stop provides a central foundation for the indicator when the flow control valve is turned off.

In a flow meter assembly, the oxygen flow meter joins downstream of all the flow meters to ensure oxygen flow, even if there is a leak in another flow meter. However, damage to the oxygen flow meter will result in a hypoxic mixture if N₂O is also being used (Fig. 20.8). Continuous monitoring of the inspired oxygen concentration, with associated alarms if a hypoxic mixture is being delivered, is the only option to ensure that a hypoxic mixture is not delivered to the patient.

Most modern machines use conventional flow control and an electronic flow sensor. The flow measured by the sensor is represented digitally and/or by a simulated flow meter on the anesthesia machine screen. An *auxiliary flow meter* for oxygen is incorporated in some modern machines that can deliver an oxygen flow of up to 10 L/min without the machine being turned on. This enables the anesthesiologist to deliver oxygen therapy during regional anesthesia and for emergency resuscitation.

The “back bar”

The back bar is a structure that supports the flow meter block and vaporizers. This term is used to describe these supporting components and the gaseous pathways connecting them. Many

(B and C) A leak in the air or N₂O flow meter does not deliver a hypoxic mixture. (D) Regardless of the sequence of flow meters, a break in the oxygen flow meter always leads to a hypoxic mixture if N₂O is being used.

machines use a system that allows the user to add or remove specific vaporizers quickly and easily while maintaining a gas-tight system. Some machines have space for a single vaporizer only; others allow the attachment of two or more vaporizers. However, only one vaporizer can be turned on at any given time. There are two popular interlock systems to achieve this: Selectatec (Datex-Ohmeda) and the Dräger medical mounting system. Once a vaporizer is attached and turned on, gas flow is diverted from the back bar into the vaporizer to provide the required concentration of anesthetic vapor.

High pressure relief valves

Anesthesia machines are also fitted with pressure-relief valves. In the intermediate-pressure section, these valves are set to open at about 95 to 110 psig to protect against a defective pressure regulator. In the low-pressure section, they are set to open at about 40 kPa (6 psig). These relief valves protect the machine (not the patient) from high pressures. The patient should be protected from excessive pressures by relief valves within the breathing system.

Vaporizers

Vaporizers are devices used in anesthesia equipment that convert volatile anesthetic liquid into vapor and facilitate inhalational anesthesia. All modern vaporizers are precise and agent specific. Color-coded filling systems are used to ensure the vaporizers cannot be filled with the wrong agent. The currently used vaporizers are constructed to be on the machine and are not suitable for use in the breathing system after the common gas outlet (CGO). They are calibrated at sea level and are flow and back pressure compensated. Several types are used in modern machines.

Variable bypass vaporizers

Sevoflurane, isoflurane, and halothane are administered using variable bypass vaporizers (e.g., Tec 5 and Tec 7 [Ohmeda] and

Dräger Vapor). The fresh gas stream is split into two streams, a bypass stream and a stream passing through the vaporizing chamber. The ratio of the two streams (i.e., the splitting ratio) depends on the saturated vapor pressure of the specific volatile agent and is controlled by the concentration dial (Fig. 12.9).

Functional analysis of the vaporizers:

1. *Method of vaporization:* The fresh gas passing through the vaporizing chamber picks up the vapor as it flows over the liquid agent (flow over or plenum). The gases are directed to flow through a spiral of wicks soaked with liquid agent, to increase the time of contact and surface area of vaporization, thus improving efficiency. The gas exiting the vaporizing chamber is fully saturated with the vapor, and the amount of vapor up picked will depend on the atmospheric pressure (ATP) and the saturated vapor pressure (SVP) of the agent (Table 20.1) per the

Figure 20.9. Schematic representation of the structure of a variable bypass vaporizer.

following equation:

$$\text{Vapor (ml)} = \text{Fresh gas flowing through vaporizing chamber (ml)} \times \frac{\text{SVP}}{\text{ATP} - \text{SVP}}$$

This equation is useful to understand the performance of a vaporizer if it is filled with the wrong agent, or if the vaporizer is being used at a different ambient pressure. The amount of vapor picked up at sea level when a given amount of fresh gas (“x” ml) passes through the vaporizing chamber is as shown here for different agents:

$$\text{Sevoflurane vapor (ml)} \times x(\text{ml}) \times \frac{157}{760 - 157} = x(\text{ml}) \times 0.26$$

$$\begin{aligned} \text{Isoflurane vapor (ml)} &= x(\text{ml}) \times \frac{238}{760 - 238} \\ &= x(\text{ml}) \times 0.456 \end{aligned}$$

$$\begin{aligned} \text{Halothane vapor (ml)} &= x(\text{ml}) \times \frac{243}{760 - 243} \\ &= x(\text{ml}) \times 0.47 \end{aligned}$$

2. *Regulating the output concentration:* The flow through the vaporizing chamber is controlled by the control dial, which adjusts the ratio of carrier gas entering the vaporizing chamber to the gas bypassing it (splitting ratio); hence, it is termed the *variable bypass vaporizer*. As the dial is turned to give a higher concentration, the proportion of gas passing through the vaporizing chamber increases and the vapor output increases. Because the splitting ratio, which controls the output concentration, remains constant over a wide range of fresh gas flows (FGFs), fairly reliable output concentration can be obtained, even at very low FGFs.
3. *Temperature compensation:* As volatile liquid vaporizes, it consumes heat, known as latent heat of vaporization. This results in the cooling of the liquid and a consequent change in the SVP, and therefore a drop in the output concentration. This heat is supplied to some extent by the metal sink used in the construction (thermostabilization). In addition, the bypass/vaporizer flow ratio is altered by either a bimetallic strip or liquid-filled bellows so that the output remains constant, even after long usage (thermocompensation).
4. *Filling with the wrong agent:* Most present-day vaporizers are fitted with agent-specific filling systems (e.g., keyed filling system, quick-fill system, easy-fill system). However, some still use the funnel-fill system, in which it is possible to fill the vaporizer with the wrong agent. Theoretically, the ratio of different vapor outputs, as calculated from the earlier equations, can be used to estimate the output concentration of an agent administered through a different vaporizer (Table 20.1).

In the event a vaporizer is filled with the incorrect agent, in addition to the different output concentrations, one is also

Table 20.1. Approximate output concentration of an agent when administered through a different vaporizer set to deliver 1%

Agent	SVP, mm HG at 20°C	Vaporizer	Output concentration %
Sevoflurane	157	Isoflurane	0.57
Isoflurane	238	Sevoflurane	1.75
Halothane	243	Isoflurane	1.03
Isoflurane	238	Halothane	0.97

likely to face a mixture of two agents. Hence, the current recommendations state that the unit must be completely drained and all the liquid discarded. Fresh gas must be allowed to flow through the emptied unit until the wicks are dry and no vapor is detected at the outlet.

5. *Performance at different ambient pressures:* The output concentration of a vaporizer, calibrated at sea level, changes when the unit is used at a different ambient pressure. At a higher altitude, the output concentration is higher than that set on the dial; in hyperbaric conditions, the output concentration is lower than that set on the dial. The magnitude of changes is significantly less when output partial pressures are considered instead of concentrations. The effect of ambient pressure on the output concentration also depends on the changes in density at different ambient pressures. Consequently, the performance of these vaporizers at different ambient pressures is variable; hence, the ASTM anesthesia workstation standards require that the effects of changes in ambient pressure on vaporizer performance be stated in the accompanying documents.

Electronic vaporizers

Desflurane vaporizer

Because of the high SVP of desflurane, a special electronic vaporizer (Tec 6; Ohmeda) is required to administer this agent (Fig. 20.10).

Functional analysis of the vaporizers:

1. *Method of vaporization:* The desflurane vaporizer electrically heats the anesthetic in a sealed chamber to 39°C, creating a pressure of approximately 1550 mm Hg. At this temperature and pressure, desflurane exists partly as liquid and partly as vapor. The vapor is added to the fresh gases in a controlled manner. There are heaters in the gas pathway to prevent condensation of vapor.
2. *Regulating the output concentration:* The FGF inlet pressure (varies with FGF) and the agent’s vapor pressure (varies with dial setting) are sensed by means of a pressure transducer (P). Based on the dial setting and FGF, the required amount of vapor is added to produce the desired output concentration. This can be considered an addition of a measured amount of vapor to the FGF. A microprocessor control achieves this through integration of a pressure regulator (R1), a variable resistor (R2), and

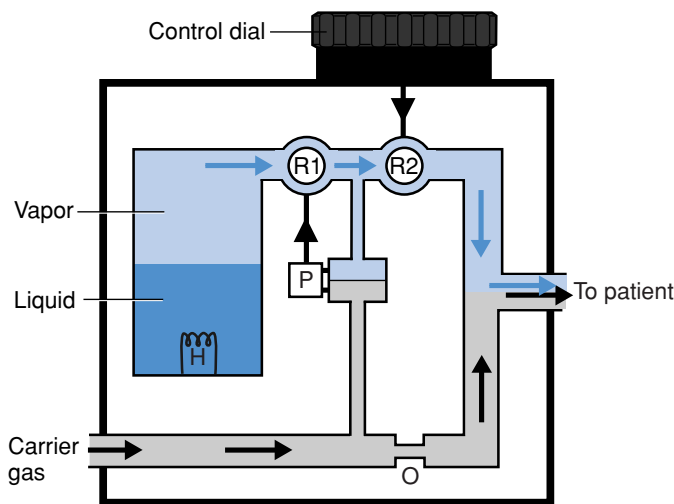

Figure 20.10. Desflurane vaporizer. H, heating element; O, flow restriction orifice; P, pressure transducer; R1: pressure regulator; R2: variable resistor.

pressure transducer (P). The saturated agent flow and FGF mix before their delivery to the CGO.

3. *Temperature compensation:* Because the liquid is heated to a constant temperature above the boiling point of desflurane and a measured amount of vapor is added to the FGF, no additional temperature compensation is required.

Aladin vaporizing system

The Aladin vaporizing system, used in Datex-Ohmeda workstations (S5/ADU and Aisys), is designed for desflurane, sevoflurane, isoflurane, enflurane, and halothane. The cassettes are magnetically coded to be recognized by the machine as they are inserted. Only one cassette can be inserted into the machine at any given time. The electronic controls and concentration dial are part of the anesthesia workstation, whereas the cassette contains the liquid anesthetic.

Functional analysis of the vaporizers:

1. *Method of vaporization:* The fresh gas passing through the vaporizing chamber picks up the vapor as it flows over the liquid agent (flow over or plenum). The fresh gas passing through the vaporizer is fully saturated with vapor because it flows between the agent-soaked wicks and baffles.
2. *Regulating the output concentration:* These vaporizers perform like variable bypass vaporizers, but with electronic controls. The FGF is split into a bypass flow in the machine and a vaporizing chamber flow in the cassette, and both flows are monitored constantly. A central processing unit (CPU) integrates the inputs from the bypass flow sensor, cassette pressure sensor, cassette flow sensor, and control dial setting to determine the ratio of bypass to vaporizing chamber flow and hence the outlet concentration, which is also monitored constantly.
3. *Temperature compensation:* Input from the cassette temperature sensor is integrated into the CPU and provides temperature compensation by adjusting the flow

through the vaporizing chamber. The metal wicks and baffles provide thermostability. If the temperature falls below 18°C, a fan is activated to facilitate heat transfer.

Direct injection of volatile agents

Technologic advances have led to innovative and reliable concepts of precise dosing of modern inhaled anesthetics. The volatile anesthetic agents are injected directly into the breathing system. When combined with a basal FGF in a circle breathing system, this technique enables rapid control of the agent concentration as well as minimal consumption of anesthetic. Direct injection of volatile agents (DIVA) has been implemented in the PhysioFlex and Zeus anesthesia machines (both from Dräger).

The DIVA unit comprises a reservoir unit, dosing chamber, and heating unit. The reservoir unit stores a quantity of liquid anesthetic in a tank and delivers it by means of an automatic injection system. The agent is vaporized in a heated vaporizing chamber, and the vapor is delivered to the breathing system via a heated pipe. The user can set the expiratory target concentration directly, independent of FGF. A closed-loop feedback mechanism is used to achieve the target concentration. A circuit flow provided by a blower located in the inspiratory limb of the breathing system provides a homogenous agent concentration.

Oxygen flush

The oxygen flush allows administration of 100% oxygen at rate of 35 to 75 L/min to the breathing system. The pressure downstream of the pressure regulator is supplied directly to the flush valve. The oxygen joins downstream of the vaporizers. There is a check valve to ensure that retrograde flow to the vaporizers is prevented when oxygen flush is activated. The flush is suitable for emergency jet ventilation in only a few models, depending on the position of the check valve; hence, it is not recommended for this purpose by the manufacturers. The flush works even if the main switch is not turned on. The valve is placed in a recessed position to prevent accidental activation. Overzealous intraoperative use may lead to patient awareness due to dilution of anesthetic agent. Accidentally sticking or activating it during inspiration may lead to pulmonary barotrauma.

Common gas outlet

The mixture of gases and vapors exits the machine via a 22-mm male/15-mm female conically tapered pipe. The connector is sometimes fixed, although some manufacturers provide a swiveling connector. The emergency oxygen flush is located close to the CGO, although this is not always the case in modern machines.

Anesthesia ventilators

Yasodananda Kumar Areti and Edward R. Garcia

The anesthesia ventilator has undergone considerable evolution since the Cattlin bag, used with Boyle's original anesthesia machine in 1917. The earliest delivery of anesthesia, in 1846, used a simple vaporization chamber that required spontaneous ventilation by the patient to inhale air and diethyl ether. Seventy years later, Boyle's anesthesia machine incorporated a breathing circuit and reservoir bag containing the anesthetic gases, finally allowing the clinician to ventilate the patient, although this required manually squeezing the reservoir bag. Blease's eventual invention of the "pulmoflator" (a simple bellows ventilator) in 1945 enabled automatic positive pressure ventilation for patients undergoing surgery. This was followed by continued refinement with the Bird and Bennett ventilators two decades later. The contemporary anesthesia ventilators on the anesthesia workstations by Dräger, Datex-Ohmeda, and others integrate many advanced intensive care unit-type ventilation features and can provide ventilation to the most challenging patients brought to the operating room. These anesthesia ventilators have sophisticated computerized controls, have several modifications to the circle breathing system, and can provide advanced types of ventilatory support, such as synchronized intermittent mandatory ventilation (SIMV), pressure-controlled ventilation (PCV), positive end-expiratory pressure (PEEP), and pressure-support ventilation (PSV), in addition to conventional control-mechanical ventilation (CMV). To use these complicated techniques safely, it is critical for every anesthesiologist to have a basic understanding of the mechanics of these ventilators and breathing circuits.

Common modes of ventilation in anesthesia ventilators

Volume-controlled ventilation

The most commonly used mode of ventilation during anesthesia is volume-controlled ventilation (VCV), also called volume-targeted or volume-limited ventilation. In VCV, the ventilator attempts to deliver a specified tidal volume by delivering a constant inspiratory flow for the programmed inspiratory time. The airway pressure rises throughout inspiration as the lung volume steadily increases. The rate of airway pressure rise depends on the inspiratory flow rate, as well as the total compliance of the lungs and chest wall. The tidal volume is delivered despite

a decrease in total compliance, at the cost of increased airway pressure, with the potential for barotrauma. To minimize the risk of barotrauma, a pressure limit is usually set, and once this pressure is reached, the ventilator no longer delivers the set tidal volume. The traditional use of large tidal volumes during ventilation in the intensive care unit (ICU) is also linked to volutrauma, and current recommendations suggest that low-volume PCV may be superior. More challenging patients are undergoing surgery and anesthesia, and the newer options available in contemporary anesthesia workstations ensure adequate intraoperative gas exchange. Some of these ventilator options may be particularly useful for patients requiring extremes of ventilation, such as neonates with very low tidal volumes and patients with stiff or resistive lungs due to diseases such as acute respiratory distress syndrome (ARDS).

Pressure-controlled ventilation

In PCV or pressure-limited ventilation, the controlled parameter is the airway pressure during inspiration. The ventilator varies the inspiratory flow rate to generate the specified inspiratory airway pressure (Fig. 21.1), which tends to produce larger tidal volumes at lower pressures; therefore it is very useful when lung compliance is low, such as in laparoscopy, obesity, ARDS, and pregnancy. In patients with lung disease, there is some evidence that PCV may result in better matching of ventilation and perfusion.

Disadvantages

Like VCV, PCV is a time-cycled method of ventilation because the inspiration terminates at the end of the set inspiratory time (as set by respiratory rate and inspiratory/expiratory ratio). Because the inspiratory flow rate varies, the total volume delivered at the end of the inspiratory time varies depending on the overall lung and system compliance during each inspiration, which sometimes may result in wide swings of resultant tidal volumes. If the compliance of the lungs and breathing circuit is constant, the volumes delivered tend to be constant. If lung compliance decreases, as with abdominal insufflation, external pressure on the chest, or a momentary contraction of the diaphragm (as with a cough), the airway pressure will increase. The ventilator will decrease the inspiratory flow to maintain the set airway pressure; consequently, the volume delivered will

Figure 21.1. Relationship among tidal volume, flow, and pressure. (A) VCV and (B) PCV.

decrease. Conversely, when there is a sudden increase in lung compliance, such as during release of abdominal pressure at the end of laparoscopy, the subsequent tidal volume will increase significantly unless the set inspiratory pressure is immediately decreased.

Synchronized intermittent mandatory ventilation

SIMV was initially introduced as a weaning mode; however, it has become a standard mode of ventilation from initiation to weaning. The ventilator delivers a preset number of breaths and allows patients to breathe spontaneously between ventilator breaths. If a spontaneous breath is initiated before a controlled breath is due, the controlled breath is synchronized with the spontaneous breath, preventing the “stacking” of the machine-delivered breath on the patient’s spontaneous breath. The total respiratory rate includes the machine breaths and spontaneous additional breaths. SIMV has found application in the operating room to facilitate emergence from anesthesia as the patient transitions from controlled to spontaneous ventilation.

Pressure-support ventilation

The use of laryngeal mask airways has led to a dramatic increase in spontaneous ventilation in the operating room. PSV is a useful adjunct to such techniques. In PSV, the ventilator supports the patient’s effort by providing programmed pressure assistance throughout the breath. Low values of pressure support primarily overcome the resistance of the endotracheal tube or laryngeal mask airway and the ventilator circuit, decreasing the patient’s work of breathing. The patient’s own ventilatory musculature provides the remainder of the work to generate the tidal volume. The level of support can be increased to provide the desired tidal volume after each breath initiation. In strict PSV, all breaths are patient initiated. Consequently, if there is inadequate stimulus for the patient to breathe, apnea will ensue. With

many ventilators, pressure support includes a “backup” or safety mode. If the patient does not initiate a breath within a certain period, the machine defaults to a mode of controlled ventilation to ensure adequate ventilation. PSV mode allows more patients to breathe spontaneously during surgery.

Positive end-expiratory pressure

General anesthesia and positioning during surgery decrease functional residual capacity, which may lead to pulmonary atelectasis and intraoperative pulmonary shunting, resulting in hypoxemia. The magnitude of shunt is correlated with the formation of pulmonary atelectasis, which appears within minutes after induction of anesthesia in 85% to 90% of patients. Application of PEEP has an obvious advantage in such situations, instead of using a very high inspired oxygen concentration, which itself predisposes to atelectasis. In addition, PEEP is essential for patients on ventilator therapy in the ICU who are undergoing surgery and anesthesia. Application of PEEP is also known to reduce the incidence of atelectasis in obese patients undergoing general anesthesia. Application of continuous positive airway pressure (CPAP) during preoxygenation also is well tolerated and has been shown to prevent atelectasis during induction, even in morbidly obese patients. Application of CPAP to the unventilated lung also has been used to improve oxygenation during one-lung anesthesia.

Challenges specific to anesthesia ventilators

Low-flow inhalational anesthesia

Inhalational anesthesia requires administration of a known concentration of oxygen, volatile agent vapor, and air or nitrous oxide. Low flows are used to save costs and minimize pollution and necessitate the use of breathing circuits with carbon dioxide absorption techniques. Traditionally, spontaneous breathing is largely unassisted (manual assistance is done if required)

Figure 21.2. Modifications in the anesthesia breathing system using a piston ventilator to achieve fresh gas decoupling.

and controlled ventilation is achieved by partially closing the adjustable pressure limiting (APL) valve and squeezing the reservoir bag.

Traditional ventilators achieve mechanical ventilation with all the aforementioned objects by enclosing the reservoir bag (bellows replaced the reservoir bag) in a rigid box, which is pressurized intermittently, mimicking the intermittent squeezing of the reservoir bag. This results in two circuits: one with inhalational agents connected to the patient and the other in which the driving gas pressurizes the rigid box – hence the name *double-circuit technology*. These ventilators also are known as “bag-in-bottle” or “bellows-in-box” ventilators. These bellows may be hanging bellows or, more commonly, ascending bellows, based on whether the bellows descend or ascend during expiratory filling. Descending bellows have the disadvantage of creating negative pressure during expiration or filling with gases from the box if there is a leak in the bellows.

Driving the ventilator

Gas-driven ventilators

The driving gas in anesthesia ventilators may be compressed air, oxygen, or a mixture of oxygen and air delivered by a Venturi

device. If oxygen is the driving gas, one must switch to manual ventilation in the event of a failure in the pipeline supply necessitating use of oxygen from a type E cylinder.

Piston ventilators

With regard to some modern ventilators (e.g., Dräger ventilators), there has been a resurgence in the use of mechanical devices such as pistons to drive them (Fig. 21.2). These piston-type ventilators use a computer-controlled stepper motor instead of compressed drive gas to actuate gas movement in the breathing system. Instead of dual circuits, with gas for the patient in one and the drive gas in another, these systems have a single gas circuit for the patient. These ventilators are classified as piston-driven, single-circuit ventilators. The piston operates much like the plunger of a syringe to deliver the desired tidal volume or airway pressure to the patient. The major advantage of the piston ventilator is its ability to deliver tidal volume accurately to all patients under a wide variety of clinical conditions. There is no oxygen cost of driving gas, and the loss of tidal volume due to internal compliance of the bellows is eliminated. However, because these ventilators run on electricity, one must depend on limited battery backup (about 30 minutes) in the event of a power failure.

Turbo-Vent

The latest advance in anesthesia ventilation is the use of Turbo-Vent (Dräger Zeus), a revolutionary closed-system ventilator consisting of an electric-driven and – controlled compressor turbine placed in the inspiratory limb. The compressor turbine is dynamically driven by a brushless DC motor, enabling it to (i) build up the breathing pressure and deliver the corresponding flow to the patient during inspiration time and (ii) deliver the circuit flow required to mix the gas within the breathing system independently from patient inspiratory effort. This ventilator allows spontaneous respiration in all breathing modes and with virtually unlimited inspiratory flow. Turbo-Vent is suitable for all forms of ventilation, even those required in the ICU.

Effect of fresh gas flow on the delivered tidal volume

Traditionally the fresh gas flow (FGF) is delivered directly into the breathing system (circle system). This flow, which is added to the tidal volume delivered by the ventilator, is termed *fresh gas coupling* (Chapter 22, Fig. 22.4). If FGF is low, this contribution will be small; if FGF is high, it significantly contributes to ventilation. For example, if FGF is set at 6 L/min, then approximately 100 ml of fresh gas flows into the circuit every second. If the ventilator is set to deliver a tidal volume of 600 ml in 2 seconds, then 200 ml of fresh gas will be added to this volume, resulting in a total inspiratory tidal volume of 800 ml. If the FGF is low at 1 L/min, then the additional volume is only about 33 ml, a minor contribution. Fresh gas coupling might be particularly hazardous to infants and small children when FGF is altered.

Fresh gas decoupling

The aim of the contemporary anesthesia ventilator is to ensure that tidal volume is not affected by FGF. There are several approaches to dealing with the problem of fresh gas coupling. The Dräger Julian, Narkomed 6000, and Fabius GS use fresh gas decoupling, that is, fresh gas is not added to the delivered tidal volume. Thus, fresh gas decoupling helps ensure that the set and delivered tidal volumes are equal. These machines use a piston ventilator, which may be present in either the inspiratory limb (Fig. 21.2) or expiratory limb. The action of the piston closes a one-way decoupling valve, diverting the FGF to the manual breathing bag during the inspiratory cycle. A series of electronically controlled valves must work in concert with the ventilatory phase to accomplish this decoupling. In machines in which the ventilator is present in the inspiratory limb, because of this decoupling valve, there is no back pressure to close the expiratory unidirectional valve. Hence, a PEEP/maximum pressure valve is interposed between the patient and the expiratory unidirectional valve.

The visual appearance of the reservoir bag during this type of decoupling is unusual:

- The manual breathing bag, normally quiescent during mechanical ventilation, moves with each breath.
- The manual breathing bag movement is opposite the movement seen in a mechanical ventilator bellows – the manual breathing bag *inflates* during inspiration (because of FGF), and *deflates* during expiration as the contents empty into the ventilator. If the reservoir bag is removed, atmospheric air is entrained and the ventilator functions without activating any alarms; hence the anesthesiologist must be aware of this potential problem.

The second approach is fresh gas compensation, which is used in the Aestiva and S/5 Anesthesia Delivery Unit (ADU). The volume and flow sensors provide feedback, allowing the ventilator to adjust the delivered tidal volume so that it matches the set tidal volume, despite the total FGF, or if there is a change in FGF. These measurements may be done in the first few breaths, and compensation is instituted from subsequent breaths, which may result in high tidal volumes during the first few breaths.

The third approach used to minimize the effects of FGF on tidal volume is FGF interruption (Dräger Julian). With this approach, FGF is measured and reported electronically and the computer controls interrupt the flow during inspiration.

Effect of breathing system compliance and leaks on delivered tidal volume

During intermittent positive pressure ventilation, a part of the tidal volume gets compressed in the breathing system, leading to a decrease in the delivered tidal volume. This is known as the internal compliance of the breathing system, which is approximately 5 to 10 ml/cm H₂O. Traditional ventilators did not compensate for this loss, and anesthesiologists had to depend on chest expansion, spirometry, and end-tidal CO₂ to ensure that the ventilation was adequate, and they could not rely on the volume indicated on the ventilator controls. Compliance compensation is incorporated in some of the modern ventilators (e.g., Datex-Ohmeda SmartVent 7900, Dräger Fabius). During the pre-use test, the ventilator assesses the internal compliance and makes the appropriate changes to ensure that the set tidal volume is delivered. One has to repeat the self-tests if the circuit is changed between patients on the surgical list. Alternately, some machines (SmartVent) monitor the volumes and flows at both the inspiratory and expiratory limbs of the breathing system and ensure that the set tidal volume is delivered through a servo-feedback loop.

Small leaks around uncuffed endotracheal tubes or laryngeal mask airways result in a loss of tidal volume, which is not detected by pre-use check. This can be compensated only by measuring the inspiratory and expiratory flows and making the necessary adjustments to deliver the set tidal volume.

Ability to switch from mechanical to manual ventilation

During induction of anesthesia, patients are transitioned through spontaneous breathing to manual ventilation, followed by controlled mechanical ventilation. The opposite occurs during recovery. The isolation of the patient circuit from the ventilator circuit helps achieve this objective. Adjusting the pressure-relief valve helps transition from spontaneous to manual ventilation. A manual switch is incorporated in the circuit to switch between the reservoir bag and the ventilator bellows. The relief valve in the ventilator circuit is distinct from the APL valve. It relieves excess gas from the patient's breathing circuit at the end of *exhalation*, contrary to the APL valve during manual ventilation, which relieves excess patient gas during *inspiration*. The relief valve in the ventilator is kept sealed during inspiration.

Use of oxygen flush

A more significant problem with fresh gas coupling may result from activation of the oxygen flush valve during the inspiratory phase of the ventilator. As with FGF, this additional flow (35–75 L/min) adds to the inspiratory flow. This translates to >1000 ml/sec of flow, leading to buildup of excessive pressures in the circuit, possibly resulting in barotrauma. Hence, activation of the oxygen flush valve during inspiration must be avoided, except if using an anesthesia machine specifically designed to allow it.

Pediatric ventilation

The loss of tidal volume due to breathing system compliance and leaks around the uncuffed endotracheal tubes has maximal effect in pediatric patients; therefore, appropriate breathing systems are chosen for pediatric subjects. In the bellows-in-box arrangement, smaller ventilator bellows must be used to deliver small tidal volumes accurately. The new piston and turbine ventilators give the clinician flexibility in delivering a wide range of tidal volumes more accurately and obviate the need to change bellows.

Waste anesthetic gas scavenging

The exhaled gases in ICU ventilators are vented to the atmosphere. However, anesthesia ventilators should be able to vent the exhaled gases to the waste gas-scavenging systems in operating rooms to eliminate operating room pollution. Both the APL valve in the circle system and the relief valve in the ventilator are suitably modified to achieve this.

Application of positive end-expiratory pressure

Application of PEEP is a solution to counter the effects of anesthesia on the pulmonary system. In the past, PEEP valves were used for this purpose; however, because of the dangers in using

them incorrectly, they no longer are recommended. Modern ventilators incorporate electronic PEEP control. In standing bellow ventilators, there normally is an end-expiratory pressure of +2.5 cm H₂O because of the PEEP effect of the ventilator relief valve. Application of PEEP might result in a loss of tidal volume set on the ventilator. The position of the PEEP valve varies in different models of anesthesia ventilators. The Datex-Ohmeda SmartVent applies PEEP at the ventilator relief valve, resulting in no loss of tidal volume. Any deviation from the tidal volume set is sensed by the inspiratory flow transducer, and a correction is made via the SmartVent compensation system.

Commonly used current models of anesthesia ventilators

Dräger Divan ventilator

The Dräger Divan is a modern ventilator offering features such as pressure-control mode, SIMV, correction for compliance losses, and integrated electronic PEEP. Its piston-driven bellows are inconspicuous and horizontally mounted. Fresh gas decoupling is achieved by diverting fresh gas to the manual breathing bag, which inflates during mechanical ventilator inspiration and deflates during expiration. A disconnect causes the manual breathing bag to lose volume gradually (in addition to activating other apnea alarms). A pressure transducer within the ventilator measures compliance losses and leaks in the total breathing circuit (absorber head and corrugated limbs), and appropriate adjustments are made by the ventilator microprocessor to ensure that the set tidal volume is delivered to the patient.

Dräger Fabius GS ventilator

The Fabius GS is an electronically controlled, electrically driven piston ventilator; it consumes no drive gas. The piston is vertical and continuously visible. This ventilator has a wide range of operating parameters to suit adult as well as pediatric patients. Fresh gas decoupling is achieved by diverting the fresh gas to a reservoir bag during inspiration. Compliance compensation is achieved by checking the circuit compliance during the pre-use check. Leaks in the reservoir bag may lead to air dilution and possible awareness.

Dräger AV-E and A-2

The Dräger AV-E and A-2 are electrically powered, double-circuit, pneumatically driven, ascending-bellows, time-cycled, electronically controlled ventilators. The tidal volume must be preset with pressure limiting. Inspiratory flow control must be set properly so that driving gas flow does not create an inspiratory pause.

Ohmeda 7000

The Ohmeda 7000 is an electrically powered, double-circuit, pneumatically driven, ascending-bellows, time-cycled,

electronically controlled ventilator. It also is a minute-volume preset ventilator (unique among current ventilators). Tidal volume cannot be set directly but is calculated from settings of minute volume and respiratory rate. Inspiratory flow stops when driving gas equivalent to the set tidal volume has been delivered to the driving circuit side of the bellows chamber, or if a pressure >65 cm H₂O is attained.

Ohmeda 7900 SmartVent

The SmartVent is a pneumatic, double-circuit, ascending-bellows ventilator. A microprocessor control delivers the set tidal volume despite changes in FGF, small leaks, or losses in breathing system or bellows compliance proximal to the sensors. The flow sensors are placed between the corrugated plastic breathing circuit and the absorber head, in both limbs. These are connected to pressure transducers in the ventilator. This ventilator offers desirable features such as integrated electronic PEEP control and PCV mode. It has been reported that the sensors may be quite sensitive to humidity, causing ventilator inaccuracy or outright failure; therefore the use of a heat/moisture exchange filter is recommended.

Datex-Ohmeda S/5 ADU ventilator

The S/5 ADU is an electronically controlled, pneumatic, double-circuit, ascending-bellows ventilator with several unique features. Single-switch activation (setting the bag/vent switch to “auto”) is all that is needed to start mechanical ventilation. FGF is located between the inspiratory unidirectional valve of the circle system and the patient. Delivered tidal volume is adjusted to compensate for changes in FGF and total breathing circuit compliance losses through the D-Lite sensor at the elbow. This ventilator can use either oxygen or air as the driving gas and can switch automatically from one to the other if pipeline pressure is lost. VCV, PCV, and SIMV modes are offered, along with integrated electronic PEEP.

Anesthesia breathing apparatuses

Jingping Wang and Charles A. Vacanti

Anesthesia breathing apparatuses represent very simple and logical devices that are exceedingly important for anesthesiologists to understand. We have elected to start with what we believe is the simplest example of a basic breathing apparatus. We explore its limitations and then suggest modifications that may be beneficial, depending on one's needs. For the purpose of this chapter, *anesthesia breathing apparatuses* are defined as devices that enhance the ability to breathe a desired or defined gas or vapor. The reader should note that this discussion does not include anesthesia machines by which one can effectively designate the compound to be delivered, ventilators that assist breathing but are not considered the actual breathing apparatus, or masks and other aids to breathing (such as Ambu bags, Venturi masks, and nasal prongs) not directly related to the administration of anesthesia.

Our first recollection of a very simple yet effective breathing apparatus was demonstrated in one of the early Tarzan films, in which the “ape man” eluded capture by submerging himself in a pond and harvesting a long reed, through which he was able to breathe until the natives lost interest and abandoned their pursuit (Fig. 22.1).

The reed through which he was breathing functioned similarly to a modern-day snorkel, with some important differences. A “standard” snorkel is about 50 cm long, with an internal diameter of 2 cm, resulting in a capacity, or dead space, of about 150 cm³. If Tarzan's reed had an internal diameter of 1 cm, it would have contained the same dead space at a length of approximately 7.5 feet. A smaller-diameter “breathing” tube would have significantly increased resistance to breathing (try breathing through a standard soda straw for a period of time), whereas a tube of larger diameter or length would have resulted in an unacceptably large dead space (see how long you can survive by breathing through a garden hose). Too large a dead space would have prevented Tarzan from effectively eliminating carbon dioxide (CO₂), resulting in rebreathing. Tarzan might effectively breathe through a tube with a very large dead space if he were to exhale into the water rather than back into the tube (this can be achieved easily by adding a one-way valve that directs inhaled air from the tube into the lungs, and exhaled air into the water rather than back into the breathing tube). This simple maneuver converts an open breathing system to a semi-closed apparatus.

In Tarzan's reed, or any effective breathing apparatus, the critical elements are:

1. A sufficiently large and sufficiently compliant reservoir of inhaled gas (air, in Tarzan's case) to fully expand the lungs as needed with little effort. The reservoir in the example is the virtually unlimited supply of air above the water that feeds directly into the breathing tube.
2. A conduit of sufficient diameter to conduct the gas being breathed without creating significant resistance to breathing. In the example, the reed was at least 1 cm in diameter.
3. A mechanism to effectively eliminate exhaled CO₂. In this case, breathing through a tube with a dead space <150 cm³. Alternatively, a one-way valve could be used to prevent rebreathing of CO₂ by diverting exhaled air into the water, rather than back into the breathing tube. In Tarzan's case, this would have created exhaled bubbles in the pond, revealing his location and resulting in a feast for the natives. That is precisely why Tarzan did not use a one-way valve but rather chose a reed with a dead space <150 cm³.

Based on this simple example, it becomes obvious that if one wishes to design an effective breathing device for any purpose, one must identify the objectives, evaluate the theoretical limitations of the device being developed, and make appropriate modifications to meet each successive need (Table 22.1). This is

Figure 22.1. “Tarzan,” with his new haircut and store-bought trunks, eluding capture by breathing through a reed while submerged in a pond.

Table 22.1. Classification of breathing systems

Type	Inhalation	Exhalation to	Reservoir	Rebreathing	Example
Open	Air + agent	Atmosphere	Nil	Nil	Open drop T-piece
Semi-open	Air + agent from machine	Atmosphere	Small	Minimal	T-piece with small reservoir
Semi-closed	From machine	Atmosphere + machine	Large	Possible	Magill attachment Mapleson systems
Closed	From machine	Machine	Large	Yes + CO ₂ absorbent	Circle system

indeed what occurred historically in the development of breathing devices used in anesthesia.

If we want to deliver a known mixture of gases and vapors (in the case of anesthesia, oxygen and anesthetic agents), we refer to the gas outlet of an anesthesia machine as the *gas source*. Because the anesthesia machine itself is presented later, we schematically represent the machine and its outlet as a box with a tube (hose) protruding from it and label it *gas source*. Now let us put Tarzan to sleep. First, we fashion the infamous “reed” or basic breathing apparatus out of corrugated tubing to add flexibility and some compliance while reducing kinks. We also place the breathing apparatus over his mouth using a mask, then examine the most effective ways to connect this breathing apparatus to the gas source (Fig. 22.2).

It appears the simplest approach is to run the gas outlet hose from the machine into the inside of the larger-diameter breathing tube. This indeed may be quite effective, depending on how far into the breathing tube the gas source hose is placed (Fig. 22.3).

We now have created one of the simplest and most effective “open circuit” breathing apparatuses, called a *Bain circuit*. Although it appears to be the simplest, most logical circuit to develop and one of the most effective open circuits, it was not described until after several less effective configurations were developed (see later). The breathing apparatus we designed thus far is also referred to as a *modified Mapleson D circuit*, or even a *modified Ayre T-piece* (that was introduced in 1937 and itself was known as a modified Mapleson E circuit). These circuits were named according to the order of their historical description, rather than by a logical or intuitive nomenclature. Described and analyzed by Mapleson in 1954, all are variations of the Mapleson circuit, but in fact, they are all simple

variations of the breathing apparatus Tarzan was described as using many years earlier. The reason seemingly more complicated breathing apparatuses were developed before these simpler, more effective designs is that earlier devices were designed around a need to provide a gas source contained in a pressurized cylinder. In 1907, Barth used a reservoir bag and Clover inhaler to deliver nitrous oxide from a cylinder. A simple anesthetic delivery system known as the “Magill circuit” was introduced later.

In one variation of the aforementioned circuit, rather than run the gas source hose through the entire internal length of the breathing apparatus, the source hose can run along the breathing tube and enter the wall of the tube near the mask (Fig. 22.4e), allowing it to function in exactly the same manner. When configured in this manner, it is referred to as a Mapleson E or Ayre T-piece (the modification in which the gas source tube runs inside the breathing tube was described later, consequently being called a *modified Ayre T-piece*). A bag (with a pop-off valve on its base) can be placed on the end of the breathing tube (Fig. 22.4f) to enable assisted ventilation, which enhances CO₂ removal and reduces the need for high fresh gas flows to prevent rebreathing. This additional modification is referred to as a *Mapleson F*, or the *Jackson-Rees modification of an Ayre T-piece*.

Other modifications to this simple breathing apparatus involve the relocation of pop-off valves at various positions in the circuit in hopes of reducing rebreathing. As they largely have been abandoned from clinical use in modern anesthesiology, they are mentioned for historical significance and because knowledge of their names and configuration may be deemed

Figure 22.2. The anesthesia machine is represented by a box labeled *gas source* with an outlet hose that supplies the gas to the breathing tube. Unless the gas hose is placed well within the breathing tube, only room air will be inspired.

Figure 22.3. If the gas outlet hose resides only slightly within the breathing tube (to A), the patient will breathe exhaled air mixed with room air and very little fresh gas from the gas source hose. Advancing the gas supply hose to B improves the delivery of gas and if the flow is sufficient, helps remove exhaled CO₂ by blowing it out of the circuit. The optimal placement of the gas source outlet tube is as far into the breathing tube (as close to the breathing mask) as possible (C). When the flow of fresh gas is 1.5 to 2 times the minute ventilation, exhaled CO₂ is effectively washed out of the breathing tube, preventing rebreathing and CO₂ buildup.

Figure 22.4. (A–D) The historical classification by Mapleson of various breathing apparatuses. (E) Rather than the gas outlet hose being run through the end of the breathing tube, it can run for a short distance outside the tube and then enter it closer to the mask. This will allow for the addition of a bag on the end of the tube to assist ventilation. (F) The gas supply hose can run external to the breathing tube and enter the tube adjacent to the mask. This is what is done in an Ayre T-piece. Again, a bag may be added to assist ventilation, making it a Mapleson F circuit or a Jackson-Rees modification to an Ayre T-piece.

important in an examination. Also analyzed by Mapleson, they are referred to as Mapleson A through D and are presented schematically in Fig. 22.4:

- Mapleson A (Magill) – The expiratory valve is near the face mask. Fresh gas enters the distal end of the tube, prior to the reservoir bag (Fig. 22.4a).
- Mapleson B – Similar to Mapleson A, but the fresh gas supply is moved near the face mask, just before the expiratory valve (Fig. 22.4b).
- Mapleson C (Ambu bag) – Same as Mapleson B, but with a much shorter conduit (Fig. 22.4c).
- Mapleson D – Identical to Mapleson B, except the expiratory valve is moved away from the mask, near the reservoir bag (Fig. 22.4d).

To–fro system

Although these circuits and modified Ayre T-piece systems are effective and efficient, a high gas flow (1.5–2 times the minute

ventilation) is necessary to prevent hypercapnia. Although this is useful in small children, in adults it necessitates fresh gas flows of 10 to 20 L/min that is expensive and inefficient and produces large amounts of waste gases to be scavenged. A simple solution to reduce gas flows and waste (called a “to–fro” system) is to add a CO₂ absorber to any of the aforementioned open circuit systems. The fresh gas inlet may be connected proximal or distal to the CO₂ absorber. An example of adding the CO₂ absorber in a line to a Mapleson F (Jackson-Rees) open system is shown in Fig. 22.5.

Figure 22.5. Mapleson F (Jackson-Rees) open system. In this example, the fresh gas flow enters proximal to the canister.

The first to–fro canister was developed by Waters to deliver cyclopropane. The system is quite effective but results in less than optimal mixing of fresh and expired gases when low flows are used. In addition, the distance from the mask to the CO₂ absorber is added as dead space. To reduce the dead space and improve mixing of gases, an expiratory limb with one-way valves may be added to the system. The expiratory limb and gases can then be directed back to the inspiratory limb of the system after being channeled through the CO₂ absorber by means of the one-way valves. These improvements result in a “circle system” as described in the following section.

Circle system

In 1926, Brian Sword developed a unidirectional rebreathing system, referred to as a circle system (Fig. 22.6). The circle system consists of a fresh gas inflow directed to an inspiratory limb and unidirectional valve, an expiratory limb and unidirectional valve, a CO₂ absorber, an expiratory pop-off valve, and a reservoir bag. Circle systems may be classified as semi-open, semi-closed, or closed, depending on the amount of fresh gas inflow.

During inspiration, the fresh gas, along with the CO₂ in the reservoir bag, flows through the inspiratory limb and its associated unidirectional valve to the patient. During expiration, the inspiratory unidirectional valve closes and the expired gas flows through the expiratory unidirectional valve in the expiratory limb to the soda lime canister and to the reservoir bag. The CO₂ is absorbed in the canister. The fresh gas flow from the machine continues to fill the reservoir bag. When the reservoir is full, the relief valve opens and the excess gas is vented into the atmosphere or, better still, a scavenging system. This system has the advantages of reduced fresh gas flow (as low as 250–500 ml/min of oxygen), economy of anesthetic consumption, reduction in atmospheric pollution, and conservation of heat and humidity. Disadvantages include a complex design with increased opportunity for malfunction or incorrect arrangement, slow changes in the inspired anesthetic concentration with low flows, increased resistance to breathing due to the CO₂ canister and valves in the system, and inhalation of soda lime dust.

Many classifications used in the literature are a source of confusion and inconsistency. Because it is important for an anesthesiologist to understand carbon dioxide homeostasis while using different systems, it is advisable to classify the systems based on CO₂ elimination (Table 22.2). One also should understand whether a system is efficient during spontaneous breathing, controlled ventilation, or both, and whether it can be used for pediatric patients, adults, or both.

Carbon dioxide absorption systems

Circle absorber systems have been used extensively in North America for more than 30 years. As mentioned earlier, they were developed to reduce the cost and use of expensive gases and

Figure 22.6. A circle system.

inhalational anesthetic agents as well as to reduce the amount of gas needing to be scavenged, and ultimately the extent of environmental pollution.

Two types of absorber are widely used: soda lime and Baralyme. Soda lime consists of 80% calcium hydroxide, 15% water, 4% sodium hydroxide, and 1% potassium hydroxide. As these pellets are fragile, small amounts of silicate are added to provide strength and prevent powdering. Baralyme, which is used more

Table 22.2. Classification based on CO₂ rebreathing (normal working condition)

No CO ₂ rebreathing	CO ₂ rebreathing is possible, but the CO ₂ level in the patient is determined by the interaction of:

commonly in the United States than in other countries, consists of 80% calcium hydroxide and 20% barium hydroxide; it also may contain some potassium hydroxide. Unlike soda lime, the addition of silica to Baralyme granules is not necessary to ensure hardness. The reaction of Baralyme differs from that of soda lime because more water is liberated by a direct reaction of barium hydroxide and CO_2 .

The reactions of CO_2 with absorbers are as follows: For both soda lime (containing sodium hydroxide) and Baralyme (containing barium hydroxide), the first several steps are the same, as they both involve reactions of CO_2 and water to form carbonic acid ($\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3$). In each system, the carbonic acid reacts with both calcium hydroxide and potassium hydroxide (present in each mixture) to form calcium carbonate, potassium carbonate, water, and heat. In addition, the carbonic acid also reacts very quickly with either the sodium hydroxide of soda lime, to form sodium carbonate, or to the barium hydroxide of Baralyme, to form barium carbonate, heat, and water. With Baralyme, this concludes the reaction, whereas with soda lime, the sodium carbonate then reacts with a calcium hydroxide mixture (as does the potassium bicarbonate) to form calcium carbonate as well as to reform the sodium hydroxide and potassium hydroxide found in the original mixture.

The absorbents interact with inhaled anesthetics to some extent. In some circumstances, interaction of sevoflurane with the strong bases present in soda lime or Baralyme results in the formation of compound A that has been shown to cause nephrotoxicity in animals. These circumstances include (1) low total gas flow rate (below 1 L/min), (2) higher concentration of sevoflurane, (3) the use of Baralyme rather than soda lime, (4) higher absorbent temperatures, and (5) desiccated CO_2 absorbent. Exposure of desflurane and isoflurane to soda lime and Baralyme results in formation of carbon monoxide. Factors increasing formation include (1) higher anesthetic concentration, (2) higher temperature, (3) dry absorbent, (4) the use of Baralyme rather than soda lime, and (5) the agent; the magnitude of CO production from greatest to least is: desflurane > isoflurane > halothane = sevoflurane.

Newer CO_2 absorbers (e.g., Amsorb; Armstrong Medical, Londonderry, Northern Ireland) have recently become available. They consist of calcium hydroxide with a compatible humectant (a hygroscopic substance with the affinity to form hydrogen bonds with molecules of water), namely calcium chloride. The absorbent mixture does not contain strong bases such as sodium and potassium hydroxide but does include two setting agents (calcium sulfate and polyvinylpyrrolidone) to improve hardness and porosity. New materials are designed to be effective absorbents of CO_2 while being chemically nonreactive with sevoflurane, isoflurane, and desflurane.

To be effective, the granules in the absorbing canisters must be properly configured to minimize resistance to airflow and to maximize the mixing of gases. To prevent rebreathing, the

intergranular space should be greater than the patient's tidal volume. Soda lime absorbs up to 26 L of CO_2 per 100 g. Soft and crushable granules are converted to hard and noncrushable ones (calcium hydroxide changes to calcium carbonate – limestone), indicating exhausted soda lime. Different manufacturers add different indicator dyes to the absorber: some change from pink when fresh to white when exhausted; others change from white to purple. Correctly packed canisters allow absorption throughout, rather than in a columnar fashion. A larger cross-sectional diameter allows less turbulence, with reduced resistance and less dust. Baffles in the canisters reduce gas tracking down the walls, where spaces are relatively larger.

Indication of absorbent exhaustion

Methods to determine whether the absorbent is exhausted include the following:

1. Capnography: Appearance of CO_2 in the inspired gas is the best way to detect absorbent exhaustion.
2. Indicators: An indicator is an acid or base whose color depends on the pH, and the color change is indicative of absorbent exhaustion. Different manufacturers use different indicators, including phenolphthalein (white to pink), ethyl violet (white to purple), Clayton yellow (red to yellow), ethyl orange (orange to yellow), and mimosa Z (red to white). Color change may be misleading in certain circumstances, particularly those resulting in regeneration (peaking) after a rest period. Amsorb turns purple when desiccated, an additional advantage that prevents use of desiccated absorbent.
3. Temperature in the canister: Because CO_2 neutralization is an exothermic reaction, changes in the absorbent temperature occur earlier than color changes. Studies have suggested that when the temperature of the downstream canister is higher than that of the upstream one, the absorbent should be changed in both canisters.
4. Clinical signs: Clinical signs of hypercapnia, such as tachycardia, hypertension, cardiac arrhythmias, and sweating, are usually late signs and are nonspecific.

In conclusion, by understanding these few relatively simple principles, one should be able to easily evaluate the advantages and disadvantages of any breathing system with which he or she is presented, and to effectively troubleshoot problems. We strongly recommend that those interested in pursuing the principles of breathing systems in more depth refer to the web site listed below.

Electrical safety

Jesse M. Ehrenfeld, Seetharaman Hariharan, and Stephen B. Corn

Introduction

Anesthesiologists have become recognized for their commitment to safety. The specialty of anesthesiology is composed of several societies whose focus includes taking a proactive role in developing safety-enhancing approaches to patient care. For example, the Anesthesia Patient Safety Foundation (APSF) was highlighted in a *Wall Street Journal* article for providing an excellent model for identifying and controlling risk not just for the specialty of anesthesiology, but for other disciplines of medicine as well.

Just as drugs and techniques have evolved in the specialty of anesthesiology, so have technologic developments. Today the anesthesiologist is faced with an array of displays, monitors, and alarm systems. Further, with the development of embedded computer and operating systems, anesthesia equipment has gotten less intuitive in design and in many instances resembles “black boxes” with complex functions.

Although anesthesiologists can, and often do, become quite skilled at using a wide variety of anesthesia delivery systems and monitoring and imaging equipment, most do not have a formal engineering or electrical safety background, nor can they be expected to be experts in all subtleties of equipment design. Therefore, this chapter provides some basic electrical information and an overview of electrical equipment safety issues in the operating room (OR). It also supplies some simple models to enhance the clinician’s understanding of OR design and devices that have been introduced to provide for electrical safety in patient care areas.

Of note, the goal of this chapter is not to give the reader the impression that he or she can or should be functioning as a clinical biomedical engineer. It is hoped that an understanding of the basic design goals and alarm devices will allow the anesthesiologist to be cognizant of a potential or real electrical safety issue so that he or she can either remedy it immediately or recognize that additional assistance is needed. Clearly, the vigilant anesthesiologist should remain focused on patient care and invoke the necessary resources.

The bird and the trolley car: a simplified approach to patient electrical isolation

A complete understanding of patient electrical safety requires familiarity with concepts such as isolated power supplies,

induced current, grounded circuits, ungrounded circuits, isolation transformers, and primary and secondary power supplies. cursory descriptions of these terms in the clinical classroom environment rarely seem to clarify the simple reason we strive to keep patients electrically isolated.

Hence, the bird and the trolley car

Electrical trolley cars get their power from high-voltage overhead lines. As the trolley travels under the high-voltage line, a “trolley pole” reaches up and makes electrical contact with the exposed wire. This contact completes an electrical circuit that allows current to flow through the trolley pole and power the motor, lights, and other critical systems of the trolley; finally, the current flows through the rails to the ground.

The power line (Fig. 23.1) to the trolley car supplies an enormous amount of electrical energy, enough to move a train at high speeds, and certainly enough to “cook” a small bird. However, birds land directly on the noninsulated power line, enjoy the sights, and fly off, without even a singed feather. They can do so because they are “isolated from ground,” that is, there is no path for the electricity from the high-voltage line to go through the bird and then to a grounding source. There is no flow of current through the bird, and no harm ensues. Similarly, the goal is to electrically isolate each patient. That is to be sure to NOT provide a potential pathway for electricity to exit the patient if we were to inadvertently contact the patient with a source of electricity, such as a faulty piece of electrical equipment. (Discussions related to arcing and other electrical phenomena are

Figure 23.1. Trolley car and power line.

Figure 23.2. A curious individual.

beyond the scope and intent of this chapter and are left to the reader to explore further.) *Ideally*, we aim to isolate the patient from *both* the power supply line and ground.

In Fig. 23.2, the curious individual makes contact with the bird and creates a path for the electrons to flow: from the wire, through the bird, through the human, and into the ground. An electrical circuit is completed, with its associated consequences. It suffices to say that this is not a pleasant experience for either the bird or the curious person.

Now imagine the bird is a patient on an operating table. The patient may be electrically connected to one or more pieces of medical equipment. We need to be sure that we are not putting the patient in danger by creating a pathway to ground as we contact the patient and connect monitoring and therapeutic devices.

These examples are used to clarify some rather complex OR and hospital circuitry and are not intended to make light of a significant risk. The examples also should serve as reminders to clinicians who may be faced with responding to a victim of electrocution: before physically approaching or contacting any individual to be rescued, make sure the person and his or her immediate environment are no longer in contact with an active power source, as you could become part of the potentially deadly circuit.

Having discussed the importance of isolating the patient, it leads us to address the line isolation monitor (LIM). Most simply, the LIM is a device that continually monitors the impedance (resistance and capacitance) from all lines in the room in relation to ground and indicates what current *might* flow to a

patient if he or she came into contact with a line conductor (i.e., defective equipment). It basically determines how much grounding is present if a power source were to be applied, as that will in part determine how much current *might* flow through the patient. An alarming LIM does *not* mean current is presently flowing through the patient – it only quantifies the grounding potential present in the room at that time.

It is understood that unlike the bird sitting on the wire, which is completely isolated from ground, the circuitry and equipment in the OR will allow some electrons to “leak” out. These small ground faults are quantified by the LIM. As long as the cumulative potential ground leak from all OR equipment remains small enough, the monitor does not alarm. However, *if* the potential ground leak is of a magnitude great enough that *if* a current were applied, significant flow *might* occur through the patient, *then* the LIM alarms.

Another device with which to be familiar is the ground fault circuit interrupter (GFCI) that is commonly found in household kitchens and bathrooms. These devices typically are not used in hospital OR environments or where lifesaving equipment is used, because when they are “tripped” or activated by a ground fault, they interrupt the power supply until they are manually reset.

It is hoped that the aforementioned models will serve to enhance the understanding of the following text, which is a more detailed discussion of some basic electrical principles in relation to equipment commonly used in hospital environments.

Basic concepts of electricity

Electricity is the flow of electrons from one point to another through a substance that is capable of conducting them. When electrons flow in a constant single direction, the current is said to be a *direct current* (DC); when the flow cyclically changes direction, it is known as an *alternating current* (AC). The frequency with which the current alternates is measured in terms of cycles per second or, equivalently, hertz (Hz).

A defibrillator delivers a short DC pulse intended to effect cardioversion. Household outlets in many countries (such as in the United States) supply a standardized AC source of 110 volts at 60 Hz to power electrical equipment. A rectifier can convert AC to DC power.

Voltage (V), the potential difference between two points of a conductor (points A and B in Fig. 23.3), is measured in *volts*. Electrons move through a conductor when a potential difference (voltage) and a conduction path exist. Current (I), the number of electrons per second flowing between the two points,

Figure 23.3. Basic principle of electricity.

is measured in amperes. Resistance (R) is a measure of how difficult it is for current to flow through the conductor. The typical unit of measure for resistance is ohms.

The simple flow of electricity through a conductor as described by voltage, current, and resistance is completely analogous to the flow of water through a garden hose connected to a spigot at point A with an open end at point B. As the tap is opened, a difference in pressure (voltage) between points A and B drives a stream of water (current) down the hose. A kink in the hose (resistance) slows the flow of water from A to B (reduces the electrical current), even though the pressure difference remains the same. If the tap is opened further, more water will flow, even though the resistance has not changed.

This somewhat intuitive relationship among voltage, current, and resistance leads to the most basic law of electrical engineering, Ohm's law. Qualitatively, the current is proportional to the voltage between two points and inversely proportional to the resistance. Thus, these three parameters are interrelated by Ohm's law:

$$I \propto V \quad \text{and} \quad I \propto 1/R$$

$$V = I \times R$$

Concept of grounding

Figure 23.4 shows the supply of electricity from a wall outlet that powers a piece of electrical equipment. Point A is the live terminal of the power source, and point B is the neutral terminal. The potential difference or voltage between points A and B alternates between +110 V and -110 V at a frequency of 60 Hz (in the United States) so that together they constitute an alternating current source. When an electrical device is plugged into an outlet, it contacts both points A and B and completes an electrical circuit between them. Current then flows between the two points – through the equipment – providing power for lights, gauges, pumps, computers, and other equipment.

The neutral terminal of an electrical outlet is connected to a very large conductor capable of receiving an infinite amount of electrical charge. This large conductor is the earth, which provides the most common and accessible voltage reference for electrical circuits and equipment. An electrical connection to the earth typically is referred to as earth or ground, and things

Figure 23.4. Concept of grounding.

that are thus connected are said to be grounded. A conductor that is grounded loses its charge and assumes a neutral potential relative to the earth. This is the concept of grounding that is the basic principle of electrical safety.

When someone plugs a piece of household electrical equipment into an outlet, he or she also is connected to the earth ground either directly or capacitively through his or her environment. Because both the person and the neutral outlet terminal are grounded, they are at the same voltage and the person could touch that terminal without issue. The live terminal, however, has an alternating voltage relative to the earth, and touching that terminal would drive current through the person to ground – resulting in an electrical shock.

Modern outlets have added a third terminal, the ground terminal, illustrated as point C in Fig. 23.4. This terminal provides a backup safety path to ground to avoid electrical shock or arcing in cases in which the electrical equipment is somehow compromised. Typically, external metallic cases of electrical equipment are connected directly to the ground terminal of the outlet – reducing the potential for a person to contact a non-grounded surface.

The outlet described earlier is quite sufficient for most household uses. However, in areas likely to come in contact with water, such as kitchens, bathrooms, and outdoor areas, safety is supplemented through the use of GFCIs. These devices are set to trip, or turn off the current source, whenever they detect a difference in current flowing in the live and neutral wires; the assumption is that the current difference represents current flowing from the live wire through an individual to ground. GFCIs work very well in most homes, where shutting down a piece of equipment is unlikely to have severe consequences. However, they are not used in ORs because of the risk of interrupting power to a piece of lifesaving equipment.

In the modern OR, two other electrical devices are commonly used to reduce the possibility of electrical shock: line isolation transformers (LITs) and LIMs. An LIT serves to isolate the circuitry providing power to OR equipment from the base power supply of the hospital that is connected to an earth ground. Creating an isolated (or floating) power supply separates the alternating current source that powers the equipment from earth ground completely. This protects clinical workers and patients by reducing the possibility of a shock due to an electrical short or ground fault within the equipment. A perfectly isolated power supply does not allow any current to flow from either terminal to earth ground. Therefore, a *single* short between earth ground and either of the isolated power supply's terminals will *not* result in arcing or shock. The floating power supply will simply “float” to the new potential and continue to operate. This has obvious advantages over GFCI protection as it allows OR equipment to operate continuously, even in the case of an earth ground fault.

It should be noted that an isolated power supply that is shorted to the earth-based power supply reverts to earth-based power supply behavior. That is, a *second fault* would lead to a short circuit that may result in arcing, shock, and/or loss of

Figure 23.5. Line isolation.

power due to a circuit breaker. Of note, isolated power supplies are sometimes referred to as *ungrounded*. This term has become part of the nomenclature, but it can be somewhat confusing. In the strictest sense, the isolated power supply still has a circuit ground – generally taken to be one of the power terminals. The distinction is simply that this is not an earth ground but rather a *floating ground*. Hence, the term *unearthed* may be more appropriate than *ungrounded*.

Working in conjunction with an LIT is an LIM (Fig. 23.5). As discussed earlier, the LIM constantly monitors the isolated power supply and determines the current that *could* flow to earth ground if either of the isolated terminals *were* to be shorted to ground. The LIM alarms when the current that *could* flow in that case, reaches a preset limit. Although a ground fault may lead to an LIM alarm, a more likely cause of a LIM alarm is the buildup of small current “leakages” from all the equipment connected to the isolated power supply and from the LIT itself. When these small leakages add up to a current sizeable enough to harm the patient, the LIM alarms.

It should be noted that *microshocks*, discussed later, may be a result of currents well below the sensitivity of a typical LIM and the LIM does NOT protect against microshock.

Interestingly, there is not universal agreement regarding the installation and use of isolated OR power supplies and devices as such as LIMs. Some argue that the incidence of medical device failures that result in patient or caregiver harm is not well quantified and that evidence should be provided to justify the cost and maintenance of these systems. It should be noted further that these complicated electrical safety systems are not without their own issues. For example, it has been reported that LIMs have produced spike-like electrocardiographic (ECG) interference.

Presently, OR design is guided by the National Fire Protection Association 99 (NFPA 99) Standard for Health Care Facilities, 2005. The scope of this document is to establish criteria to minimize the hazards of fire, explosion, and electricity in health care facilities providing services to humans.

ECRI, formerly the Emergency Care Research Institute (www.ECRI.org), is a nonprofit organization with the mission of bringing the discipline of applied scientific research to health care to uncover the best approaches to improving patient care.

The 2010 NFPA 99 document is pending at the time of this writing. This proposed standard is worded to require that isolated power, or other protective mechanisms, be included in ORs by default, and may be omitted only when a risk assessment indicates it is not needed. ECRI has submitted commentary to the NFPA because ECRI does not believe that isolated power offers significant electrical safety benefits for most ORs. The evidence demonstrating adverse incidents is lacking. Of note, there may be exceptions, such as rooms in which large amounts of fluids are routinely present on the floor; in these cases, isolated power is advisable. However, ECRI believes it is reasonable for most ORs not to have isolated power, and that this can be decided for specific rooms or facilities on an individual basis when there are special concerns (personal communication).

Electrical hazards in the operating room environment

Electric shock

An electric shock occurs when the human body contacts any source of voltage high enough to cause sufficient current through the tissues.

Static electricity

In earlier days, when highly flammable volatile anesthetic agents such as diethyl ether were used, most anesthetic equipment (including the anesthesiologist’s shoes) was required to be “antistatic” to prevent discharge of static electricity. Static electricity is produced by surface contact that builds up an electrical charge that gets discharged when the surface comes into contact with a conductor. This discharge is sufficient to produce a spark that may cause a fire in the presence of highly flammable anesthetics.

Macroshock

Macroshock is caused by large voltages or currents applied to the skin or tissues. The effects of the current passing through human tissue depend on the strength of the current (Table 23.1). Electrical burns usually are caused by high-density current if the strength is $>100 \text{ mA/cm}^2$.

Table 23.1 Effects of 60-Hz AC on an average human for a 1-second duration of contact

Current	Effect
Macroshock	
1 mA (0.001 A)	Threshold of perception
5 mA (0.005 A)	Threshold of pain and accepted as maximum harmless current intensity
10–20 mA	“Let-go” current before sustained muscle contraction
50 mA	Pain, possible fainting, mechanical injury; heart and respiratory functions continue
100–300 mA	Ventricular fibrillation will start, but respiratory center remains intact
6000 mA	Sustained myocardial contractions, followed by normal heart rhythm; temporary respiratory paralysis; burns if current density is high
Microshock	
100 μ A (0.1 mA)	Ventricular fibrillation
10 μ A (0.01 mA)	Recommended maximum allowable 60-Hz leakage current

Reproduced with permission from Ehrenwerth J. Electrical safety. In: Ehrenwerth J, Eisenkraft JB, eds. *Anesthesia Equipment Principles and Applications*. St. Louis: Mosby-Year Book Inc.; 1993.

Microshock

Microshock is caused by small voltages or currents applied directly or in close proximity to the heart. Microshock may be applied intentionally, as in pacemaker electrodes; however, when it occurs inadvertently, it may lead to life-threatening cardiac dysrhythmias such as ventricular fibrillation. Saline-filled central venous catheters and arterial lines are potential sources of microshock if the electrodes of the transducers come in contact with an electrical source. The present design of pressure transducers is such that they are connected to the monitors by means of telephone cables using very small voltages, thus they are relatively safer than older models.

Surface ECG electrodes are relatively safe with regard to producing microshock. With the increasing use of monitored anesthesia care for interventional radiologic procedures, and given the number of indwelling catheters filled with electrolyte solution, the potential for the electrical hazard of microshock exists and needs to be thoroughly understood by the anesthesiologist and all members of the team.

The American National Standards Institute has set 10 μ A as the maximum allowable current leakage level in the connections of catheters and electrodes contacting the heart. LIMs cannot detect this small leakage because 2 mA (i.e., 2000 times larger) is the level at which LIMs warn of leakage.

Electrical hazards from surgical diathermy

Electrically operated surgical electrocautery units discharge high-intensity currents through a pointed tip to a small surface area of high resistance. This generates intense heat in the area, causing tissue coagulation and cutting. The electrocautery units discharge currents at very high frequency levels, in the range of 300 kHz to 2 MHz. Because excitable tissues cannot respond to

such high frequencies, frequency electrocautery currents do not cause ventricular fibrillation.

Two types of electrosurgical electrocautery units are commonly used by surgeons: unipolar and the bipolar. In unipolar electrocautery, the more commonly used modality, the current is passed through the tip of the pencil point equipment (active electrode), which passes through the tissues of the patient, and the circuit is completed by the passage of current through the dispersive electrode pad or return pad (sometimes incorrectly referred to as the grounding pad). The return pad is often applied to the patient's body surface. This pad should be applied to a wide surface area well coated with conducting gel, and as far from the heart as possible. Burns may occur if the area is dry of gel, or if the contact of the dispersive electrode pad is poor if, for example, it is applied to very hairy skin. Similarly, when a patient becomes wet, which commonly happens during surgery, the electrocautery current may take different routes other than the return electrode. ECG electrodes may become the alternate route for completion of the circuit and may cause electrical burns if the return electrode contact is defective.

Bipolar electrocautery is commonly used by neurosurgeons and vascular surgeons. In this mode, the cauterization is done by an appliance resembling forceps with two prongs. The current is discharged by one prong and passes through the tissue and then through the other prong back to the console of the electrosurgical unit.

Another, newer modality, known as the argon beam coagulator, is also a type of electrocautery; anesthesiologists should not confuse it with argon beam lasers. A jet of ionized argon gas carries electrical charge from a probe to tissue. This system also utilizes a return electrode from the patient, as in conventional electrocautery.

Many concerns with electrical safety in the OR arise from the use of electrosurgical units, because they can cause electric shock, burns, explosions, arrhythmias, and disturbances in pacemakers. In patients who have cardiac pacemakers, electrocautery units may cause interference with the pacemaker's discharge of cardiac impulses. Unipolar units may be more hazardous than bipolar ones in patients with implanted pacemakers. Hence, for these patients, bipolar electrocautery is advised whenever possible. If unipolar electrocautery is used, the return electrode pad should be placed so that the path of the current from the operative site to the return electrode does not cross the pacemaker. Backup plans with appropriate pacemaker magnets and pharmacologic support should always be available. Though beyond the scope of this chapter, one must exercise extreme caution when utilizing electrical equipment in the presence of oxygen sources.

In summary, to prevent electrical hazards in the OR environment, the following points are noteworthy:

- Anesthesiologists should be aware of the concepts of electricity in general and know specifically about the circuitry in their particular hospital.

- They also should have a thorough knowledge of the operating principles of anesthetic and electrosurgical equipment.
- Proper maintenance of electrical equipment such as monitors, anesthetic machines, modern vaporizers, and electrocautery units is paramount for electrical safety. All equipment should be checked at regular intervals for electrical leakage and other malfunctions.
- Meticulous efforts should be undertaken to prevent macro- and microshock.
- There should be interaction among all the OR personnel with respect to the application and use of electrical equipment such as electrosurgical units.
- In special situations, such as patients with cardiac pacemakers, anesthesiologists should be well prepared to prevent patient morbidity due to the use of electrical equipment.

Acknowledgments

Hemodynamic patient monitoring

Amit Asopa, Theodore E. Dushane, and Swaminathan Karthik

Anesthesiologists have many and varied perioperative roles. Clearly, one of the most important roles is serving as the ever-vigilant set of “eyes” to ensure patient safety. Despite the introduction of new methods to monitor the anesthetized patient, hemodynamic monitoring and the analysis of these well-known parameters remain central to assessing patient well-being.

Standards for basic anesthetic monitoring

In an effort to ensure patient safety, the American Society of Anesthesiologists (ASA) has created “Standards for Basic Anesthetic Monitoring” (approved by the ASA House of Delegates on October 21, 1986 and last affirmed on October 25, 2005).

In general:

These standards apply to all anesthesia care although, in emergency circumstances, appropriate life support measures take precedence. These standards may be exceeded at any time based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but observing them cannot guarantee any specific patient outcome. They are subject to revision from time to time, as warranted by the evolution of technology and practice. They apply to all general anesthetics, regional anesthetics, and monitored anesthesia care. This set of standards addresses only the issue of basic anesthetic monitoring, which is one component of anesthesia care. In certain rare or unusual circumstances 1) some of these methods of monitoring may be clinically impractical and 2) appropriate use of the described monitoring methods may fail to detect untoward clinical developments. Brief interruptions of continual[†] monitoring may be unavoidable. These standards are not intended for application to the care of the obstetrical patient in labor or in the conduct of pain management.

STANDARD I states, “Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics and monitored anesthesia care.”

STANDARD II states, “During all anesthetics, the patient’s oxygenation, ventilation, circulation and temperature shall be continually evaluated.”

Standard II includes specific recommendations with regard to hemodynamic evaluation.

Specifically, Standard II aims to “ensure the adequacy of the patient’s circulatory function during all anesthetics”:

1. Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.*
2. Every patient receiving anesthesia shall have arterial blood pressure and heart rate determined and evaluated at least every five minutes.*
3. Every patient receiving general anesthesia shall have, in addition to the above, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

The need for real-time invasive hemodynamic data versus noninvasive assessment of cardiovascular function is determined by several factors, including the ASA physical status, type of surgery, anticipated blood loss, and likelihood for hemodynamic instability during surgery. The ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery can be used as a risk assessment tool.

Of note, “These guidelines are intended for physicians and nonphysician caregivers who are involved in the preoperative, operative, and postoperative care of patients undergoing noncardiac surgery. They provide a framework for considering cardiac risk of noncardiac surgery in a variety of patient and surgical situations.”

Hemodynamic monitoring is an essential part of every anesthetic and includes directly or indirectly monitoring pressure, flow, and resistance in the arterial and venous systems of every patient. The ASA standards of basic anesthetic monitoring require assessment of adequate circulatory function during all anesthetics, including measurement of arterial blood pressure (ABP) and heart rate at least every 5 minutes and continuously monitoring the electrocardiogram (ECG). Other clinical signs, such as skin and mucosal color, palpation of a peripheral pulse, and auscultation of heart sounds, may aid in the assessment of the cardiovascular system. An adequate signal from a pulse

[†] Note that “continual” is defined as “repeated regularly and frequently in steady rapid succession,” whereas “continuous” means “prolonged without any interruption at any time.”

* Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient’s medical record.

Table 24.1. Methods for NIBP measurement

Auscultatory	<ul style="list-style-type: none"> • 1st Korotkoff sound at systolic pressure • Disappearance of sounds at diastolic pressure • Mean pressure may be estimated as diastolic pressure + 1/3 pulse pressure
Oscillatory	<ul style="list-style-type: none"> • Uses the oscillation of the mercury column to determine the mean arterial pressure • The basis of automated sphygmomanometers • Pressure at maximal oscillations closely estimates mean arterial pressure • Pressures at 50% of maximal oscillation on either side of the mean pressure yield estimates of the systolic and diastolic pressures • Cannot be used in the presence of nonpulsatile flow, such as during cardiopulmonary bypass or when an LVAD is in place
Palpation	<ul style="list-style-type: none"> • Appearance of a distal pulse at systolic pressure • Cannot determine diastolic or mean pressure
Ultrasound Arterial tonometry	<ul style="list-style-type: none"> • Similar to palpation • Uses the principle of photoplethysmography • Blood flow detected by reflectance of infrared light • Dynamic pressure applied by cuff to determine real-time pressures • Might potentially work during cardiopulmonary bypass

LVAD, left ventricular assist device

oximeter or the presence of expired CO₂ on capnography may be a gross indicator of circulation.

The need for real-time invasive hemodynamic data versus continual noninvasive assessment of cardiovascular function is determined by the acuity of the patient, type of surgery, and physiologic reserve of the patient.

Noninvasive arterial blood pressure monitoring

Noninvasive arterial blood pressure (NIBP) monitoring may involve direct palpation, use of a Doppler probe, auscultation, arterial tonometry, or more commonly, oscillometry. Several methods of NIBP estimation are described in Table 24.1.

Automated NIBP machines frequently use the oscillometric method. Blood pressure cuff oscillations are sensed by a transducer. The lowest cuff pressure with the greatest average oscillation amplitude is sensed as the mean arterial pressure (MAP). Systolic and diastolic blood pressures are determined by identifying the cuff pressures where the amplitudes of oscillations are specific ratios of the maximum oscillation amplitude.

Here are some important points to consider:

- Cuff width influences the accuracy of blood pressure measurements. A narrow cuff may overestimate blood pressure, whereas a wide cuff may underestimate the pressure. This is because the pressure necessary to occlude

Table 24.2. Complications of NIBP monitoring

- Bruising and petechiae formation
- Neuropathy
- Measurement errors
- Limb ischemia

the artery is greater with a narrow cuff and less with a wide one. Importantly, a narrow cuff more greatly *overestimates* the systolic blood pressure than a wide cuff *underestimates* the systolic blood pressure.

- Patient movement during oscillometric measurement, including shivering, may cause artifact and can result in inaccurate measurement.
- Counter-intuitively, more peripheral arterial measurements result in an exaggeration of the systolic and pulse pressures as the result of changes in the waveform morphology. For example, the dorsalis pedis artery pressure reading may be higher than the aortic root pressure. It should also be noted that changes in vascular resistance, such as from hypothermic cardiopulmonary bypass and vasodilating drugs, can further affect relative differences in pressure measurements recorded from site to site.
- Korotkoff described five sounds heard when taking blood pressure measurements with the auscultatory method. Typically, systolic blood pressure is measured as the pressure at which the first Korotkoff sound is first heard, whereas diastolic blood pressure measured as the pressure at which the fourth Korotkoff sound is just audible. Interestingly, the mechanism by which Korotkoff sounds are generated has not been well understood and many theories exist.
- The auscultatory gap is the period during which sounds indicating true systolic pressure fade away and reappear at a lower pressure point. Failure to recognize this gap can result in not indentifying hypertensive patients.

Potential complications of NIBP monitoring are listed in Table 24.2.

Invasive pressure monitoring

Principles of invasive pressure monitoring

Placing a hollow cannula in a vessel of the cardiovascular system connecting to calibrated transducers with a fluid-filled high-pressure tubing system allows for accurate invasive pressure measurements (Table 24.3). Cannulas may be placed in

Table 24.3. Checklist for invasive monitoring

- Intravascular cannula (arterial line/CVC/PAC)
- Infusion and tubing
- Transducer
- Display screen
- Mechanism for zeroing and calibration

virtually any portion of the cardiovascular system. Commonly, they are placed in central or peripheral arteries for arterial pressure, the superior vena cava or right atrium for central venous pressure (CVP), and the pulmonary artery for pulmonary artery pressure and pulmonary artery wedge pressure (PAWP).

Electronic transducer

The cannula is connected to high-pressure tubing that is filled with saline. This acts as a continuous column of fluid that transmits intraluminal pressure changes to the transducer diaphragm that oscillates in response to the pressure waveform. The movement is converted to an electrical signal by a transducer. The transducer accomplishes this by acting as part of a capacitor, inductor, or, most commonly, a strain gauge.

The strain gauge uses variable resistors, the electrical resistance of which increases with increasing length. The diaphragm of the transducer moves a small plate connected to four strain gauges. With any one movement, two gauges are compressed and the other two stretched. All four strain gauges form part of a Wheatstone bridge, increasing the sensitivity.

Calibration

Calibration is the process of validating a measurement technique or equipment. It was an important consideration for older electronic transducers. The standard calibration is a 50 microvolt change in potential per 10 mm Hg. Modern systems typically do not require external calibration because they are manufactured in a standardized manner to tight standards.

Zeroing

Zeroing removes the effect of atmospheric pressure on transmural pressure of the tubing system by exposing the transducer system to ambient atmospheric pressure. Zeroing is performed by opening the transducer to atmospheric pressure and electronically setting this atmospheric pressure to zero. Occasionally, this zero baseline may drift and should be checked frequently, because even a 5 mm Hg drift can represent a significant difference in low-pressure systems such as CVP.

Leveling

Leveling refers to the placement of an *already zeroed* transducer at a particular height where the pressures are sought to be measured (a reference point). The electrical transducer needs to be aligned to the superior aspect of the right atrium to measure the pressure at the level of the heart. This eliminates errors of measurement that might occur from the hydrostatic pressure exerted by the column of blood above or below the point of reference to be measured. A 10 cm change in height will increase or decrease the pressure reading by 7.5 mm Hg.

To standardize measurements, the position of the right atrium is assumed to be along the mid axillary line. For intracranial procedures, in which the pressure in the circle of Willis is important, the transducer may be leveled to the tragus.

Figure 24.1. Influence of hydrostatic pressure on monitoring arterial blood pressure.

Invasive blood pressure monitoring devices measure blood pressure at the *level of transducer* and are not affected by level of the insertion point in the extremity as long as the *transducer* is maintained level to the heart. NIBP measurement devices measure pressure at the level of peripheral artery. Therefore, if the NIBP measurements are made above or below the level of heart, then a correction for hydrostatic pressure should be made before extrapolating the pressure at the level of heart (Fig. 24.1).

Resonance and damping

The arterial pressure waveform can be represented as a sum of sine waves (using Fourier analysis). Transducer systems have their own natural oscillatory frequency, or resonant frequency, and if the resonant frequency of the transducer system coincides with one of the frequencies making a substantial contribution to the arterial waveform, resonance and subsequent distortion of the signal will occur. Arterial pressure monitoring is designed to keep its natural frequency above 40 Hz, which is above any of the frequencies making up the arterial waveform, thus minimizing resonance. Venous waveforms generally do not require high-frequency response systems because they do not have steep waves or high-frequency components of significant amplitude. Simply, the natural frequency of the *monitoring system* needs to exceed the natural frequency of the *arterial system*.

Damping is an effect that reduces the amplitude of oscillations in an oscillatory system. It acts to slow the rate of a change in signal. The amount of damping in a system is indicated by the damping coefficient (Fig. 24.2, Fig. 24.3), which describes how rapidly an oscillating system comes to rest.

Resonance is the tendency of a system to oscillate with larger amplitude at some frequencies than at others.

- Optimally damped: The system responds rapidly to a change in signal by allowing a small amount of overshoot (damping coefficient 0.7).
- Critically damped: No overshooting occurs, but the system may be too slow (damping coefficient 1.0).

Figure 24.2. Damping coefficient–natural frequency plot displaying different areas into which pressure monitoring systems fall. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

- **Underdamped:** Resonance occurs, causing the signal to oscillate and overshoot (damping coefficient < 0.7).
- **Overdamped:** The signal takes a long time to reach equilibrium but will not overshoot. It may not reach equilibrium in time for a true reading to be given (damping coefficient > 1.0). This may be the result of soft tubing, an air bubble, a blood clot, or a constriction.

Factors affecting errors in invasive monitoring

1. Zeroing error
2. Leveling error
3. Simultaneous infusion of fluids and drugs
 - Rapid administration of fluid in the CVP catheter will alter measurements
4. Variation with respiration
 - Variations occur in all pressure measurements with spontaneous and positive pressure ventilation
 - Considerable variations may occur in CVP and pulmonary artery pressures during both spontaneous ventilation and positive pressure ventilation
 - Variations may be the result of changes in intrapleural pressure during the respiratory cycle
 - All CVP/pulmonary artery measurements should be performed at end expiration, when intrapleural pressure is zero
 - Arterial pressure waveform variation with respiration may be suggestive of hypovolemia or other conditions, such as cardiac tamponade
5. Excessive positive end-expiratory pressure (PEEP)
 - Measured CVP is the intraluminal pressure
 - True filling pressure is the transmural pressure in the right atrium, which is equal to the right atrial pressure (RAP) minus the sum of intrathoracic pressure and intrapericardial pressure

Figure 24.3. Fast flush method to calculate natural frequency and damping coefficient of a pressure monitoring system as described by Gardner. The graph is at tracing speed of 25 mm/sec and shows the arterial pressure waveform and two square wave flush. Natural frequency is determined by measuring the period of one cycle between adjacent oscillation peaks (1.7 mm) and the recording speed (25 mm/sec). The natural frequency is $25 \text{ mm/sec} \times 1 \text{ cycle}/1.7 \text{ mm} = 14.7 \text{ Hz}$. The damping coefficient is determined by measuring the height of adjacent oscillation peaks (17 and 24 mm), calculating the ratio $(A_2/A_1)(17/24 = 0.71)$, and using the formula derived by Gardner: $D = \text{LN}\{(A_2/A_1)/[\pi^2 + \ln(A_2/A_1)]^{1/2}\}$ to arrive at damping coefficient (D) of 0.11. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

- As transmural pressure varies throughout the ventilatory cycle, there is a corresponding variation in venous return
- Application of PEEP increases intrathoracic pressure throughout the respiratory cycle
- Compliant lungs tend to transmit this pressure to the right atrium and impede venous return

Arterial pressure

Arterial pressure waveform

The systemic arterial blood pressure (ABP) waveform is generated when the blood is ejected from the left ventricle into the aorta during systole, followed by peripheral arterial runoff of this stroke volume during diastole (Fig. 24.4 and Fig. 24.5).

The morphology of ABP waveform changes as the wave travels from the aorta to the periphery. Compared with aortic pressures, peripheral arterial waveforms have a higher systolic pressure, a lower diastolic pressure, and thus a wider pulse pressure. The pulse arrives at the peripheral site after some delay, and this is seen in the waveform display. Pressure wave reflection off the tapering arterial tree is the predominant factor that influences the shape of the arterial blood pressure waveform. Patients with reduced arterial compliance (e.g., atherosclerosis, advancing age) have an increased pulse pressure, late systolic pressure peak, and disappearance of the diastolic pressure wave (Fig. 24.6), which is the result of an early return of the reflected pressure wave.

Figure 24.4. The systolic components following the R wave on ECG consist of (1) steep pressure upstroke, peak; (2) systolic peak pressure; and (3) decline, which correspond to the period of left ventricular systole. The down-slope is interrupted by the (4) aortic valve closure, which reflects aortic valve closure at end systole. The remaining decay of waveform, (5) diastolic runoff, occurs during diastole following the ECG T wave and reaches its nadir at end diastole, (6) end-diastolic pressure. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Indications for invasive arterial pressure monitoring include the following:

1. The need for real-time blood pressure monitoring
2. The need for repeated arterial blood gas sampling

Figure 24.5. Systolic (S) and diastolic (D) pressures are shown with arrows. Mean arterial pressure (MAP) is represented by the area beneath the arterial pressure curve divided by the beat period, and it incorporates the S and D portions of the cardiac cycle. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Figure 24.6. Arterial blood pressure waves recorded simultaneously from the aortic arch and femoral artery have different morphologies. In this example, the femoral artery waveform has a wider pulse pressure (1 and 2); a delayed upstroke (3); a delayed, slurred dicotic notch (arrows); and a more prominent diastolic wave following the dicotic notch. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

3. Unreliable noninvasive blood pressure; for example, during cardiopulmonary bypass, severe shock, extreme peripheral vasoconstriction, arrhythmias, severe burns, morbid obesity, or patients with an LVAD
4. Dynamic monitoring of fluid resuscitation: systolic pressure variation, mean pressure variation, or pulse pressure variation may be used as an indicator of volume status

Arterial line placement

The most common site for arterial line cannulation is the radial artery, given its superficial location and the presence of good collateral circulation. Other sites include the femoral, axillary, brachial, ulnar, dorsalis pedis, and posterior tibial arteries (Table 24.4).

Table 24.4. Sites of insertion of arterial lines

Radial	<ul style="list-style-type: none"> • Most commonly performed; technically easy • Allen’s test not shown to be predictive of ischemic sequelae
Ulnar	<ul style="list-style-type: none"> • Not recommended if multiple cannulation attempts were made on the ipsilateral radial artery
Brachial	<ul style="list-style-type: none"> • Primary source of hand blood flow • Risk of median nerve damage
Axillary	<ul style="list-style-type: none"> • Anatomic end artery • Risk of nerve injury • Good collateral circulation • Hematomas may be difficult to tamponade • Higher risk of air or atherosclerotic emboli into cerebral vessels
Femoral	<ul style="list-style-type: none"> • Risk of retroperitoneal hemorrhage • Large artery – ease of placement in emergencies • Risk of atherosclerotic emboli to lower extremity • Rarely used in pediatrics because of the high risk of thrombosis
Dorsalis pedis	<ul style="list-style-type: none"> • Overestimates systolic pressure
Posterior tibial	<ul style="list-style-type: none"> • Avoid in peripheral vascular disease

Figure 24.7 Positioning the wrist.

The Allen's test is used to demonstrate collateral circulation in a hand prior to cannulating the radial artery. After elevating the patient's hand and having the patient make a fist for 30 seconds, pressure is applied over the ulnar and radial arteries to occlude them. The hand is opened and ulnar pressure is released. If color does not return or returns after 7–10 seconds, then the ulnar arterial supply to the hand is considered not sufficient and the radial artery cannot be safely cannulated.

Utility of the test, however, is questionable as there are case reports of ischemic complications despite a normal Allen's test. Specifics of the surgery and the patient's characteristics often influence the site and side of arterial cannulation.

Several techniques of insertion of the arterial line are used, including direct arterial puncture, the Seldinger technique, and the transfixion-withdrawal technique. Ultrasound guidance can be of value in arterial line placement.

Technique

The wrist is placed in the supine position and dorsiflexed on a roll of gauze, thus stabilizing the artery and making it more superficial. A soft board and tape may be used to secure and position the wrist (Fig. 24.7). The radial artery is palpated between the bony head of the distal radius and the flexor carpi radialis tendon. The radial nerve is usually found lateral to the artery. Infiltration of local anesthetic around this area may prevent arterial spasm and also makes the procedure more tolerable for an awake patient.

Catheter over needle

A soft catheter mounted on a sharp metallic needle (or an intravenous catheter) is introduced at about a 45° angle. Once the pulsatile flash of blood is seen at the hub, the angle of the catheter is lowered to about 10° to 15°. The catheter-over-needle assembly is advanced a few millimeters to ensure that the tip of catheter is in the artery. The catheter is then advanced over the needle into the artery (Fig. 24.8).

Figure 24.8. Over-the-needle technique.

Catheter over wire (Seldinger technique)

A metallic hollow cannula is used to access the artery (with or without a syringe at the end of the needle). When pulsatile flow is seen, a guidewire is inserted through the cannula into the artery. Then, the hollow cannula is removed and a soft arterial catheter is advanced over the wire into the artery (Fig. 24.9).

Transfixation

Transfixation is a modification of the catheter-over-wire technique. Following entry of the cannula into the artery, the needle is advanced through the posterior wall of the artery. The cannula is then withdrawn slowly until pulsatile blood flow is seen. The guidewire is then advanced into the artery through the cannula. Then, the cannula is removed, and the soft arterial catheter is advanced over the wire into the artery.

Ultrasound or Doppler guidance may sometimes be required in cases of difficulty with blind techniques.

Ultrasound for arterial cannulation

Ultrasound may be used as an aid in the placement of arterial cannulas. All the techniques described previously can be used under ultrasound guidance. Improved success and decreased

Figure 24.9. Over-the-wire technique.

Figure 24.10. Radial artery short-axis view.

complications are some of the advantages of using ultrasound guidance. However, these benefits have not yet been shown consistently. Both short-axis (Fig. 24.10) and long-axis (Fig. 24.11) approaches may be used for cannulation.

Complications

Major complications are extremely rare in the absence of other contributing factors, such as previous arterial injury, protracted shock, high-dose vasopressor administration, prolonged cannulation, and severe atherosclerosis (Table 24.5).

Central venous and pulmonary artery pressure monitoring

Physiology

Blood returns to the right atrium and generates a pressure that is referred to as right atrial pressure (RAP) or central venous

Figure 24.11. Radial artery long-axis view.

Table 24.5. Complications of arterial catheterization

Mechanical complications	<ul style="list-style-type: none"> • Hematoma • Bleeding • Vasospasm • Pseudoaneurysm • Nerve damage • Atrioventricular fistula

pressure (CVP). The terms *right atrial pressure* and *central venous pressure* generally can be used interchangeably. Direct left atrial pressure (LAP) measurement is far less common than RAP measurement because of the inherent dangers in its measurement, most notably arterial air embolus and cardiac tamponade.

Cardiac preload is defined as the resting end-diastolic length of myofibrils and is clinically represented by end-diastolic right ventricular volume.

Pressure–volume dynamics

The relationship between change in volume and change in pressure yields a compliance curve. Pressure can be measured using a central venous catheter (CVC), whereas volume measurement is more difficult, requiring calculation. Therefore, this relationship between pressure and volume is used to extrapolate right ventricular end-diastolic volume from measured filling pressure or CVP. This pressure–volume compliance curve is not constant and varies among individuals and also under different physiologic conditions, even within the same patient. Thus, assessment of volume status from CVP is fraught with error. The reader is referred to elsewhere in the textbook for further discussion of the limitations of CVP in reflecting patient volume status.

Compliance = change in volume/change in pressure

In normal hearts, CVP also reflects the preload of the left ventricle. In patients with ventricular dysfunction or pulmonary vascular disease, this relationship is lost and a PAWP will be more reflective of LAP and left ventricular end diastolic volume.

CVP waveform

A tracing of the CVP yields three positive waves – a, c, and v – and two negative descents – x and y. These are described further in Table 24.6. Both the atria and the ventricles have systolic and diastolic phases. For clarity, the ventricular phases of the cardiac cycle are used to describe the timing of various events. Therefore, *systole* refers to ventricular systole. These phases can be identified most accurately if an ECG tracing is also used

Table 24.6. CVP/RAP waves

Component wave	Atrial phase	Ventricular phase	ECG phase	Causative event	Normal pressures, mm Hg
a wave	Systole	End diastole	P wave	Atrial contraction	2–7
c wave	Diastole	Isovolumic ventricular contraction	After R wave	Tricuspid valve motion toward the atrium	
x descent	Diastole	Late systole	S-T segment	Atrial relaxation and geometric changes due to ventricular systole	2–7
v wave	Diastole	Late systole to isovolumic ventricular relaxation	After T wave	Pressure produced when the blood filling the atrium comes up against a closed tricuspid valve	
y descent	Diastole	Early diastole		Atrial emptying into ventricle on opening of tricuspid valve	

Figure 24.12. CVP waves synchronized to ECG. (From Mark JB. *Atlas of Cardiovascular Monitoring*.)

Table 24.7. Uses of CVCs

- Measurement of CVP

- Administration of hypertonic solutions and parenteral nutrition
- Administration of chemotherapy, antibiotics, and immunosuppressants
- Hemodialysis and hemofiltration
- Diagnosis of dysrhythmias, particularly nodal rhythms

(Fig. 24.12). Electrical activity always precedes mechanical activity; there is usually a very short delay of less than 0.1 second before pressure changes are noted on the CVP waveform. Alterations in the ECG rhythm often are reflected in the CVP waveform, as explained later in this chapter.

Mean CVP is measured as the mean a-wave pressure and normally ranges from 2 to 6 mm Hg. It can be approximated by

averaging the a wave pressure and the trough of the y descent. (See also Tables 24.7 and 24.8.)

Abnormal CVP waves

Atrial arrhythmias

Because a coordinated atrial contraction does not occur in atrial flutter/fibrillation, an a wave will be absent from the CVP tracing. Occasional flutter waves may be discernible instead of a single a wave (Fig. 24.13).

Junctional rhythm and complete heart block

Atrial contraction is usually normally timed to coincide with ventricular diastole, thus allowing the tricuspid valve to open

Figure 24.13. Absent a wave as well as a larger c wave seen in atrial fibrillation. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Figure 24.14. Tall cannon a waves are the result of atrial contraction against a closed tricuspid valve.* denotes an example of a cannon wave. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

and allow blood flow. In cases of altered rhythms such as junctional rhythms, reentrant supraventricular tachycardia, or complete heart block, atrial contraction occurs during ventricular systole. Atrial contraction during tricuspid closure results in tall “cannon” a waves (Fig. 24.14). False cannon a waves can be produced when a transduced port passes through the mitral valve and detects right ventricular pressures.

a-c Wave

In cases in which the PR interval is shortened, the a and c waves may temporally appear to have merged, resulting in an a-c wave. In the case of tachycardia, diastolic shortening may result in v and a waves appearing fused.

Tricuspid regurgitation and decreased right ventricular compliance

Tricuspid regurgitation is a ventricular systolic event resulting in a rise in atrial pressure due to transmission of ventricular systolic pressure to the atrium. This coincides with the v wave of the atrium, resulting in a tall systolic c-v wave and an obliteration of the x descent (Fig. 24.15). Differential diagnosis includes conditions in which right atrial compliance is decreased, because this also may lead to a large v wave. Note that the common clinical sign of acute tricuspid regurgitation is an enlarged y-descent, whereas the common clinical sign of acute mitral regurgitation is a large v wave. This occurs because the compliance of the pulmonary veins is much lower than the compliance of the central venous system, so the regurgitant volume produces a larger pressure increase (v wave) in the left side compared with the right.

Figure 24.15. Tricuspid regurgitation showing tall c-v waves is shown with a lack of a well-defined x descent. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Figure 24.16. Tricuspid stenosis, with a tall a wave and a blunted y descent. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Tricuspid stenosis

In tricuspid stenosis, the higher pressure gradient required for flow across the tricuspid valve results in atrial hypertrophy as well as impedance of passive emptying of the atrium. Thus, a tall a wave and attenuated y wave are seen (Fig. 24.16). Decreased right ventricular compliance also may result in a tall a wave. Because right ventricular diastolic pressure is elevated when compliance is poor, a higher atrial pressure is required to fill the ventricle. This is achieved by more forceful contraction of the atrium.

Pericardial tamponade

Fluid in the pericardium results in decreased ventricular compliance, resulting in impairment of diastolic filling. Because the y wave occurs as the result of early diastolic filling, y-descent attenuation is seen in tamponade (Fig. 24.17). The x descent occurs during ventricular systole, which is unaffected by fluid in the pericardium.

Pericardial constriction

Chronic constrictive pericarditis results in similar hemodynamic alterations to that of pericardial tamponade restrictive. Diastolic filling of the ventricles is restricted, reducing stroke volume and cardiac output. As in tamponade, the x descent is unchanged but the y descent is prominent because of rapid initial filling of the ventricle, which is abruptly terminated by pericardial restraint. This is often described as the *M* or *W* configuration. Following the deep y descent, a mid-diastolic plateau is often seen, which is called the *dip and plateau* or the *square root sign* (Fig. 24.18).

Figure 24.17. Pericardial tamponade showing a dampened y descent. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Figure 24.18. Pericardial constriction showing deep x and y descents as well as a flutter curve after the y descent marked by an asterisk (*). (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Figure 24.19. The CVP pattern for right ventricular ischemia can mimic that seen in pericardial restriction or restrictive cardiomyopathy with pronounced x and y descents. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Right ventricular ischemia

Right ventricular ischemia depresses ventricular systole as well as diastole. Diastolic impairment results in a tall a wave. Systolic impairment may result in tricuspid regurgitation, causing a tall v wave, which may be accompanied by a deep x and y descent (Fig. 24.19). This may appear similar to the tracing seen in pericardial constriction.

Central venous cannulation

Seldinger’s technique of using a guidewire to insert central lines has become the standard method. An additional finder needle is often used in internal jugular venous access to decrease the incidence of carotid puncture with a large-bore needle. This step is typically omitted at other sites.

Ultrasound guidance may increase safety and is typically used at two stages: first, to surface-mark the anatomy of the

Figure 24.20. Landmarks and position for internal jugular venous cannulation.

target vessel, and second, to access the vein as well as visualize intraluminal placement of the guidewire in real time.

A number of sites for central venous cannulation are available (Table 24.9).

Internal jugular vein cannulation

For internal jugular vein (IJV) cannulation, the patient is placed in Trendelenburg position, which helps distend the vein. The IJV lies deep to the sternocleidomastoid muscle and follows a course from just anterior to the mastoid process to behind the sternoclavicular joint (Fig. 24.20). The IJV may be cannulated at different sites along the course, using landmarks or

Table 24.9. Insertion sites for central venous cannulation

Site	Location	Advantages	Disadvantages
Internal jugular	Central	<ul style="list-style-type: none"> Ease of access to the neck for the anesthesiologist Ease of floating PACs 	<ul style="list-style-type: none"> Risk of stroke from carotid punctures Difficult to place in patients with unstable cervical spine Difficult threading of catheter under clavicle

From Clutton-Brock TH, Hutton P. *Monitoring in Anaesthesia and Intensive Care* 1st ed. Edited by Hutton P. Philadelphia, PA: W.B. Saunders; 1994:145–155.

ultrasound guidance. A finder needle is invariably used in landmark-guided IJV cannulation to decrease the incidence of carotid punctures.

Anterior (high) approach

The IJV is cannulated at the level of the larynx. The needle is inserted along the medial border of the sternocleidomastoid, angled at 30° to the skin, and directed toward the ipsilateral nipple.

Middle approach

The cannula is inserted at the apex of the triangle formed by the two heads of the sternocleidomastoid muscle. This landmark is more reliable when carotid pulsation is weak or absent (as in cardiac arrest).

Posterior approach

The cannula is inserted along the lateral border of the sternocleidomastoid muscle at the level of the external jugular vein.

Subclavian vein cannulation

The subclavian vein is the continuation of the axillary vein and arises at the lateral border of the first rib. It passes over the first rib anterior to the subclavian artery, separated from it by the scalenus anterior, to join the IJV at the medial end of the clavicle (Fig. 24.21).

The insertion point is at the junction of medial third and middle third of the clavicle. This point is also marked by a notch that can be felt on the undersurface of the clavicle. The needle is introduced while aspirating under the clavicle at this point and is directed toward the sternal notch. When the vein has

Figure 24.21. Landmarks and position for subclavian vein cannulation.

been cannulated, the Seldinger technique is used to introduce the catheter over the wire. The subclavian vein cannot be compressed with direct pressure – therefore, this route is contraindicated in patients with a coagulopathy (Table 24.10).

It should be noted that there is a risk, in any patient, of inadvertent cannulation and even laceration of the subclavian artery. This can cause a large uncontrolled hemorrhage into the thoracic cavity. For this reason, many centers do not attempt percutaneous subclavian access without the personnel and equipment immediately available to accommodate this rare, but potentially catastrophic, complication.

Ultrasound for central venous cannulation

Vascular access by the landmark technique depends on the anatomic landmarks; however, anatomic variations often are encountered. In addition, vessels may be diminutive, thrombosed, or even absent in certain circumstances. Ultrasound offers the advantage of real-time visualization of the vessels, demonstrates patency and flow, and differentiates arteries from veins using color Doppler or pulse wave Doppler. B-mode ultrasound provides two-dimensional (2-D) images that can be used to examine structures in the transverse and longitudinal planes. For differentiation, arteries are pulsatile and difficult to compress with the ultrasound probe while veins are nonpulsatile and collapse or distend, depending on probe pressure, patient position, and respiration.

Ultrasound is becoming increasingly popular for CVC insertion because it has been shown to reduce the complication rate and allows for cost saving. The use of ultrasound has increased catheterization success rates, reduced the number of needle passes required for success, and decreased the incidence of complications compared with traditional landmark techniques. The Agency for Healthcare Research and Quality recommends the use of ultrasound guidance for placing CVCs to improve patient care and patient safety.

The *Guidance on the Use of Ultrasound Locating Devices for Placing Central Venous Catheters* from the National Institute for Clinical Excellence provides the following major recommendations:

- 2-D imaging ultrasound guidance is the preferred method for insertion of CVCs into the IJV in adults and children in elective situations.
- The use of 2-D imaging ultrasound guidance should be considered in most clinical circumstances in which CVC insertion is indicated.
- Everyone involved in placing CVCs using 2-D imaging ultrasound guidance should undertake appropriate training to achieve competence.
- Audio-guided Doppler ultrasound guidance is not recommended for CVC insertion.

The American College of Surgeons supports the uniform use of real-time ultrasound guidance for the placement of CVCs in all patients.

Table 24.10. Derived parameters

Derived parameter	Formula	Normal value
Cardiac index	CO/BSA	2.6–4.2 L/min/m ²
Systemic vascular resistance	(MAP – CVP)/CO × 80	900–1300 dyn * s/cm ⁵
Pulmonary vascular resistance	(MPAP – PAWP)/CO – 80	40–180 dyn * s/cm ⁵
Left ventricular stroke work	SV × (MAP – PAWP) × 0.0136	58–104 gm-m/beat
Right ventricular stroke work	SV – (MPAP – PAWP) × 0.0136	8–16 gm-m/beat
Stroke volume (SV)	CO/HR × 1000	60–100 ml/beat
Coronary artery perfusion pressure	Diastolic BP – PAWP	60–80 mm Hg
Arterial oxygen content (CaO ₂)	(0.0138 × Hb × SaO ₂) + (0.0031 × PaO ₂)	17–20 ml/dl
Venous oxygen content (CvO ₂)	(0.0138 × Hb × SvO ₂) + (0.0031 × PaO ₂)	12–15 ml/dl
A-V oxygen content difference [C(a-v)O ₂]	CaO ₂ – CvO ₂	4–6 ml/dl
Oxygen delivery	CaO ₂ × CO × 10	950–1150 ml/min
Oxygen consumption	[C(a-v)O ₂] × CO × 10	200–250 ml/min

A-V, arteriovenous; BP, blood pressure; BSA, body surface area; gm-m, gram-meter; Hb, hemoglobin; HR, heart rate; MAP, mean arterial pressure; MPAP, mean pulmonary artery pressure; SaO₂, arterial oxygen saturation; SvO₂, venous oxygen saturation.

However, ultrasound guidance does not eliminate all adverse outcomes. For example, difficulty in visualizing the tip of the inserted needle and the related potential for injury is driving the development of advanced ultrasound machines. Incorporating embedded sensors in both the needle and ultrasound probe, these new ultrasound machines are capable of tracking the tip of the needle in real time.

Performing real-time ultrasound-guided vessel cannulation

Ultrasound can be used to assist with venous cannulation of internal jugular or femoral veins at their usual locations. The subclavian vein is accessed at the level of the axillary vein. Asepsis is maintained by using sterile gel and a sterile sheath to cover the probe and cable. The vessels may be visualized in long-axis (Fig. 24.22) or short-axis (Fig. 24.23) views. Both views have

Figure 24.22. IJV with the guidewire visualized in long-axis view.

their advantages and disadvantages. The short-axis view of the vessel allows for simultaneous visualization of the artery, but the needle appears as a pinpoint. This may lead to confusion as to the exact location of the needle tip. Long-axis allows for visualization of the entire needle at all times but, depending on the patient and location, may or may not allow for simultaneous visualization of the artery. This may lead to inadvertent cannulation of the artery if care is not taken.

The image of the vessel to be cannulated should be kept in the middle of the screen while the needle is introduced. It is important to minimize pressure on the transducer, particularly for the internal jugular approach, as excessive pressure will distort the anatomy visualized, often compressing the internal jugular vein, making the placement of the needle more difficult. The needle is usually visible, but often its initial presence is seen as a distortion of local tissues. As the needle tip approaches the

Figure 24.23. IJV visualized in short-axis view. The normal relationship with the carotid artery also is seen in this view.

Figure 24.24. Access needle seen within the lumen of the IJV on real-time ultrasound.

anterior wall, an indentation is seen until a “give-way” sensation is felt and the vein re-expands. The needle tip should then be visible within the lumen (Fig. 24.24). The probe is temporarily set aside on a sterile drape and the guidewire passed in the usual way. The probe then may be used to confirm that the guidewire is within the lumen. Visualization of the guidewire in the correct vessel may not imply that the tip of the wire is in the vein or the right side of the heart; thus, it may still be necessary to use manometry or echocardiography to confirm venous access.

Pulmonary artery catheters

Pulmonary artery catheters (PACs) play a vital role in the hemodynamic monitoring of critically ill patients. However, there has been considerable debate about their use.

In 1993, the ASA published practice guidelines looking at the evidence supporting the clinical effectiveness of PACs; these guidelines were updated in 2003. The guidelines suggest that PAC monitoring may reduce perioperative complications if critical hemodynamic data obtained from an “appropriately” placed PAC are “accurately” interpreted and “appropriate” treatment is initiated.

“Assessment of the clinical effectiveness of Pulmonary Artery Catheters in Management of patients in intensive care (PAC-Man): a randomized controlled trial concluded that there is no clear evidence of benefit or harm in managing critically ill patients with a PAC. The decision to use PAC must be taken considering risks and benefits on a case by case basis.”

Measured and derived parameters

Measured parameters include the following:

- Intracardiac pressures (normal values mentioned)
 - CVP/RAP: 2 to 6 mm Hg
 - Pulmonary artery systolic pressure (PASP): 15 to 25 mm Hg
 - Pulmonary artery diastolic pressure (PADP): 8 to 15 mm Hg

- Mean pulmonary artery pressure (MPAP): approximated by $\text{PASP} + (2 \times \text{PADP})/3 = 10$ to 20 mm Hg
- PAWP: 6–12 mm Hg
- Thermodilution cardiac output (CO)
- Mixed venous oxygen saturation
- Calculation of shunt fractions and gradients
- PCWP may be used to indirectly assess left ventricular preload. This relationship is based on the assumption:

$$\text{PCWP} \cong \text{LAP} \cong \text{LVEDP} \cong \text{LVEDV}$$

Derived parameters are listed in Table 24.10.

Invasive methods to measure cardiac output

Fick principle

The Fick principle, developed by Adolf Eugen Fick, is based on the conservation of mass and states that the amount of a substance taken up by an organ (or whole body) per unit time is equal to the arterial minus venous concentration of the substance multiplied by blood flow.

This principle can be used to measure the blood flow through any organ that adds substances to, or removes substances from, the blood. The heart does not do either of these, but the CO equals the pulmonary blood flow and the lungs add oxygen to the blood and remove carbon dioxide from it. CO is a function of VO_2 , CaO_2 , and CvO_2 , where:

- VO_2 , oxygen consumption, can be measured from the difference in oxygen concentration between expired and inspired gas
- CvO_2 – venous oxygen content of blood
- CaO_2 – arterial oxygen content of blood

$$\text{CO} = \text{VO}_2 / (\text{CaO}_2 - \text{CvO}_2)$$

Substituting normal values, $\text{CO} = (250 \text{ ml/min}) / 5 \text{ ml dl}^{-1} = 50 \text{ dl/min} = 5 \text{ L/min}$

The Fick method is accurate and can be calculated using a PAC. Several variants of the basic method have been devised, but their accuracy usually is not validated.

Dilution techniques

Dye dilution technique

A known amount of dye is injected into the pulmonary artery, and its concentration is measured peripherally. A curve is generated and is graphed semi-logarithmically to correct for recirculation of the dye. CO is calculated from the injected dose, the area under the curve (AUC), and its duration (Fig. 24.25).

Thermodilution technique

A known volume of cold saline is injected through the port of a PAC. A distal thermistor measures temperature changes. The degree of change in the temperature is inversely proportional to the CO. A plot of temperature change against time gives a curve

Figure 24.25. CO is derived from the area under curve. Note that the curve is made by extrapolation. (From Allsager CM, Swanevelder J. Measuring cardiac output. *Br J Anaesth CEPD Rev* 2003; 3(1):15–19.)

similar to the dye curve (but without the second peak). CO is calculated using the Stewart-Hamilton equation. This makes certain assumptions:

1. Complete mixing of blood and indicator
2. No loss of indicator between the injection site and detection site and constant blood flow

$$\dot{Q} = \frac{n}{\int c dt} = \frac{k(T_{\text{core}} - T_{\text{indicator}}) V_{\text{indicator}}}{\int_{t_1}^{t_2} -\Delta T dt}$$

$$\dot{Q} = \frac{n}{\int c dt} = \frac{k(T_{\text{core}} - T_{\text{indicator}}) V_{\text{indicator}}}{\int_{t_1}^{t_2} -\Delta T dt}$$

The amount of indicator (n) is related to its mean concentration (c), CO (Q), and the time for which it is detected ($t_2 - t_1$).

Some newer catheters allow for continuous measurement by using a thermal filament. However, the accuracy of the thermal dilution technique may be influenced by various factors:

1. Right and left ventricular output may differ in the presence of a cardiac shunt.
2. Tricuspid or pulmonary valve regurgitation may cause underestimation or overestimation of CO.
3. Core blood temperatures may vary.
4. Positive pressure ventilation produces beat-to-beat variations in right ventricular stroke volume during the respiratory cycle; measured CO will depend on the timing of the bolus injection.
5. Volume of injectate: even small errors in injectate volume may result in errors of CO measurement.
6. Speed of injection: duration of injection should be brief (<3 seconds) and consistent across measurements.

7. Errors in measurement can be created by simultaneous administration of fluids at a significant rate, even if administered via a peripheral IV site.

Pulmonary artery catheter flotation

The PAC may be inserted in any of the large central veins. The right IJV is the preferred route, as it offers the straightest course to the right heart. When an RAP waveform is seen, approximately 20 cm from the right IJV (see CVP waveform section), the balloon is gently inflated with 1.0 to 1.5 ml of air and then advanced until it crosses the tricuspid valve.

The position of the PAC in the heart is recognized by different waveforms (Fig. 24.26). Right ventricular pressure is characterized by a marked increase in systolic pressure (systolic rise). The PAC then enters the right ventricular outflow tract and floats across the pulmonic valve into the main pulmonary artery. Often, this may be complicated by arrhythmias, as the catheter irritates the right ventricular infundibulum. The pulmonary arterial waveform is characterized by an increase in diastolic pressure (Fig. 24.27). On reaching wedge position, the waveform resembles an LAP waveform, with a, c, and v waves as described earlier. At this point, the balloon occludes the blood flow and creates a static column of blood between the catheter tip and the left atrium (Fig. 24.28). As a surrogate for LAP, the PAWP waveform shares many of its morphologic features: a and v waves and x and y descents are usually identifiable (Fig. 24.29). However, PAWP is a representation of LAP that is delayed by about 160 ms.

Guidelines for catheter placement

Guidelines for catheter placement are as follows:

1. Prior to insertion, proper assembly and functioning should be confirmed (Table 24.11).
2. A defibrillator and a transcutaneous pacemaker should be available.
3. As the balloon fills with air, it tends to float to nondependent regions; certain maneuvers help in flotation:
 - Head down aids flotation past the tricuspid valve.
 - Right tilt and/or head up aids flotation out of the right ventricle.
 - Head up may reduce the frequency of arrhythmias.
 - Valsalva maneuver and release during spontaneous ventilation increase right heart venous return and may help flotation.
 - Continuous positive airway pressure of 30 to 40 cm H₂O and release during mechanical ventilation increase right heart venous return and may help flotation.
4. Transesophageal echocardiography may be used to visualize the catheter position during flotation.
5. Typical distances observed when placing a PAC from the RIJ insertion site are mentioned in Table 24.12.

Figure 24.26. Pressure waveforms recorded from a PAC as it passes through the heart. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Complications of pulmonary artery catheterization are listed in Table 24.13.

Minimally invasive hemodynamic monitors

- Esophageal Doppler:** The esophageal Doppler monitor measures blood flow velocity in the descending thoracic aorta using a flexible ultrasound probe. This is then combined with estimated aortic cross-sectional area to give stroke volume and cardiac output measurements. Disadvantages include that the aortic cross-sectional area is typically taken from stored normograms, which limits accuracy. Erroneous readings may also result from suboptimal probe positioning. Advantages include that the device is simple to use and does not require access to the circulation. There are many clinical studies proving its utility. Further, it can calculate corrected flow time (FTc) as a measure of cardiac preload and thus be used to monitor volume responsiveness in goal-directed therapy. Of note, the ultrasound CO monitor (USCOM) is a completely noninvasive Doppler device that measures CO from a suprasternal Doppler probe.
- Lithium dilution device:** Lithium chloride is injected into either a peripheral or a central vein, and lithium concentration decay is then measured with a lithium-sensitive electrode attached to an arterial line. Cardiac output is then calculated by integrating the area under the curve of concentration versus time. Disadvantages include that the system requires access to the circulation with repetitive blood draws and that nondepolarizing neuromuscular antagonists interfere with the sensor and can give erroneous results. Advantages include ease of setup and continuous CO measurement.

Figure 24.27. The diastolic contour helps distinguish right ventricular from pulmonary artery pressure. (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

with just one arterial line. Further, it can be used to measure stroke volume and stroke volume variation for use in goal directed therapy.

- Partial nonbreathing systems:** These systems use the Fick method for determining CO. Disadvantages include many technical difficulties, including that changes in dead space or V/Q matching affect CO measurement. The device also measures only CO and is not useful for evaluating intravascular volume and fluid responsiveness. Advantages include that the device is easy to set up, it does not require access to the circulation, and it provides for continuous CO determination.

- Arterial pulse contour analysis:** The origin of the pulse contour method for estimation of beat-to-beat stroke volume is based on the Windkessel (air chamber) model described by Otto Frank in 1899. The Windkessel effect is the distension of the aorta when blood is ejected from the left ventricle. Advanced statistical principles are applied to the arterial pressure tracing to calculate cardiac output. Disadvantages of this method include requirement for access to the circulation and the need for a high-fidelity arterial waveform. Initial systems required calibration, although a newly released device requires no calibration with an intravascular indicator and does not need to be

Figure 24.28. In the wedged position, the PAC creates a static column of blood connecting the catheter tip to a junction point, where flow resumes in the pulmonary veins (PV) near the left atrium (LA). (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Figure 24.29. The PAWP waveform generally displays two pressure peaks (a and v waves) compared with the CVP tracing, which displays three pressure peaks (a, c, and v waves). Note that the a and v waves of the PAWP trace are delayed relative to the CVP trace, both because the right ventricle normally contracts before the left ventricle and because of the timing delays in the propagation of left atrial waves to an occluded pulmonary artery (Modified from Mark JB. *Atlas of Cardiovascular Monitoring*.)

Table 24.11. Components of a typical PAC

Component	Function
Proximal lumen	<ul style="list-style-type: none"> Measures RAP Injects fluid for thermodilution CO

recalibrated during hemodynamic instability. Advantages include its ease of use, the need for only an arterial line (no central line), continuous CO measurements are provided, and stroke volume and stroke volume variation can be measured.

- **Transpulmonary thermodilution technique (TTT):** The TTT system uses a central line to calculate CO by transpulmonary thermodilution and an arterial line (femoral, axillary or brachial, but *not* radial) as a pulse contour device to measure CO. Disadvantages include the requirement of a central line *and* arterial catheter placed in a major artery. As such, the technology is not truly minimally invasive. Advantages include the provision of continuous CO measurements, estimation of extravascular fluid, and use in goal-directed therapy. Further, the system can be used with in-situ arterial and central lines.
- **Thoracic electrical bioimpedance (TEB):** TEB is based on the assumption that thoracic impedance is dependent on the blood flow within thoracic cavity. High-frequency low-amplitude current is transmitted from electrodes and the impedance to the current flow is measured with

another set of electrodes. Disadvantages include that the system relies on numerous mathematical assumptions and is prone to errors from hemodynamic instability, arrhythmias, changes in venous blood and lung water, ventilation, electrocautery, and surgical manipulation. Although the device is completely noninvasive, current iterations of the technology do not suggest that the device will become a routine modality for measuring CO.

In a well-written recent study, Harvey et al. note that of the available minimally invasive CO monitors, the esophageal Doppler and arterial pulse contour devices have the best likelihood of replacing the PAC for CO measurement. Further, both the esophageal Doppler and the arterial pulse contour devices have been shown to reduce postoperative morbidity when used with an intraoperative goal-directed fluid strategy.

The electrocardiogram and approach to diagnosis of common abnormalities

Usha B. Tedrow

In 1924, William Einthoven received the Nobel Prize in Medicine for his description of the electrical waves coming from the heart measured at the body surface. He named the components of the waves, which are discussed later, and identified many disease states of the heart associated with abnormalities of these waves. The electrocardiogram (ECG), as we use it today, is an essential tool for the management of patients. It represents a variety of vectors from each of the body surface electrodes placed in standard fashion. The information gleaned from these vectors can give information about heart rhythm disorders, presence of ischemic heart disease, cardiomyopathy, and even some extracardiac processes.

The ECG is printed on standard paper with single square millimeter boxes and heavier 5-mm increments. These heavier increments are further demarcated into 25-mm square boxes. The standard paper speed is 25 mm/sec, so the 25-mm squares each represent 1 second of time, the 5-mm increments represent 200 ms, and the 1-mm boxes represent 40 ms. The amplitude of the signals is determined by the standardization signal at the upper left of the ECG, indicating the number of boxes for a 1-mV signal. A normal standardization shows 10 mm for a 1-mV signal (Fig. 25.1), although in patients with hypertrophy, standardization may be only 5 mm.

Figure 25.1. Grid, standardization, and measurements for ECG.

ECG leads

There are two types of leads represented on the surface ECG: limb leads and precordial leads. The limb leads are the result of vectors between electrodes placed on the right arm, left arm, right leg, and left leg. The standard precordial leads are derived from electrodes placed on the anterior chest wall from the sternum to the midaxillary line.

Limb leads

Limb lead I has the negative electrode on the right arm and the positive electrode on the left arm, and points at 0° in the cardiac frontal plane (Fig. 25.2). Therefore, right-sided cardiac impulses create a positive deflection in lead I, and left-sided cardiac impulses create a negative deflection in lead I. Limb lead II has the negative electrode on the right arm and the positive electrode on the left leg and points at 60° in the frontal plane. Limb lead III has the negative electrode on the left arm and the positive electrode on the left leg, and points at 120° in the frontal

Figure 25.2. Frontal plane axis. The standard and augmented limb leads are shown on a plot of the frontal plane axis. The curved arrow indicates the range of normal axis, from -30° to 110° .

plane. Leads II and III, along with lead aVF (described later) are the “inferior” leads. Impulses initiating from high to low in the heart inscribe a positive deflection on these leads, whereas an impulse from near the diaphragmatic surface heading in a more superior direction would inscribe a negative deflection.

The augmented limb leads are aVL, aVR, and aVF. The augmented vector left (aVL) has a positive electrode on the left arm and a shared negative electrode on the right arm and left leg, and it points at -30° (Fig. 25.2). This lead gives left–right information similar to lead I. The augmented vector right (aVR) points at -150° and has a positive electrode on the right arm and a shared negative electrode on the left arm and left leg. It is sometimes termed an *intracavitary* lead because it can give vector information about the direction of endocardial activation of the left ventricle. Last, lead aVF, the augmented vector foot, is formed by the positive electrode on the left leg and the combined negative electrode on the right and left arms. This lead points at 90° and is one of the inferior leads.

Precordial leads

The standard precordial leads in adults are placed across the left chest. They are unipolar leads, unlike the limb leads discussed earlier. Their negative electrode is a shared common ground for the whole ECG system, called the Wilson’s central terminal. The positive electrode for V_1 is placed to the right of the sternum at the fourth intercostal space. The electrode for V_2 is placed opposite, to the left of the sternum at the fourth intercostal space. V_4 is placed at the midclavicular line in the fifth intercostal space, and V_3 is placed between V_2 and V_4 . V_6 is placed at the midaxillary line, and V_5 is placed between V_4 and V_6 . The precordial leads give a horizontal depiction of the cardiac activation, in contrast to the limb leads, which give a depiction of the vertical axis. Leads V_1 and V_2 give an idea of the direction of ventricular basal septal activation, and V_5 and V_6 give an idea of apical left ventricular activation.

Electrical events in the heart

The normal heartbeat originates from the sinoatrial node, a structure located on the outside (epicardial) surface of the junction between the superior vena cava and the right atrium. The signal from these pacemaker cells propagates through the atrium to the atrioventricular (AV) node, located at the junction between the atria and the ventricles at the septum. The atrial depolarization is from high to low and therefore produces a positive P-wave deflection in the inferior ECG leads (II, III, and aVF).

The AV node has slow conduction relative to the rest of the myocardium and acts mainly to delay impulses traveling from atrium to ventricle, producing the isoelectric component of the PR interval. The AV node consists of a compact portion and two or three lobes that join with the His bundle, the beginning of the His–Purkinje system, located at the anterior aspect of the ventricular side of the tricuspid annulus. In contrast to the AV node, the His–Purkinje system, consisting of the right and left

bundle branches, has very rapid conduction relative to the rest of the myocardium; therefore, conduction spreads rapidly down the bundle branches, with subsequent activation from apex to base. The left bundle branch is activated slightly before the right, producing the initial upward deflection in V_1 in normal hearts and the physiologic septal Q waves in V_6 . Ventricular depolarization proceeds from endocardium to epicardium, inscribing the rest of the QRS complex (Fig. 25.1). Ventricular repolarization then produces the ST segment and T wave.

A place to start

As is the case for chest radiography or other diagnostic tests, it is important to have a system for assessing the ECG, so that both important and subtle ECG abnormalities are discovered. One proposed sequence for looking at the ECG is to evaluate the rate, rhythm axis, and intervals and then turn to chamber enlargement, bundle branch blocks, and ST-T-wave abnormalities.

Rate

A normal adult heart rate is between 60 and 100 bpm; slower rates are considered bradycardia and faster ones tachycardia. The heart rate can be estimated by taking the number of milliseconds between heartbeats and dividing it into 60,000 ms/min. For example, if there are 10 1-mm boxes between QRS complexes, each representing 40 ms, or a total of 400 ms/beat, this would yield a heart rate of 150 bpm (60,000 ms/min divided by 400 ms/ = 150 bpm). For irregular rhythms, the number of QRS complexes on a rhythm strip in 3 seconds multiplied by 20 can give an estimate of the average heart rate.

Rhythm

The assessment of heart rhythm is more challenging. First, is there a P wave in front of each QRS complex? Does the P wave look like a sinus rhythm P wave (positive in the inferior leads)? Is the rhythm regular or irregular? Are there more P waves than QRS complexes, such as in atrial flutter, or are there more QRS complexes than P waves, as in ventricular tachycardia? Is pacing present?

Bradycardia

If bradycardia is identified, typically defined as a heart rate less than 60 bpm, it requires further assessment for the etiology. Young, healthy athletes may have asymptomatic sinus bradycardia and even sinus pauses nocturnally due to vagal tone. However, older patients with age-related sinus node dysfunction also may have sinus bradycardia or even junctional rhythm. Sinus bradycardia has a P wave in front of each QRS complex with a fixed PR interval. If the P waves are regular, the PR interval prolongs with each successive beat, and ultimately there are blocked P waves with no accompanying QRS complex, this is considered second-degree heart block, Mobitz type I (Fig. 25.3). This suggests an AV conduction problem at the level of the AV node. If the P waves are regular and the PR interval is fixed with blocked

Sinus Bradycardia

Figure 25.3. Bradycardia.

P waves, this is a second-degree Mobitz type II block. Mobitz II is more serious than Mobitz I in that Mobitz II suggests a diseased infranodal conduction system and potentially unreliable ventricular rhythm. Even more serious is complete heart block, in which the P waves are regular and normal to bradycardic in rate, the QRS complexes are regular, there is AV dissociation, and the ventricular rate is slower than the atrial rate. Whereas complete heart block may occur paroxysmally related to delay in the AV node, complete AV block often is an unstable rhythm associated with a severely diseased distal conduction system and an unreliable ventricular escape.

Tachycardia

Patients with tachycardia also warrant close inspection of the ECG to determine the etiology. Sinus tachycardia – a heart rate >100 bpm and P waves positive in the inferior leads, similar to normal sinus rhythm – is most common. Etiologies include pain, hypovolemia, and hyperadrenergic states such as hyperthyroidism. More rarely, sinus tachycardia may be an

intrinsic state (inappropriate sinus tachycardia) or even the consequence of sinus node reentry.

Narrow complex (QRS < 120 ms) or supraventricular tachycardias (SVTs) are divided into regular and irregular categories (Fig. 25.4). Regular tachycardias include several entities. Atrial tachycardia, in which the P wave is different from that of sinus rhythm, has an RP that is longer than the PR interval. AV node reentrant tachycardia is the result of a reentrant circuit involving the tissue of the AV node and most typically has an RP that is exceedingly short, because the atria and ventricles are activated nearly simultaneously. AV-reciprocating tachycardia is a circuit involving an accessory pathway for the retrograde limb; it also has a short RP, but the retrograde conduction times are slightly longer than for AV node reentrant tachycardia. Common atrial flutter is a regular tachycardia caused by a large macroreentrant circuit with a wave front revolving around the tricuspid annulus. In typical counterclockwise atrial flutter, the wave front proceeds up the atrial septum and down the right atrial free wall, inscribing negative P waves in the inferior leads. Patients in

Atrial Fibrillation

Figure 25.4. Narrow tachycardia.

typical atrial flutter may present with variable heart rates but often present with a heart rate near 150 bpm with P waves at twice the ventricular rate (Fig. 25.4). Regular narrow complex tachycardias, including junctional ectopic tachycardia and junctional reciprocating tachycardia, are rarer in adults but more common in the pediatric population.

Irregular narrow complex rhythms include multifocal atrial tachycardia (Fig. 25.4), in which there are P waves in front of each QRS complex, but they are of differing morphologies. A minimum of three different P waves is required to diagnose multifocal atrial tachycardia. The arrhythmia is commonly secondary to an active pulmonary process. In contrast, atrial fibrillation is irregularly irregular, with no clear P waves seen.

Wide complex rhythms (QRS duration >120 ms) are more challenging. They may result from a supraventricular rhythm with bundle branch block (see later). Ventricular tachycardia is marked by evidence of AV dissociation, sometimes with fusion or capture beats interrupting the rhythm. These beats represent AV conduction capturing the ventricle during AV dissociation, and one is marked C in Fig. 25.5. Ventricular pacing also may produce a wide complex. More rarely, an accessory pathway acting as the antegrade limb for SVT also may produce a wide complex rhythm.

Special scenario: accessory pathways and Wolff–Parkinson–White syndrome

When the normal His–Purkinje system is bypassed by a band of myocardial tissue connecting the atrium and ventricle, this is termed an *atrioventricular bypass tract*. Bypass tracts or accessory pathways allow antegrade-only, retrograde-only, or bidirectional conduction. Antegrade-only conducting accessory pathways are rare, occur most commonly on the right side of the heart, and connect atrial tissue to portions of the right bundle branch. Because they insert directly into Purkinje tissue, these are called *atriofascicular fibers*, also known as *Mahaim fibers*. In contrast, retrograde-only AV accessory pathways are called *concealed* because their existence is not apparent on the surface ECG; however, the pathway can still support orthodromic AV reentry. Wolff–Parkinson–White (WPW) syndrome is defined as occurring in the setting of a bidirectional conduction accessory pathway.

WPW syndrome is a common cause of SVT and atrial fibrillation, and may be a cause of sudden cardiac death. In sinus rhythm, the ECG demonstrates a delta wave: fusion of conduction down the normal His–Purkinje system and the accessory pathway producing a slurred upstroke to the QRS complex and a shortened PR interval (Fig. 25.6). During AV reentry

Ventricular Tachycardia with Capture Beat

Ventricular Pacing

Atrial Pacing with Bundle Branch Block

Figure 25.5. Wide complex.

tachycardia (AVRT), the arrhythmia may be orthodromic with conduction down the normal AV node and His–Purkinje system and retrograde conduction up the pathway. In this setting, the QRS complex is narrow in tachycardia and no delta wave is seen, because the accessory pathway is being used for the retrograde limb of the tachycardia (as seen in Fig. 25.4).

Less commonly, the AVRT circuit also may proceed in the opposite direction, with conduction down the accessory pathway and retrograde up the AV node, termed *antidromic AVRT*. The tachycardia in this case is a regular wide complex tachycardia that at times is difficult to distinguish from

ventricular tachycardia. In WPW syndrome, the accessory pathway refractory period may be exceedingly short, allowing for rapid conduction to the ventricles not possible via the AV node. The presence of the accessory pathway itself also predisposes to atrial fibrillation. The danger of sudden cardiac death in WPW syndrome comes in the setting of atrial fibrillation when the accessory pathway refractory period is short. In this situation, conduction through the pathway may be exceedingly rapid (Fig. 25.7), producing a rapid, irregular, wide complex rhythm. Because of the rapid ventricular conduction, degeneration to ventricular fibrillation is possible.

Figure 25.6. Delta wave.

Axis

The normal frontal plane axis ranges from -30° to 110° (Fig. 25.2). More negative axes are termed *left axis deviation* and more positive ones are known as *right axis deviation*. If leads I and II are completely positive, the frontal plane axis is normal. If lead I is positive and leads II and III are negative, there is left axis deviation. If lead I is positive, lead III is negative, and lead II is indeterminate, this is a leftward but physiologic axis (Fig. 25.8). Conversely, if lead I is negative, there is right axis deviation, usually accompanied by positive deflections in the inferior leads.

Figure 25.7. Preexcited atrial fibrillation in WPW syndrome.

Figure 25.8. Normal and left frontal plane axis.

Figure 25.9. ECG intervals.

When thinking about the axis, it is important to consider the causes of an abnormal axis. Common causes of left axis deviation include left ventricular hypertrophy (LVH), left anterior hemiblock, elevated hemidiaphragm, and posterior pathway preexcitation in WPW syndrome. Causes of right axis deviation may include mechanical shifts due to emphysema or pneumothorax, right ventricular hypertrophy, left posterior hemiblock, anterior pathway preexcitation in WPW, and dextrocardia.

Intervals

The normal intervals on surface ECG should be assessed from the limb leads only, and from the lead that gives the longest measurement. The upper limit of the PR interval (Fig. 25.9) is 200 ms, or five 40-ms 1-mm boxes. Prolongation of the PR interval suggests so-called first-degree AV block. The upper limit of

normal QRS duration is 120 ms, or three 1-mm boxes. Prolongation suggests ventricular myocardial conduction delay, in the form of a bundle branch block, preexcitation, ectopic ventricular beats, or ventricular pacing.

The QT interval is heart-rate-dependent and is normally shorter at faster heart rates and longer at slower ones. Thus, an instantaneous measurement of the QT should be corrected to the QTc using Bazett's formula to account for the heart rate dependence. The QTc is equal to the measured QT divided by the square root of the RR interval in seconds. For a heart rate of 60 bpm, the QTc is equal to the measured QT. A normal QTc ranges from 300 to 450 ms. Prolongation of the QT may be congenital, as in congenital long QT syndrome. (See Fig. 25.10.)

Perhaps more importantly, however, QT prolongation may be drug induced. Antiarrhythmic drugs, methadone, phenothiazines, and macrolide antibiotics are frequent causative agents (www.Qtdrugs.org). Dramatic QT prolongation is associated with sudden cardiac arrest due to torsades de pointes and therefore is very important to recognize. Drug-induced torsades de pointes is typically induced by a short-long-short interval sequence with a characteristic undulating disorganized ventricular arrhythmia that follows (Fig. 25.11).

Chamber enlargement

P-wave morphology can help determine whether there is atrial enlargement or abnormality. Leads II and V₁ give the best assessment of atrial enlargement. If the P wave is more than 2.5 1-mm boxes wide (100 ms) in lead II (Fig. 25.12), this suggests left atrial enlargement. Supporting evidence is that the larger component of the P wave in V₁ is downgoing and at least a 1-mm square in size. Conversely, right atrial enlargement is suggested by a P wave that is more than 2.5 1-mm boxes in height.

Figure 25.10. ECG with QT prolongation.

Figure 25.11. Torsades de pointes.

An upgoing component to the P wave in lead V_1 is also supportive of right atrial enlargement.

The QRS morphology can give evidence of LVH. The following assumes a normal QRS duration. A simple criterion for LVH is an R wave in $aVL > 11$ mm, as seen in Fig. 25.13. An S wave in lead V_2 or V_3 plus an R wave in $V_5 > 35$ mm also suggest LVH. A leftward axis (as in Fig. 25.8) or frank left axis deviation may accompany LVH. Additionally, repolarization abnormalities consequent to strain are often seen in the lateral and apical leads in this setting.

Bundle branch blocks

Bundle branch blocks occur when there is disease of the His–Purkinje system causing more delay in one of the bundle branches relative to the other. Bundle branch block may be caused by ischemia or infarction of the heart, cardiomyopathy, or age-related calcification. Because the His–Purkinje tissue has more rapid conduction than the surrounding myocardium, when the bundle branches are functioning normally, the QRS complex is narrow. When one of the bundle branches is diseased, conduction proceeds rapidly down the unaffected bundle branch, then propagates more slowly through the myocardium on the affected side. The result is lengthening of the QRS duration beyond 120 ms (three 1-mm boxes). Additionally, when the QRS is prolonged, the normal axis of the T wave (repolarization) is opposite the main axis of the QRS, also known as appropriate T-wave discordance.

Left Atrial Enlargement

Right Atrial Enlargement

Figure 25.12. Atrial enlargement.

Left bundle branch block

In the case of left bundle branch block, the complex is mainly downgoing in lead V_1 with a QS wave or rS wave in lead V_1 and a monotonic R wave in leads I and V_6 . The example in Fig. 25.14 shows an rS in lead V_1 (small R wave, large S wave). It also is notable in the example that where the QRS is downgoing (leads V_1 – V_3), the T wave is upgoing. Conversely, where the QRS is upgoing (e.g., in leads II, III, and aVF), the T wave is downgoing. Left bundle branch block does not completely preclude the diagnosis of ischemia or infarction in patients with chest pain. ST-segment or T-wave changes from a baseline ECG may indicate ischemia or infarction. Normally, T-wave changes are in the direction opposite the major QRS deflection. Certain findings are highly suggestive of acute infarction, including ST elevation ≥ 1 mm in same direction as the major deflection of the QRS complex, ST depression > 1 mm in V_1 through V_3 , and ST elevation > 5 mm in the opposite direction of the major deflection of QRS.

Fascicular blocks or hemiblocks

The left bundle has two fascicles: anterior and posterior. Block of only one of these results in a hemiblock, also known as a fascicular block. Left anterior hemiblock manifests as left axis deviation without a discernable cause, whereas left posterior hemiblock presents as marked right axis deviation. The QRS duration typically is between 100 and 120 ms. The left axis deviation seen in Fig. 25.8 is an example of left anterior hemiblock.

Right bundle branch block

In right bundle branch block, the complex in V_1 is mainly positive with a terminal R wave. The complex may have an rSR' pattern, as shown in Fig. 25.15, but a qR or an R wave also is acceptable. There also should be a slurred S wave in leads I and V_6 , which is seen best in lead I in our example. Interestingly, in right bundle branch block, some leads are wide and others are narrow. In the narrow leads (e.g., I, V_5 , and V_6), the T wave is the same direction as the QRS complex. In the wide leads (e.g., III and V_1 – V_3), the T wave again exhibits normal T-wave discordance, with the T wave opposite the main axis of the QRS. These are all part of the normal repolarization pattern in right bundle branch block. Ischemia and infarction are identified more readily in right bundle branch block and have similar criteria to those described in the following section.

Figure 25.13. Left ventricular hypertrophy.

ST and T waves

Ischemia and infarction

An important application of the ECG and the analysis of ST segments and T waves is the diagnosis of ischemia and infarction. Acute infarction is the result of a coronary artery occlusion. Early phases of infarction may display tall-peaked T waves on the surface ECG, called *hyperacute T waves*. As early as minutes into the infarction, ST-segment elevation (Fig. 25.16) is seen in characteristic leads. Infarction of a small territory can also manifest as ST-segment depression or T-wave inversion in some patients. Injury usually is not reversible without prompt restoration of blood flow to the myocardium. In

contrast, ischemia is caused by an insufficient blood supply to meet the demands of the myocardium. Ischemia usually is a combination of fixed coronary narrowing and increased myocardial demand (e.g., hypertension, tachycardia, anemia, metabolic stress) and can be controlled in most settings by decreasing myocardial demand with medication. The ECG in ischemia most typically shows ST-segment depression but also may show T-wave inversion.

The coronary arteries usually supply stereotypic areas of the heart, reflected in particular leads on the surface ECG. The left anterior descending coronary artery supplies the anterior

Figure 25.14. Left bundle branch block.

Figure 25.15. Right bundle branch block.

wall, the anteroseptum, and the anteroapex of the left ventricle. Leads V_1 and V_2 represent the septum, V_3 and V_4 represent the midanterior wall, and V_5 and V_6 represent the anteroapex. The left anterior descending coronary artery usually has diagonal branches supplying the lateral wall, represented by leads I and aVL. The right coronary artery supplies the inferior wall of the left ventricle in most patients and is represented on the surface ECG by leads II, III, and aVF, the inferior leads. The left circumflex supplies the posterior wall in most patients, and depending on the size of the artery, it also may supply some

of the inferior and even lateral territory. The posterior wall is least well seen on surface ECG, but acute injury can manifest as ST-segment depression in V_1 and V_2 (opposite that seen in the anterior wall). Right ventricular infarction also may be difficult to discern on surface ECG, but if a right-sided precordial rV_4 lead is placed (at the right midclavicular line at the fifth intercostal space), ST-segment elevation can confirm right ventricular infarction.

If coronary blood flow is not restored quickly after an acute infarction, Q waves will develop in the infarcted zones.

Figure 25.16. Acute myocardial infarction.

Figure 25.17. Old myocardial infarction.

Pathologic Q waves generally are defined as those lasting 40 ms (one 1-mm box) or with an amplitude 25% of the QRS complex. T-wave inversions appear next and may persist for weeks; if they persist beyond 6 weeks, this suggests development of an aneurysm.

Figure 25.16 shows an acute anterior infarction due to occlusion of a large left anterior descending coronary artery. This artery was large enough to “wrap around” some of the inferior wall and produce the ST-segment elevation in the inferior leads. Fig. 25.17 shows the same patient weeks later, with resolution of most of the ST-segment elevation and repolarization change. Large pathologic Q waves are present in leads V₁ through V₅ as well as leads III and aVF.

It is important to mention that other entities can mimic myocardial ischemia and infarction. Repolarization abnormalities with strain in LVH can produce T-wave inversion and ST-segment depression. Early repolarization and rare entities such as Brugada syndrome may produce ST-segment elevation. WPW syndrome can produce Q waves similar to those seen in old infarction because of preexcitation of the ventricle via an accessory pathway. Pericarditis and electrolyte abnormalities such as hyperkalemia also can mimic acute ischemia and infarction.

Electrolyte abnormalities

Many electrolyte abnormalities can produce characteristic changes on the surface ECG. Hyperkalemia causes dramatic prolongation of the cardiac action potential. Signs of hyperkalemia on ECG include tall-peaked T waves, which sometimes

are confused with the early stages of acute myocardial infarction (hyperacute T waves). The QRS complex may become prolonged in a pattern often uncharacteristic of a typical bundle branch block pattern (Fig. 25.18), and the heart rate may be slowed. P waves may be reduced in amplitude or may be absent. The PR interval may be prolonged, and AV dissociation may be present. When hyperkalemia is severe (e.g., >7.0 mmol/L), both bradyarrhythmias and ventricular tachycardia may occur. Pacemaker systems also may fail to capture the myocardium in this setting despite good positioning of the leads and other connections. Hypokalemia, in contrast, can produce an ECG similar to that seen in hypocalcemia (discussed later). There may be flattening of the T waves or even ST depression or T-wave inversion; a prominent U wave may be seen as well.

In hypercalcemia, the action potential repolarization is accelerated, which can produce tall-peaking T waves with a slightly shortened QT interval. When hypercalcemia is severe, the QRS may become broadened, in a pattern very similar to that seen in hyperkalemia. In the setting of hypocalcemia (Fig. 25.18), the QT interval is prolonged consequent to delayed action potential repolarization. The T waves are characteristically flattened, sometimes with a prominent U wave. The QRS typically is narrow. The PR interval may be shortened, and the ST segment may be slightly depressed.

Digitalis effect and toxicity

Digitalis (or digoxin) blocks the sodium–potassium adenosine triphosphatase-mediated exchanger in myocardial cells and also has modest vagolytic properties. The normal effect of

Hyperkalemia

Hypocalcemia

Figure 25.18. Common electrolyte abnormalities.

Figure 25.19. Digitalis effect/toxicity.

digoxin compounds is to slow the heart rate without lowering blood pressure, although this effect is limited in the setting of high sympathetic tone. Digoxin also mildly increases contractility, although an important effect in outcomes of heart failure populations has not been consistently demonstrated. At normal levels, slight depression of the ST segment is often seen, predominantly in V₃ through V₆, and is termed *digitalis effect*; it is not evidence of toxicity. At higher doses, toxicity may be present. It is important to remember that digitalis toxicity is a continuum and that despite a “normal” digoxin level, a susceptible patient may have toxicity if his or her clinical syndrome is characteristic. The classic arrhythmia seen in early digitalis toxicity is paroxysmal atrial tachycardia with block. The patient in Fig. 25.19 has classic signs of digitalis effect, seen in leads V₅ and V₆, but also has an oddly slow atrial tachycardia with prolonged PR interval, suggesting digitalis toxicity. As the degree of toxicity worsens, bradyarrhythmias and ventricular tachycardia may be present. To reverse toxicity in this setting, use of the antidote compound Digibind (GlaxoSmith-Kline, Research Triangle Park, NC), a purified Fab fragment of a digoxin-specific antibody raised in sheep, should be considered. Ventricular arrhythmias, when present, are best treated with the sodium channel blocker phenytoin or lidocaine, and temporary pacing should be considered to bridge the patient through bradyarrhythmias.

Summary

Overall, when approaching the surface ECG, it is important to have an organized system for looking at the large amount of information contained therein. Suggested in this chapter is a system for looking at the rate, rhythm, axis, and intervals. This

is followed by assessment of chamber enlargement and bundle branch blocks. Last, ST and T waves are examined carefully for evidence of ischemia and infarction or metabolic derangement. Although not exhaustive, this system may give the reader a starting point for learning more about the surface ECG and its implications.

Pulse oximetry and capnography

Zhiling Xiong and Bhavani S. Kodali

Pulse oximetry

Pulse oximetry (oximeter) is a standard of care for monitoring oxygen during anesthesia. It is a noninvasive method of measuring oxygen saturation of hemoglobin (SpO_2) on a continuous basis to detect hypoxia. The device displays digital numbers for oxygen saturation and pulse rate, in addition to a continuous display of perfusion waveform (plethysmography).

Principles of pulse oximetry

The general principle of pulse oximetry is based on the Beer-Lambert law. It is a measurement of the transmission of red (600- to 750-nm wavelength) and infrared (850- to 1000-nm) light through the pulsatile tissue beds, which subsequently determines the light absorption characteristics of oxygenated and deoxygenated hemoglobin (Hb). According to the Beer-Lambert law, the intensity of transmitted light decreases exponentially as both the concentration of the substance (due to absorption) and the distance traveled through the substance increase. Oxygenated Hb absorbs more infrared light and allows more red light to pass through, thus appearing bright red to the naked eye. In contrast, deoxygenated (or reduced) Hb absorbs more red light and allows more infrared light to pass through, thus appearing blue or cyanotic (Fig. 26.1).

Sensing the pulsatile arterial flow is required for pulse oximetry to work. At the measuring site, many constant light absorbers are always present. These include the skin, soft tissue, bone, as well as venous, capillary, and nonpulsatile components of arterial blood, all constituting baseline absorption of the light. The pulsatile expansion of the arteriolar bed increases the light path length and further increases light absorbency over the baseline (Beer-Lambert law; see earlier). This change in light absorption during arterial pulsation is the basis of oximetry determinations. The variation in the absorbability of light during pulsatile flow compared with baseline is displayed as the arterial waveform (plethysmography).

Pulse oximetry sensor

The pulse oximetry sensor consists of a pair of small red (R; 660-nm) and infrared (IR; 940-nm) light-emitting diodes (LEDs) and a single silicone photodetector mounted inside a rigid

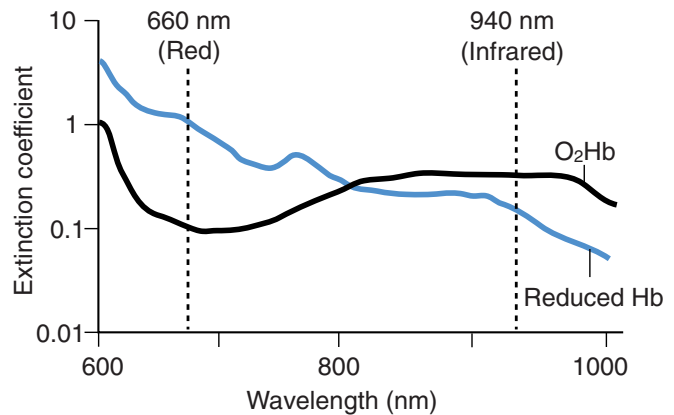

Figure 26.1. Hemoglobin light spectrum absorption curve. The *black curve* denotes the oxygenated hemoglobin (O_2Hb), and the *blue curve* denotes the deoxygenated (reduced) hemoglobin. The two *vertical dotted lines* represent wavelengths in the red (660-nm) and infrared (940-nm) parts of the spectrum used by the LEDs of pulse oximeters.

spring-loaded clip, a flexible probe, or an adhesive wrap. The sensor is placed on a translucent site of the patient's body such as a fingertip, toe, earlobe, nose, lip, or even the foot or palm (for an infant).

There are two modes of sending light through the measuring site: transmittance and reflectance. In the transmittance sensor (Fig. 26.2), the LEDs and photodetector are opposite each other, with the measuring site between them. The light passes through the site. In the reflectance mode, the LEDs and photodetector are mounted side by side on top of the measuring site, and the light bounces from the LEDs to the detector across the site. The transmittance mode is the more commonly used type.

Figure 26.2. Fingertip pulse oximetry sensor.

The absorption ratio of R/IR is calculated by a microprocessor and is compared with a “lookup” table (based on experimental studies in healthy human volunteers) that converts the ratio to an SpO₂ value. For example, an R/IR ratio of 0.5 equates to approximately 100% SpO₂, 1.0 to approximately 85% SpO₂, and 2.0 to 0% SpO₂.

Functional versus fractional hemoglobin saturations

It should be noted that the SpO₂ measured by pulse oximetry differs from the arterial oxygen saturation (SaO₂) measured by a laboratory carbon monoxide (CO) oximeter. Pulse oximetry measures the functional Hb SaO₂, which is defined as Hb capable of carrying oxygen. It is the ratio of oxyhemoglobin (O₂Hb) to O₂Hb plus reduced Hb:

$$\text{Functional SaO}_2 = \text{O}_2\text{Hb}/(\text{O}_2\text{Hb} + \text{reduced Hb}).$$

Laboratory CO-oximeters measure the fractional Hb SaO₂, which is defined as the ratio of O₂Hb to total Hb, which includes nonfunctional Hb such as methemoglobin (MetHb) and carboxyhemoglobin (COHb; incapable of carrying oxygen):

$$\text{Fractional SaO}_2 = \text{O}_2\text{Hb}/(\text{O}_2\text{Hb} + \text{reduced Hb} + \text{MetHb} + \text{COHb}).$$

Therefore, the SpO₂ number measured by pulse oximetry (functional SaO₂) should be higher than the SaO₂ reported by the laboratory blood gas. In the usual clinical circumstances, however, patients' concentrations of MetHb and COHb are so low that the values of both functional and fractional saturations are nearly identical.

Calibration and practical limitations

Pulse oximeters are calibrated during manufacture, and their internal circuits are automatically checked when they are switched on; they cannot be altered by users. They are accurate in the range of oxygen saturations from 70% to 100%, with a standard error of $\pm 2\%$, but less accurate in the range of 70% to 50% ($\pm 3\%$).

Pulse oximeters have been used widely for monitoring patients' oxygenation and pulse rates in a variety of clinical settings, including perioperative, intensive care unit, and intravenous (IV) conscious sedation cases. Their use has improved the margin of safety for patients. However, pulse oximetry provides no indication of the adequacy of ventilation because of lack of information about CO₂ level. In addition, several factors and clinical situations limit the effectiveness and accuracy of pulse oximetry, including:

1. Nonfunctional hemoglobins (COHb and MetHb). The light absorption of COHb and O₂Hb at 660 nm is identical, meaning the COHb is red and “detected” by pulse oximetry as O₂Hb; therefore, in the presence of a large amount of COHb (e.g., in patients with CO poisoning or

heavy tobacco smokers), the pulse oximetries read the sum of O₂Hb and COHb, registering a falsely high SpO₂ reading. In this situation, CO oximetry is required to measure the COHb level. In contrast, MetHb has the same absorption at 660-nm and 940-nm wavelengths. This 1:1 absorption ratio is interpreted by pulse oximetry as 85% of SpO₂ regardless of the true saturation.

2. A reduction in peripheral pulsatile blood flow due to vasoconstriction, hypovolemia, severe hypotension, hypothermia, or shock.
3. Surgical dyes such as methylene blue, indocyanine green, and indigo carmine. These transiently decrease pulse oximetry readings and absorb light in the region of 660 nm.
4. Excessive ambient lights, such as the high-intensity overhead lights in operating rooms or some IR heat lamps. These may interfere with photodetector signal sensing.
5. Artifacts due to motion, shivering, and radiofrequency diathermy apparatus.
6. Nail polish, especially black, blue, and green.

In summary, pulse oximetry is a mandatory monitor for patients receiving anesthesia, and it plays an important role in early detection of hypoxia. Although it rarely may cause local tissue injury due to the heat (from the light source) and sensor pressure, there are no contraindications for its use. “New-generation” pulse oximetry with advanced technology has demonstrated significant improvement in the ability to read through motion and low perfusion states, thus making this medical device more reliable.

Capnography

Capnography is the continuous monitoring of instantaneous CO₂ concentration using a graphic display (waveform) in respired gas. This CO₂ waveform is also called a *capnogram*, and a device that generates the CO₂ waveform is called a *capnograph*. Use of capnographic monitoring can reliably and quantitatively provide vital respiratory information of intubated patients. Alterations in cardiac output, distribution of pulmonary blood flow, and metabolic activity may also be reflected by the change of CO₂ concentration in expired gases. The American Society of Anesthesiologists mandates the use of capnography in all patients undergoing anesthesia. Many intensive care units use capnography as an adjunct to ensure patient safety and the adequacy of ventilation.

Principles of capnography

Whereas a variety of techniques may be used for CO₂ measurement, such as mass spectrometry, Raman scattering, and photoacoustic measurement, by far the most widely used method is IR absorption spectrometry. The principle of this technique is based on the fact that CO₂ is a polyatomic gas that absorbs IR radiation of a specific wavelength. CO₂ shows strong absorption in the far IR light at 4.3 μm , which lies way beyond the visible

Figure 26.3. Normal capnogram with three phases of expiration: phase I, dead space; phase II, mixture of dead space and alveolar gas; phase III, alveolar gas plateau. Point X delineates the PETCO₂, which is the best reflection of the alveolar CO₂ tension.

wavelength (0.4–0.8 μm). The basic elements of IR spectrometry include an IR light source, a sample chamber, and an IR detector. The absorption of the IR light also is governed by the Beer-Lambert law, that is, the absorption is proportional to the concentration of the absorbing gas in the sample chamber.

Types of capnographs

Depending on the location of the CO₂ sensor, capnographs can be divided into two types: sidestream (aspiration) and mainstream (flow-through) capnographs. In sidestream capnographs, the gas sample is continuously aspirated by a fine tube from the breathing circuit (usually located at the T-piece); it then passes to a measuring unit containing the CO₂ sensor. The CO₂ concentration is determined by comparing the IR light absorption in the sample cell with a chamber free of CO₂. A unique advantage of sidestream capnography is that it allows monitoring of spontaneously breathing nonintubated patients, as a sample of the expired gas can be obtained from the face mask or nasal cannula. In mainstream capnographs, a cuvette containing a CO₂ sensor with an IR source and detector is inserted between the breathing circuit and the endotracheal tube, so CO₂ is measured within the breathing circuit. Compared with sidestream capnography, the advantages of mainstream capnography are that the response time is faster, no gas is subtracted from the breathing circuit, and there is no need for sampling pumps. Disadvantages include the relatively heavy measuring adapter with an electrical cord (which may lead to an endotracheal tube kinking), added dead space, and the high cost of maintenance and repair. Needless to say, the newer-generation mainstream sensors are remarkably lighter and smaller.

Calibration

Capnographs must be calibrated at specific intervals based on manufacturer recommendations, but usually at least daily. Modern instruments use a self-calibration process and maintain a satisfactory degree of accuracy, usually about $\pm 0.1\%$ in the range of 0% to 10% CO₂ (0–76 mm Hg). They are fairly accurate, even in the extended range up to 100 mm Hg,

which is useful in rare cases of hypoventilation or malignant hyperthermia.

Normal capnogram

A capnogram may be displayed as CO₂ versus time (time capnogram) or versus volume (volume capnogram). The time capnogram is the method most commonly used in anesthesia and other clinical practices, because the volume capnogram needs elaborated equipment for plotting the trace. Thus, all capnograms mentioned in this chapter are time capnograms unless indicated otherwise.

A standard nomenclature has been assigned for delineating various phases of a capnogram. A capnogram may be considered as having two segments, an inspiratory and an expiratory segment, and two angles, an alpha and a beta angle. The inspiratory segment is also designated phase 0. The expiratory segment is divided further into phases I, II, and III, and occasionally phase IV, which represents the terminal rise in CO₂ concentration (Fig. 26.3). Phase I represents the initial stage of expiration; there is no rise in expired CO₂ as anatomic and apparatus dead space gases are exhaled. As expiration continues, there is a sharply rising upstroke (phase II) due to the mixing of dead space gas with CO₂-containing alveolar gas, followed by a plateau phase (phase III). The CO₂ concentration at the end of the plateau is referred to as end-tidal CO₂ (PETCO₂). PETCO₂ is the best reflection of alveolar CO₂ (PACO₂), and normally the arterial CO₂ (PaCO₂)–PETCO₂ difference is about 5 mm Hg because of the dead space. It is important to note that the expiratory plateau is not an isocapnic trace; rather it progresses with a very slight and steady increase in PCO₂ as the alveolar fraction is expelled from the lungs. As the patient begins to inspire, fresh gas is entrained and there is a steep downstroke back to the baseline (phase 0). The angle between phases II and III, called the alpha angle, increases as the slope of phase III increases; normally it is about 100° to 110°. Airway obstruction increases the angle because of the increasing slope. The response time of the capnograph, the sweep speed, and the respiratory cycle time also affect the angle. The angle between phases III and 0, called the beta angle, normally is about 90°.

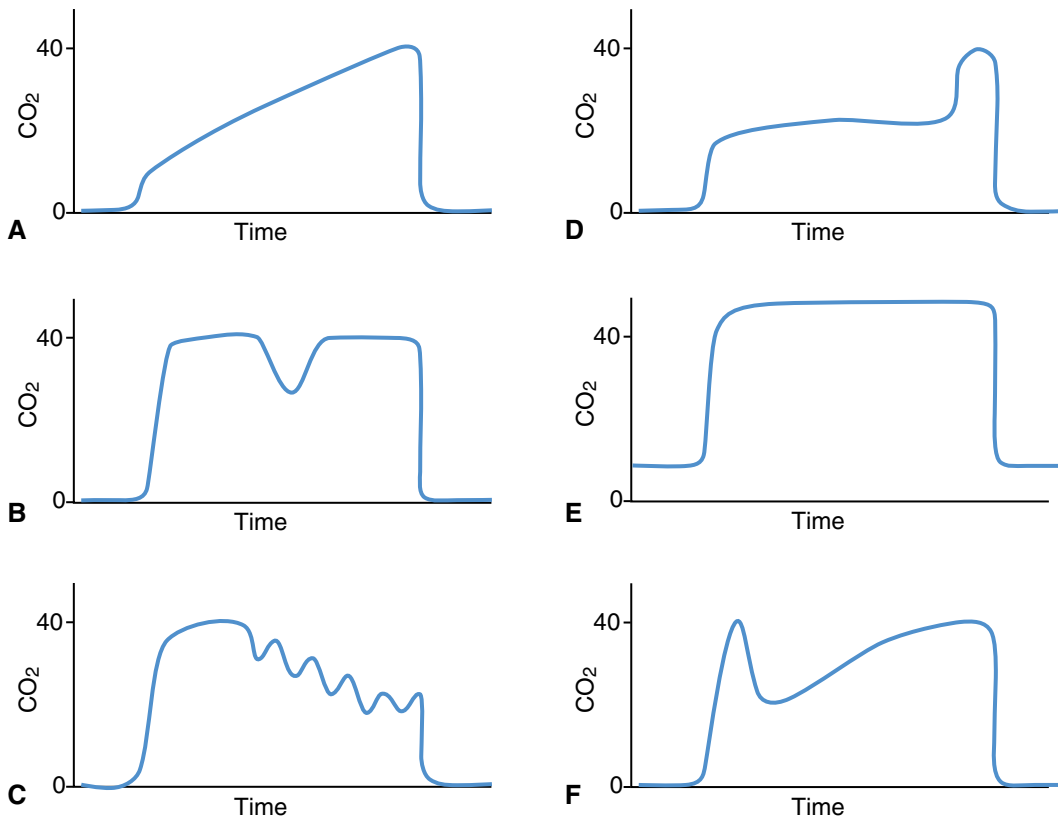

Figure 26.4. Abnormal capnograms. **(A)** Capnogram from a patient with severe obstructive pulmonary disease or another cause leading to increased airway resistance, such as asthma, endobronchial intubation, or endotracheal tube kinking. No plateau is reached before the next inspiration. The gradient between PETCO₂ and arterial CO₂ is increased. **(B)** Downward wave during the plateau phase, indicating spontaneous respiratory effort. **(C)** Cardiogenic oscillations appearing as small regular, tooth-like “humps” at the latter part of the expiratory phase. The rate of the humps is identical to the patient’s heart rate. **(D)** A leak in the sampling line during positive pressure ventilation. **(E)** Failure of inspired CO₂ to return to zero because of an incompetent expiratory valve or exhausted CO₂ absorbent. **(F)** Bifid waveform of expired CO₂ in a patient with emphysema undergoing elective surgery after unilateral lung transplantation. The initial upstroke represents gas from the normal (transplanted) lung, which is followed by gas exhaled from the remaining (emphysematous) lung.

During rebreathing, this angle increases. Occasionally, an upward blip or spike, known as phase IV, may occur toward the end of phase III; this is akin to phase IV of the single-breath nitrogen curve. This terminal elevation represents the emptying of alveoli with long-time constants containing a higher CO₂ concentration.

Abnormal capnograms and clinical considerations

In analyzing an abnormal capnogram, five characteristics should be evaluated: size (height), shape, frequency, rhythm, and baseline. For example, in patients with an obstructed airway (e.g., those with emphysema or asthma), the capnogram shows a slow rate of rise of phase II (upstroke) and the increased slope of phase III (plateau). In an unrecognized esophageal intubation, the capnograms are flat or may have occasional baseline blips. However, after attempted face mask ventilation (driving some expired gas into the esophagus and stomach) or in patients who have recently consumed carbonate beverages, some CO₂ waves may be observed as the result of gastric CO₂ returning

to the breathing system. However, such a CO₂ tracing has a peak effect only with a progressively decreasing amplitude, and it does not resemble the usual end-tidal plateau. The CO₂ concentration decreases to zero after about five breaths of ventilation. Fig. 26.4 shows several capnograms in a variety of clinical scenarios.

The PETCO₂ concentration measured from the capnogram provides important clinical information about a patient’s ventilatory status. Because the measurement of PETCO₂ is an estimate of PaCO₂, the characteristic abnormal CO₂ waveforms and concentrations may help in the diagnosis of many clinical and technical abnormalities. Table 26.1 summarizes the common causes that may be reflected by PETCO₂ changes during anesthesia care, including alterations in metabolism, circulation, ventilation, airway, or breathing. Abnormal CO₂ measurements also may occur as a result of a malfunction in sampling or measurement of CO₂.

Although it is believed that capnograms predominantly identify respiratory abnormalities, they also can forewarn of major impending depression of the cardiovascular system, such

Table 26.1. Factors that may change PETCO₂ during anesthesia

Increase in PETCO ₂	Decrease in PETCO ₂
Due to an increase in CO ₂ production	Due to a decrease in CO ₂ production
Increases in metabolic rate	Decreases in metabolic rate
Sepsis	Hypothermia
Malignant hyperthermia	Hypothyroidism
Shivering/seizure	Due to an increase in CO ₂ elimination
Hyperthyroidism	Hyperventilation
Due to a decrease in CO ₂ elimination	Due to a decrease in alveolar CO ₂ delivery
Hypoventilation	Hypoperfusion
Rebreathing	Pulmonary embolism
CO ₂ absorber exhaustion	Due to artifact
Due to artifact	Gas sampling tube leak or loose connection
Malfunction of CO ₂ measuring system	Malfunction of CO ₂ measuring system

as hypotension associated with massive blood loss, impending circulatory arrest, or pulmonary embolism.

In summary, capnography has become an important, integral part of monitoring in anesthesia. The proper use and

understanding of it not only can help in the correct placement of endotracheal tubes, but can also rapidly facilitate a differential diagnosis of hypoxia, impending hypoxia, or equipment malfunction so that corrective action can be implemented before the patient suffers irreversible, life-threatening injury.

Monitoring of neuromuscular blockade

Kai Matthes and Neelakantan Sunder

Introduction

Muscle paralysis commonly is desired during general anesthesia to facilitate endotracheal intubation and to blunt responses to surgical stimuli. Endotracheal intubation without the use of muscle relaxation is possible but requires profound anesthesia, and intubation conditions are less optimal compared with complete neuromuscular blockade. Improving intubation conditions decreases postoperative hoarseness, vocal cord damage, and patient discomfort. Neuromuscular reversal of muscle relaxation and return of respiratory function must be achieved before the trachea is extubated. Neuromuscular blockade can improve surgical conditions and is most beneficial in abdominal surgery. Muscle relaxation also may be used to prevent patient movement with lighter anesthesia or in procedures such as intracranial or complex eye surgery, in which even slight movement may result in major complications. Muscle paralysis occurs over a narrow range of receptor occupancy. There is no detectable block until 75% to 85% of receptors are occupied, and paralysis is complete at 90% to 95% receptor occupancy. Therefore, adequate muscle relaxation corresponds to a narrow range of 85% to 90% receptor occupancy, requiring an adjustment to the individual patient as there is considerable variation in individual responses.

To monitor muscle relaxation, a peripheral nerve is stimulated electrically by a battery-powered device that delivers a depolarizing current via two electrodes. The response of the corresponding muscle is assessed and depends on the current applied, the duration of the current, and the position of the electrodes. A current in the range of 60 to 80 mA is usually chosen. Durations of 0.1 to 0.2 ms are acceptable. The threshold current is the lowest current required to depolarize the most sensitive fibers in a given nerve bundle to elicit a detectable muscle response. Supramaximal current is approximately 10% to 20% higher than the current required to depolarize all fibers of the nerve bundle, generally a current two to three times higher than the threshold current.

Electrocardiogram electrodes placed on the skin are used to apply the current on the appropriate nerve. Subcutaneous needles deliver the impulse in the immediate vicinity of the nerve and have the advantage of bypassing the tissue impedance. Disadvantages include local irritation, infection, nerve damage, and diathermy burns. Thus, surface electrodes are commonly

preferred over needle electrodes. The first electrode should be placed on the skin overlying the nerve to be stimulated. The second electrode is positioned proximally or distally along the stimulated nerve, avoiding stimulation of neighboring nerves. Practically, no differentiation between positive and negative electrodes is considered for proximal or distal placement along the nerve. In theory, if the negative electrode is placed directly on the nerve in the proximal location, the threshold to supra-maximal stimulation is less than for the positive electrode.

Monitoring modalities

Recording the response

The electrical stimulation of a peripheral nerve can be assessed by visual and tactile evaluation of the twitch response of the corresponding muscle (Table 27.1). Using the train-of-four (TOF), four successive stimuli are delivered at 2 Hz (every 0.5 seconds). Immediately available stores of acetylcholine are depleted with each current, and the amount released by the nerve decreases with each successive stimulus until it levels off. In the presence of a nondepolarizing block, the twitches progressively fade starting with the fourth, and one by one eventually disappear with increasing degrees of block. The ratio of the height of the fourth response to the first has been defined as the TOF ratio (T₄/T₁). It has been shown that a TOF ratio >0.9 at the adductor pollicis is necessary to achieve adequate airway protection to avoid postoperative atelectasis or pneumonia. At TOF ratios < 0.9, a significantly reduced upper esophageal sphincter resting tone and reduced muscle coordination have been demonstrated (Table 27.2).

The assessment of TOF is prone to subjective assessment errors, as the quantitative determination of the TOF ratio is difficult to make during recovery and depends on the experience of the observer. TOF ratios as low as 0.3 may remain undetected, but with double-burst stimulation, fade can be detected reliably in the range of 0.5 to 0.6.

High-frequency stimulation (≥ 50 Hz) results in sustained or tetanic contraction of the muscle during normal neuromuscular transmission despite a decrement in acetylcholine release. During tetanus, progressive depletion of acetylcholine output is balanced by increased synthesis and transfer of transmitter from its mobilization stores. The presence of nondepolarizing

Table 27.1. Indications for and specifics of various nerve stimulation techniques

Technique	Indication	Frequency/time/interval	Location/muscle	Limitations
Single twitch	Assessment of onset of muscular blockade	Single square wave stimuli lasting 0.2 ms are applied at intervals of > 10 sec Usually supramaximal current is applied Amplitude may be varied in increments up to 80 mA	Central muscles (facial nerve) to assess readiness for intubation is preferred over peripheral muscles (adductor pollicis)	Response must be compared to control preblockade twitch. Difficult to assess magnitude of response over time.
TOF	Monitoring of muscle relaxation during surgery or readiness for reversal of muscular blockade	Four 2-Hz square wave stimuli each lasting 0.2 ms Observation of degree of fade between fourth and first stimulus: interpretation as a fraction of 1 (TOF ratio) Intervals of 12–15 sec between measurements Surgical relaxation: TOF 0.15–0.25 TOF > 0.9 is sufficient recovery for extubation	Central muscles (facial nerve) to monitor adequate surgical relaxation (proximity to diaphragm) Peripheral muscles (adductor pollicis) to detect residual paralysis before extubation	Does not require preblockade control measurement Difficult to evaluate by visual or tactile means Not ideal for determining residual paralysis before extubation because of subjective difficulty determining residual block if TOF \geq 0.4
Tetanus	Assessment of residual muscular blockade Sensitivity for detecting residual block > single twitch or TOF	5-sec stimulus with a frequency > 30 Hz Observation of fade (more fade is seen with 100 Hz than with 50 Hz) Intervals of 1–2 min between measurements	Preferably peripheral muscles (adductor pollicis) to detect residual paralysis before extubation	Does not require preblockade control measurement Difficult to evaluate by visual or tactile means At 100 Hz, fade may be seen even in the absence of neuromuscular blockade Posttetanic facilitation depends on frequency and duration of stimulation
PTC	Assessment of profound neuromuscular blockade if there is no response to the other modalities	50-Hz tetanus for 5 sec followed by a 3-sec pause and then stimulation at 1 Hz Count of visible twitches correlates inversely with time required to return of single twitch or TOF (PTC of 1 to reappearance of first twitch is 10–20 min, PTC of 10 indicates immediate reappearance of first twitch) Intervals of 1–2 min between measurements	Central muscles (facial nerve) to detect recovery from profound muscular blockade Peripheral muscles (adductor pollicis) to detect residual paralysis before extubation	Does not require preblockade control measurement Commonly used to detect profound muscular blockade
Double-burst stimulation	Assessment of residual muscular blockade Sensitivity for detecting residual block > single twitch or TOF	Three 0.2-ms impulses at 50 Hz separated by 750 ms Fade ratio correlates closely with TOF ratio but is easier to detect manually Intervals of 12–15 sec between measurements	Preferably peripheral muscles (adductor pollicis) to detect residual paralysis before extubation	Does not require preblockade control measurement Fade can be detected reliably up to TOF ratios of 0.5–0.6

muscle relaxants impairs the mobilization of acetylcholine within the nerve terminal, thereby contributing to the fade in response to tetanic and TOF stimulation. This perhaps is the most painful method of monitoring the neuromuscular junction and therefore is not suitable for patients being lightly anesthetized. Tetanic stimulation facilitates the neuromuscular response during and after its application, artificially shifting all subsequent neuromuscular events toward normality. Because it provides only one point on the continuum of neuromuscular response, it is less useful than TOF. With 100-Hz tetanic stimulation, fade might be detected at TOF ratios of 0.8 to 1.0 but also may be seen in individuals with no neuromuscular block.

During profound neuromuscular blockade, quantification of neuromuscular blockade can be done using the posttetanic count (PTC), based on the principle of posttetanic facilitation. Mobilization and enhanced synthesis of acetylcholine continue during and after cessation of tetanic stimulation. Following the end of tetanus, there is an increase in the immediately available store of acetylcholine and the quantal content. Thus after tetanus, there is an increase in the amount of transmitter released in response to nerve stimulation, and a single twitch evoked after cessation of tetanus may be stronger than the pretetanic control. The number of evoked posttetanic twitches detected is referred to as the PTC. The number of posttetanic twitches correlates inversely with the time

Table 27.2. Relationship between receptor occupancy, T1, T4, T4/T1 ratio, and tetanus during nondepolarizing muscular blockade

Percentage blocked	T1, % normal	T4, % normal	T4/T1, % normal	Tetanus
100				
95			T1–T4 lost	
90	10		T2–T4 lost	
85	20		T3–T4 lost	
80	25		T4 lost	Onset of fade at 30 Hz
	80–90	55–65	TOF 0.6–0.7	
	95	70	TOF 0.7–0.75	
75	100	75–100	TOF 0.75–1	
70			TOF 0.9–1	Onset of fade at 50 Hz
50				Onset of fade at 100 Hz
30				Onset of fade at 200 Hz

for spontaneous recovery. PTC is a prejunctural event; the response may vary with the nondepolarizing muscle relaxant used.

Following intense neuromuscular blockade by vecuronium, the first detectable twitch of the TOF will appear an average of 8.5 minutes (6–15 minutes) after a PTC of 1. A PTC of 8 to 9 indicates imminent return of TOF. The recovery of atracurium is similar to that of vecuronium; the interval is larger for pancuronium. It takes approximately 38 minutes after the first post-tetanic twitch for the reappearance of the first response to TOF stimulation. A PTC of 9 to 11 predicts imminent return of TOF response. Children have a shorter interval between PTC 1 and onset of T1. The PTC may be useful for cases in which profound muscle relaxation is required (e.g., ophthalmic surgery) or for the continuous infusion of intermediate nondepolarizing muscle relaxants.

Because of the unreliability of visual/tactile assessment of neuromuscular function, there has been an emerging interest in the development of quantitative devices for the assessment of neuromuscular blockade (Table 27.3). These devices measure either the compound muscle action potential (MAP) or the evoked contractile response. The compound MAP is the cumulative electrical signal generated by the individual action potentials of individual muscle fibers.

For research purposes, mechanomyography is the gold standard for objective muscle relaxation monitoring. The most versatile method in the clinical setting is acceleromyography because it can be applied at various muscles and has a long track record of clinical utility.

Choice of muscle

Muscles differ in terms of onset, offset, and peak effect of neuromuscular blockade. There is a variation in responses of individual muscles to electric stimulation, which serve different purposes or indications. Possible causes for the varying responses of different muscle groups are the differences in the

margin of safety of the neuromuscular junction of different muscle groups, fiber composition, innervation ratio (number of neuromuscular junctions), blood flow, and muscular temperature (Fig. 27.1).

Important means of providing optimal relaxation should consider monitoring muscles of the surgical site or, alternatively, muscles that adequately reflect neuromuscular blockade at the surgical site (Table 27.4). Complete neuromuscular blockade at the adductor pollicis does not necessarily mean complete relaxation of the diaphragm. Monitoring the corrugator supercilii better reflects the degree of relaxation at the surgical site during thoracic surgery. In general, for surgery of the upper or lower extremities, monitoring of the adductor pollicis, or any other hand muscle, is preferable. For surgery within the chest or abdomen in which relaxation of the diaphragm is necessary, monitoring of the corrugator supercilii might be used.

Current evidence shows that monitoring of the corrugator supercilii should be used to establish the earliest time for optimal conditions for tracheal intubation, as it reflects laryngeal relaxation better than monitoring of the adductor pollicis. Recovery of neuromuscular transmission is best monitored at the adductor pollicis because, in general, this is the last muscle group to recover from neuromuscular blockade. TOF stimulation with a ratio >0.9 indicates sufficient recovery of neuromuscular transmission for awakening the patient and ensuring safe tracheal extubation.

Factors affecting the monitoring of neuromuscular blockade

Many drugs interfere with neuromuscular function. Certain clinical settings make the interpretation of monitoring of neuromuscular blockade difficult. Neuromuscular blockade is prolonged if the patient is hypothermic due to a decreased metabolism of the blocking drug.

Overestimation of neuromuscular blockade may occur in a cold extremity without central hypothermia. Underestimation of neuromuscular blockade is seen in the setting of central hypothermia. Central and peripheral nerve damage leads to a resistance to nondepolarizing muscle relaxants at the affected site (e.g., hemiplegia) presumably as a result of an extrajunctional expression of acetylcholine receptors on the paretic site. A misinterpretation of the relaxation of the patient carries the potential of overdosing muscle relaxants because of a decreased response to the monitoring methods. Central and peripheral nerve damage can be based on nerve trauma, cord transection, or stroke.

Maintenance of neuromuscular blockade

The goal of muscle relaxation is to maintain the minimum depth of block required for surgery. Adequate relaxation for abdominal surgery can be achieved with >80% twitch depression, which correlates with one or two twitches present in the TOF. The diaphragm is relatively resistant and requires a greater

Table 27.3. Objective assessment of neuromuscular blockade

Assessment tool	Technique	Advantages/disadvantages
Mechanomyography	<p>Mechanomyographic device objectively quantifies the force of isometric contraction of adductor pollicis muscle in response to ulnar nerve stimulation. The force is translated into an electrical signal that can be displayed on an interfaced pressure monitor and then recorded.</p> <p>Balloon pressure methods may be used to monitor the larynx or corrugator supercilii. Measurement of force indirectly by change of pressure exerted onto the balloon compressed by movement of the thumb or contraction of the corrugator supercilii.</p> <p>A constant amount of baseline muscle tension (preload) should be applied to the monitored muscle, which serves to align the contractile elements (actin and myosin filaments).</p>	<p>Gold standard of muscle relaxation monitoring.</p> <p>Requires most stringent preparations and precautions (e.g., placement of arm in a molded cast to prevent changes of position).</p> <p>Mechanomyographic devices are awkward and bulky to prepare. Drift may be a problem, implying that the response does not return to the control amplitude. Slight movement of the hand may lead to a change in amplitude of the evoked potential.</p>
Electromyography	<p>Measurement of electrical response of muscle after evoked stimulation of a motor nerve; interpretation as an integrated EMG response.</p> <p>The latency of the compound MAP is the interval between stimulus artifact and evoked muscle response. The amplitude of the compound MAP is proportional to the number of muscle units within the designated time interval (epoch). This correlates with the evoked mechanical responses.</p> <p>Mostly for experimental studies.</p>	<p>May be used at various muscle sites (larynx, diaphragm, adductor pollicis; with restrictions, corrugator supercilii and oculus oculi).</p> <p>Smaller muscles create a smaller action potential and therefore are more difficult to monitor.</p> <p>Monitoring of the diaphragm is possible (measuring the pressure induced within the esophagus).</p> <p>May underestimate the degree of paralysis.</p> <p>Drift over time may arise (failure to descend completely in fully relaxed muscles).</p> <p>Interference with other electronic devices may occur.</p>
Accelerometry	<p>A miniature piezoelectric transducer is used to determine the rate of angular acceleration of the thumb (adductor pollicis). The principle is based on the constant relationship between force (F) and acceleration (a), as long as mass (m) is constant (Newton's second law: $F = ma$). One requirement for accelerometry is that the muscle must be able to move freely. The piezoelectric crystal is distorted by the movement of the crystal inlaid transducer applied to the finger, and an electric current is produced with an output voltage proportional to the deformation of the crystal.</p> <p>Interpretation is from a digital readout.</p> <p>Elastic preload to the thumb has been shown to decrease TOF variability.</p>	<p>Easy to use, practical, versatile, and inexpensive; may be applied to various muscles.</p> <p>Good correlation with mechanomyography and electromyography.</p> <p>Has been shown to reduce the incidence of residual paralysis.</p> <p>Difficult to use with muscles that do not create a distinct movement (e.g., corrugator supercilii). Cannot be used at the larynx or diaphragm.</p>
Kinemyography	<p>Measurement of the movement of the end organ (e.g., thumb) by a piezoelectric transducer.</p> <p>Use of a molded plastic device with the contour of the outstretched thumb and index finger.</p>	<p>Slight clinical differences from mechanomyography in studies.</p> <p>Accuracy is not superior to that of accelerometry.</p> <p>Careful hand positioning is necessary to avoid artifact.</p> <p>Monitoring of recovery may be misleading.</p>
Phonomyography	<p>Contracting muscle emits low-frequency sounds, which are recorded with special microphones.</p> <p>Interpretation of fade of TOF.</p>	<p>Easy to apply at various muscles.</p> <p>Promising agreement with mechanomyography.</p> <p>Change in contact with the skin surface may change the signal amplitude.</p> <p>Currently, no commercial devices are available.</p>

Figure 27.1. Approximate time course of twitch height after administration of rocuronium, 0.6 mg/kg, to different muscles. (Modified with permission from Barash PG, Cullen BF, Stoelting RK. *Clinical Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2006.)

Table 27.4. Comparison of various monitoring sites

M. adductor pollicis (ulnar nerve)	Stimulation of ulnar nerve: first electrode on proximal wrist on the radial side of flexor carpi ulnaris muscle, second electrode 2 cm proximal on volar forearm or over the olecranon groove Relatively sensitive to nondepolarizing neuromuscular blocking drugs During recovery, more blocked than respiratory muscles
First dorsal interosseous muscle (ulnar nerve)	Preferably used for electromyography Electrodes are relatively undisturbed by hand movement Sensitivity of this muscle correlates with M. adductor pollicis
M. abductor digit quinti (ulnar nerve)	Less sensitive than M. adductor pollicis to muscle relaxants May overestimate recovery from blockade Prone to stimulus artifact
Muscles surrounding the eye (facial nerve)	Stimulation of facial nerve 2–3 cm posterior to the lateral border of the orbit; use less current (20–30 mA) M. orbicularis oculi: covers eyelid movement Monitoring the onset of neuromuscular blockade at the orbicularis oculi can predict good intubation conditions M. corrugator supercilii: small muscle around the eyebrow, responsible for vertical frowning Movement of eyebrow is similar to that of laryngeal adductors Onset of blockade is more rapid and recovery occurs sooner vs. adductor pollicis Accurately reflects the response of laryngeal muscles or diaphragm Acceleromyography is difficult to perform because of the small size of the muscle
Vastus medialis (femoral nerve)	The vastus medialis muscle has been used as an alternative monitoring site Stimulation of muscular branches of the femoral nerve Onset and recovery from neuromuscular blockade are faster vs. the adductor pollicis
Muscles of the foot (tibial nerve)	Stimulation of posterior tibial nerve behind the internal malleolus to produce flexion of the big toe by contraction of the flexor hallucis Response is better vs the adductor pollicis but with inconsistent results, limiting usability Stimulation of external peroneal nerve produces dorsiflexion Sensitivity of muscles has not been measured
Laryngeal muscles (recurrent laryngeal nerve)	Neuromuscular blockade at the larynx is less intense vs. the adductor pollicis, with more rapid onset and offset Monitoring of the larynx is based on mechanomyography, electromyography, or phonomyography Placement of the endotracheal cuff between the vocal cords allows measurement of the force of the adducting laryngeal muscles via the degree of pressure changes within the cuff A special endotracheal tube with incorporated electrodes may be used for electromyography; alternatively, small microphones may be placed at the larynx to monitor the laryngeal muscles This technique obviates the risk of endotracheal tube dislodgement, as associated with techniques requiring tube positioning Transcutaneous stimulation of the recurrent laryngeal nerve may be accomplished medially, between the jugular notch and the thyroid cartilage or lateral to the sternocleidomastoid muscle in the tracheoesophageal groove
Diaphragm (phrenic nerve)	Neuromuscular blockade at the diaphragm is less intense vs. adductor pollicis, with more rapid onset and offset Monitoring of the diaphragm is possible with electromyography and mechanomyography using transcutaneous needles or superficial skin electrodes The seventh or eighth intercostal space, between the anterior axillary and midclavicular line, may be used to record the signal Mechanomyography may be used indirectly by inserting a balloon in the esophagus to record pleural pressure and another in the stomach to record abdominal pressure. The balloons are connected to air-filled catheters to identical transducers. Transdiaphragmatic pressure = gastric (intra-abdominal) pressure – esophageal (intrathoracic) pressure. However, this technique is more invasive and difficult to apply. It cannot be used in open abdominal or laparoscopic cases.

plasma concentration of nondepolarizing muscle relaxants. When paralysis of the diaphragm is required, the administration of neuromuscular blockade is titrated to paralysis of the corrugator supercilii muscle, whose recovery profile is similar to that of the diaphragm.

Detecting reversible block

Airway patency and adequate ventilation require more than an intact diaphragm. Therefore, it is important to assess the degree of block at a muscle that does not overestimate the rate of recovery of muscles maintaining the airway. The increased sensitivity and slower time course of the adductor pollicis muscle make

this site preferable for monitoring recovery. PTC may be used when no twitch response is attainable. The time to recovery of twitch response is inversely proportional to the number of PTC. In the absence of objective monitoring devices, double-burst stimulation may be preferable to TOF to reliably detect a fade. Atracurium-, vecuronium-, and pancuronium-induced neuromuscular blockade is antagonized by neostigmine in 30 minutes when the single twitch height is $\geq 10\%$ of control or just prior to emergence of the second twitch of the TOF count and in 10 minutes, when all four responses to TOF stimulation are present. When zero twitches are present in the TOF, the block is considered not antagonizable.

Table 27.5. Clinical tests to assess recovery from neuromuscular blockade

Both legs lifted off the bed	TOF 0.6 Probably not sufficient to ensure protection of airway
Head lift >5 sec	TOF 0.6 Probably not sufficient to ensure protection of airway
Normal hand grip strength	TOF 0.7
Teeth clenched to prevent removal of wooden spatula (masseter muscle strength)	TOF 0.86 Most sensitive test to ensure adequate recovery, but not all patients may be able to demonstrate

Clinical tests to evaluate residual muscular blockade

Aside from peripheral nerve stimulation, a variety of clinical tests are used in clinical practice to assess for adequate recovery from neuromuscular blockade. Subjective evaluation consists of the assessment of residual paralysis based on the patient's ability to perform certain tasks. These tests depend on the degree of consciousness and cooperation of the patient (Table 27.5).

Ensuring adequate neuromuscular function before extubation

Safe extubation from the trachea can be performed only after adequate restoration of neuromuscular function. A TOF ratio >0.75 at the thumb correlates with restoration of strength of the muscles of respiration and airway protection, vital capacity, maximum expiratory force, peak expiratory flow rate, hand grip, and 5-second head lift. Historically, a TOF ratio of 0.7 was used as an indication of adequate recovery from neuromuscular blockade. Current evidence, however, indicates that a TOF ratio of 0.9 rather than 0.7 is required to ensure recovery. A residual block (TOF < 0.9) is associated with functional impairment of the pharynx and upper esophagus, likely predisposing to regurgitation and aspiration.

Postoperative residual curarization (PORC) might occur because of administration of excess neuromuscular blocking agents, early administration of reversal, or an abnormal response of the patient. PORC continues to be a common problem in postanesthesia care units. Given that PORC is a potentially preventable patient safety problem, it is important to find ways to reduce the incidence. PORC is a major risk factor for many critical events in the immediate postoperative period, such as ventilatory insufficiency, hypoxemia, and pulmonary infections.

Subjective evaluation of the evoked muscular response to TOF stimulation is extremely inaccurate. In addition, many practitioners are unclear about the current standards that define adequate recovery from neuromuscular blockade. Also, there is conflicting evidence regarding the utility of conventional peripheral nerve stimulators in preventing PORC. The

incidence of PORC was found to be significantly lower after the use of intermediate neuromuscular blocking drugs.

Not all clinicians believe PORC is a clinical problem that may affect their patients. Disinclination to use peripheral nerve stimulator devices suggests that many practitioners do not accept the premise that these devices are helpful. Thus, four decades after the first battery-operated nerve stimulators were described, unacceptable levels of residual paresis in postanesthesia care units continue to be reported. It should be emphasized that objective monitoring of neuromuscular blockade may provide enhanced safety to prevent PORC.

Thermoregulation and temperature monitoring

Matthias Stopfkuchen-Evans, Elliott S. Farber, and Francis X. Vacanti

Introduction

Control of body temperature is mediated via behavioral and autonomic mechanisms to maintain effective enzymatic activity and normal bodily functions. Behavioral mechanisms are far more powerful than autonomic thermoregulatory defenses in allowing humans to survive in diverse environments. Once anesthetized, the patient loses all behavioral means to self-regulate temperature.

Thermoregulation

Under normal conditions, the hypothalamus seeks to establish an equilibrium of heat generation and dissipation to maintain core temperatures in a very narrow range. Core temperature consists of the well-perfused tissues, and this compartment maintains a warmer and more uniform state. Sensory information is gathered primarily from the transient receptor potential (TRP) family of ion channels and conveyed by unmyelinated C and myelinated A- δ fibers. Thermal inputs from the skin surface, deep abdominal and thoracic tissues, the spinal cord, and nonhypothalamic regions in the brain contribute equally and are further integrated on several levels within the brain and spinal cord, before the information gets relayed to the anterior hypothalamus, the dominant thermoregulatory controller. The thresholds for increasing or decreasing core temperature lie within approximately 0.2°C of the hypothalamic thermoregulatory set point; however, there is a nearly 1°C sinusoidal circadian variation around the set point temperature, with the maximum occurring midafternoon and the minimum occurring 12 hours later. The primary autonomic response to heat consists of sweating and active capillary vasodilation, whereas the primary autonomic response to cold results in shivering and vasoconstriction.

Heat production

The energy lost in the biochemical conversion of glucose to adenosine triphosphate (ATP) and in the expenditure of ATP appears as heat. Human activity is such that ATP utilization varies immensely, and the human body must be able to deal with significant swings in endogenous heat production. Humans handle the heat load of varying activities such as sleeping with an energy expenditure of approximately 0.7 metabolic

equivalents (MET) to vigorous activity of 10 to 12 MET, where 1 MET is defined as the caloric consumption of 1 kcal/kg/h. Anesthetic agents, opioids, and sedatives incapacitate or alter some mechanisms of heat production (shivering to generate heat). Infants are capable of increased heat production via nonshivering thermogenesis from the metabolism of brown fat. This fat is loaded with mitochondria and is found close to the large blood vessels and intrascapular space. When sympathetically activated, it can increase the production of heat by as much as 100%.

Mechanisms of heat loss: transfer of thermal energy

The transfer of thermal energy from humans (i.e., heat loss) occurs through four mechanisms:

- Conduction
- Convection
- Radiation
- Evaporation

Conduction resulting in heat loss occurs via direct contact with surrounding substances (e.g., air, water, intravenous [IV] fluids, operating room [OR] table, laryngoscope blades) and is related to the area of contact and differences in temperature. Convection is related to conduction, as contact with a substance is required; however, convection differs in that continued renewed contact with that substance (i.e., a breeze or a current of water) occurs. However, *most* heat is lost in the form of infrared electromagnetic waves via radiation. All objects above absolute zero emit electromagnetic radiation, and the rate of heat loss by this mechanism is related to the temperature of the object. The human body radiates energy in the infrared portion of the electromagnetic spectrum, as do the surrounding walls and other objects. It is usually the case that the temperature of the surrounding objects is lower than that of the human body, and there is a net loss of heat from the body to the environment. The body loses 0.58 kcal of heat with each gram of water that evaporates from its surfaces. Approximately 20% of the total heat loss normally is the result of evaporation, but this can increase markedly under thermal stress, and evaporation then becomes the major means of heat loss. Evaporation is the only mechanism whereby heat energy is transferred to a warmer

Table 28.1. Intraoperative phases of heat redistribution and loss

Phase	I	II	III
Temperature	↓ core temperature by 1–2°C during first hour	Gradual decline over 3–4 h Heat loss exceeds heat production	Equilibrium at around 33°C T_{core} Heat production equals loss
Characteristics	Heat redistribution from abdomen and thorax to extremities	Linear reduction	Core-to-peripheral temperature gradient is restored
Mechanisms	Inhibition of tonic thermoregulatory vasoconstriction	Radiation, 60%; convection, 30%; conduction, 5%; evaporation, 5%	Peripheral vasoconstriction
Heat loss	No net heat loss	Net heat loss	No net heat loss
Prophylaxis	Preemptive skin warming before surgery (decrease core-to-peripheral temperature gradient)	Active warming measures intraoperatively	Active warming to maintain core temperature plateau at or above 36°C

environment. Sympathetic cholinergic neurons activate sweat glands to excrete sweat, which is then evaporated from the skin surface.

Altered regulation and environmental response under anesthesia

Table 28.1 summarizes the three phases of intraoperative core temperature changes. The ability to self-regulate temperature is greatly affected under anesthesia. Anesthetics alter the range of normal adaptive response to temperature changes by some 20-fold, such that mechanisms for heat production and dissipation may not be triggered until detrimental effects of hypo- or hyperthermia are already present. In the normal awake state, heat is unevenly distributed throughout the body as a result of tonic thermoregulatory vasoconstriction. Redistribution of body heat, however, occurs from the alteration of this vasoconstriction by various anesthetics and is responsible for the initial decrease in core temperature that follows induction (Fig. 28.1). The magnitude of redistributory heat loss is inversely proportional to the percentage of body fat and the weight-to-surface area ratio. Following this redistribution, temperature changes happen at a slower rate. This nearly linear decrease in temperature is a result of heat loss dominating over metabolic heat production. Again, the magnitude of the core cooling rate during the second phase is inversely proportional to the weight-to-surface ratio. The mechanisms for increased heat generation, heat conservation, and heat dissipation remain intact; however, trigger responses for these mechanisms are blunted and response curves are shifted such that wider temperature ranges will occur. Fig. 28.2 shows changes in thermoregulatory thresholds seen with various anesthetic agents.

Phase 3 is characterized by reaching a thermal steady state at which heat loss equals metabolic heat production and no heat is lost. This stage may be reached either by effective warming efforts, thus reaching a passive thermal steady state, or by allowing sufficient hypothermia to occur, which leads to the reactivation of thermoregulatory vasoconstriction and therefore to the reestablishment of the normal core-to-peripheral temperature gradient. This, of course, is attained at significantly lower core temperature levels, as outlined in Fig. 28.3.

Untoward effects of hyper- and hypothermia

Hypothermia

Hypothermia exists when core temperature is <36°C. At increased risk of perioperative hypothermia are elderly patients, neonates, and those with cachexia, burns, or paraplegia because of their already-existent altered heat conservation. Despite the demonstrated benefits in some clinical scenarios (severe traumatic brain injury with Glasgow Coma Score < or = 8, comatose patients after an out-of-hospital cardiac arrest, potentially after acute ischemic stroke), the untoward effects of hypothermia generally outweigh the ischemic protection benefits. Untoward effects of hypothermia include impaired coagulation from decreased activation of the coagulation cascade and inhibited platelet function, increased oxygen and metabolic demand from postoperative shivering, and slowed drug metabolism, contributing to a delayed recovery from anesthesia. In addition, hypothermic patients have impaired resistance

to developing surgical wound infections. [Table 28.2](#) summarizes the effects of hypothermia on various organ systems.

Shivering is a complex response to hypothermia that often is perceived as particularly uncomfortable and increases postoperative pain sensation. It may double or triple oxygen consumption and carbon dioxide production and double metabolic heat production. It is absent in newborns and infants and is rarely seen in elderly patients because of impaired thermoregulatory control. Pharmacologic interventions to decrease shivering in the postoperative care unit may consist of central α_2 -adrenergic agonists or small doses of meperidine, which decreases the shivering threshold temperature significantly more than the vasoconstriction threshold.

Hyperthermia

Hyperthermia exists when core temperature is >38°C and is different from fever in that it is in excess of the hypothalamic set point. For comparable deviation from normothermia, hyperthermia is more detrimental to the body than hypothermia, with the brain and central nervous system (CNS) being most sensitive. Hyperthermia increases the release of excitatory neurotransmitters and has been shown to worsen neurologic injury following ischemic events and status epilepticus. Under anesthesia, most cases of hyperthermia result from excessive intraoperative warming techniques; however, excessive metabolic production of heat in the setting of impaired heat dissipation also is possible. Common causes of hyperthermia are listed in [Table 28.3](#).

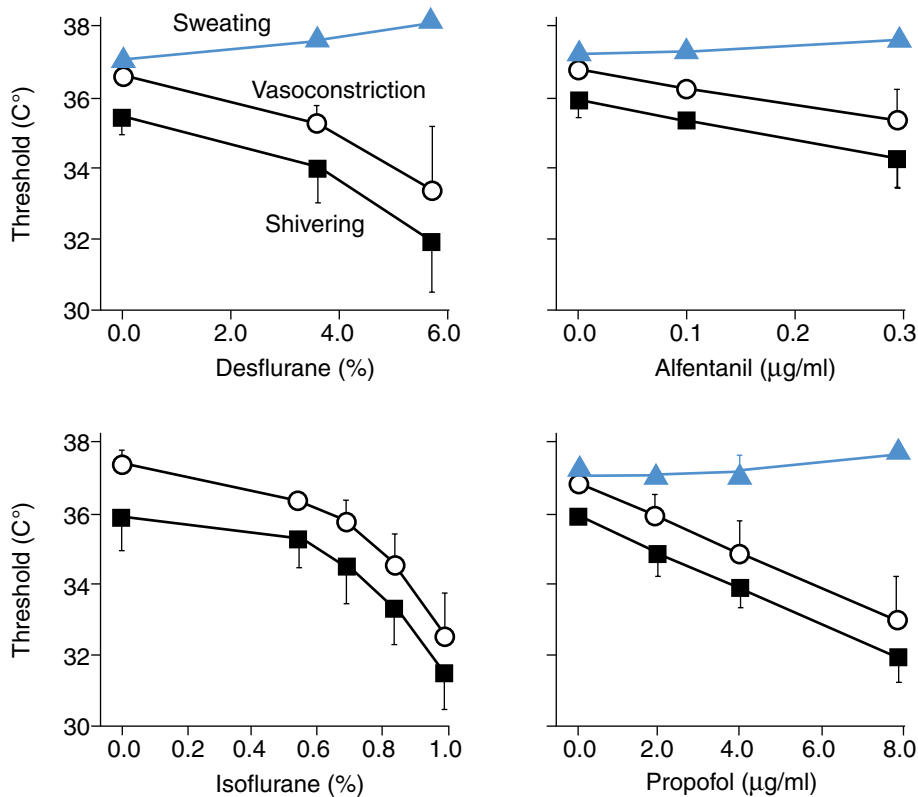

Figure 28.2. Anesthetic-induced inhibition of thermoregulatory control usually is the major factor determining perioperative core temperature. Concentration-dependent thermoregulatory inhibition by desflurane, isoflurane (halogenated volatile anesthetics), alfentanil (a μ -agonist opioid), and propofol (an intravenous anesthetic). The sweating (triangles), vasoconstriction (circles), and shivering (squares) thresholds are expressed in terms of core temperature at a designated mean skin temperature of 34°C. Anesthesia linearly, but slightly, increases the sweating threshold. In contrast, anesthesia produces substantial and comparable linear or nonlinear decreases in the vasoconstriction and shivering thresholds. Typical anesthetic concentrations thus increase the interthreshold range (difference between the sweating and vasoconstriction thresholds) approximately 20-fold from its normal value near 0.2°C. Patients do not activate autonomic thermoregulatory defenses unless body temperature exceeds the interthreshold range; surgical patients thus are poikilothermic over a 3°C–5°C range of core temperatures.

Accuracy and reliability of temperature monitoring

The gold standard for temperature monitoring is a thermistor within the pulmonary artery, as it most accurately reflects core temperature in a continuous manner. Its invasiveness, however, lends to other monitoring techniques. The nasopharynx and tympanic membrane are close to the blood flow to the brain and thus reliably reflect core temperature. Continuous tympanic membrane monitoring is possible; however, it requires that a transducer be placed in contact with the tympanic membrane, which may be technically undesirable. An esophageal probe

positioned above the hard palate allows continuous monitoring of the nasopharynx. Rectal temperature may be confounded by heat-producing bacteria; fecal insulation of the temperature probe, delaying responsiveness; or blood return from the lower extremities. Bladder temperature closely approximates core temperature but can be affected by an open abdomen and is subject to the same delayed responsiveness as rectal monitoring in settings of reduced urinary output. An appropriately placed temperature probe in the distal esophagus accurately reflects core temperature. When the site is not distal enough, readings may be affected by inhaled gases. Table 28.4 shows possible sites for temperature measurement.

Techniques for maintaining normothermia

Because patients under anesthesia are more susceptible to the temperature influences of their environment and the standard OR environment is cold, active techniques must be employed to maintain normothermia. Patient covering is extremely effective because as much as 80% of heat loss is from radiation and convection. This is most effective when a patient is covered prior to the induction of anesthesia, especially with prewarming of the skin to minimize early intraoperative hypothermia. Forced-air convection blankets are extremely effective when covering >25% of the body surface area and require continuous temperature monitoring to prevent hyperthermia. Table 28.5 outlines various techniques to prevent perioperative heat loss and maintain normothermia.

Table 28.4. Sites for temperature monitoring

Figure 28.3. The relative effects of warming methods on mean body temperature. Figure 28.3 (A) shows the change in mean body temperature according to the time elapsed since the start of treatment; (B) shows the change in mean body temperature according to the quantity of fluid administered. Mean body temperature is the average temperature of body tissue and is usually somewhat lower than core temperature. The calculations are for a hypothetical, undressed patient weighing 70 kg, with a metabolic rate of 80 kcal/h, in thermal steady state in a typical OR (ambient temperature, 21°C). Line A indicates the change in mean body temperature in a patient inspiring warmed humidified gas. Line B indicates the change in a patient with all skin below the neck covered by a warmed or unwarmed blanket. Line D indicates the change in mean body temperature in a patient similarly covered with three blankets. (Similar amounts of heat loss are prevented by one or three layers of other passive insulators.) Line C indicates the change in a patient on a full-length circulating-water mattress and line E the change in mean body temperature in a patient covered with a full-length forced-air blanket. Lines F, G, H, and I indicate the change in mean body temperature per liter of administered blood or crystalloid at various fluid temperatures.

Postoperatively, these devices may be less effective in the presence of peripheral vasoconstriction, as this might limit heat transfer. Concerns regarding increased airborne bacterial wound contamination with the use of these devices have not been confirmed by studies. Radiant heat lamps are more effective for use with infants because of their greater surface

Table 28.5. Measures to prevent heat loss and reverse hypothermia

Use blankets during transport from the scene
Increase trauma room and OR temperatures >80°F
Minimize duration of exposure to cold environment
Use warming devices for all infusions in the trauma room and OR
Cover patient's head and other parts of the body with warming devices (Bair Hugger ^a)
Irrigate nasogastric and thoracostomy tubes with warm saline
Irrigate open body cavities with warm saline
Consider extracorporeal warming

^a Registered trademark of Arizant, Eden Prairie, MN.

area–volume ratio compared with adults. Radiant heat lamps also are more effective in terminating postoperative shivering than the application of warm blankets. Thermal mattresses have been more effective in the infant than in the adult population. Warming is hampered by decreased tissue perfusion from compressive contact with these devices. Heat loss from ventilation represents 8% to 10% of the total caloric expenditure of the infant. Active heating and humidification of inhaled gases can minimize damage to respiratory cilia. Fluid and blood warming help minimize intraoperative heat loss, especially when large volume resuscitation is required, as each liter of IV fluid at ambient temperature that is infused into adult patients decreases mean core body temperature by about 0.25°C. Fig. 28.3 shows the relative effects of warming methods on mean body temperature.

Neurophysiologic monitoring

Kai Matthes and Mary Ellen McCann

Introduction

The assessment of neurologic function during surgery can be challenging because many general anesthetics depress the central nervous system (CNS). Fortunately, a variety of neuromonitoring techniques have been devised to monitor the integrity of the CNS, which may be compromised by ischemia, hypothermia, hypotension, or direct structural damage. Electroencephalography and evoked potentials are used to assess ischemia, surgical injury, and anesthetic depth. Monitoring of intracranial hypertension is utilized primarily in the intensive care unit and occasionally in the operating room. Methods to assess cerebral blood flow (CBF) and oxygen saturations also have been developed to aid in the detection of intraoperative ischemia.

Electroencephalography

Electroencephalographic (EEG) monitoring analyzes the spontaneous electrical potentials generated by pyramidal cells of the granular cortex via scalp electrodes, which are interpreted as waveforms on a monitor. EEG waveforms are interpreted by pattern recognition and quantification, which involves measuring frequency and amplitude. Frequency is measured in hertz (Hz) and is defined as the number of times per second the wave crosses the zero voltage line. Amplitude is measured in microvolts (μV) and represents the electrical height of the wave. Commonly, EEG is a plot of voltage versus time using 16 channels. The scalp EEG oscillations have characteristic frequency ranges which are divided into different bands that are associated with different states of brain functioning (Table 29.1).

Certain EEG changes are observed during anesthesia. During induction of anesthesia, a decrease in alpha activity and an increase in beta activity are observed. With a more profound depth of anesthesia, theta and delta activity is predominant. By further deepening of anesthesia, a burst suppression pattern may be observed as a depression of cerebral metabolic activity. Isoelectricity is the maximum degree of suppression achievable with anesthetic agents, which is the goal when inducing barbiturate coma.

The primary use of intraoperative EEG is to monitor for cerebral ischemia and hypoxia during carotid endarterectomy, cerebral aneurysms, arteriovenous malformations, and

Table 29.1. EEG frequency ranges

Delta rhythm (0–3 Hz)	Deep sleep Deep anesthesia Pathologic states: brain tumors, hypoxia, metabolic encephalopathy
Theta rhythm (4–7 Hz)	Sleep and anesthesia in adults Hyperventilation in awake children and young adults
Alpha rhythm (8–13 Hz)	Resting, awake adult with eyes closed; predominantly in occipital leads
Beta rhythm (>13 Hz)	Mental activity Light anesthesia

cardiopulmonary bypass procedures. Other indications for EEG monitoring include the assessment of barbiturate-induced burst suppression, CBF during deliberate hypotension, coma and death states, and diagnosis and treatment of epilepsy (Table 29.2).

The major advantage of intraoperative EEG monitoring is that it allows early detection of cerebral hypoxia and ischemia, because inadequate PaO_2 or insufficient CBF is reflected within seconds in the EEG.

Electrocorticography

Electrocorticography (ECoG) is the localization of epileptic foci by the placement of electrodes directly on the exposed surface of the cortex to record electrical activity. In cooperative patients, ECoG can be performed in the operating room while the craniotomy is accomplished with light sedation and local anesthesia. Agents used for this light anesthesia include nitrous oxide,

Table 29.2. Factors affecting the EEG

PaO_2	Hypoxia initially may produce EEG activation, followed by slowing or electrical silence
PaCO_2	Hypocarbica: EEG slowing Mild hypercarbia: increased frequency Severe hypercarbia: decreased frequency and amplitude
Temperature	Hypothermia: progressive slowing Electrical silence at 15°C – 20°C
Sensory stimulation	EEG activation

opioids, and low-dose isoflurane (maximum 0.25% end-tidal concentration). Seizure activity is provoked with agents or techniques that lower the seizure threshold (methohexital, alfentanil, hyperventilation).

In noncooperative patients and children, likely areas of epileptic foci are identified prior to the craniotomy. “Grids and strips” of electrodes embedded in a matrix are implanted into the cortex, and ECoG is performed after the surgery.

Although ECoG is the “gold standard” used to define epileptogenic zones, newer technologies using structural MRI and scalp EEG to integrate information and define first principal vectors have proven to be a promising noninvasive approach to locating epileptogenic zones.

Evoked potentials

Somatosensory evoked potentials

Somatosensory evoked potentials (SSEPs) monitor the integrity of the sensory pathways of the spinal cord. The waves of evoked potentials are thought to represent potentials from specific neural generators. A peripheral stimulus is applied to a distal nerve – usually the median or posterior tibial nerve – and the cephalad progression of the stimulus is monitored along the popliteal fossa, lumbar spine, cervical spine, and cortex. The amplitude of the cortical responses is very small (0.1–20 μ V) and difficult to discern from background bioelectrical activity (EEG, electrocardiogram, muscle activity) and extraneous electrical activity in the room, such as infusion pumps and blood warmers. However, this background noise is eliminated by the averaging process.

The individual peaks in the waveform of sensory evoked potentials are described by:

- Polarity (negative, positive)
- Poststimulus latency (ms)
- Peak-to-peak amplitude (μ V or nV)
- Distance separating neural generators and recording electrodes (near-field, far-field)

Compromise or injury to a neurologic pathway is manifested by an increase in latency and/or decrease in amplitude of evoked potential waveforms. In general, it must be stressed that because most anesthetics affect evoked potential monitoring, it is very important to maintain constant anesthetic drug levels so that changes seen in the monitoring can be seen as a reflection of possible neurologic damage. Specifically, bolus administration of intravenous agents and step changes in inspired agent concentration should be avoided, especially during parts of the surgery when neurologic injury might occur. High concentrations of end-tidal inhalational agents essentially eliminate cortical evoked potentials (SSEPs or visual evoked potentials [VEPs]). Newer inhalational agents, such as desflurane and sevoflurane, may permit higher inhaled concentrations during electrophysiologic monitoring than older agents. In general, volatile agents cause a dose-dependent increase in latency and a decrease in amplitude of cortical SSEPs or VEPs.

Many intravenous agents, such as narcotic infusions, propofol, ketamine, dexmedetomidine, and methohexital alter SSEPs less than volatile anesthetics or nitrous oxide.

Motor evoked potentials

Motor evoked potentials (MEPs) may be produced by direct (epidural) or indirect (transosseous) stimulation of the brain or spinal cord. Following transcranial stimulation, the signal descends through motor pathways located in the corticospinal tract of the spinal cord. The signal is localized primarily in the pyramidal tracts and can be recorded from the spinal cord, peripheral nerves, and muscle using conventional electromyographic (EMG) and evoked potential techniques. Stimulation of the motor cortex elicits contralateral peripheral nerve signals, EMG signals, or limb movements. Transosseous activation of motor neurons is accomplished by either electrical or magnetic stimulation. Transcranial electrical stimulation is achieved by delivering brief high-voltage pulses through scalp electrodes. Transcranial magnetic stimulation is produced by placing a magnetic coil over the motor cortex. With either electrical or magnetic stimulation, it is possible for repetitive stimulation to induce epileptic activity, neural damage, and cognitive or memory dysfunction. In patients with seizures, skull fractures, implanted metallic devices, or pulmonary artery catheters, this technique should be used with caution.

In addition, it is very important to make sure that a soft bite block is in place orally to prevent injury to the patient’s tongue and teeth during MEP stimulation. MEPs are particularly useful in monitoring for surgically induced damage during scoliosis surgery or resection of cerebral tumors. Myogenic MEP monitoring can detect ventral horn ischemia during aortic reconstruction (Tables 29.3 and 29.4).

Physiologic changes in systemic blood pressure, PaO₂, PaCO₂, and temperature may alter evoked potentials. Systemic hypotension below levels of cerebral autoregulation produces progressive decreases in amplitude of evoked potentials.

Wake-up test

The purpose of the wake-up test is to monitor voluntary motor function of the lower extremities once the vertebrae have been distracted during scoliosis surgery. This test was frequently used in scoliosis surgery but now is generally reserved for cases in which there is a decrease or loss of evoked potentials after excessive retraction during surgery. The wake-up test involves gradually lightening the anesthetic depth while maintaining adequate analgesia, to the point at which the patient can respond to verbal commands such as “squeeze my hands” or “wiggle your toes.” The patient needs to be educated about the wake-up test prior to surgery, including reassurance about not feeling any pain during the test and very small likelihood of intraoperative awareness.

During the actual wake-up test, it is important to remember that patients with idiopathic scoliosis generally are young, healthy, and strong. Therefore, some anesthesiologists

Table 29.3. Evoked potentials monitoring

Monitoring	Technique	Anesthetic considerations
SSEPs	Evaluation of functional integrity of ascending sensory pathways by somatosensory stimulation	A significant change of SSEPs is considered if the amplitude is reduced by 50% from baseline in response to surgical manipulation. TIVA may be preferred over inhalational agent anesthesia. End-tidal concentrations of 0.6 MAC of volatile agent are compatible with satisfactory readings. Nitrous oxide in combination with a volatile anesthetic produces profound depression unless total MAC < 1.0.
VEPs	Evaluation of functional integrity of ascending sensory pathways by visual stimulation	TIVA may be preferred over inhalational agent anesthesia. End-tidal concentrations of 0.5 MAC of volatile agent are compatible with satisfactory readings. VEPs tend to be more sensitive than SSEPs to the effect of inhalational anesthetics. Nitrous oxide in combination with a volatile anesthetic produces profound depression.
BAEPs	Evaluation of functional integrity of ascending sensory pathways by auditory stimulation at the brainstem	BAEPs are less vulnerable than SSEPs or VEPs to anesthetic influences. Most anesthetic regimens are compatible. Increase of latency with minimal amplitude effects. An increase in latency of > 1 ms is considered clinically significant. Large step of inhalational agent increases (>0.5 MAC) should be avoided during critical periods.
MEPs	Evaluation of functional integrity of descending motor pathways	MEPs are extremely sensitive to volatile agents, but less so to nitrous oxide. Benzodiazepines, barbiturates, and propofol produce marked depression of myogenic MEPs. Fentanyl, etomidate, and ketamine have little or no effect. Muscle relaxants affect the recorded EMG response by depressing myoneural transmission but may be used as a continuous infusion maintaining 1 or 2 twitches.

BAEPs, brainstem auditory evoked potentials; MAC, minimum alveolar concentration; TIVA, total intravenous anesthesia.

administer a small dose of nondepolarizing muscle relaxant (i.e., 0.015 mg/kg of vecuronium) just before the test to mildly weaken the patient. It is important to inform the neurophysiologist if any muscle relaxants are given. It is advisable to have an assistant, in addition to the anesthesiologist, at the head of the bed just before the test and to have an additional assistant under the drapes viewing the patient's feet. In general, volatile agents should be discontinued 20 minutes before the test and nitrous oxide discontinued 1 to 3 minutes before the test. If an infusion of methohexital or propofol was used, then it needs to be discontinued for a sufficient period. After the test is accomplished, the anesthesiologist can reanesthetize the patient with a small dose of an induction agent and/or midazolam. The induction agent must be given carefully considering that the patient might demonstrate hemodynamic changes such as hypotension in the setting of hypovolemia. In most cases, only a small amount of induction agent is needed to reinitiate general anesthesia. The anesthesiologist then must reassess the patient's positioning and padding because some patients move more than their hands and feet.

It is very important that the wake-up test is performed by an experienced anesthesiologist, because an uncontrolled wake-up test may lead to inadvertent extubation of the trachea as well as disconnection of arterial and venous catheters and patient injury.

Table 29.4. Effect of intravenous agents on evoked potentials

Agent	Effect
Propofol	Increases latency and decreases amplitude of SSEPs; decreases amplitude of VEPs
Etomidate	Increases latency and amplitude of cortical SSEPs; increases latency of VEPs
Thiopental	Induction dose may increase latency and decrease amplitude of SSEPs; increases latency and decreases amplitude of VEPs Increasing doses result in dose-dependent increase in latency and decrease in amplitude of cortical SSEPs and progressive increases in latency in BAEPs
Pentobarbital	Increases latency and decreases amplitude of SSEPs and VEPs
Ketamine	Increases latency and amplitude of SSEPs; increases latency and decreases amplitude of VEPs
Midazolam	No change or increase in latency and decrease of amplitude of SSEPs
Diazepam	No change or increase in latency and decrease of amplitude of SSEPs; decreases amplitude of VEPs
Opioids	Minimal change in SSEP waveforms

BAEPs, brainstem auditory evoked potentials.

Table 29.5. ICP monitoring techniques

Method	Technique	Advantages	Disadvantages
Intraventricular catheters (standard)	Small scalp incision Small burr hole through skull Insertion of a soft nonreactive plastic catheter into the lateral ventricle, connection to transducer	Relatively reliable measurement of ICP Allows CSF drainage and compliance measurement	Occlusion of tubing may obliterate recording Ventricle is difficult to locate in the setting of brain swelling Brain injury is possible during passage of catheter Risk of hematoma and infection of catheter
Subdural–subarachnoid bolts or catheters	Hollow screw fixed into the skull with the tip passing through the incised dura	No brain tissue penetration or knowledge of ventricular position May be placed in any skull location with avoidance of venous sinuses	Occlusion of tubing may obliterate recording Brain tissue may obstruct the tip of the bolt Risk of infection, epidural bleeding, or focal seizures if bolt is positioned too deeply
Epidural transducers	Placement of epidural catheter with a pressure-sensitive membrane or a Numoto pressure switch (Ladd transducer)	Lower risk of brain infection because of extradural placement	Difficult placement in potential space Risk of bleeding No possibility for compliance testing or CSF drainage
Intraparenchymal fiber-optic devices	Fiber-optic catheter introduced within cortical gray matter	Direct measurement of brain tissue pressure Easy insertion Small diameter Less disruptive of brain tissue Lower risk of infection (no fluid column) New fiber-optic ICP monitors allow measurement of local CBF, PO ₂ , PO ₂ , PCO ₂ , pH, and other metabolic markers	No possibility of calibration in situ No possibility of compliance testing or CSF drainage

CSF, cerebrospinal fluid.

Cranial nerve monitoring

Potential injury to the cranial nerves may occur during posterior fossa and lower brainstem procedures. The integrity of these cranial nerves can be preserved by monitoring the EMG potential of cranial nerves with motor components (CN V, VII, IX, X, XI, and XII). Both spontaneous and triggered muscle activity can be recorded. With accidental surgical contact, spontaneous neural activity changes into phasic “bursts” or “train” activity, which allows the surgeon to realize that he or she is in danger of damaging the cranial nerve. It is recommended that muscle relaxants not be administered during cranial nerve monitoring.

Intracranial pressure monitoring

Continuous intracranial pressure (ICP) monitoring has been used to guide the perioperative management of patients with head injury, large brain tumors, ruptured intracranial aneurysms, cerebrovascular occlusive disease, and hydrocephalus (Table 29.5). With continuous ICP monitoring, one can optimize cerebral perfusion pressure, which is critical in the treatment of brain hemorrhage, swelling, and herniation. Another important indication for ICP monitoring is to detect intracranial hypertension during neurosurgical procedures.

Transcranial Doppler ultrasound

Transcranial Doppler ultrasound (TCD), used for clinical imaging of intracranial vasculature, uses a 2-MHz range-gated probe. This probe is placed over low-density bone regions of the skull, and the beam is focused on the appropriate vessel, usually between the junction of the middle cerebral artery and the anterior cerebral artery. The blood flow of the vessel produces a Doppler shift proportional to the blood velocity, and thus a continuous assessment of systolic, diastolic, and mean flow velocities is possible. TCD primarily is a technique to measure relative changes in blood flow rather than a method to determine the actual blood flow. TCD can be used to measure CO₂ reactivity and autoregulation and to estimate cerebral perfusion pressures by using the pulsatile index: systolic velocity – diastolic velocity/mean velocity. TCD is used to identify patients with vasospasm, hyperemia, emboli, stenosis, abnormal collateral flow, and inadequate CBF.

Cerebral oxygenation metabolism

Several monitoring modalities are available to prevent ischemia by measuring the cerebral oxygen saturation during cardiac and vascular surgery (Table 29.6).

Table 29.6. Cerebral oxygen/metabolism monitoring techniques

Monitoring method	Technique	Anesthetic considerations
Brain tissue oxygenation	A multiparameter sensor is available for measuring brain tissue PO ₂ , PCO ₂ , pH, and temperature using a combined electrode-fiber-optic system	The placement of the sensor requires insertion into the cortex tissue under direct visualization.
Jugular bulb venous oximetry	Measurement of SjVO ₂ through a percutaneous retrograde cannulation of the internal jugular vein using a catheter with embedded optical fibers. Normal SjVO ₂ is 60%–70%.	Increases in SjVO ₂ indicate relative hyperemia as a result of reduced metabolic requirement (comatose or brain-dead patient) or excessive flow (severe hypercapnia). A value <50% reflects increased oxygen extraction and potential risk of ischemic injury. This also may be caused by increased metabolic demand (fever, seizure) or by an absolute reduction in flow. A major limitation is the inability to detect focal ischemia.
Transcranial oximetry	NIRS is a noninvasive optical method for monitoring cerebral regional oxygenation. It reflects off oxy- and deoxyhemoglobin and allows quantitative assessment of those based on the absorption of light at several wavelengths. It is used as a monitor during carotid endarterectomy, head injury, and subarachnoid hemorrhage.	Major limitations include intersubject variability, variable optical path length, potential contamination from extracranial blood, and lack of a definable threshold. It can be used only as a trend monitor. As a bilateral monitor, it is useful to detect regional ischemia during carotid endarterectomy and temporary clip application during intracranial aneurysm surgery.

Cerebral oximetry

Near-infrared spectroscopy (NIRS) provides a noninvasive assessment of the cerebral intravascular oxyhemoglobin, deoxyhemoglobin, and mitochondrial cytochrome aa3 oxygen levels by measuring the ability of these chromophores to absorb near-infrared light. The pathway of light photons in mammalian tissue is characterized by light attenuation as photons are absorbed by tissues and by scattering of the pathways as the photons are deflected from the different types of tissues. NIRS technology takes advantage of this by having the light emitter and detector on the same plane and measuring light that takes an elliptical pathway. In experimental settings, NIRS has been used along with other monitoring modalities to assess O₂ delivery and extraction, cerebral blood volume, CBF, and the redox state of the brain.

Most medical uses of NIRS center on its ability to measure relative changes in oxygen extraction in the total blood volume in a small brain area. Approximately 75% of the blood volume in the brain is venous, thus measures of the oxyhemoglobin content of this blood volume gives an estimate of venous oxygen saturation and thus extraction. This modality is called *regional cerebral oximetry* (rSO₂; INVOS, Somanetics Corporation, Troy, MI), and it is currently being used in cardiac and neurosurgical as well as pediatric critical care units.

Brain tissue oxygen monitors

Brain tissue oxygen monitors are catheters inserted through an intracranial bolt that measures O₂, brain tissue temperature, and ICP. The interstitial partial pressure of oxygen in brain tissue (P_{bt}O₂) depends on the CBF and arteriovenous difference in oxygen tension, thus these types of monitors may be a more sensitive tool in assessing cerebral hypoxia. Intensivists can individualize the care of a patient with traumatic brain injury

(TBI) because the P_{bt}O₂ is dependent not only on CBF but also on hemoglobin and lung function.

Jugular venous bulb oximetry

Continuous jugular venous bulb oximetry (Sjvo₂) provides a means to indirectly assess the brain's ability to extract and metabolize oxygen. Cerebral oxygen delivery depends on CBF and arterial oxygen content. In healthy patients, the extraction ratio between arterial and venous blood remains constant because CBF increases when cerebral oxygen requirements increase. However, >50% of patients with TBI exhibit evidence of cerebral dysautoregulation and thus are at risk for localized or generalized cerebral hypoxia. A study comparing brain tissue oxygen Pao₂ levels with Sjvo₂ found that both monitoring methods provided complementary information and that neither method alone identified all episodes of ischemia. Brain tissue monitors are capable of monitoring only a local area, whereas SjVO₂ monitors give a broader picture of the overall oxygen extraction. Because of difficulties in positioning the probe in a retrograde fashion from the internal jugular vein, these probes are used rarely in a clinical operating room setting.

Summary

Neuromonitoring during anesthesia and critical care allows for more insightful therapeutic management of patients who have had nonsurgical brain injury or who are at risk for neurologic injury during neurosurgical and back procedures. More studies are needed to determine which monitoring modalities or which combinations of monitoring modalities lead to optimal outcomes during the perioperative and critical care periods. It is possible that in the future, some of these techniques will become standard of care, but it also is important for outcome studies to demonstrate a therapeutic advantage before they are adopted as standard of care.

Intraoperative awareness

Scott D. Kelley

One of the fundamental goals in providing general anesthesia is to render the patient unconscious and oblivious to the events of the surgical procedure. If the anesthetic state becomes inadequate, a patient may regain consciousness and potentially form memories of the intraoperative period. This complication of anesthesia – intraoperative awareness with recall – has been recognized for decades, and it recently has become the focus of concerted efforts to reduce its frequency. Anesthesia strategies can be developed to minimize the occurrence and consequences of intraoperative awareness.

Incidence and etiology

Several prospective investigations documented the prevalence of intraoperative awareness with recall at approximately 0.1% to 0.2%; that is, it occurs in one in 500 to 1000 patients undergoing general anesthesia. These incidence measures have used a specific and simple structured interview to determine whether intraoperative memories have been formed. Patient recall of intraoperative events may be delayed; consequently, several interviews during the first 7 days will detect a greater occurrence of awareness. Initial interviews in the postanesthesia care unit likely detect only two-thirds of awareness episodes. The incidence of awareness determined using a patient interview approach may be substantially lower than the frequency of spontaneous patient complaints of awareness. In one survey of a large anesthesia practice, a quality assessment survey detected a much lower incidence of awareness based on patient feedback.

Based on clinical experience and investigation, the incidence of intraoperative awareness is greater in a recognized spectrum of patient types, surgical procedures, and anesthetic techniques (Table 30.1). In some of these clinical situations, such as emergency trauma surgery or a patient's cardiovascular status may preclude the administration of an adequate anesthetic dose to produce unconsciousness and suppress memory formation, and can increase the risk of awareness tenfold, up to 1%. Intravenous anesthesia may lead to a higher incidence of awareness due to the inability to monitor anesthetic drug levels with the equivalent of end-tidal agent analysis. General anesthesia provided solely by the combination of nitrous oxide and opioid administration has a higher incidence of awareness. Administration of neuromuscular blocking agents is associated with an increased risk of awareness, presumably because these

Table 30.1. Potential risk factors for awareness

Surgical procedures	Cardiac, trauma, emergency surgical procedures; emergent cesarean section
Patient characteristics	Substance use or abuse Chronic pain patients on high doses of opioids ASA physical status 4 or 5 Limited hemodynamic reserve
Anesthetic history	Anticipated or history of difficult intubation Previous episode of awareness Total intravenous anesthesia Nitrous oxide–opioid anesthesia
Anesthetic management	Planned use of neuromuscular blocking agents during maintenance phase Reduced anesthetic doses during paralysis

agents mask somatic signs of inadequate anesthesia. The early period of a general anesthetic, particularly in cases involving endotracheal intubation, is a high-risk period for intraoperative awareness. During management of anticipated or unexpected difficult intubation, the focus and attention of securing the airway may allow the anesthetic level to decrease and permit consciousness and recall. Similarly, the acute increase in anesthetic requirement with surgical incision represents another high-risk period for the occurrence of awareness.

By definition, intraoperative awareness occurs when an inadequate anesthetic effect permits a patient to regain consciousness, permitting memory formation. Inadequate anesthesia may result from an inadequate dose selected by the clinician, a failure (mechanical and/or human error) of the anesthetic delivery system to deliver the intended dose of anesthesia, or potentially, unrecognized resistance to anesthetic agents. The last etiology has been particularly difficult to characterize. To date, no genetic link to anesthetic requirement has been identified. In contrast, however, a patient's medication and substance use may alter the anesthetic dose required to maintain consciousness.

Consequences of intraoperative awareness

The consequences of intraoperative awareness are quite varied, ranging from tragic and horrific patient experiences to episodes that appear to have no sequelae. In one large prospective investigation, the occurrence of awareness was the greatest risk

factor for patient dissatisfaction with anesthesia care. In addition, a detailed follow-up of patients who experienced intraoperative awareness demonstrated that awareness may result in substantial psychological injury. During the period of intraoperative awareness, a patient may experience varying degrees of sensation (e.g., audible, tactile, pain, paralytic) as well as acute psychological symptoms (e.g., fear, panic, helplessness). The variety of these experiences and the duration of the awareness episodes likely are factors that contribute to the severity of psychological injury following awareness. The psychological injury may be transient and minor but also has been documented to result in substantial permanent long-term psychological disturbance, classified as posttraumatic stress disorder.

The occurrence of intraoperative awareness may be the basis for medicolegal action against the anesthesia professional who cared for the patient. The American Society of Anesthesiologists (ASA) Closed Claims Project has examined the settlement history for awareness claims in the database. In the most recent report, claims involving anesthesia awareness accounted for approximately 3% of cases. Payment was made in 46% of claims, and the median payment was \$41,210 (range, \$3960–\$1,016,470). Although the *frequency* of payments is similar to that of other general anesthesia claims, the *median* payment is

significantly less than that for other anesthesia claims. Several experts believe the recent focus on intraoperative awareness may increase the likelihood of medicolegal claims; however, it will be several years before this concern is reflected in the Closed Claims Project.

Preventing intraoperative awareness

The continued occurrence of awareness in modern anesthesia practice – in both high-risk and routine cases – has prompted efforts to develop practice strategies to prevent awareness. In the past 5 years, several anesthesia professional societies around the world, including the ASA, issued guidelines for their members regarding awareness. In addition, the Joint Commission for Accreditation of Healthcare Organizations (JCAHO) issued a Sentinel Event Alert to hospitals encouraging them to develop policies to prevent and manage intraoperative awareness. Common themes from these approaches include appropriate patient assessment and risk stratification, intraoperative use of routine clinical monitoring techniques, specific consideration of brain function and anesthetic agent monitoring in select cases, and postoperative assessment of patients to detect and manage awareness, if it occurred (Fig. 30.1).

Figure 30.1. Approach to avoiding awareness.

Preoperative period

Preoperative patient assessment should include identification of patient and procedural factors known to increase the risk of awareness. If a patient is at higher risk for awareness, this should be communicated during the informed consent process. Preoperative administration of benzodiazepine – despite its known amnestic effect – should not be considered protection against intraoperative awareness. In addition, preanesthesia checkout of the anesthetic machine and other drug delivery devices is essential to ensure the delivery of the intended anesthetic dose.

Clinical monitoring techniques

The routine clinical monitoring of the patient's vital signs and responses is important to assess the adequacy of the anesthetic state. However, intraoperative awareness may be particularly difficult to recognize based on routine clinical monitoring. A common assumption is that other indicators of inadequate anesthesia will alert the anesthesia clinician to a patient regaining consciousness. However, based on detailed reviews of anesthesia records from cases of intraoperative awareness, most patients did not exhibit hemodynamic signs of hypertension or tachycardia that would indicate inadequate anesthesia. As described earlier, neuromuscular blocking agents can prevent a patient from exhibiting somatic movement as a sign of inadequate anesthesia.

Brain function monitoring

Brain function monitoring devices provide anesthesia clinicians with another method to assess anesthetic effect. These devices use the patient's electroencephalogram (EEG) and/or auditory evoked responses as biological signals of anesthetic effect. To improve the utility of these devices, the manufacturers developed signal processing techniques and algorithms to translate raw EEG waveforms into numeric indicators of anesthetic effect. Typically, these devices scale anesthetic depth from a dimensionless score of 100, indicating the "awake" state, to 0, indicating maximal anesthetic effect on the EEG. As a class, these devices are very accurate in distinguishing an awake patient from an "unconscious" one. Consequently, the utility of this monitoring modality has been investigated as a measure to minimize intraoperative awareness.

Although other devices are available, only the bispectral index (BIS) monitor has been used in prospective trials to date. Two large trials studied the incidence of awareness when BIS monitoring was added as an adjunct to routine patient care and management. In a prospective investigation of 4945 patients undergoing routine anesthesia including neuromuscular blocking administration, addition of BIS monitoring led to a 78% reduction in the incidence of awareness compared with a historical cohort of 7826 patients. In a more rigorous prospective randomized controlled trial enrolling 2463 patients at high risk for awareness, the addition of BIS monitoring resulted in an 82% reduction in the incidence of awareness.

Anesthetic agent monitoring

The broad availability of end-tidal anesthetic agent analysis allows anesthesia clinicians to accurately measure the effective dose of delivered volatile anesthetic. In addition, the well-appreciated concept of volatile anesthetic potency, measured by minimum alveolar concentration (MAC), offers the ability to determine anesthetic requirements such as MAC_{awake} . A recent prospective trial measured the incidence of awareness in 1941 high-risk patients randomly assigned to undergo a BIS-guided anesthesia protocol (maintaining BIS between 40 and 60) or an end-tidal anesthetic-guided protocol (maintain 0.7–1.3 MAC). There were two cases of awareness in each treatment group, substantially less than would be expected in high-risk patients. This study did not find a difference in the incidence of awareness between the BIS-guided and MAC-guided anesthetic requirement techniques. However, the study may have been underpowered to detect a difference between the interventions.

Currently, anesthetic agent monitoring is available only for volatile anesthetic agents and nitrous oxide. Real-time measurement of intravenous anesthetic concentration is not available. There are no data available comparing the effectiveness of target-controlled infusions of propofol as a method to reduce awareness with that of conventional propofol infusion regimens. During anesthesia involving total intravenous anesthesia, brain function monitoring may provide additional confirmation of anesthetic delivery and effect.

Postoperative assessment and management

Early detection of awareness may minimize patient consequences. Although the Joint Commission recommends that all patients be assessed to detect the occurrence of awareness, other organizations suggest that only patients at increased risk need to be assessed. If intraoperative conditions (e.g., mechanical failure of anesthetic delivery, prolonged cessation of anesthetic agent administration due to hypotension) suggest an increased likelihood of awareness, the patient should be assessed as soon as possible. A structured approach modified from Brice is the easiest to use: What is the last thing you remember before you went to sleep? What is the first thing you remember when you woke up? Do you remember anything in between? Did you have any dreams? All patients who report intraoperative awareness should be followed up by the anesthesia team. It is important to express empathy with the patient's experience and concerns. The anesthesia team is in the best position to determine whether a patient's report of awareness represents intraoperative recall or perhaps recall during emergence, during extubation, or at a later time point. A discussion of the possible etiology or risk factors for awareness should be presented. Because of the potential for psychological injury, additional consultations should be obtained regarding the best course of counseling and other follow-up. Awareness cases should be discussed at departmental quality assurance meetings to increase efforts to avoid them in the future.

Inhalation Anesthetics

James H. Philip, editor

Inhalation anesthetics

Matthias Stopfkuchen-Evans, Lina M. Bolanos-Diaz, Alimorad G. Djalali, and Beverly K. Philip

The term *inhalation anesthetic* refers to anesthetics administered in a gaseous form. These include nitrous oxide (N_2O), a gas at room temperature, and the volatile anesthetics, which are nonflammable liquids at room temperature. Inhalation anesthetics are the most common drugs used for maintenance of general anesthesia because of their ease of administration and the ability to reliably monitor their effects with clinical signs and end-tidal concentration. This chapter presents the clinical pharmacology of commonly used and future inhaled anesthetics (Table 31.1).

Halothane

Physical properties

Halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) is a halogenated alkane compound. It is colorless and pleasant smelling but unstable in light; therefore, it is packaged in amber bottles with thymol preservative. Halothane became popular as a nonflammable general anesthetic, replacing older, flammable volatile anesthetics such as diethyl ether and cyclopropane. Halothane is a potent bronchodilator and is the least expensive volatile anesthetic. Although it is still used in developing countries, especially for the inhalation induction of anesthesia in children, it is no longer available in the United States.

Biotransformation and toxicity

The MAC (minimum alveolar concentration; see Chapter 33) for halothane is 0.75%, and its blood/gas partition coefficient ($\lambda_{b/g}$) is 2.4. Approximately 25% of administered halothane is metabolized to trifluoroacetic acid (TFA), chloride, and bromide. The major metabolite in humans is TFA, formed from oxidative metabolism primarily by CYP2E1. The TFA metabolite also reacts with tissue proteins to form trifluoroacetylated protein adducts (discussed later in the chapter).

Nitrous oxide

Physical properties

N_2O is a colorless, odorless, nonflammable gas. Although nonflammable, N_2O will support combustion. The MAC is 105%; therefore, N_2O is frequently used in combination with other anesthetic agents. The blood/gas partition coefficient ($\lambda_{b/g}$) is

0.47, and with its lower solubility, N_2O has a very rapid uptake and elimination. N_2O also is analgesic and is commonly used for dental sedation/analgesia.

N_2O increases the volume of air-filled cavities, air bubbles in blood, and air-containing intestines. All air-filled spaces contain nitrogen, which has a very low blood/gas partition coefficient (0.014). Compared with nitrogen, N_2O is much more soluble and much more diffusible. When N_2O enters an air-filled cavity down a partial pressure gradient, nitrogen cannot leave the cavity as quickly as N_2O enters. Hence, the volume of, of the gas pressure in, the cavity increases until its N_2O partial pressure equals that in the blood that is perfusing it. There are several clinical scenarios when this effect is particularly undesirable. N_2O should not be used when a pneumothorax is suspected. N_2O added to trapped air in the skull after head trauma may lead to brain damage. An air embolus becomes more dangerous when N_2O is in the bloodstream. The common presence of intravascular air during cardiopulmonary bypass makes N_2O an undesirable agent for cardiac surgery. In abdominal procedures, N_2O may cause an increase in the volume of the gas-filled intestine, depending on the concentration and duration of N_2O administration and the composition of the bowel gas. If an ileus is present, the volume change may cause bowel ischemia and difficulty closing the abdomen. Breathing 70% to 80% N_2O and air may double the volume of the intestinal gas in approximately two hours. For elective abdominal surgery, this change may not be of any significance. Because diffusion coefficients of CO_2 and N_2O are similar, N_2O may be used during laparoscopic procedures using CO_2 for insufflation.

Biotransformation and toxicity

N_2O is minimally metabolized (0.004%), and during emergence almost all is eliminated by exhalation. It has a very low short-term toxicity. Long-term, intensive care unit use of N_2O has been associated with clinical sequelae of inhibition of methionine synthase. N_2O irreversibly oxidizes cobalamin, a cofactor (along with folic acid) for methionine synthase, thus impairing DNA synthesis and causing hyperhomocysteinemia. Bone marrow depression may occur after prolonged exposure. Symptoms of vitamin B_{12} deficiency, including sensory neuropathy, myelopathy, and encephalopathy, may develop after several days of exposure to N_2O anesthesia. Patients with heterozygous

Table 31.1. Properties of inhalation agents

Parameter	Nitrous oxide	Isoflurane	Sevoflurane	Desflurane	Halothane

mutations in the gene encoding for methionine synthase or with vitamin B₁₂ deficiency are at risk for acute hyperhomocysteinemia and neuropathy, even after a single exposure to N₂O for as few as 80 minutes.

Isoflurane

Physical properties

Isoflurane (2-chloro-2-[difluoromethoxy]-1,1,1-trifluoroethane) is a halogenated ether with a moderately high pungency that can irritate the respiratory system.

Biotransformation and toxicity

The MAC of isoflurane is 1.17%, and its blood/gas partition coefficient ($\lambda_{b/g}$) is 1.4. There has been controversy regarding the use of isoflurane in patients with coronary artery disease because of the possibility of “coronary steal,” which is diversion of blood from areas of myocardium with inadequate perfusion to myocardium with more adequate perfusion. However, this has not been shown to be any clinical significance. Isoflurane exposure has been demonstrated to induce cognitive decline in mice. Exposure of cultured human cells to isoflurane has been reported to induce apoptosis as well as accumulation and aggregation of amyloid beta protein. However, no link between clinical exposure to isoflurane and cognitive decline or dementia in humans has been established.

Sevoflurane

Physical properties

Sevoflurane (2,2,2-trifluoro-1-[trifluoromethyl]ethyl fluoromethyl ether) is a sweet-smelling drug used for induction and maintenance of general anesthesia. Sevoflurane is the preferred agent for mask (inhalational) induction because of its low airway irritation; it also is a potent bronchodilator.

Biotransformation and toxicity

The MAC of sevoflurane is 2.05%, and its blood/gas partition coefficient ($\lambda_{b/g}$) is 0.65. Sevoflurane metabolites include

fluoride (F⁻), which has the potential to cause high-output renal failure. However, because of sevoflurane’s low blood/gas solubility and its rapid elimination, fluoride concentrations fall very quickly after surgery and renal toxicity from fluoride does not occur. The interaction of sevoflurane with dry carbon dioxide absorbents produces a chemical toxic to rats called “*compound A*.”

Desflurane

Physical properties

Desflurane (2-[difluoromethoxy]-1,1,1,2-tetrafluoroethane) is structurally similar to isoflurane but differs in its substitution of a fluoride for isoflurane’s single chloride atom. This change results in (1) low solubility in blood and tissues, allowing tissue levels to follow inhaled levels closely; (2) a decrease in potency; and (3) high vapor pressure. Desflurane boils at 22.8°C, which is near room temperature, requiring a unique anesthetic administration device that heats the desflurane liquid to 39°C (and <2 atm) to deliver desflurane as a vapor (Chapter 20).

Biotransformation and toxicity

Desflurane’s MAC is 6.0%, and its blood/gas coefficient ($\lambda_{b/g}$) is 0.42. It is minimally metabolized. The interaction of desflurane with dry CO₂ absorbents produces carbon monoxide (possibly resulting in increased levels of blood carboxyhemoglobin). The major clinical drawbacks of desflurane are its airway pungency and cardiovascular reactivity.

Xenon

Xenon is a nonflammable, colorless, and odorless gas that does not irritate the respiratory tract. Xenon is a trace gas in atmospheric air, unlike all other inhaled anesthetics, and is not an environmental pollutant. Xenon has a low blood/gas partition coefficient (0.14), allowing rapid uptake and elimination. The MAC is 60% to 70%, which prohibits the use of overpressure as an induction technique.

Xenon is well tolerated for inhalation induction, producing unconsciousness with analgesia, a degree of muscle

relaxation, and respiratory depression. It has minimal cardiovascular effects. Xenon is not metabolized in the body and is eliminated rapidly via the lungs. It is nontoxic, not associated with allergic reactions, and stable in storage, with no interaction with alkali CO₂ absorbents. Xenon should not be used with rubber anesthesia circuits as there is a high loss through the rubber. The high price of xenon has prevented its use in clinical anesthetic practice. Xenon, therefore, needs to be delivered in a closed circuit. The accumulation of nitrogen is a significant problem within the closed circuit and necessitates flushing, which in turn increases gas expenditure.

Clinical effects of inhalational anesthetics

Central nervous system

Volatile inhalation agents produce general anesthesia, which comprises a lack of awareness and lack of physical and physiologic response to surgical stimulation as primary therapeutic effects. All volatile inhalation agents produce a dose-dependent increase in cerebral blood flow through vasodilation, increased intracranial pressure (ICP), and decreased cerebral metabolic rate of oxygen (CMRO₂). Below 1 MAC, the decrease in CMRO₂ effect dominates; above 1 MAC, the cerebral vasodilatory effect dominates. Hypocapnia, opioids, and barbiturates can attenuate the increase in ICP if needed in patients with intracranial lesions or head injuries. Because of their vasodilator properties, volatile anesthetics diminish cerebral blood flow autoregulation. Halothane is the most potent cerebral vasodilator, and isoflurane is the least potent. Volatile anesthetics cause predictable EEG changes. During induction, volatile anesthetics increase the frequency and amplitude of EEG, which may relate to the excitement phase (stage II). As 1 MAC is reached, the EEG begins to slow, and then becomes isoelectric at 1.5 to 2 MAC. Volatile anesthetics also affect evoked potentials, increasing latency and decreasing amplitude.

Cardiovascular system

Volatile anesthetics cause a concentration-dependent decrease in mean arterial blood pressure by a variety of mechanisms. All volatile anesthetics decrease systemic vascular resistance (SVR), with halothane having the least effect on SVR. Halothane decreases blood pressure mainly by decreasing cardiac contractility, more so than do isoflurane, desflurane, or sevoflurane. In contrast, isoflurane, sevoflurane, and desflurane decrease blood pressure primarily by decreasing SVR. Volatile anesthetics have a protective effect on the myocardium called *anesthetic preconditioning*.

Volatile anesthetics increase heart rate as a compensatory response to the decrease in blood pressure, except for halothane, which blunts the baroreceptor reflex. With desflurane, a rapid increase in inspired concentration may lead to a rapid increase in heart rate and/or blood pressure, likely as a result of sympathetic stimulation. This effect may be attenuated by the prior administration of a β -blocker or moderate doses of opioid. All

inhaled anesthetics, especially isoflurane and desflurane, prolong the QT interval.

N₂O is a mild negative inotrope, slightly reducing contractility by inhibiting transsarcolemmal Ca⁺² flux. It does not change heart rate, it maintains SVR by increasing sympathetic tone, and it causes vasoconstriction of epicardial coronary arteries. N₂O further increases pulmonary vascular resistance in patients with preexisting pulmonary hypertension. Unlike other agents, halothane sensitizes the heart to the arrhythmogenic effects of epinephrine, predisposing to arrhythmias. Combined use of halothane with local anesthetics containing epinephrine should be limited to epinephrine doses <1.5 μ g/kg. Beta-blockers and calcium channel blockers may exacerbate the myocardial depression induced by halothane. Halothane also slows sinoatrial conduction, which may result in junctional rhythms; adults are more susceptible than children.

Respiratory system

Inhaled anesthetics produce concentration-dependent depression of respiratory drive via depression of the ventilatory centers in the medulla and reduction of intercostal muscle function. The result is a rapid, shallow breathing pattern, even in the absence of surgical stimulation, with decreased tidal volume and a compensatory increase in respiratory rate. However, this compensation may be insufficient to maintain adequate minute ventilation. Resting PaCO₂ is elevated, as is the apneic threshold. Ventilatory responses to arterial hypoxemia and hypercapnia are diminished by inhaled anesthetics. Desflurane, more than isoflurane, can cause airway irritation during induction, resulting in coughing, breath holding, laryngospasm, and salivation. Among the other volatile anesthetics, the order of airway irritation is isoflurane > halothane > sevoflurane. Halothane, sevoflurane, and isoflurane are potent bronchodilators, while desflurane may cause bronchoconstriction, especially in smokers and persons with asthma.

Hepatic system

Ether-based anesthetics (isoflurane, sevoflurane, desflurane) decrease portal vein blood flow but increase hepatic artery blood flow, thus maintaining total hepatic blood flow and oxygen delivery. This is in contrast to halothane anesthesia, in which decreases in portal vein blood flow are not compensated by increases in hepatic blood flow. Postoperative liver dysfunction has been associated most commonly with halothane use, although there are reports after isoflurane and, rarely, desflurane use. There are two major types of hepatotoxicity, type I and type II.

Type I hepatotoxicity

Type I hepatotoxicity is benign and self-limiting. It occurs in 25% to 30% of those who receive halothane. Signs are mild transient increases in serum transaminase, nausea, fever, but usually not jaundice.

Type II hepatotoxicity

Type II hepatotoxicity (also called “halothane hepatitis”) has been reported in one per 35,000 cases of halothane administration. It is immune-mediated and believed to result from the metabolism of halothane to TFA via oxidative reactions in the liver. Clinical signs of liver injury include fever, eosinophilia, jaundice, and grossly elevated serum transaminase levels, with positive IgG against TFA. Severe cases are associated with massive centrilobular liver necrosis that may lead to fulminant liver failure, with a mortality rate of 50%. Risk factors for halothane hepatitis include (1) multiple exposures, especially at intervals of < 6 weeks – reexposure at short intervals is the single greatest risk factor for halothane hepatitis; (2) a history of postanesthetic fever or jaundice, which may indicate previous subclinical disease; (3) obesity; (4) female sex; and (5) age > 50 years. There also may be a genetic predisposition.

The incidence of liver injury caused by fluorinated inhaled anesthetics follows the order of halothane > isoflurane > desflurane, and it correlates with the extent of their oxidative metabolism, which is halothane (20%), isoflurane (0.2%), and desflurane (0.02%). Because all these inhaled anesthetics appear to form protein adducts that are identical or related in structure to those produced by halothane, it seems probable that they cause liver injury by a similar mechanism. The reduced incidence of injury from the other inhalational anesthetics compared with halothane appears to result from the lower levels of potentially immunogenic protein adducts formed when they are oxidatively metabolized by CYP2E1. Sevoflurane does not produce TFA, so it does not cause hepatotoxicity.

Renal system

Volatile anesthetics produce a concentration-dependent reduction in renal blood flow, glomerular filtration rate, and urinary output due to decreases in blood pressure and cardiac output. These may be attenuated by adequate perioperative hydration. Inorganic fluorides are released by the oxidation of halogenated anesthetics. Fluoride levels of >50 $\mu\text{mol/L}$ may cause renal injury, consisting of polyuria hypernatremia, the inability to concentrate urine, and increased serum osmolality. Methoxyflurane is the only agent known to cause clinical fluoride-induced toxicity by this mechanism.

Sevoflurane in contact with the soda lime in a CO_2 absorber forms several degradation products, including *compound A*. Larger amounts of breakdown products are produced at lower fresh gas flows, as a result of increased temperature of the soda lime, and when the soda lime is desiccated. Compound A causes serious injury to kidneys in rats but is not proven to cause the same in humans. It is hypothesized that the difference is the result of different levels of renal cysteine conjugate β -lyase enzymes, which catalyze the conversion of compound A into thiol, which may cause toxicity. However, β -lyase is eight to 30 times less active in humans.

Neuromuscular system

Volatile anesthetics produce skeletal muscle relaxation and potentiate the effect of neuromuscular blocking drugs (both nondepolarizing and depolarizing). Sevoflurane can produce adequate muscle relaxation for intubation of children and adults, at sufficient depth.

Malignant hyperthermia

Malignant hyperthermia (MH) is a pharmacogenetic disorder of skeletal muscle triggered in susceptible individuals by all volatile inhalation anesthetics (desflurane, halothane, isoflurane, and sevoflurane). In addition to volatile agents, depolarizing skeletal muscle relaxants (e.g., succinylcholine) can also trigger MH. This syndrome has been linked to a missense mutation in the type 1 ryanodine receptor (RyR1) in more than 50% of cases studied to date. Signs of MH include tachycardia, increased expired CO_2 , muscle rigidity, and increased temperature, and are related to increased metabolism (hypermetabolic state).

The treatment of MH is dantrolene (see [Chapter 110](#)). Dantrolene markedly attenuates the loss of calcium from sarcoplasmic reticulum, restoring the metabolism to normal and reversing the signs of metabolic stimulation.

Inhalational induction technique

Since Morton's demonstration of the inhalation of ether in 1846, inhalation induction has been a useful technique to produce unconsciousness. Subsequently, chloroform, cyclopropane, N_2O , and halothane became popular agents for inhalational induction. Halothane was administered to millions of adult and pediatric patients worldwide for more than 30 years, but because of its cardiac depressive effect, arrhythmogenicity, and potential for hepatic dysfunction, it has been replaced by newer and safer agents, such as sevoflurane.

Sevoflurane is a sweet-smelling agent, having a nonirritant odor and a low blood/gas partition coefficient. It can be rapidly and conveniently administered without discomfort, and its low solubility facilitates precise control over the depth of anesthesia. This agent's low solubility, clinically useful overpressure capability, and high airway and cardiovascular tolerability combine to produce a rapid and smooth induction of general anesthesia.

Inhalation induction is widely used in the pediatric population and is a great alternative for adult patients with difficult intravenous access or an aversion to needles. Among the advantages of inhalation induction is the avoidance of the discomfort of a painful injection (propofol) and the “hangover” associated with intravenous agents (thiopental). Anesthesia “masks” have improved in the past several years and now are clear and more comfortable. They can be flavored with fruit essence or mint to make the induction a more pleasant experience.

Several clinical trials have evaluated and described mask inhalation induction techniques with sevoflurane, including:

- Gradual technique: The gradual technique consists of increasing the sevoflurane concentration by 1% every two breaths. This technique may be initiated with 66% N₂O before introducing sevoflurane, because N₂O is odorless and has a pleasant effect.
- Vital capacity single-breath technique: The anesthesia circuit is primed with 8% sevoflurane and up to 75% N₂O in O₂ at 4 L/min (3:1) for at least 1 minute. The patient exhales to residual volume, then inhales to vital capacity and attempts to hold his or her breath as long as tolerated or until unconsciousness.

Studies have shown that there is little statistical or clinical difference between the two induction techniques, or between the vital capacity technique and intravenous induction with propofol.

Pharmacokinetics of inhalational agents

James H. Philip

The kinetics of inhaled anesthetics is fundamental to the clinical practice of anesthesia. This subject is often called the *uptake and distribution of anesthetics*. It explains the time course of anesthetic movement from the delivery system to the site of action, which is the patient's central nervous system. Although the site of action of inhaled anesthetic agents includes the brain and spinal cord, the word *brain* is used alone in the remainder of this chapter. See [Chapter 35](#) for further discussion of anesthesia site of action.

Inhaled agents are either gases or vapors, depending on their physical state at room temperature and pressure. Nitrous oxide and xenon are gases. For these agents, the anesthetic source is a flow controller with flow meter. Halothane, isoflurane, sevoflurane, and desflurane are vapors. In this chapter, the agent source for all these is called a *vaporizer*. The physical properties of some of these agents are listed in [Table 32.1](#).

Definitions

The measure of anesthetic concentration in a compartment or location is the partial pressure. Partial pressure is also called tension. *Tension* is a generic term that applies to variables that equalize in connected locations. Examples are hydrostatic tension (water height) and electrical tension (voltage). The interchangeable terms *high-tension wires* and *high-voltage wires* are familiar examples of this.

Anesthetic partial pressure or tension could be expressed in common pressure units such as mm Hg, Pa, or kPa. However, the most commonly used unit for anesthetic partial pressure is % atm (percent of one sea level atmosphere). One percent partial pressure represents $1\% \times 760 \text{ mm Hg} = 7.6 \text{ mm Hg}$. The anesthetic tension is then said to be 1%. Commercial vaporizers state their delivered tension as a percentage and thus are consistent with this description.

Equilibrium is achieved when the tensions in compartments are equal. The locations or compartments of interest for inhaled agents are breathing circuit (inspired gas), lungs (alveolar gas), arterial blood, and the idealized body compartments: the vessel-rich group (VRG; brain, heart, liver, and kidneys), muscle, fat, and venous blood. [Fig. 32.1](#) displays the Gas Man model (registered trademark of the author), showing the compartments and their partial pressures. The model has been validated for induction and emergence of anesthesia

and has been used to elucidate fine points of inhalation kinetics.

Although equilibrium is achieved when the anesthetic tensions in compartments are equal, anesthetic concentrations in connected compartments differ at this equilibrium according to agent solubility in each location. For blood and gas in equilibrium, the ratio of concentration in blood to concentration in gas is the blood/gas solubility ratio or blood/gas solubility. The following example explains this.

A 10-ml syringe is filled with 5 ml blood and 5 ml air. A small amount of liquid or vapor anesthetic is added to the syringe, which is then capped and shaken. In the syringe, the tension of anesthetic in the blood and gas compartments equalizes while the concentrations equilibrate. At equilibrium, the ratio of concentration in the blood to concentration in the gas is the blood/gas solubility ratio or blood/gas solubility. The ratio of drug quantity in these two equal-size compartments also equals the blood/gas solubility. When the term *solubility* is used by itself, it usually refers to blood/gas solubility or blood/gas solubility ratio.

Movement of anesthetic

As blood passes through the capillaries of the lungs, anesthetic equilibrium is achieved across the alveolar-capillary membrane. Thus, arterial tension equals alveolar tension. The concentration of anesthetic in blood is equal to the product of the partial pressure and the solubility.

Arterial blood perfuses each tissue, and tissue tension rises toward arterial tension. During this period, anesthetic tension in venous blood leaving the tissue equals that in each tissue itself. Eventually, anesthetic tension in the tissue equals that in arterial blood. At this time, venous tension equals arterial tension and there is no longer anesthetic uptake into that tissue. The tissue is in equilibrium with blood. All tissues, fast and slow, eventually reach equilibrium, some after many hours. When this final equilibrium is reached, anesthetic tensions in all gas, liquid, and tissue compartments are equal.

The alveolar tension curve

To understand the kinetics of inhaled agents, we analyze the time course of anesthetic tension in the patient's lungs or alveoli

Table 32.1. Physical and kinetic properties of anesthetic agents

	Units	Halothane	Isoflurane	Sevoflurane	Desflurane	N ₂ O	Xenon	
MAC	%	0.8	1.1	2.1	6.0	110	70	
Blood/gas solubility		2.47	1.30	0.65	0.42	0.47	0.13	
VRG/blood solubility		1.94	1.62	1.69	1.29	0.89	1.30	
Muscle/blood solubility		4.01	3.46	3.69	2.31	1.15	2.00	
Fat/blood solubility		60.7	53.8	52.3	31.0	2.30	10.0	
Alveolar plateau height		0.24	0.38	0.55	0.66	0.63	0.86	
VRG = brain	Tau	Minutes	3.1	2.6	2.7	2.0	1.4	2.1
Muscle	Tau	Hours	2.4	2.1	2.3	1.4	0.7	1.2
Fat	Tau	Hours	49	43	42	25	2	8

(P_A) in response to a step change in inspired tension (P_I), as described by Kety in 1950. This is called the *alveolar step response* or, sometimes, the *alveolar tension curve*. The alveolar tension curve describes the time course of alveolar tension (P_A) in response to a step change in inspired tension (P_I).

Initial rise of the alveolar tension curve

The alveolar tension curve has the same general shape for all inhaled agents because they share the same physiology of drug delivery and removal. The alveolar tension curve components are called the *initial rise*, *plateau*, *knee*, and *tail*, as described by Kety. The alveolar tension curve for isoflurane is shown in Fig. 32.2.

The first portion of the curve is called the initial rise (Fig. 32.3). This is what the shape would look like if there were no removal of anesthetic from the alveoli by blood. This would happen in the following imaginary situations: if cardiac output

were zero, if the lungs were not connected to the cardiovascular system, or if the agent's solubility in blood were zero. The initial portion of the alveolar tension curve follows this shape for all inhaled agents whose inspired tension rises in the shape of a step. The curve shape of the initial rise is an exponential curve, shown in Fig. 32.3 and expressed mathematically as

$$\frac{P_A}{P_I} = 1 - e^{-\frac{t}{\tau}} \quad (\text{Eqn. 1})$$

where τ (Greek letter tau) is called the *time constant*. The time constant can be computed as the ratio of volume to flow in the alveolar compartment. The volume (V) is the functional residual capacity (FRC), or resting volume, of the lung and the flow (F) is the alveolar ventilation (VA), equal to the effective average minute ventilation of the alveoli:

$$\tau = \frac{V}{F} = \frac{\text{FRC}}{\text{VA}} \quad (\text{Eqn. 2})$$

For the average adult, $\text{FRC} = 2 \text{ L}$ and $\text{VA} = 4 \text{ L/min}$, so

$$\tau = \frac{\text{FRC}}{\text{VA}} = \frac{2 \text{ L}}{4 \text{ L/min}} = 0.5 \text{ min} \quad (\text{Eqn. 3})$$

The shape of the exponential curve of Eqn. 1, shown in Fig. 32.3, can be understood as follows. Initially, $t = 0$ and $e^0 = 1$, like any number raised to the zero power. Thus, $P_A/P_I = 0$ initially.

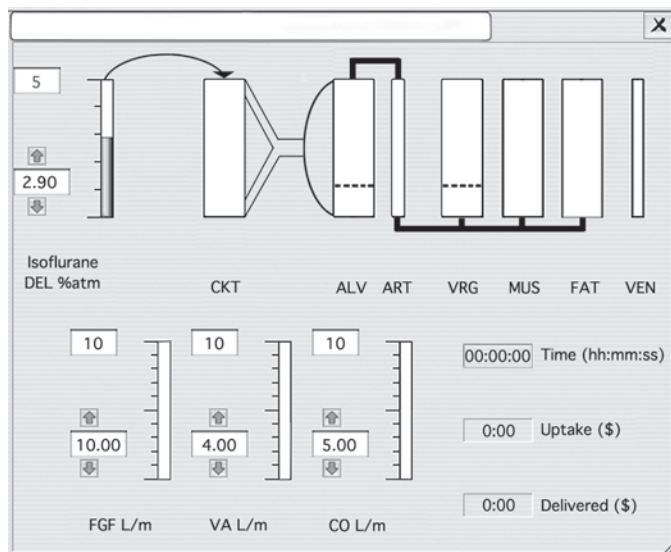

Figure 32.1. Gas Man[®] picture showing the schematic representation of the model for inhalation kinetics. The upper half shows compartments in which anesthetic partial pressure will rise from left to right. The lower half shows the flows that link the compartments, FGF, alveolar ventilation (VA), and cardiac output (CO). With permission of the owner, James H. Philip, and the licensee, Med Man Simulations, Inc. (www.gasmanweb.com), a nonprofit charitable organization, PO Box 67160, Chestnut Hill MA 02467. (Gas Man is a registered trademark of James H. Philip and Med Man Simulations, inc., a nonprofit charitable organization.)

Figure 32.2. Alveolar tension curve for isoflurane. The vertical axis labeled A/I reflects the alveolar over inspired ratio of concentration, fraction, partial pressure, or tension. The curve shows the characteristic initial rise, knee, and tail described in the text.

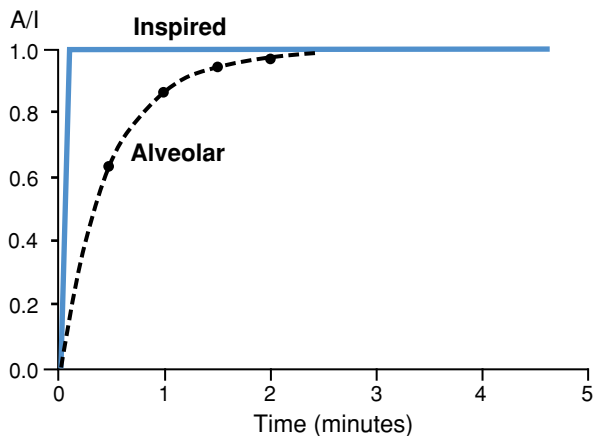

Figure 32.3. Rise in alveolar tension in response to a step change in inspired tension in the absence of uptake into blood. *Small circles* represent values at 1, 2, 3, and 4 time constants, which occur at 0.5, 1.0, 1.5, and 2.0 minutes.

As time passes, t eventually reaches the value of τ . This is at 0.5 minute in the example. At this time, the exponent of e is -1 and $e^{-1} = 1/e = 1/2.72718 \sim 0.37$. One minus this value is 0.63. Thus, when $t = \tau$, $P_A/P_I = 0.63$. After a second time constant has passed ($2 \times 0.5 = 1$ minute in this example), P_A/P_I has reached 0.63 of the remainder or 0.84 of the total. The value at $3 \times \tau = 0.92$ and at $4 \times \tau = 0.98$. Thus, at the end of four time constants, the curve has reached 0.98 on its way toward 1. It will reach 1.0 only after infinite time has elapsed.

An exponential curve depicts the input–output relationship for any fully mixed single compartment subjected to a step change in the tension entering it. This applies to tissue compartments as well. For a tissue compartment, the effective volume is the actual volume times the tissue/gas solubility. The effective flow is the actual blood flow times the blood/gas solubility. Solubilities of successive areas relate to each other such that tissue/gas solubility ($\lambda_{t/g}$) equals tissue/blood solubility ($\lambda_{t/b}$) times blood/gas solubility ($\lambda_{b/g}$).

$$\lambda_{t/g} = \lambda_{t/b} \times \lambda_{b/g} \quad (\text{Eqn. 4})$$

Plateau of the alveolar tension curve

The next portion of the alveolar tension curve is called the alveolar plateau. It reflects the added effect of removal of anesthetic by the blood (Fig. 32.4). This portion of the alveolar tension curve is created by the balance between delivery of anesthetic by alveolar ventilation (VA) and the removal of anesthetic by the product of cardiac output (CO) and blood/gas solubility ($\lambda_{b/g}$). The alveolar plateau height is computed as:

$$\frac{P_A}{P_I \text{ plateau}} = \frac{1}{1 + \frac{CO \times \lambda}{VA}} \quad (\text{Eqn. 5})$$

The equation and plateau height can be understood as follows. Imagine a drug with solubility = 1 and call it *unithane*. Further, consider the patient whose cardiac output equals his

Figure 32.4. The alveolar plateau is formed as alveolar ventilation delivers agent to the alveoli while blood flow removes it. The removal rate equals cardiac output times blood/gas solubility.

or her alveolar ventilation. In this situation, $CO \times \lambda/VA = 1$ and the alveolar plateau height is calculated to equal $\frac{1}{1+1} = 0.5 = 1/2$. Thus, the height of the plateau tension is half the height of inspired tension. This shows the balance of delivery exactly offset by removal, establishing equilibrium where alveolar tension is halfway between zero and inspired tension. If ventilation is higher, the plateau is higher. If cardiac output or solubility is higher, the plateau is lower.

The presence in the plateau equation of the mathematical term $CO \times \lambda/VA$ is clinically very significant. A change in any one of these parameters is offset by a proportional or inverse change in another term. Thus, halving the ventilation is the same as doubling the solubility. Moreover, doubling the ventilation is the same as halving the solubility, and tripling the ventilation is the same as reducing the solubility by a factor of three. This is important in that desflurane, sevoflurane, and isoflurane have relative solubilities of 1, 2, and 3. Table 32.1 shows solubilities and plateau heights, and Fig. 32.5 shows the plateaus.

Figure 32.5. Alveolar plateaus for real anesthetics and the imaginary zerothane (solubility zero) and infinithane (solubility infinity) anesthetics.

Figure 32.6. Tail of the alveolar tension curve. The rise in alveolar tension that transforms the plateau into a knee is produced by venous return of anesthetic-laden blood to the lungs.

Knee and tail of the alveolar tension curve

The final portion of the alveolar tension curve is called the tail. It is formed as a result of venous blood from tissues returning anesthetic to the alveoli; this causes alveolar tension to rise. Because arterial blood anesthetic tension follows alveolar tension closely, arterial tension also rises. As anesthetic tension from fast tissues (VRG) rises in the first few minutes after the inspired step, the flat plateau is transformed into an upgoing knee and the name of this portion of the curve changes (Fig. 32.6). The plateau exists in theory, whereas the knee and tail exist in reality. The first portion of the tail is formed by anesthetic-laden blood from VRG, the next portion by anesthetic-laden blood from muscle (a few hours later), and the final portion by anesthetic-laden blood from fat (more than 10 hours later). The alveolar tension curve for many agents is shown in Fig. 32.7 along with lines depicting the plateau heights. Actual plateau heights and values are shown in Table 32.1.

Figure 32.7. Alveolar tension curves of several anesthetics. Graphs are redrawn from the data of Yasuda, Eger et al., *Anesth Analg* 1991; 72:316–324.

Fine points of end-tidal, alveolar, and arterial tension

Lung shunt

Arterial blood anesthetic tension follows alveolar gas tension closely. Blood that passes through alveolar capillaries attains an anesthetic tension identical to that in alveolar gas. However, some blood flow does not pass through alveolar capillaries equilibrating with alveolar gas. This blood is called *lung shunt*. Lung shunt adds mixed venous blood with its lower anesthetic tension to the perfect alveolar-equilibrated blood. Thus, arterial tension is slightly lower than alveolar tension during deepening and higher than alveolar tension during lightening of anesthesia.

Alveolar dead space

Agent monitors measure end-expired gas tension. In reality, this “end-expired” gas comprises alveolar gas plus a small amount of inspired gas. The fraction of inspired gas mixed into the expired gas is the alveolar dead space fraction. This is usually around 10%.

End-expired gas monitor errors

The end-tidal agent tension measured by agent monitors differs from arterial blood tension by two errors: alveolar shunt and alveolar dead space. The total error with isoflurane is approximately 20%. Stated differently, $P_{art}/P_{ET} = 0.8$.

End-expired gas misinterpretations that ignore brain delay

At all times during anesthesia, anesthetic tension in the brain lags behind that in the arterial blood. The brain is a compartment perfused by blood and takes time to equilibrate with it. Based on brain/blood solubilities all being approximately 1.5 (Table 32.1), the brain time constant is between 1.5 and 3 minutes for all anesthetic agents.

Clinical kinetics: control of anesthetic depth

The goal of administering inhaled anesthetics is to bring the anesthetic tension in the brain to the desired level, manipulate it as clinical conditions dictate, and reduce the brain level to as close to zero as possible at the end of anesthesia. During anesthesia, brain tension is held somewhere near 1 MAC with pure inhalation anesthesia and < 1 MAC when other agents form a significant part of the patient’s anesthetic. Even if inspired agent tension could be controlled accurately, alveolar and VRG tension would be lower and delayed according to the alveolar tension curve described earlier.

In clinical care, the vaporizer dial is set and fresh gas flow (FGF) with the delivered tension enters the breathing circuit. The FGF mixes with the patient’s exhaled gas flow, producing an inspired tension that is an average of exhaled and delivered

tensions, each weighted by its relative flow and possibly affected by uneven mixing. Dilution of the delivered tension occurs unless FGF greatly exceeds ventilation. This occurs rarely in clinical practice, in which such excess is considered wasteful. The limit of low FGF is closed circuit anesthesia, in which FGF is set to exactly match the patient's uptake of oxygen and inhaled anesthetic agent. Closed circuit anesthesia is not addressed in this chapter.

Careful adjustment of the vaporizer setting combined with consideration of FGF, ventilation, cardiac output, and blood/gas solubility of the chosen anesthetic are required to achieve and maintain the desired brain anesthetic tension. FGF, vaporizer setting, inspired tension, and expired tension should all be observed for good control and understanding of brain anesthetic tension. This is important because changing FGF and patient ventilation often requires changes in the vaporizer setting, and these changes might not otherwise be appreciated if only expired tension is observed and recorded.

Emergence from anesthesia

Emergence from anesthesia of very long duration is the inverse of anesthesia induction. The alveolar tension curve is inverted. The shape could be described as comprising the initial fall, the knee, and the tail of the curve.

The level of anesthesia in the VRG at which 50% of patients follow commands is termed MAC_{awake} . For all agents, MAC_{awake} is approximately 0.33 MAC. Other benchmark levels of anesthesia are 0.75 MAC, 0.5 MAC, 0.2 MAC, and 0.1 MAC. Figure 32.8 shows a graph of emergence after very long anesthesia created by inverting the anesthesia induction curves of Fig. 32.7. It can be seen that for most agents, even in the context of a very long anesthetic at 1.0 MAC, the 0.75 MAC level is reached immediately and the 0.5 MAC level is attained in just a few minutes. The time to reach one-half the steady-state initial value is called

Figure 32.8. Alveolar tension fall for various anesthetic agents after an infinitely long anesthetic. These curves are created by inverting the curves of Fig 32.7. Dotted lines are shown at reduction from 1 MAC to 0.75, 0.50, 0.33, 0.20, and 0.10 MAC, reflecting fractional reductions of 0.25, 0.50, 0.67, 0.80, and 0.90 MAC.

the *half-time*. This value is commonly used as a benchmark for drugs. More sensitive differentiation among drugs is achieved by observing 0.67, 0.80, and 0.90 reduction (shown as dotted lines in Fig. 32.8).

Emergence is faster after short anesthetics than after long anesthetics. This is because very slow body compartments, such as fat, remain empty enough to remove anesthetic from blood. The effect of the muscle compartment changes within clinical durations of anesthesia. As muscle fills with anesthetic, it is transformed from a compartment that augments awakening to one that retards it. Any compartment with a tension lower than that in the blood helps emergence, whereas any compartment with a tension above that in blood hinders it.

Subtle kinetic effects

The concentration effect

The concentration effect and second gas effect describe the effect of gas uptake on the gas volume and the concentration that remains in the alveolar compartment. The concentration effect describes the kinetic impact of breathing a gas in a high concentration or fraction. When a high concentration is breathed, most of the gas taken up from the lung is that gas. When alveolar volume is reduced by uptake into blood during one breath, inspired tidal volume is increased in the next breath to offset the missing volume.

This phenomenon increases alveolar ventilation during the period of rapid uptake into blood. The high-concentration effect is usually described regarding nitrous oxide, because currently it is the only agent safe to breathe in a high concentration. Fig. 32.5 shows that the plateau height for nitrous oxide is lower than that for desflurane. In Fig. 32.5, the line is drawn as if nitrous oxide were breathed in a low concentration like the other gases. To avoid confusion, Fig. 32.7 omits the curve for nitrous oxide because in the actual experiment depicted, nitrous oxide was breathed in a high concentration (65%–70%) and the concentration effect displaced the nitrous oxide curve above that of desflurane. Figure 32.9 demonstrates the

Figure 32.9. The concentration effect refers to the effect whereby high-concentration (70%) nitrous oxide increases the rise of alveolar nitrous oxide compared with a low concentration of nitrous oxide (7%). The figure was created using Gas Man.

Figure 32.10. Second gas effect shows the higher alveolar tension curve for isoflurane combined with 70% nitrous oxide compared with the curve for isoflurane alone. The figure was created using Gas Man.

impact of concentration by overlaying simulated alveolar tension curves when breathing high-concentration (70%) and low-concentration (7%) nitrous oxide.

The second gas effect describes the impact of the presence of a high-concentration first gas such as nitrous oxide on the alveolar tension curve for a second, lower-concentration gas, such as isoflurane (Fig. 32.10). The absorption of the high-concentration high-volume nitrous oxide concentrates the isoflurane remaining in the alveoli. This absorption also augments all ventilation into the lungs by the increased inspired ventilation from the concentration effect. Because the alveolar isoflurane concentration is low compared with the inspired concentration, the alveolar concentration of the second gas can be raised by the presence of the first gas. For the less soluble drugs sevoflurane and desflurane, the second gas effect has less clinical impact.

The effect of tissue solubilities and blood flows

The clinical impact of tissue/blood solubility and the shape of the tail of the alveolar tension curve are subtle. Simulation

provides insights. When anesthetic tension in a tissue compartment exceeds MAC_{awake} or any other specified threshold, that tissue compartment delays blood and brain tension from reaching the threshold level. Early in the course of anesthesia, low muscle and fat anesthetic tensions will speed emergence, whereas later, high anesthetic tensions will delay it. The subtleties of tissue solubility and unknown tissue volume and blood flow make this even more complex.

Summary

Inhalation anesthesia kinetics is important. The alveolar tension curve in response to a step change in inspired tension unveils the kinetic relationship created by the interconnection of the inspired gas with the alveolar gas, blood, and key body compartments.

Pharmacodynamics of inhalational agents

Jan Boublik and Richard D. Urman

The minimum alveolar concentration (MAC) of an inhaled anesthetic is the concentration at 1 atm that prevents visible skeletal muscle movement in response to skin incision in 50% of patients. MAC is the inhaled anesthetic equivalent to the 50% effective dose (ED₅₀) of other medications. Several basic assumptions form the foundation of the concept of MAC.

First, alveolar concentration is an assessment of blood level. The brain is perfused by this blood, but the effect on the brain occurs several minutes after it appears in end-tidal gas, which we use to estimate alveolar gas. MAC equals the partial pressure of anesthetic at the anesthetic site of action. This is based on the assumption that the alveolar partial pressure is transmitted without change to arterial blood and that, given sufficient time for equilibration, the partial pressure at the site of action equals the partial pressure in arterial blood. The time constant for the brain and spinal cord is approximately 3 minutes for all inhaled agents. Thus, alveolar level to assess brain level can be applied only when anesthetic level is constant for several brain time constants. In research studies, end-expired anesthetic level is held constant for 15 minutes before measures of anesthesia depth are made.

The second assumption is that alveolar and end-tidal concentrations are equal. This is true only when there is no alveolar dead space and no alveolar shunt. Otherwise, dead space and shunt cause end-tidal and arterial concentrations to differ. Third, when the term *concentration* is used, it applies only at sea level. For the term to apply universally, *partial pressure* must replace *concentration* in the definition. (Chapter 32 explores this concept further.) The final assumption is that it is possible to elicit an all-or-nothing response to skin incision.

Mechanism of immobility

The immobility produced, as measured by MAC, is primarily mediated by the effects of volatile anesthetics on the spinal cord, with only a minor cerebral component. For example, decerebration of animals does not change MAC, whereas delivery of inhaled anesthetics only to the brain increases the MAC more than 2.5-fold and selective delivery to the spinal cord decreases MAC by a third.

The effects of volatile anesthetics on the spinal cord represent a diverse combination of drug-induced depression of excitement as well as enhancement of inhibition. Inhaled

anesthetics inhibit excitatory α -amino-3 adenosine monophosphate-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) receptor currents independently of γ -aminobutyric acid A (GABA_A) and glycine receptor activity. Sodium, but not potassium, ion channels also may be important in producing immobility. Cholinergic receptors do not seem to be involved in producing immobility at the spinal cord level. Opioids and α_2 -adrenoreceptor stimulation decrease MAC, but it is unlikely that the immobility produced by volatile anesthetics is mediated via these receptors. In summary, immobility cannot be explained by action of volatile anesthetics on a single group of receptors, nor does immobility seem to be the effect of concurrent action on several receptors.

Significance of MAC

The value of the MAC concept lies in the fact that it establishes a common measure of potency (partial pressure at steady state) for inhaled anesthetic with relatively small (10%–20%) variation among individuals (Table 33.1). The concept serves as a guide for several important clinical issues.

MAC provides a means for uniform dosage comparison of inhaled anesthetics. It establishes relative amounts of inhaled anesthetics to reach set clinical end points (described later). MAC serves as a guide to elucidate potential mechanisms of inhaled anesthetic/anesthetic action, and the use of MAC as a benchmark allows examination of the effect of equally potent doses (at spinal level) on other organ systems.

It is of crucial importance to understand that MAC represents only one point on the dose–response curves of the inhaled anesthetics. A modest increase to 1.3 MAC abolishes movement in at least 95% of patients as a result of the steep dose–response curves. This is why in clinical practice in which the inhalational

Table 33.1. Comparative MACs at sea level for adults aged 30 to 55 years

Agent	MAC, %
Nitrous oxide	104
Isoflurane	1.15
Sevoflurane	2.05
Desflurane	6.0
Halothane	0.75
Xenon	70

Table 33.2. Factors affecting MAC

Factor	Effect on MAC	Mechanism
Age	Young age (6 mo): increase Increasing age: decrease	Brain development and neuron formation before and loss of neurons after age 6 mo
Red hair	Increase	? Increased pheomelanin concentrations caused by melanocortin-1 receptor gene mutations, antagonism with opioid receptors, or influence on nociception
Body temperature	Hyperthermia: increase Hypothermia: decrease	Intrinsic properties in the brain
Blood pressure (MAP)	< 40 mm Hg: decrease	? Possibly impaired brain perfusion
Postpartum	Decrease by 30% immediately postpartum	Cardiovascular and hormonal changes of postpartum period
Oxygenation	PaO ₂ < 38 mm Hg: decrease	Attenuation of glutamate excitotoxicity
Cardiopulmonary bypass surgery	Decrease	Not known
Length of surgery	Constant or decrease	Not known
Sodium	Hypernatremia: increase Hyponatremia: decrease	Inhaled anesthetics inhibit synaptosomal sodium channels; amount of sodium in the body affects level of inhibition
Cyclosporine	Increase	Pharmacodynamic interaction seems to be likely, perhaps consequent to an effect of cyclosporine on ligand-gated sodium channels
Opioids	Decrease	Indirect (modulating) role but not a direct (mediating) role; provide analgesia and thus decrease MAC
Benzodiazepines	Decrease	Modulation by inhibition of GABA receptor
Ketamine	Decrease	NMDA receptor antagonism decreases temporal summation of pain stimuli
Lithium	Decrease	Not known
Lidocaine	Decrease	Modulating effect by providing analgesia
Alcohol	Acute: decrease Chronic: increase	Acute alcohol ingestion: synergistic with inhaled anesthetics Chronic alcoholism causes tolerance (?) by alteration of cytochrome P-450 system

agent is the sole anesthetic, >1 MAC often is needed to prevent the patient from moving in response to surgical stimulation. Several other “MACs” are of clinical relevance, as discussed below.

Various MAC parameters

MAC_{awake} represents the point on the volatile anesthetic concentration curve that defines the return of response to verbal command during emergence from anesthesia. For most agents, MAC_{awake} is 0.33 MAC. Interestingly, the transition from awake to unconscious requires 0.4 to 0.5 MAC.

MAC_{intubation} is the concentration of volatile anesthetic at which no movement or cough occurs during endotracheal intubation. Its value is approximately 2.0 MAC.

MAC_{BAR} is the concentration at which we observe blocked autonomic response (no blood pressure, heart rate, or catecholamine release) to an incision. Its value is 1.6 to 1.7 MAC.

The ratios among MAC_(skin), MAC_{BAR}, MAC_{intubation}, and MAC_{awake} are constant for the respective inhaled anesthetics.

Factors affecting MAC

MAC lends itself to the analysis of physiologic and pharmacologic factors that may or may not affect inhalational anesthetic

requirements in humans (Tables 33.2 and 33.3, respectively) as a result of the remarkable homogeneity of inhaled anesthetic requirements in humans.

Physiologic variables

Several factors may significantly alter MAC requirements. Maximum MAC requirement is achieved at 6 months after birth. Age accounts for a 6% average decrease in MAC per decade of life for all inhaled anesthetics. This is attributed to brain development and formation (increase MAC) and degeneration of neurons (decrease MAC) in the human brain.

Hyperthermia increases MAC, whereas hypothermia decreases it. In the early postpartum period, MAC is decreased by nearly 30% and returns to normal within 12 to 72 hours as a result of postpartum hormonal and cardiovascular changes.

Table 33.3. Factors not affecting MAC

Gender (except for xenon)
Duration of anesthesia (see Table 33.2)
Anesthetic metabolism
Thyroid gland dysfunction
Hypo-/hyperkalemia
PaO ₂ variation if > 38 mm Hg
Hypertension
Hypotension

Although gender does not affect MAC, women with naturally red hair have a 20% increase in MAC, stemming from increased pheomelanin concentrations caused by melanocortin-1 receptor gene mutations. Most sources describe MAC as time independent, but there is some evidence to suggest that the MAC for isoflurane decreases with length of surgery as well as cardiopulmonary bypass use. Hypoxia with a $\text{PaO}_2 < 38$ mm Hg decreases MAC by attenuating glutamate excitotoxicity. Changes in the sodium concentration in the blood alter MAC requirements by affecting synaptosomal sodium channels, whereas changes in potassium levels have no effect.

Pharmacologic variables

MAC values for different inhaled anesthetics are additive, meaning that 0.5 MAC each of two anesthetics provides the same effect as 1 MAC of either agent alone. Nitrous oxide cannot be used as the sole inhaled anesthetic in young patients, as its MAC surpasses safe concentrations. Opioids at clinical doses can reduce MAC by up to 50% in a modulating, indirect fashion when they provide profound analgesia. Comparatively smaller effects on MAC are observed with benzodiazepines and ketamine through GABA_A inhibition and NMDA antagonism (causing decreased temporal summation of nociceptive stimuli). Whereas acute alcohol ingestion decreases MAC, chronic alcohol use increases it. Table 33.2 summarizes the various factors affecting MAC.

Limitations of MAC

Although the MAC concept is undoubtedly useful in discussing the potency of volatile anesthetics and the depth of anesthesia, it also has several inherent limitations. MAC determination requires a constant alveolar concentration to be maintained for 15 minutes to allow for equilibration of the vessel-rich group and blood. The best use of MAC is in interpreting the end-tidal anesthetic agent concentration in the recent past to predict the level of anesthetic in the brain at present. Lung shunt and alveolar dead space cause differences between end-tidal and arterial anesthetic tension.

It is important to remember that MAC is a measure of ED₅₀ established in clinical trials, not ED₁₀₀ on a population level. The required concentration to prevent movement in response to skin incision therefore differs slightly from patient to patient. MAC measures somatic response, not lack of awareness. It applies only to inhaled not intravenous anesthetics, thereby limiting the ability to compare the two classes of drugs. MAC always depends on a specific clinical end point, and different values have to be elucidated for each end point (e.g., skin incision, awake).

Intravenous Anesthetics and Adjunct Drugs

Mark Dershwitz, editor

Intravenous induction agents

Aakash Agarwala and Mark Dershwitz

Sedative–hypnotic agents such as barbiturates, benzodiazepines, etomidate, and propofol, as well as medications such as ketamine, all may be used to induce general anesthesia and are therefore classified as induction agents. They also may be used for maintenance of sedation or general anesthesia, either via intermittent bolus injection or constant intravenous (IV) infusion. When administered in large doses, as during the induction of general anesthesia, they may cause significant cardiovascular and ventilatory effects. These effects, as well as the adverse effects specific to each agent, are discussed in this chapter. The choice of medications used for induction should be tailored to each patient based on his or her medical history and the pharmacologic effects of each drug. The choice may consist of an induction agent alone or may include the use of opioids, muscle relaxants, inhalational agents, and/or vasoactive medications to maximize patient safety and comfort and provide optimal surgical conditions.

Overview

Benzodiazepines, barbiturates, etomidate, and propofol function primarily through their interaction with the γ -aminobutyric acid (GABA) neurotransmitter system. Through different mechanisms, they augment the function of this inhibitory system. GABA receptor activation results in the influx of chloride ions into neurons, causing hyperpolarization and inhibition of the neuron by increasing the potential difference that must be overcome to generate an action potential (see [Chapter 35](#)).

Ketamine, in contrast to the other induction agents, acts primarily by antagonizing the *N*-methyl-D-aspartate (NMDA) receptor, although it also inhibits neuronal nicotinic acetylcholine receptors (see [Chapter 35](#)). Through its interaction with NMDA receptors, it causes a simultaneous depression of the thalamocortical system and stimulation of the limbic system, resulting in what is called “dissociative anesthesia.”

During induction, a rapid onset of action is generally desired to minimize the time the patient is in the excitatory stage of anesthesia. Characteristics of these drugs that favor a more rapid onset include high lipid solubility and greater fraction of drug in the nonionized form. Following administration, these drugs distribute rapidly to the central nervous system

(CNS) because of the large fraction of cardiac output received by the CNS as well as their lipophilic nature.

The effects of opioids and IV induction agents are synergistic, and the use of opioids prior to induction generally reduces the dose of induction agent required to produce unconsciousness. In addition, opioids typically potentiate the cardiovascular and ventilatory effects of the IV induction agents.

Elderly patients usually require lower doses of most agents used for induction because of decreased CNS sensitivity, decreased metabolic and renal clearance, and decreased plasma protein concentration that results in an increased fraction of “free” drug within the circulation. Elderly hypovolemic patients who have been pretreated with opioids and/or benzodiazepines may have more cardiovascular instability with a given dose of an induction agent; thus, a lower dose of induction agent and concomitant administration of vasoactive medications should be considered in these patients.

Induction agents

Barbiturates

Thiopental and methohexital are the shortest-acting of the barbiturates and are used for induction of general anesthesia. Through rapid redistribution, they produce a loss of consciousness, followed by prompt awakening following the usual induction doses ([Table 34.1](#)). Thiopental is prepared as a 2.5% solution that is relatively painless when injected intravenously. Allergies to barbiturates are rare, estimated at one in 30,000, and barbiturates are contraindicated in patients with porphyria. Thiopental may cause hyperalgesia in sedative doses.

CNS effects

Thiopental decreases the cerebral metabolic rate of oxygen consumption ($CMRO_2$), cerebral blood flow (CBF), and intracranial pressure (ICP) ([Table 34.2](#)). By decreasing cerebral metabolism, the administration of thiopental protects the brain against ischemic injury during periods of decreased oxygen delivery. This neuroprotective effect may be advantageous for patients undergoing surgery for intracranial aneurysms or arteriovenous malformations. Although thiopental also causes decreases in mean arterial pressure, reductions in ICP may be greater, favoring increased cerebral perfusion in these patients.

Table 34.1. Pharmacokinetic characteristics of IV anesthetic agents

Drug	Induction dose, mg/kg	Onset, sec	Duration, min	Redistribution half-life, min	Terminal half-life, h
Thiopental	4–7	< 30	5–10	2–4	6–12
Methohexital	1–3	< 30	5–10	5–6	2–5
Propofol	1–3	< 30	3–8	1–2	4–6
Etomidate	0.2–0.3	< 30	5–10	2–4	2–5
Diazepam	0.3–0.6	45–60	15–30	10–15	20–40
Lorazepam	0.03–0.06	60–120	60–120	3–10	10–20
Midazolam	0.2–0.4	30–60	15–30	7–15	2–4
Ketamine	1–2	45–60	10–20	11–17	2–3

Adapted with permission from Dershwitz M, Rosow CE. Intravenous anesthetics. In: Longnecker DE, Brown D, Newman M, Zapol WM, eds. *Anesthesiology*. 3rd ed. New York: McGraw-Hill; 2008.

The neuroprotective effect of thiopental occurs only if administered prior to an anticipated reduction of cerebral perfusion. No benefit has been found if thiopental is given following the onset of cerebral ischemia.

Progressively increasing doses of thiopental result in changes in the electroencephalogram (EEG) from alpha and beta waves to delta waves that are characteristic of surgical anesthesia. At higher doses, an isoelectric EEG may be attained, a state characterized by significant decreases in cerebral oxygen metabolism and blood flow. Thiopental's anticonvulsant properties make it useful in the treatment of status epilepticus, although the cardiovascular and ventilatory effects may necessitate mechanical ventilation and the use of vasopressors.

Methohexital, in contrast to thiopental, has some epileptogenic activity at lower doses, which makes its use less desirable in patients with seizure disorders. This property is of benefit, however, when trying to isolate epileptic foci in the brain during surgical ablation. It is often used to induce anesthesia in patients undergoing electroconvulsive therapy.

Cardiovascular effects

Induction doses of thiopental (4–7 mg/kg) may cause hypotension, although to a lesser degree than following induction with propofol. Decreases in blood pressure and cardiac output occur primarily through preload reduction due to venodilation and secondarily through decreases in myocardial contractility

Table 34.2. CNS effects of IV anesthetic agents

Drug	CMRO ₂	CBF	CPP	ICP
Thiopental	--	--	±	--
Methohexital	--	--	±	--

(Table 34.3). Decreases in blood pressure are usually accompanied by reflex tachycardia. The hypotension may be exaggerated in the elderly, in hypovolemic patients, or in those who have been pretreated with opioids, benzodiazepines, or antihypertensive medications. Thiopental also causes nonimmunologic histamine release that also contributes to hypotension, but histamine levels return to normal soon after thiopental administration.

Ventilatory effects

Apnea is common following an induction dose of thiopental. Lower doses cause ventilatory depression with decreases in rate, tidal volume, and carbon dioxide responsiveness. Airway responsiveness is increased more than with propofol. Bronchospasm and laryngospasm resulting from airway stimulation occur more frequently because barbiturates do not depress laryngeal or cough reflexes as much as propofol does.

Metabolism and elimination

The short period of unconsciousness following an induction dose of thiopental is the result of redistribution. Repeated bolus doses or a continuous infusion results in accumulation and a longer period of unconsciousness following the last dose or termination of the infusion.

Table 34.3. Cardiovascular effects of IV anesthetic agents

Drug	MAP	HR	CO	Contractility dP/dt	SVR	Venous dilation

Adapted with permission from Dershwitz M, Rosow CE. Intravenous anesthetics. In: Longnecker DE, Brown D, Newman M, Zapol WM, eds. *Anesthesiology*. 3rd ed. New York: McGraw-Hill; 2008.

Thiopental is oxidatively metabolized by cytochrome P450 (CYP) to several metabolites. One of these metabolites results from replacing the sulfur atom in the barbituric acid ring with an oxygen atom, yielding the active metabolite pentobarbital. Because pentobarbital has a longer duration of action than thiopental, its presence as an active metabolite causes thiopental to appear longer acting than it actually is. These characteristics make thiopental less ideal for maintenance of anesthesia or sedation; therefore, it rarely is given by repeated bolus dosing or by infusion.

Patients with liver disease generally maintain normal total clearance of thiopental. This observation may be explained by the opposing effects of decreased hepatic clearance and decreased protein binding due to hypoalbuminemia. All barbiturates induce δ -aminolevulinic acid (ALA) synthase, the initial enzyme in heme biosynthesis. Patients with certain types of porphyria (acute intermittent porphyria, hereditary coproporphyrin, variegate porphyria) are deficient in enzymes downstream from ALA synthase in the heme biosynthesis pathway. Administration of barbiturates to such patients may result in accumulation of ALA, which is neurotoxic. Barbiturates thus are contraindicated in patients with these types of porphyria.

Thiopental and methohexital are supplied as sodium salts in powdered form and are mixed with sterile water prior to administration. Barbiturates may precipitate when dissolved in an acidic solution such as lactated Ringer's. If thiopental is accidentally given by intraarterial injection, vasospasm, thrombosis, and tissue necrosis may occur. Treatment includes vasodilator therapy with papaverine or nitroglycerin and anticoagulation with heparin.

Propofol

Propofol is the most commonly used induction agent because its use is characterized by rapid return of consciousness with minimal residual CNS effects (Table 34.1). It also has antiemetic and amnesic properties at subhypnotic doses.

CNS effects

Like thiopental, propofol decreases $CMRO_2$, CBF, and ICP (Table 34.2). It has an anticonvulsant effect and may be used for treatment of status epilepticus. Although it has not been studied as extensively as thiopental for neuroprotection, it appears to have a similar profile. Relative to thiopental, however, the decreases in systemic blood pressure may be more significant than decreases in ICP, potentially resulting in a greater reduction in cerebral perfusion pressure.

Cardiovascular effects

Propofol causes a greater decrease in systemic vascular resistance than does thiopental, but it causes a similar decrease in cardiac contractility (Table 34.3). By virtue of its inhibition of the barostatic reflex and vagal stimulation, there is a smaller increase in heart rate for a given decrease in blood pressure,

thereby exaggerating the hypotensive effect as compared with thiopental. Elderly persons, patients with hypovolemia, and patients with ventricular dysfunction are more likely to become hypotensive.

Ventilatory effects

Compared with thiopental, propofol causes diminished airway reactivity, decreasing the incidence of coughing or laryngospasm. Induction doses result in apnea, and lower doses cause decreases in tidal volume, minute ventilation, and carbon dioxide responsiveness. Pretreatment with benzodiazepines or opioids may augment the ventilatory depressant effect. Propofol does not cause histamine release.

Metabolism and elimination

Propofol is short acting following an induction dose because of its rapid redistribution. Compared with thiopental, it is metabolized more rapidly, not only by the liver, but by the kidney as well. Even in the presence of liver and kidney disease, propofol clearance is usually not significantly decreased. Propofol therefore is often given by infusion, and recovery is typically predictable (see Chapter 36). Propofol is approximately 98% bound to plasma protein. Unlike thiopental, propofol is safe in patients with porphyria.

In the United States, propofol is available as a 1% emulsion containing soybean oil, glycerol, and lecithin. Depending on the manufacturer, the bacteriostatic agent is EDTA, metabisulfite, or benzyl alcohol. Different lipid preparations are available in other countries, and some of them cause less pain on injection. Aseptic technique is important when withdrawing and administering propofol, and vials or syringes that have been exposed to air should be discarded 6 hours after exposure.

True allergy to propofol, if it exists, is exceedingly rare. Although the emulsion contains soybean oil and egg lecithin, it contains no soy protein or egg albumin. Therefore, persons allergic to soy or egg protein can be given propofol safely. IV administration of propofol often causes pain during the injection, especially if it is given via a small vein. The pain may be minimized by choosing a larger vein for IV placement. Alternatively, placing a tourniquet proximal to the IV catheter and then preceding the administration of propofol with an IV injection of lidocaine (0.5 mg/kg) may be effective in reducing this discomfort. Accidental arterial administration of propofol may be very painful but generally does not cause the potentially severe consequences of thrombosis and tissue necrosis that often occur with intraarterial injection of thiopental.

Etomidate

Etomidate, an imidazole derivative, is structurally different from other induction agents. However, like thiopental and propofol, it increases GABA activity. Induction doses result in both rapid onset of anesthesia and rapid emergence

(Table 34.1). In contrast to thiopental and propofol, it produces only minimal changes in blood pressure and cardiac output.

CNS effects

Etomidate produces CNS effects similar to those of propofol and thiopental. Etomidate decreases CMRO₂, CBF, and ICP (Table 34.2). Because etomidate reduces ICP while having little effect on mean arterial pressure, it typically produces an increase in cerebral perfusion pressure. Etomidate is an anti-convulsant and may be used in treating status epilepticus. It also may increase EEG activity in epileptogenic areas, a property that makes it useful in locating seizure foci during brain mapping surgery. Unlike other induction agents, which depress somatosensory evoked potentials (SSEPs), etomidate increases both the amplitude and latency of SSEPs. Following induction of anesthesia with etomidate, there is increased incidence of myoclonic jerking compared with thiopental or propofol.

Cardiovascular effects

Perhaps the greatest pharmacologic advantage of etomidate is the hemodynamic stability that follows its administration. Induction of anesthesia with etomidate, in contrast to propofol or thiopental, results in minimal changes in blood pressure, heart rate, or cardiac output because it has minimal effect on cardiac contractility and vascular tone (Table 34.3). Etomidate therefore may be the induction agent of choice in patients with hypovolemia or significant ventricular dysfunction.

Ventilatory effects

Etomidate causes less ventilatory depression than propofol and thiopental, but transient apnea still occurs with induction doses. Opioids often are given in conjunction with etomidate to minimize the sympathetic response to intubation.

Metabolism and elimination

Etomidate inhibits 11 β -hydroxylase, the mitochondrial isozyme of CYP responsible for the final reaction in the biosynthesis of cortisol. Following a typical induction dose, cortisol release from the adrenal gland is suppressed for about 12 hours. Whether the short-term adrenal suppression that occurs with a single dose of etomidate is of clinical significance remains controversial. However, the adrenal suppression that occurs with continuous infusions of etomidate may have significant adverse consequences. Etomidate infusions given for several days have been associated with increased mortality in critically ill patients.

Etomidate is metabolized primarily via ester hydrolysis in the liver to a water-soluble metabolite excreted in the urine. Compared with thiopental and propofol, a slightly smaller fraction of etomidate is bound to plasma proteins. Because etomidate has a high hepatic extraction ratio of about 0.7, decreased hepatic blood flow will decrease its clearance. Because etomidate induces ALA synthase in rats, it should be used with caution in patients with porphyria.

Etomidate is supplied as a 0.2% solution in 35% propylene glycol at neutral pH. Intravenous injection may be painful,

Table 34.4. Comparative clinical effects of IV anesthetic agents

Drug	Advantages	Disadvantages
Thiopental	Rapid onset, rapid recovery No pain on injection ↓ CMRO ₂ , CBF, ICP	↑ Airway responsiveness ↓ BP, CO ↓ Ventilatory drive
Propofol	Rapid onset, rapid recovery ↓ Airway resistance ↓ CMRO ₂ , CBF, ICP ↓ Nausea and vomiting	Pain on injection ↓ BP, CO ↓ Ventilatory drive
Etomidate	Minimal changes in BP, CO Rapid onset, rapid recovery ↓ CMRO ₂ , CBF, ICP	Adrenal suppression Pain on injection ↑ Nausea and vomiting ↓ Ventilatory drive
Midazolam	Anxiolysis, amnesia Minimal changes in BP, CO Minimal ventilatory depression Effects reversible with flumazenil ↓ CMRO ₂ , CBF, ICP Effective by IM route	Longer duration than other agents
Ketamine	Minimal ventilatory depression Preservation of airway reflexes ↑ HR, BP, CO Effective by IM route	Emergence delirium Longer duration than other agents ↑ Ischemia risk in CAD

BP, blood pressure; CAD, coronary artery disease; CO, cardiac output; HR, heart rate.

although much less than with propofol. Etomidate is the most emetogenic of the intravenous induction agents. The combination of etomidate and an opioid may further promote its emetogenic effects. Therefore, antiemetic therapy is advisable with its use. See Table 34.4 for more details.

Benzodiazepines

Diazepam, lorazepam, and midazolam have properties that differentiate them from other induction agents. They are used most commonly for premedication to produce sedation, anxiolysis, and anterograde amnesia, accompanied by minimal ventilatory depression, prior to induction. Although they act primarily by augmenting the inhibitory effects of GABA, they do so via a mechanism distinct from that of other induction agents. They bind to a specific benzodiazepine receptor located near the GABA receptor and increase the affinity of the GABA receptor for GABA. Midazolam and diazepam occasionally are used for induction of anesthesia because of their rapid onset following IV administration; however, emergence is delayed compared with that following thiopental, propofol, or etomidate administration (Table 34.1).

CNS effects

Benzodiazepines decrease CMRO₂, CBF, and ICP, although more modestly than thiopental, propofol, or etomidate (Table 34.2). Benzodiazepines are excellent anticonvulsants and may be used to treat status epilepticus. Even following very large doses, benzodiazepines do not cause burst suppression on the

EEG, and cannot cause an isoelectric EEG. Benzodiazepines produce anterograde amnesia at doses that may be only minimally sedating. In most patients, this is a desirable effect. They also cause skeletal muscle relaxation, an effect probably mediated by agonism at the glycine receptor.

Many patients take benzodiazepines chronically for management of anxiety disorders. Such patients develop tolerance with continued use, that may result in cross-tolerance to thiopental, propofol, or etomidate. The development of cross-tolerance leads to an increased dose requirement for these induction agents, as well as to benzodiazepines, administered in the perioperative period.

Cardiovascular effects

Benzodiazepines produce minimal depression of the cardiovascular system in normovolemic patients. They cause a mild decrease in blood pressure secondary to decreased systemic vascular resistance (Table 34.3). Myocardial contractility is relatively unaffected. The decrease in preload and afterload resulting from induction with a benzodiazepine makes them reasonable choices for induction in patients with heart failure. Benzodiazepines may cause a significant decrease in blood pressure in patients with hypertension due to anxiety.

Ventilatory effects

When used alone in sedating doses, benzodiazepines cause minimal ventilatory depression. However, when given in combination with opioids, benzodiazepines act synergistically to produce sedation and ventilatory depression. When used in higher doses (e.g., for induction of anesthesia), benzodiazepines may cause transient apnea.

Metabolism and elimination

Allergy to benzodiazepines is rare. They also generally do not cause nausea or vomiting. In contrast to diazepam and lorazepam, which cause pain on injection because of their propylene glycol solvent, midazolam is relatively painless when given intravenously owing to its water solubility. Benzodiazepines may be given orally, although the extensive first-pass metabolism of midazolam requires that high doses be given. Midazolam (along with ketamine) is one of the few induction agents that may be given intramuscularly, resulting in reliable absorption into the circulation.

Midazolam, diazepam, and lorazepam are metabolized by the liver. Because a high fraction of diazepam and lorazepam is bound to protein, these agents are cleared by the liver more slowly. Metabolism of midazolam results in a metabolite with only minimal activity, and it is rapidly conjugated to glucuronic acid and excreted. Lorazepam is metabolized to an inactive metabolite. Diazepam is metabolized to several active metabolites, including nordazepam that has a long half-life (100 hours), and oxazepam. Unless these medications are given by multiple repeated bolus doses or by a prolonged infusion, termination of the drug effect is the result of redistribution. When given by infusion, midazolam has a longer context-sensitive half-time

than thiopental or propofol (see Chapter 36). Patients with porphyria generally should avoid benzodiazepines, as some of these agents were found to induce ALA synthase in rats.

Benzodiazepines are the only induction agents for which there is a specific antagonist: flumazenil. Therefore, it is possible, although not always advisable, to reverse the CNS effects of a benzodiazepine by administering flumazenil. Flumazenil is an antagonist at the benzodiazepine receptor. The relative concentrations of benzodiazepine and flumazenil determine the overall level of pharmacologic effect. Some studies found flumazenil to have inverse agonist activity, meaning it produces an effect opposite that of the agonist. Thus, flumazenil may cause anxiety and panic if given alone. Patients on chronic benzodiazepine therapy who are given flumazenil may have symptoms and signs of acute withdrawal, including seizures.

Reversal of benzodiazepine effects with flumazenil should be done with caution, not only because of the adverse effects that may occur, but because flumazenil is much shorter acting than the benzodiazepines whose effects it may be used to reverse. Thus, repeated dosing may be necessary to maintain benzodiazepine antagonism. Flumazenil does not reliably reverse the ventilatory depression caused by benzodiazepines, and ventilatory support may be required in patients receiving flumazenil to treat a large overdose of benzodiazepine. If opioids also were administered with the benzodiazepine, then naloxone may be needed to reverse the ventilatory depression.

Ketamine

Ketamine, unlike other induction agents, acts primarily by NMDA receptor antagonism as opposed to GABA potentiation. It is structurally related to phencyclidine. It is supplied as a racemic mixture, and the S-isomer produces more analgesia, less delirium, and shorter emergence times than the R-isomer.

Anesthesia with ketamine is markedly different from that of other agents. It produces a cataleptic state, often termed “dissociative anesthesia,” typically characterized by signs consistent with continued consciousness. Patients given ketamine may have open eyes and nystagmus; they may move and vocalize, yet they do not respond to stimuli, cannot communicate, and have no recollection of events. They may report vivid dreams, hallucinations, or dysphoria postoperatively. These effects may be mitigated by the concurrent administration of propofol or a benzodiazepine.

Ketamine produces profound analgesia that typically persists into the postoperative period. Its ability to produce amnesia and analgesia in the presence of minimal ventilatory depression makes it a useful analgesic when trying to maintain spontaneous ventilation while managing pain.

CNS effects

In contrast to the other induction agents, ketamine increases CMRO₂, CBF, and ICP (Table 34.2). Thus, ketamine generally is not used in patients with increased ICP, intracranial lesions, or recent head trauma. The EEG changes caused by ketamine

are quite different from those of the other induction agents. Therefore, monitors of anesthesia depth that rely on processing the EEG signal, such as the bispectral index (BIS) monitor, do not reliably indicate the depth of ketamine-induced anesthesia. Like etomidate, ketamine is associated with a high risk of postoperative nausea and vomiting.

Cardiovascular effects

Ketamine is the only induction agent that causes cardiovascular stimulation through centrally mediated increased sympathetic tone and increased release of adrenal catecholamines. Patients experience a transient increase in heart rate, systemic vascular resistance, pulmonary artery pressure, and cardiac output (Table 34.3). These effects may be beneficial in maintaining hemodynamic stability in a hypovolemic patient or in a patient with reduced ventricular function. These same properties make ketamine a poor choice in patients with coronary artery disease or poorly controlled hypertension, because the increase in myocardial oxygen demand may exceed the increase in oxygen delivery, causing ischemia. Although the cardiovascular effects of ketamine are indirect, ketamine may cause direct myocardial depression in patients whose sympathetic tone is maximal.

Ventilatory effects

Ketamine does not cause significant ventilatory depression when given to healthy patients or those with chronic obstructive pulmonary disease. Ketamine causes bronchodilation, making it useful for induction in patients prone to bronchospasm. However, it depresses airway reflexes to a lesser degree than other induction agents. Nevertheless, aspiration is still a risk in patients anesthetized with ketamine and not intubated. Laryngospasm may occur during light anesthesia with ketamine as it causes an increase in salivary, tracheal, and bronchial secretions. Pretreatment with an antisialagogue (e.g., glycopyrrolate) is generally recommended.

Metabolism and elimination

Ketamine may be given intravenously or intramuscularly. Like midazolam, it is reliably absorbed following intramuscular injection. Ketamine undergoes high first-pass metabolism following oral administration, although it is sometimes given orally in children.

In contrast to induction of general anesthesia with thiopental, propofol, or etomidate, unconsciousness following IV induction with ketamine may last up to a half hour, and it may take much longer for the patient to become fully oriented (Table 34.1). Upon emergence from anesthesia following ketamine administration, patients may experience “emergence delirium,” characterized by confusion, impaired short-term memory, auditory and visual hallucinations, or even nightmares. Concurrent administration of propofol or a benzodiazepine may decrease the incidence and severity of these adverse effects.

The prolonged effect of ketamine is partly a result of its metabolism by CYP to norketamine, an active metabolite with approximately one-fourth the potency of ketamine. After norketamine is hydroxylated and conjugated, forming a water-soluble metabolite, it is renally excreted. Because ketamine has a high hepatic extraction ratio of about 0.8, decreased hepatic blood flow will decrease its clearance. Ketamine is generally considered safe in patients with porphyria.

Mechanisms of anesthetic actions

Ken Solt and Douglas E. Raines

General anesthetics are structurally diverse (Fig. 35.1). Drugs with anesthetic activity include noble gases, alkanes, alcohols, ethers, and other structurally unrelated compounds. To account for this diversity, early theories regarding general anesthetic action were heavily influenced by the notion that all anesthetics act by a common mechanism.

Lipid theories of anesthetic action

At the end of the 19th century, Meyer and Overton independently reported a strong correlation between the potencies of general anesthetics and their lipid solubilities (Fig. 35.2a). Their observations suggested that all anesthetics produce their behavioral effects in the same manner, by interacting nonspecifically with lipid components of neuronal cell membranes. Although the details were vague regarding how these interactions led to specific anesthetic effects, the Meyer-Overton correlation and lipid theories of anesthetic mechanisms dominated thinking in the field for many years.

Evidence has accumulated over the past several decades, however, that argues against lipids as anesthetic targets. *First*, anesthetic-induced changes in lipid properties (i.e., fluidity) are mimicked by small changes in temperature that do not alter behavior in animals. *Second*, anesthetics act stereoselectively to produce anesthesia, a characteristic generally associated with specific interactions with protein targets. For example, the R⁺ enantiomer of etomidate is more than an order of magnitude more potent than the S-enantiomer. Similarly, optical isomers of isoflurane possess different anesthetic potencies, although the magnitude of this difference is relatively small. *Third*, there is a “cutoff” in anesthetic potency in homologous anesthetic compounds. Anesthetic cutoff is the phenomenon in which the anesthetic potencies of homologous compounds increase with anesthetic size until a cutoff point is reached, after which anesthetic activity either no longer increases or disappears completely. This is best illustrated with straight-chain alcohols (e.g., methanol, ethanol, n-propanol, n-butanol) in which anesthetic potency increases with alkyl chain length up to n-dodecanol, but longer alcohols are devoid of anesthetic activity. *Fourth*, some volatile compounds (e.g., di-[2,2,2,-trifluoroethyl]ether) possess no anesthetic activity even though they are highly lipid soluble and therefore are predicted by the Meyer-Overton correlation to be potent anesthetics.

These compounds, termed *nonimmobilizers*, typically produce convulsions when given at partial pressures predicted to produce anesthesia.

A series of experiments by Franks and Lieb in the 1980s demonstrated that anesthetic inhibition of firefly luciferase, a water-soluble protein in a lipid-free system, obeys the Meyer-Overton correlation (Fig. 35.2b). This work led most researchers to abandon lipid theories and agree that proteins are the likely targets of general anesthetics. Recent work has focused largely on identifying the specific proteins involved in producing anesthetic effects.

Ion channels in the central nervous system

Anesthetics have been shown to bind to a diverse range of proteins, but ion channels in the central nervous system (CNS)

Figure 35.1. The structural diversity of general anesthetics. Although the pharmacologic profiles of these drugs vastly differ, all of them are capable of producing amnesia and immobility in response to noxious stimuli.

Figure 35.2. (A) The Meyer-Overton correlation, illustrating the relationship between anesthetic potency and lipid solubility. (B) The strong correlation between anesthetic potency and potency for luciferase inhibition demonstrates that a protein target can account for the observations of Meyer and Overton. (Modified from Figure 3 in Franks NP. Molecular targets underlying general anesthesia. *Br J Pharmacol* 2006; 147:S72–S81.)

are considered to be among the most likely targets that mediate the behavioral effects of these drugs. In particular, neurotransmitter-gated ion channels that regulate synaptic transmission are thought to play important roles; among these, γ -aminobutyric acid (GABA) receptors have been studied most extensively.

The GABA type A (GABA_A) receptor belongs to a family of neurotransmitter-gated ion channels that include the nicotinic acetylcholine, serotonin type 3 (5-HT₃), and glycine receptors. GABA_A receptors are the most abundantly expressed inhibitory receptors in the brain. Binding of GABA to these receptors causes opening of a chloride-selective ion channel and hyperpolarization of the neuronal membrane. Many inhaled and intravenous anesthetics have been shown to enhance the activity of GABA_A receptors, leading to an increase in inhibitory neurotransmission in the CNS.

Propofol and etomidate

Although many anesthetic-sensitive ion channels, such as GABA_A receptors have been identified, it is difficult to prove from *in vitro* data whether a specific target is responsible for a drug's behavioral effects. Recent advances in genetic engineering have provided a powerful new tool for testing the relevance of putative anesthetic targets, and genetic approaches have been particularly successful in elucidating the mechanisms underlying the actions of propofol and etomidate.

Electrophysiologic studies have demonstrated that a single amino acid substitution in the β_3 subunit of the GABA_A

receptor renders the entire receptor insensitive to the enhancing effects of propofol and etomidate. When this point mutation was introduced in mice to produce “knock-in” animals, the mutants were highly resistant to the hypnosis, immobility, and respiratory depression produced by these anesthetics. This result indicates that GABA_A receptors containing β_3 subunits play a critical role in mediating important CNS effects of propofol and etomidate.

Ketamine, nitrous oxide, cyclopropane, and xenon

Unlike propofol and etomidate, ketamine, nitrous oxide, cyclopropane and xenon have little or no effect on GABA_A receptors. However all these drugs are potent inhibitors of *N*-methyl-D-aspartate (NMDA) receptors. NMDA receptors are a subtype of glutamate receptors, which are the most widely expressed excitatory receptors in the brain. Unlike inhibitory GABA_A receptors, glutamate receptors cause neuronal depolarization upon glutamate binding. NMDA receptors have received the most attention among the glutamate receptor subtypes, as they play important roles in learning and memory as well as nociception. Anesthetic-induced inhibition of NMDA receptors may produce behavioral effects by decreasing excitatory neurotransmission in the CNS.

In addition to inhibiting glutamate receptors, ketamine and nitrous oxide inhibit neuronal nicotinic acetylcholine receptors, which are also important excitatory receptors in the CNS. TREK-1, a tandem-pore K⁺ channel widely expressed

in the CNS, also is activated by nitrous oxide, xenon, and cyclopropane, leading to neuronal hyperpolarization. Although ketamine, nitrous oxide, cyclopropane, and xenon all appear to produce their behavioral effects by similar mechanisms, the relevance of their proposed targets has yet to be elucidated.

Halogenated volatile anesthetics

Halogenated alkanes (e.g., chloroform, halothane) and ethers (e.g., isoflurane, sevoflurane, desflurane) exhibit the least selectivity for putative anesthetic target proteins. Targets sensitive to halogenated volatile anesthetics include GABA_A receptors, glutamate receptors, tandem-pore K⁺ channels, neuronal nicotinic acetylcholine receptors, 5-HT₃ receptors, mitochondrial adenosine triphosphate-sensitive K⁺ channels, and HCN (hyperpolarization-activated cyclic nucleotide-gated) channels, among others. Effects on some targets may be important in mediating anesthetic side effects such as nausea and vomiting, whereas others may lead to potentially beneficial effects, such as ischemic preconditioning. So far, genetic methods to identify targets relevant to immobility have produced only modest results for these anesthetics, suggesting that many molecular targets may contribute to their behavioral effects.

Anatomic sites of anesthetic actions

General anesthetics have myriad reversible effects on the CNS, including sedation, excitation, confusion, amnesia, euphoria, hypnosis, and immobility. Although most scientists had assumed that the brain was responsible for mediating all the

CNS effects of general anesthetics, a series of animal studies conclusively demonstrated that anesthetic-induced immobility in response to noxious stimuli is the result of an effect on the spinal cord, not the brain. Therefore, even a single anatomic site cannot account for all the CNS effects of general anesthetics.

Summary

Although early theories focused on a single, lipid-based mechanism of anesthetic action, it has become evident that multiple sites and mechanisms likely are responsible for the behavioral effects of general anesthetics. Furthermore, the sites and mechanisms likely are different depending on the anesthetic. As we continue to learn more about how general anesthetics act to produce their desirable and undesirable effects, the design of safer drugs with improved therapeutic indices may be attainable.

Pharmacokinetics of intravenous agents

Lisbeth Lopez Pappas and Mark Dershwitz

Pharmacokinetics is the study of “what the body does to the drug,” whereas pharmacodynamics is the study of “what the drug does to the body.” This chapter considers the pharmacokinetics of anesthetic drugs given by the intravenous route. Age and certain diseases (e.g., heart failure, liver failure, renal failure) may require adjustments from the typical doses of a drug. An understanding of pharmacokinetic parameters, which may be altered by certain disease states, provides a rational approach to drug and dosage selection. These parameters include the volume of distribution (V_d), drug clearance (CL), and drug half-life ($t_{1/2}$).

Pharmacokinetic parameters

Drug distribution

The injection of a medication intravenously provides complete absorption, with a rapid and predictable rise in the drug concentration in the plasma. From the systemic circulation, drugs rapidly distribute to highly perfused organs such as the brain, heart, lungs, liver, and kidneys. This vessel-rich group accounts for about 10% of total body mass, yet it receives about 75% of the cardiac output. Factors that influence drug distribution and tissue uptake include lipid solubility, ionization, and protein binding.

For drugs that are lipid soluble, nonionized, and unbound to protein, the concentration gradient will dictate the degree and direction of transfer. A tissue's capacity to function as a drug reservoir depends greatly on the drug's solubility in that tissue, its binding to macromolecules, and tissue pH. Saturation of these stores, as may occur with repeated or large initial doses of the drug, results in a prolonged duration of action. This effect might convert an apparently “short-acting” drug such as thiopental or fentanyl into one that actually has a long duration of action. As the drug's concentration in the circulation falls with respect to that in highly perfused tissues (e.g., brain), redistribution of drug to less perfused tissues (e.g., muscle, fat) occurs. This process accounts for the “short” duration of action of medications such as propofol and sufentanil.

Ionization

The degree of ionization is determined by the drug's pK_a (dissociation constant) and the pH of the liquid in which it is

dissolved. The pK_a is the pH at which 50% of the drug exists in the ionized form and 50% in the nonionized form. Small variations in pH may have significant effects on the ratio of ionized to nonionized drug. Nonionized molecules typically have greater lipid solubility. Most clinically used medications are either weak acids or weak bases and therefore exist in both ionized and nonionized forms. At a low (acidic) pH, weak acids (e.g., barbiturates) become uncharged and more lipid soluble whereas weak bases (e.g., local anesthetics, opioids) become charged and more water soluble.

Protein binding

Drug disposition is significantly affected by the degree of protein binding. Factors that determine the extent of protein binding include the concentrations of both the drug and the protein to which it binds, the affinity of the drug for the protein, and the number of available protein binding sites. In general, the binding of drugs to proteins is reversible and involves hydrophobic or ionic interactions. The ability of a drug to bind to proteins in the circulation or within a tissue affects the drug concentration in that compartment. In general, drugs with high lipid solubility also have greater protein binding.

In the circulation, acidic drugs (e.g., barbiturates) tend to bind to albumin, whereas basic drugs (e.g., opioids) tend to bind to α_1 -acid glycoprotein (AAG), an acute-phase reactant that increases with physiologic stresses such as surgery and trauma. It is the free (i.e., unbound) fraction of a drug that largely contributes to the pharmacologic effect. For drugs with negligible protein binding (i.e., free fraction ≈ 1), there is no relationship between changes in protein concentration and changes in the free fraction of drug. However, for drugs that approach 100% protein binding (i.e., free fraction ≈ 0), there is an inverse relationship between the change in protein concentration and the change in the free fraction of drug in the plasma. For example, a small decrease in the binding capacity (e.g., from 98% to 96%) of diazepam, a highly protein-bound drug, doubles the free fraction of drug in the circulation.

Factors that affect protein binding include age, liver disease, kidney disease, and physiologic stress or trauma. Both kidney and liver disease can produce a quantitative as well as qualitative change in the binding of drugs to proteins. Protein binding also may be altered by changes in tissue pH (e.g., acidosis,

alkalosis) and the presence of other drugs or endogenous compounds (e.g., bilirubin) that can compete for protein binding sites. Only unbound drug equilibrates between the circulation and tissues and ultimately undergoes metabolism and elimination. With reduced protein binding (e.g., hypoalbuminemia), the increased free fraction of drug produces a larger gradient between the circulation and peripheral tissues; as a result, equilibrium is achieved at a lower drug concentration in the circulation. In addition, the concentration of drug at the site of action increases (i.e., increased apparent potency), which translates to a lower required dose.

Elimination

Elimination includes the processes of metabolism and excretion. The primary organ involved in drug metabolism is the liver via hepatic microsomal enzymes (e.g., cytochrome P450 [CYP]). Microsomal enzymes are induced by many drugs (e.g., barbiturates, rifampin, phenytoin) and inhibited by others (e.g., cimetidine, azole antifungal agents, macrolide antibiotics, antiretroviral protease inhibitors). The biotransformation of drugs involves phase I and/or phase II reactions. Phase I reactions include oxidation, reduction, and hydrolysis, whereas phase II reactions involve conjugation to moieties such as glucuronic acid or sulfate. The overall effect is to convert lipid-soluble drugs to water-soluble metabolites that are more easily excreted in urine and bile.

Factors that affect hepatic drug metabolism include hepatic blood flow and the intrinsic capacity of the liver to metabolize the drug. The fraction of unbound drug cleared by the liver is known as the hepatic extraction ratio (ER). Hepatic clearance is calculated by the following equation:

$$CL = Q \times ER,$$

where Q is the hepatic blood flow.

For drugs that have a high hepatic extraction ratio ($ER > 0.9$), drug clearance is affected primarily by hepatic blood flow (perfusion-dependent metabolism), whereas drugs that have a low extraction ratio ($ER < 0.2$) are minimally affected by hepatic blood flow and greatly affected by the metabolic capacity of the liver (capacity-dependent elimination). For example, propofol ($ER \approx 1$), shows a linear relationship between drug clearance and hepatic blood flow, whereas alfentanil ($ER \approx 0.1$) demonstrates a linear relationship between drug clearance and the intrinsic metabolic capacity of the liver. Alfentanil therefore is much more likely than propofol to participate in drug interactions due to induction or inhibition of CYP.

In general, biotransformation of drugs by the liver results in metabolites that are less pharmacologically active. There are exceptions, however, such as codeine and morphine, and variations in the extent of hepatic metabolism may cause clinically significant differences in the drug's effects. For example, codeine is metabolized to morphine by CYP2D6, which exhibits a greater degree of genetic polymorphism than any other isozyme of CYP. Morphine is metabolized further to

morphine-6-glucuronide, an active metabolite with greater potency than morphine. These metabolites are responsible for the analgesic effects of codeine. Patients with nonfunctional versions of CYP2D6 (about 10% of persons of western European descent) experience no analgesic effect from codeine, whereas patients with CYP2D6 gene duplication or amplification demonstrate ultrarapid codeine metabolism and an exaggerated opioid effect.

Some drugs undergo extrahepatic metabolism. For example, certain tissues are rich in esterases, and several important medications undergo extrahepatic hydrolysis, including succinylcholine (plasma), remifentanyl (skeletal muscle), and esmolol (red blood cells). The overall clearance of propofol significantly exceeds hepatic blood flow because of substantial metabolism in the kidney. In addition, other drugs (e.g., atracurium, cisatracurium) undergo nonenzymatic Michael (occasionally referred to as Hofmann) elimination in the circulation at physiologic pH and temperature. This reaction is independent of disease or genetic variations.

The clearance of water-soluble metabolites or drugs that do not undergo metabolism occurs primarily in the kidney, and the clearance is correlated with creatinine concentration or creatinine clearance. Excretion of drugs by the kidney involves both glomerular filtration and tubular secretion. The glomerular filtration rate, protein binding, lipid solubility, and urine pH can influence the rate and extent of renal clearance. Alkalinization of the urine can enhance the renal excretion of weak acids such as glucuronides by shifting the fraction of drug in the ionized form so that tubular reabsorption occurs to a lesser degree.

Pharmacokinetic models

The first fundamental pharmacokinetic parameter, the volume of distribution (V_d), represents the volume into which a drug appears to be diluted. It is calculated by the following formula:

$$V_d = \frac{\text{Dose}}{\text{Concentration}}.$$

The classic yet simplest one-compartment pharmacokinetic model has served as the basis for calculating dosage regimens (Fig. 36.1). Applying this model to the lipid-soluble drugs used in anesthesia (e.g., hypnotics, opioids) results in huge deviations from physiologic behavior. A multicompartmental model involves more complex mathematic equations but is better suited to predicting the behavior of most anesthetic medications.

Figure 36.1. The one-compartment pharmacokinetic model. Clearance equals $k \times V$. (Redrawn with permission from Figure 52-13 in Shafer SL. Principles of pharmacokinetics and pharmacodynamics. In *Principles and Practice of Anesthesiology*. 2nd ed. St. Louis: Mosby; 1998.

Figure 36.2. The three-compartment pharmacokinetic model. Drug is administered into a central compartment from which it is cleared by metabolism and/or elimination. Drug rapidly distributes into a peripheral compartment, and this compartment reaches equilibrium with the central compartment quickly. Drug distributes more slowly into a third compartment. The volume of distribution at steady state, $V_{d,ss}$, equals $V_1 + V_2 + V_3$. Redrawn with permission from Figure 52-16 in Shafer SL. *Principles of pharmacokinetics and pharmacodynamics*. In *Principles and Practice of Anesthesiology*. 2nd ed. St. Louis: Mosby; 1998.

The three-compartment pharmacokinetic model divides the body into theoretic volumes from which pharmacokinetic parameters are derived (Fig. 36.2). The initial volume into which a drug is introduced is referred to as the central volume of distribution, V_1 , and represents some fraction of the circulating volume. Two peripheral compartments, one representing rapidly equilibrating tissues (V_2) and the other the slowly equilibrating tissues (V_3), are linked to the central compartment. Drug transfer from one compartment to another is known as intercompartmental clearance and is represented by a rate constant, k . Drug transfer directly out of the central compartment is known as central clearance, k_{10} . The distribution of drug throughout the body results in the ultimate equilibration of drug throughout all body tissues, also known as steady state. In this situation, the volume of distribution at steady state, $V_{d,ss}$, includes the central as well as the peripheral compartments and can be calculated as follows:

$$V_{d,ss} = V_1 + V_2 + V_3 = \frac{X}{C},$$

where X is the dose of drug administered and C is the drug concentration in the plasma at steady state.

Anesthetic drug distribution is typically extensive and reflects the properties of the drug (e.g., solubility, protein binding) as well as the composition of a given compartment (e.g., protein vs. fat, water content). In general, drugs that are lipid soluble undergo extensive distribution out of the central compartment and have large volumes of distribution (e.g., propofol, diazepam). Conversely, drugs that are water soluble tend to distribute to body water and thus have smaller volumes of distribution (e.g., vecuronium, epinephrine). The volume of distribution of lipid-soluble drugs often greatly exceeds the total anatomic volumes (e.g., V_d for propofol ≈ 5000 L).

The second fundamental pharmacokinetic parameter is clearance (CL). It refers to the portion of the volume of distribution from which a drug *appears* to be removed during a

Table 36.1. Drug concentration as a function of half-lives

Elapsed half-lives, n	Original concentration remaining, %
1	50
2	25
3	12.5
4	6.25
5	3.125
6	1.5625

given period. From the one-compartment model, the relationship between clearance and volume of distribution is:

$$CL = k \times V_d,$$

where k is the rate constant.

In the one-compartment model, the half-life ($t_{1/2}$) is defined as the time it takes drug concentration to decrease by 50%. The half-life is related to the rate constant, k , according to the following equation:

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k}.$$

As each half-life elapses, the drug concentration decreases to 50% of its previous value. Thus, the decrease in drug concentration as a function of the number of half-lives that have elapsed is shown in Table 36.1.

The rate at which the central compartment drug concentration decreases depends on clearance (primarily hepatic metabolism) as well as on the distribution of drug out of the central compartment into the peripheral compartments, also known as the intercompartmental clearances. The intercompartmental clearances reflect blood flow to the peripheral tissues as well as the properties of the drug itself (e.g., lipid solubility).

The three-compartment model is necessary to approximate the pharmacokinetic behavior of the lipid-soluble intravenous anesthetic agents. A graphic depiction of drug concentration as a function of time following an intravenous bolus injection of 10 mg of morphine is shown in Fig. 36.3. The shape of the curve is characterized by three phases. The first phase lasts about 6 minutes and has a half-life of 1 minute. It is characterized by a steep decrease in the plasma concentration of morphine, primarily as a result of drug distribution from the central compartment to the rapidly equilibrating compartment. The second phase lasts about 50 minutes and has a half-life of 8 minutes. It is characterized by a more gradual decrease in the plasma drug concentration and results primarily from drug distribution into the slowly equilibrating compartment. The third, or terminal, phase has a half-life of 96 minutes, is characterized by a much slower decrease in plasma drug concentration, and results from the metabolism and renal elimination of morphine as well as the return of morphine from both peripheral compartments to the central compartment.

Figure 36.3. The plasma concentration of morphine as a function of time following a 10-mg bolus dose. The three phases of the disappearance curve have half-lives of 1 minute, 8 minutes, and 96 minutes, respectively. Redrawn with permission from Figure 5 in Dershwitz M, Walsh JL, Morishige RJ, et al. Pharmacokinetics and pharmacodynamics of inhaled versus intravenous morphine in healthy volunteers. *Anesthesiology* 2000; 93:619–628.

The plasma drug concentration as a function of time following the administration of the intravenous bolus, $\text{Conc}(t)$, can be calculated as follows:

$$\text{Conc}(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t},$$

where t is the time following the bolus; A , B , and C are fractional coefficients; and α , β , and γ are rate constants. The first, second, and third exponential terms in the equation correspond to the rapid, intermediate, and slow phases of the disappearance curve shown in Fig. 36.3, respectively. The fractional coefficients describe the importance of each of the three phases in the overall disappearance of the drug.

The rate constants used in the three-compartment model are related to the half-lives of each of the three phases:

$$t_{1/2\alpha} = \frac{\ln 2}{\alpha} \quad t_{1/2\beta} = \frac{\ln 2}{\beta} \quad t_{1/2\gamma} = \frac{\ln 2}{\gamma}.$$

For all practical purposes, a pharmacokinetic process may be considered complete after five half-lives have elapsed (although it should be apparent that such a process is *never* complete in a mathematic sense).

The use of half-lives as the basis for drug dosing may be misleading. Although the terminal half-lives of most of the commonly used intravenous anesthetics are quite long (e.g., propofol ≈ 5 hours, sufentanil ≈ 9 hours), recovery from a bolus dose of a lipophilic drug can occur in minutes because of its rapid redistribution. When intravenous anesthetics are administered by infusion, redistribution continues to play a significant role in the termination of the drug's effect.

Intravenous anesthetics have become widely used in the practice of anesthesia. It is intuitive that when a volatile agent is

used for maintenance of general anesthesia, the longer the duration of administration the longer it will take to eliminate the agent to permit the patient to awaken. Analogously, the longer the duration of intravenous drug infusion, the longer the time required for emergence from anesthesia. However, the terminal half-life cannot be used to predict the decline in drug concentration in the central compartment.

Although intravenous anesthetics have been in clinical use since the 1940s, it was not until the 1990s that quantitative methods were introduced to permit the clinician to predict accurately the amount of time required for emergence following the intravenous infusion of an anesthetic drug. This concept, called the *context-sensitive half-time* (CSHT), describes the time required for the central compartment drug concentration to fall by 50% as a function of the duration of the infusion. The term *context* refers to the duration of an infusion designed to maintain a constant central compartment drug concentration. It has been demonstrated that the CSHTs of commonly used anesthetic drugs are substantially shorter than their respective terminal half-lives.

As expected, the time to recovery (i.e., awakening) after the termination of a continuous intravenous infusion depends on the drug concentration in the central and peripheral compartments at the time the infusion is discontinued. At the end of a short infusion, there remains a large concentration gradient between the central and peripheral compartments, and the drug concentration in the central compartment will decrease rapidly. In contrast, at the end of a long infusion, both the rapidly and the slowly equilibrating compartments may approach steady state with the central compartment; therefore, the decline in the central compartment drug concentration will occur more slowly.

The CSHTs for five common intravenous anesthetics as a function of infusion duration are illustrated in Fig. 36.4. From

Figure 36.4. The context-sensitive half-times for midazolam, alfentanil, sufentanil, propofol, and remifentanil as a function of infusion duration. The simulations were performed using the program RECOV, written by Steven Shafer.

this graph, it is apparent that the choice of anesthetic to be given by a continuous intravenous infusion can be made based on the anticipated duration of the surgical procedure. As shown in the figure, midazolam has a CSHT of about 120 minutes after a 2-hour infusion; thus, it would not be a good choice for a hypnotic agent when rapid emergence is desired. Alfentanil, an opioid with a short terminal half-life that often is used in brief procedures, is not short acting when given by a continuous infusion. Although alfentanil has shorter distribution and terminal half-lives than sufentanil, recovery following a sufentanil infusion is much more rapid than that with alfentanil for infusions less than 9 hours. Sufentanil and propofol display similar curves, suggesting that these anesthetic agents may be discontinued simultaneously in the course of an anesthetic. The CSHT of remifentanil remains constant at about 4 minutes, regardless of the duration of the infusion. This is because metabolic clearance of remifentanil is so much greater than its intercompartmental clearances that accumulation of remifentanil does not occur, even after prolonged infusions. Because there is no accumulation, a remifentanil infusion may be discontinued at the very end of surgery.

Effects of coexisting diseases

Effects of hepatic disease

Hepatic drug clearance involves numerous metabolic pathways and liver disease effects, each to a different degree. Typically liver disease affects hepatic phase I reactions to a greater degree than hepatic phase II reactions. Currently, there is no clinically available laboratory test that predicts the degree of impairment of metabolic reactions (although such tests are commonly used in research protocols).

In chronic liver disease (e.g., cirrhosis), decreased hepatic blood flow, altered enzyme activity, and reduced protein synthesis may coexist and result in altered pharmacokinetic behavior and drug disposition. The severity of disease, as well as drug characteristics (e.g., protein binding, hepatic extraction ratio), will affect the pharmacokinetic alterations.

Metabolism of drugs with a low hepatic extraction ratio (e.g., alfentanil) depends on liver function and not on hepatic blood flow. Clearance of these drugs may be severely impaired in the setting of end-stage liver disease, in which the enzyme capacity of the liver is limited. In contrast, decreased hepatic blood flow (e.g., shock, congestive heart failure) may impair the metabolism of drugs with a high extraction ratio (e.g., fentanyl). Overall, reduced drug clearance results in an increased plasma drug concentration and a prolonged terminal half-life.

Advanced liver disease alters protein binding as a result of decreased protein synthesis. A common finding in advanced liver disease is a low serum albumin concentration, which results in an increased free fraction of drugs bound to albumin. Clinically significant changes in protein binding generally are seen with drugs that are highly bound to albumin (e.g.,

warfarin) such that a small decrease in plasma protein concentration produces a significant rise in the circulating free drug concentration. Drug binding to AAG does not appear to be affected by liver disease.

Effects of renal disease

The most useful indicator of renal function is creatinine clearance. Significant renal dysfunction primarily affects the clearance of water-soluble drugs (e.g., pancuronium) and metabolites (e.g., normeperidine, morphine-6-glucuronide). In the setting of renal failure, such drugs or metabolites may accumulate significantly and result in an increased pharmacologic effect as well as a prolonged duration of action. In addition, increased drug effects also may be expected in patients with uremia as a result of decreased protein binding. Repeated dosing or infusions of long duration may cause significant drug accumulation.

Individual pharmacokinetic variability

In addition to the genetic polymorphisms previously discussed, there also may be pharmacokinetic differences due to age. The effects of aging include a loss of nephrons and changes in the volumes of distribution and protein binding. In the older patient population, total body water decreases while the percentage of body fat increases, resulting in a smaller central compartment V_d . Renal clearance is decreased because of the decrease in the number of nephrons. Protein binding capacity is decreased as a result of reduced albumin levels. These effects result in increased drug sensitivity as a result of increased plasma drug concentrations and the potential for drug accumulation.

The concurrent administration of multiple drugs may result in drug–drug interactions and account for multiple and diverse variations in pharmacokinetic behavior. As discussed earlier, there are numerous drugs that can cause inhibition or induction of CYP and alter the metabolism of other drugs (see Chapter 35).

Opioids

Darin J. Correll and Carl E. Rosow

Opioids are the oldest known anesthetic and analgesic agents, with documented use as early as 6000 B.C. by the Sumerians, Babylonians, and Egyptians. Opium is derived from the exudate of the seed pod of *Papaver somniferum*. An opioid is any substance – natural or synthetic, endogenous or exogenous – with activity at opioid receptors. An opiate is an alkaloid derived naturally from opium, such as morphine or codeine. *Narcotic* is not a medical term but rather a legal term in the United States applied to any substance with abuse potential.

Mechanism of action

Opioids bind to G protein–coupled receptors located in the central nervous system (CNS; e.g., cortex, midbrain, thalamus, spinal cord), peripheral nervous system (e.g., mesenteric plexus of the gastrointestinal tract, primary afferent neuron), and peripheral tissues (e.g., joints and lung). The receptors are both presynaptic (inhibitory and excitatory) and postsynaptic (inhibitory). Opioid binding to presynaptic receptors inhibits voltage-sensitive calcium channels, decreases adenylyl cyclase activity, and decreases the release of various neurotransmitters (e.g., substance P, glutamate, acetylcholine, norepinephrine, and serotonin). Opioid binding to postsynaptic receptors increases outward potassium conductance, which results in hyperpolarization and a reduction of neural transmission.

Opioid receptors

Four distinct opioid receptors have been identified and cloned: μ , κ , δ , and nociceptin-orphanin FQ. These are sometimes abbreviated MOP, KOP, DOP, and NOP respectively. Most opioids used in clinical anesthesia are agonists that are relatively selective for μ -opioid receptors, and they produce a similar group of clinical effects. There are multiple human μ -opioid receptor subtypes, and their expression differs between tissues and among individuals. Each opioid has different efficacies after binding to the various μ -opioid receptor subtypes, and this may help explain why some patients respond better to a particular drug. Different subtypes also may account for the fact that tolerance to one μ -opioid agonist does not produce complete cross-tolerance to all other μ -opioid agonists. κ -Opioid and δ -opioid receptors mediate analgesia and also may contribute to

the analgesic effect when high doses of μ -opioids are administered. A few κ -opioid agonists are used clinically, and κ -opioid actions probably account for the dysphoria and hallucinations occasionally reported with these drugs. There are no selective δ -opioid or NOP agonists available for clinical use.

Endogenous opioids

The body produces five different classes of opioid peptides that act throughout the CNS and peripheral nervous system to affect nociception, thermoregulation, hormone release, gastrointestinal function, and cardiovascular control.

- The enkephalins are pentapeptides derived from proenkephalin A. They are moderately selective for δ -opioid receptors and probably act within the spinal cord and brainstem.
- The dynorphins (A and B) are polypeptides derived from prodynorphin (also called proenkephalin B). They are agonists at the κ -opioid receptor.
- β -Endorphin, derived from proopiomelanocortin, is the most important of the humoral endogenous opioids, and an important endogenous ligand at μ -opioid receptors.
- Orphanin FQ (also called nociceptin), derived from proorphanin, binds the NOP receptor. Orphanin FQ is found in the hippocampus and sensory cortex. It has a supraspinal *antianalgesic* effect while producing spinal analgesia. It may have roles in pain modulation, learning, and drug reward.
- The endomorphins are tetrapeptides with high affinity for the μ -opioid receptor. No precursor molecule has been identified yet. In vivo studies suggest that endomorphin-1 acts via stimulation of μ -opioid receptors. Endomorphin-2 is less specific, acting at both μ -opioid and κ -opioid receptors.

Pharmacokinetics

Because all the commonly used opioids produce similar effects, the choice of opioid generally is based on pharmacokinetics, that is, the speed of onset, the duration of action, or the desired route of administration (Table 37.1). The lipid solubility of opioids is most commonly expressed as an octanol/water partition coefficient (Table 37.2). The partition coefficient is adjusted for

Table 37.1. Equianalgesic opioid doses, time to peak effect, and duration of analgesia

Agent	Dose, mg ^a	Peak effect, min	Duration of effect, h ^b

Alfentanil	0.75	1.5–2	0.2–0.3
Remifentanyl	0.1	1.5–2	0.1–0.2

^a Approximately equianalgesic doses. Data for fentanyl derivatives are derived from intraoperative studies, the remainder from postoperative pain studies.

^b Typical duration of initial dose.

the amount ionized at pH 7.4, because only uncharged species will partition between aqueous and lipid environments. Opioids are weak bases, and most have a dissociation constant (pK_a) > 7.4; therefore, they are predominately ionized at body pH.

Distribution

After intravenous (IV) bolus injection, a relatively lipophilic opioid (e.g., fentanyl) undergoes rapid distribution into highly perfused tissues such as brain, lung, heart, and viscera. After a single bolus dose, the effects of such a drug usually appear rapidly and then disappear rapidly as the opioid is redistributed into muscle and fat. More hydrophilic opioids, such as morphine, hydromorphone, and oxycodone, have a slower onset and offset. It must be emphasized that lipid solubility is only one factor determining the rate of equilibration with receptor sites in the brain. Alfentanil is less lipophilic than sufentanil, yet its $t_{1/2k_{e0}}$ (equilibration half-time) is shorter. This may be a result of its lower pK_a (more uncharged drug) as well as a smaller cerebral volume of distribution. Opioids undergo variable amounts of protein binding in tissues and plasma. In plasma, opioids usually bind to α_1 -acid glycoprotein, an acute-phase reactant that changes concentration in many disease states. Drug that is protein bound in plasma will not diffuse across membranes, may not be metabolized in the liver, and will not be filtered by the kidney.

Table 37.2. Lipid solubility, pK_a , and protein binding of opioid agonists

Drug	Octanol/water partition coefficient at pH 7.4	pK_a	Protein binding, %
Morphine	1.42	7.9/9.4	30–35
Hydromorphone	1.28	8.1	8–19
Methadone	117	8.25	85–90
Meperidine	38.8	8.5	64
Fentanyl	860	8.4	80–85
Sufentanil	1757	8.0	93
Alfentanil	128	6.5	92
Remifentanyl	17.9	7.07	70

Clearance

The offset of opioid effects after a bolus dose initially is the result of rapid redistribution. All opioids, except remifentanyl, then undergo hepatic metabolism with renal excretion of active or inactive metabolites. The biotransformation pathways include oxidative metabolism by various cytochrome P-450 (CYP) isozymes as well as glucuronidation. The polar opioid metabolites are then eliminated in urine and bile.

Pharmacokinetics of commonly used opioids

Morphine

Morphine has a relatively slow onset of action. It is rapidly distributed and eliminated from the circulation. More than 90% of morphine is metabolized and excreted within 24 hours. The drug is metabolized to the 3- and 6-glucuronides, as well as to normorphine. The metabolites are then excreted in the urine (90%) and bile (10%). Morphine-6-glucuronide (M6G), which represents about 15% of the total metabolites, has significant agonist activity. M6G probably has little effect after a single morphine dose, but it accumulates with repeated dosing and then contributes substantially to the overall opioid effect. The blood concentration of M6G may reach high values in patients with renal insufficiency and result in adverse effects such as sedation and ventilatory depression.

Hydromorphone

Compared with morphine, hydromorphone has a slightly faster onset of action and a slightly shorter duration of action. Hydromorphone is rapidly metabolized to inactive compounds. Its water solubility allows it to be formulated in a high-concentration solution useful for patients who are opioid tolerant.

Methadone

Methadone is much more lipophilic than morphine and has high oral bioavailability. The commercial preparation is a racemic mixture with all opioid activity residing in the *l*-isomer. There is huge interindividual variability in the metabolic clearance of both isomers, and clearance is subject to many drug interactions. Because the terminal half-life is about 35 hours, repeated doses may result in substantial accumulation, with subsequent doses lasting much longer than the initial dose. Methadone undergoes metabolism in both the liver and gastrointestinal mucosa, primarily via *N*-demethylation. The metabolite is then excreted mostly by the kidneys, and some also in bile.

Meperidine

Compared with morphine, meperidine has a faster onset of effect and a shorter duration of action. Meperidine has a very high rate of hepatic clearance and is primarily *N*-demethylated in the liver to form normeperidine, which is then renally excreted. Normeperidine is an active metabolite that may cause

CNS excitation, manifested as restlessness, tremors, myoclonus, seizures, and occasionally death. It has a long terminal half-life of about 21 hours and repeated doses of meperidine may cause normeperidine to accumulate in persons with renal failure, leading to significant toxicity.

Fentanyl

Fentanyl is extremely lipophilic and is readily absorbed through intact skin and mucous membranes. After IV injection, it has a rapid onset and relatively short duration of action. It is rapidly distributed to the brain, heart, and other highly perfused tissues. Termination of effect occurs when fentanyl rapidly redistributes away from the CNS. Elimination is much slower (terminal half-life, 4–5 hours) due to the slow return of drug from peripheral tissues to the bloodstream. Fentanyl is metabolized in the liver and gastrointestinal mucosa to inactive metabolites excreted by the kidneys (90%) and in the bile (10%).

Sufentanil

Sufentanil is even more lipophilic than fentanyl, and its pharmacokinetic profile is similar, with a slightly shorter duration of action. Despite a terminal half-life of about 9 hours, sufentanil has a relatively short context-sensitive half-time (see [Chapter 36](#)). Its duration of action remains relatively short when administered by infusion for up to about 12 hours. Sufentanil is metabolized in the liver and the gastrointestinal mucosa, and the metabolites are excreted in urine and bile.

Alfentanil

Alfentanil has an extremely rapid onset and relatively short duration of effect after a bolus dose. Alfentanil is less likely than fentanyl to produce cumulative effects after repeated doses. Despite its short terminal half-life of 90 minutes, it has a longer context-sensitive half-time than sufentanil when given by infusion for up to about 12 hours (see [Chapter 36](#)). Alfentanil is metabolized in the liver, primarily by CYP3A4, and inhibitors of this isozyme (e.g., erythromycin) can greatly reduce its clearance.

Remifentanil

Remifentanil is an ester hydrolyzed by nonspecific esterases, primarily in skeletal muscle. The onset of effect is extremely rapid and similar to that of alfentanil. A bolus dose lasts only a few minutes, so the drug generally is administered by continuous infusion. Its high clearance gives the drug a context-sensitive half-time of about 4 minutes, irrespective of the duration of infusion. Redistribution of remifentanil occurs, but it plays a minor role in termination of the drug effect. Remifentanil is not a substrate for pseudocholinesterase; therefore, the dose does not need to be altered in persons with pseudocholinesterase deficiency.

Clearance is unchanged in patients with hepatic or renal failure, and the dose does not need to be adjusted in such patients. Extremes of age and body weight may influence clearance, but

recovery is still very rapid. The primary remifentanil metabolite has very weak opioid activity, but significant amounts do not accumulate with typical clinical dosing. The ultra-short duration of this analgesic may be a drawback in patients who are expected to have significant postoperative pain. These patients should receive a longer-acting opioid prior to stopping the remifentanil infusion.

Pharmacodynamics

Nervous system

Analgesia

The analgesic effects of opioids are the result of actions at many locations. In the brain, opioids activate various endogenous descending inhibitory (antinociceptive) pathways via action in the periaqueductal gray matter, locus ceruleus, and raphe nuclei. Opioids also act at receptors in the limbic system to alter the emotional response to a noxious stimulus. Opioid analgesia sometimes leads to feelings of euphoria – a possible etiology of the abuse potential of opioids – but dysphoria also may occur. In the spinal cord, opioids act both pre- and postsynaptically on the nociceptive neurons in the dorsal horn. In the periphery, opioids reduce activity in the primary nociceptor during states of inflammation.

The relative potencies of the older opioid agonists are derived from studies of acute pain, whereas the fentanyl analogues primarily have been studied in intraoperative settings. These data have been used to estimate equianalgesic doses ([Table 37.1](#)). However, there is large interindividual variability, and doses necessary for a given intensity of effect may vary as much as tenfold between patients.

The opioids listed in [Table 37.1](#) are all considered full μ -opioid agonists, and all are capable of producing intense analgesia and complete cessation of breathing in opioid-naïve patients. Some animal data suggest that higher-potency opioids (e.g., fentanyl derivatives) may be more effective analgesics in patients with a high degree of opioid tolerance. Tolerance involves down-regulation of a portion of the available receptor population, and higher-potency opioids exert a full effect with lower levels of receptor availability (i.e., they have more “spare receptors”).

Sedation

All opioids produce sedation, even at moderately analgesic doses, and the effect varies greatly among patients. When opioids are used concomitantly with other CNS depressants (especially benzodiazepines), the sedative effects may be marked. Sleep disturbances and even hallucinations may occur during opioid use. Intraoperatively, opioids should not be used as the primary agents to produce hypnosis or amnesia.

Miosis

Pupillary constriction occurs as the result of stimulation of the Edinger-Westphal nucleus, the accessory parasympathetic

nucleus of cranial nerve III (oculomotor nerve). A maximal miotic effect may occur in tolerant individuals, even after relatively low doses of μ -opioid agonists, so this is not a reliable end point for analgesia. However, absence of miosis suggests absence of opioid effect. In cases of opioid overdose, mydriasis may occur if the patient becomes hypoxemic.

Antitussive effect

Opioids depress the cough reflex, at least partly, by action at a putative medullary cough center. The effect is mediated by a receptor mechanism different from that of analgesia; low-potency analgesics (e.g., codeine) and analgesically inactive stereoisomers (e.g., dextromethorphan) are effective antitussives.

Pruritus

Itching may be generalized but often is limited to the area around the nose. The etiology is activation of μ -opioid receptors in the rostral medulla, although some animal data suggest a peripheral component as well. The itching is specifically antagonized by low doses of naloxone or nalbuphine, but these μ -opioid antagonists often reverse some analgesia. Opioid-induced itching rarely involves histamine, so the small amount of relief produced by diphenhydramine is probably a result of its sedative properties.

Nausea and vomiting

Opioids stimulate the chemoreceptor trigger zone on the floor of the fourth ventricle, which then activates the emetic center in the pontine lateral reticular formation. The emetic effect is increased by input from the vestibular apparatus in the inner ear. Thus, patients may not be nauseated while lying still but may become so when they are moved or sat upright. Any of the various antiemetics may be used, but none has been proven to be specific for opioid-induced nausea. In theory, an antiemetic with strong anticholinergic effects (e.g., scopolamine or promethazine) should be effective if the problem is triggered by motion. The various opioid analgesics appear to cause a similar incidence of nausea and vomiting, and despite numerous assertions to the contrary, there are no data that reproducibly indicate an advantage or disadvantage for one opioid. In animals, high doses of opioids directly depress the emetic center, and it is possible that this effect may occur during some high-dose intraoperative use.

Ventilatory depression

Opioids produce a dose-dependent depression of ventilation by decreasing medullary sensitivity to hypercarbia. This results in a rightward shift and a decrease in the slope of the carbon dioxide response curve. Tidal volume initially is preserved, but minute ventilation falls because of a decrease in respiratory rate. When a patient falls asleep, ventilation is depressed further and the degree of hypercarbia and hypoxemia will increase. Other patient-related risk factors for increased ventilatory

depression include advanced age, a history of obstructive sleep apnea, morbid obesity, and the concomitant use of other CNS depressants.

Opioids also decrease hypoxic ventilatory drive and may cause a periodic or Cheyne-Stokes breathing pattern. Sufficient opioid will cause apnea, but the patient may still be arousable and will often breathe if told to do so. All the opioids produce equivalent amounts of ventilatory depression at equianalgesic doses. Treatment depends on the degree of depression and ranges from supplemental oxygen administration to assisted ventilation, with slow naloxone titration.

Muscle rigidity

Generalized hypertonus of skeletal muscle may occur during induction with moderate to large doses of opioids, which can make ventilation extremely difficult. The etiology is a μ -opioid receptor-mediated inhibition of GABAergic neurons in the striatum. For many years, this has been characterized as “chest wall” or “truncal” rigidity. Although there undeniably is a loss of compliance in the chest wall and abdomen, difficulty in ventilation probably is caused by constriction of the laryngeal and pharyngeal musculature. This upper airway obstruction can mimic laryngospasm and may be severe enough to require treatment with a skeletal muscle relaxant. The effect also may be reversed with naloxone, although this is usually undesirable during induction.

Cerebral blood flow/intracranial pressure

Opioids do not directly affect cerebral blood flow, but intracranial pressure (ICP) may be elevated if ventilatory depression is allowed to produce hypercarbia and cerebral vasodilatation. During anesthesia induction, however, the opioids are excellent adjuncts for patients with increased ICP. In this circumstance, ventilation can be controlled, and the opioid will help blunt the increased ICP due to laryngoscopy and intubation.

Tolerance

Tolerance is a physiologic phenomenon in which the response to a drug's effect diminishes over time. To maintain the same effect, the dose needs to be increased as the result of both receptor uncoupling and down-regulation. There are two types of tolerance to opioid action: *acute* tolerance, which occurs immediately after a single large dose, and *chronic* tolerance, which occurs when opioids are administered frequently over longer periods of time.

In general, tolerance develops to all the depressant effects described earlier but not to the stimulant effects, such as constipation and miosis. In addition, when tolerance to an opioid occurs, there is simultaneous development of *cross-tolerance* to all other opioid agonists, although this cross-tolerance is often incomplete (perhaps because of the heterogeneity of μ -opioid receptor subtypes). Thus, a patient who is tolerant to one opioid often can get additional relief by switching to another – a process known as “opioid rotation.”

The precise mechanisms of both acute and chronic tolerance are still unclear, although down-regulation of adenylyl cyclase and other second-messenger mechanisms play a role. A current area of active investigation suggests that chronic opioid administration may actually cause hyperalgesia, and this may be mediated by activation of the glutamate *N*-methyl-D-aspartate (NMDA) receptor. Inhibitors of NMDA can reduce tolerance development in animals, but the data are inconsistent in humans.

Dependence

Physical dependence is a physiologic state defined by the occurrence of a specific withdrawal syndrome when the drug is stopped abruptly, the dose is reduced dramatically, or an antagonist is given. The symptoms of withdrawal can be terminated rapidly with small doses of IV opioids. The presence of physical dependence (and tolerance) is not the same as psychological dependence or *addiction*, which is a chronic, multifactorial neurobiological disease manifested by drug-seeking behavior, impaired control over drug use, and continued use despite negative social and physiologic consequences. Epidemiologic studies have shown that the risk of addiction from *appropriate* medical use of opioids is very low.

Other CNS effects

High doses of opioids may cause myoclonic activity, but without evidence of seizure activity on the cortical electroencephalogram (EEG). As stated previously, chronic administration of meperidine may cause accumulation of its metabolite, normeperidine, which is a true convulsant. Unlike with propofol or volatile anesthetics, even high doses of opioids will not produce EEG suppression.

Cardiovascular system

Vasomotor tone

Opioids produce peripheral vasodilation by depressing vasomotor centers in the medulla, causing a reduction in sympathetic activity. Unlike volatile anesthetics or propofol, they do not block high- or low-pressure baroreflex responses. There is little effect on blood pressure in the awake, normovolemic patient, although analgesic doses can sometimes cause orthostatic hypotension. More significant hemodynamic effects may be seen when higher doses are used or when opioids are combined with other sedative medications (e.g., benzodiazepines). Opioids are most likely to cause hypotension in patients relying on a high sympathetic tone to maintain their blood pressure (e.g., hypovolemia, congestive heart failure).

Heart rate

Opioids produce a dose-dependent reduction in heart rate by stimulating the central vagal nuclei. Bradycardia is most likely to occur when large doses of opioids are administered rapidly.

It may be prevented or reversed by atropine, pancuronium, or other vagolytic drugs.

Contractility and excitability

Opioids do not produce significant direct myocardial depression, and they do not sensitize the myocardium to the effects of catecholamines.

Smooth muscle effects

Gastrointestinal

Through both central (brain and spinal cord) and peripheral (enteric muscle and nerve) effects, opioids cause a reduction in propulsion throughout the entire length of the gastrointestinal system. Therefore, there can be delayed gastric emptying and the development of ileus or constipation. With extended use of opioids, constipation is common, so prophylactic use of stool softeners and stimulant laxatives is recommended. New quaternary opioid antagonists (see “Antagonists”) appear to antagonize the constipating effects without influencing analgesia.

Biliary

Opioids increase smooth muscle tone throughout the biliary tree and sphincter of Oddi. This effect may be less with the agonist-antagonist opioids. The increase in biliary pressure occasionally may lead to epigastric distress or frank biliary colic. Opioid-induced biliary spasm can be relieved specifically with naloxone or nonspecifically with smooth muscle relaxants such as nitroglycerin. The latter is important because biliary pain can sometimes be hard to distinguish from the pain of myocardial ischemia.

Urinary

Urinary retention may result from decreased contraction of the detrusor muscle and an increase in tone of the involuntary sphincter. The patient also may become inattentive to the stimulus of a full bladder. The effect is more prevalent in males and often occurs after neuraxial opioid administration. A part of the effect appears to be peripheral, because it can be reversed by the quaternary antagonist *N*-methylnaltrexone.

Opioid effects not mediated by opioid receptors

Histamine release

Morphine and meperidine can cause dose-dependent histamine release from tissue mast cells and circulating basophils. This cannot be prevented by administration of an opioid antagonist, thus it is not mediated through opioid receptors. The effect often is manifested as a short-lived wheal-and-flare reaction near the site of an IV cannula. After larger doses of morphine, sufficient histamine may be released to cause flushing and transient hypotension. It must be emphasized that this reaction is the result of a nonspecific displacement of the amine

from mast cells and does not involve an immunologic mechanism. True allergy to any of the opioids is extremely rare.

Inhibition of serotonin reuptake

Meperidine (and probably normeperidine) and tramadol appear to inhibit the presynaptic serotonin transporter. This effect may form the basis for the well-described and potentially fatal interaction between meperidine and monoamine oxidase inhibitors (MAOIs). Patients chronically taking MAOIs (isocarboxazid, phenelzine, tranylcypromine, or selegiline) who are given meperidine or tramadol may suffer a serotonergic crisis, manifested as clonus, agitation, hyperreflexia, hyperthermia, and occasionally death.

Inhibition of shivering

Subanalgesic doses of meperidine (12.5–25 mg IV) are effective for treating shivering from a variety of causes (e.g., general or regional anesthesia, bacteremia, transfusion reactions). The mechanism partly may be a result of the serotonin mechanism mentioned earlier, because serotonin is an important neurotransmitter in the posterior hypothalamus. Meperidine also is known to be an agonist at α_{2B} -adrenoceptors, so it may work in a manner similar to that of dexmedetomidine.

NMDA antagonism

Methadone is available commercially as a racemic mixture containing the *l*-isomer (a μ -opioid agonist and noncompetitive NMDA antagonist) and the *d*-isomer (a noncompetitive NMDA antagonist). NMDA antagonism has led some to propose that methadone may have advantages over other opioids in reversing or attenuating the development of opioid tolerance and possibly in treating hyperalgesia or neuropathic pain. The data supporting these advantages are inconsistent at best. Methadone is capable of producing substantial tolerance with chronic dosing, which is why addicts on methadone maintenance have such high opioid requirements.

Perioperative opioid uses

Opioids are used for premedication, IV sedation, balanced general anesthesia, total IV anesthesia (TIVA), and postoperative analgesia. There is little reason to give opioids prior to transfer to the operating room unless the patient is already in pain. Opioid use for premedication makes most sense when sedation is accompanied by the need for analgesia (e.g., during painful procedures like line placement or the performance of regional blocks). The use of small doses of opioids immediately prior to induction might properly be considered part of the anesthetic technique.

Intraoperatively, opioids produce a concentration-dependent suppression of the hemodynamic responses to painful stimuli. The effective concentration varies widely among individuals, although the transition from inadequate to adequate analgesia occurs over a small range for each patient

Figure 37.1. Alfentanil plasma concentrations versus effect curves for each patient during the intra-abdominal part of upper abdominal surgery. (Patients also were receiving 66% nitrous oxide in oxygen.) The plasma concentration for 50% probability of response Cp_{50} and slope (γ) of these curves were defined from the quantal responses of the individual patients to the stimulus using logistic regression. (Redrawn with permission from Ausems ME, Hug CC Jr, Stanski DR, Burm AG. Plasma concentrations of alfentanil required to supplement nitrous oxide anesthesia for general surgery. *Anesthesiology* 1986; 65:362–373.)

(Fig. 37.1). Increasing doses of opioids reduce the requirements for other intravenous and inhaled anesthetics. For example, low plasma concentrations of fentanyl (2–3 ng/ml) or remifentanyl (3 ng/ml) can reduce the amount of propofol necessary to prevent the movement response to pain by about 75%. The opioid agonists all reduce minimum alveolar concentration (MAC) for various volatile anesthetics by a maximum of about 70%. Recent data suggest that there is less of an effect in lowering MAC_{awake} .

Opioids are not reliable hypnotics. They do not consistently produce amnesia or unconsciousness or suppress movement by themselves, so they should not be considered anesthetics. The use of high opioid doses (e.g., 50–150 μ g/kg fentanyl) with only oxygen was popular for a time, particularly in cardiac anesthesia, because it was thought to produce stable hemodynamics. Unfortunately, many patients given fentanyl–oxygen “anesthesia” still had wide fluctuations in blood pressure, some remembered intraoperative events, and all required prolonged postoperative ventilation. Currently, almost all intraoperative opioid use is in combination with true hypnotics, such as propofol (i.e., TIVA), or with volatile agents.

Individualization of doses

The range of effective concentrations (therapeutic window) is narrow for each patient but varies widely among patients. The clear implication is that “cookbook” analgesia likely is inadequate or excessive much of the time. With this caveat, Table 37.3 presents some “typical” intraoperative doses for various opioids. It is intended only as a reasonable place to start titration.

Table 37.3. Typical IV opioid dosages

Agonist	Adjunct to induction	Bolus for maintenance	Infusion for maintenance
Morphine	0.1–0.25 mg/kg	0.02–0.05 mg/kg	NA ^a
Hydromorphone	0.015–0.04 mg/kg	0.003–0.0075 mg/kg	NA ^a
Methadone	Patients who are on methadone chronically may require very large opioid doses intraoperatively. A reasonable starting dose is to administer intravenously the same daily oral dose on which the patient is maintained.	–	NA ^a
Fentanyl	1.5–5 µg/kg	0.4–1.5 µg/kg	0.01–0.1 µg/kg/min
Sufentanil	0.2–0.5 µg/kg	0.1–0.2 µg/kg	0.002–0.01 µg/kg/min
Alfentanil	10–75 µg/kg	3–15 µg/kg	0.1–2 µg/kg/min
Remifentanil	0.5–1 µg/kg	0.1–0.3 µg/kg	0.025–1 µg/kg/min

^a Rarely given intraoperatively via infusion.
NA, not applicable.

The choice of doses will depend on factors unique to the patient and to the procedure:

- Lower starting or maintenance doses are advisable in some circumstances. Elderly patients, for example, may be sensitive, but some elderly patients may require substantial doses. (Undertreatment of pain in the elderly is a significant problem.)
- Lower doses also should be considered in patients who are hypovolemic, debilitated, hypothyroid, or treated with other CNS depressants.
- Patients with obstructive sleep apnea may need normal doses but require more intensive postoperative monitoring for ventilatory depression.
- Patients with hepatic or renal insufficiency may become excessively sedated or experience ventilatory depression from accumulation of the parent drug or metabolites.
- Higher starting or maintenance doses should be considered in some cases – for example, a thoracotomy in which intense postoperative pain is anticipated. However, multimodal analgesia, including epidural analgesia, often is a better choice in cases such as these.
- A patient with obvious opioid tolerance or a history of recent, consistent opioid use may require a substantial amount of opioid. In many cases, intraoperative dosing can be guided by the response (or lack of response) to opioids given preoperatively. One should not hesitate to give adequate doses to patients who have become highly tolerant. Checking intraoperatively for spontaneous ventilation may be reassuring in such cases. If the patient will breathe during general anesthesia, there is a high likelihood that ventilation will continue in the postoperative period.

Agonist–Antagonists

The clinically available agonist–antagonists bind to both μ -opioid and κ -opioid receptors, but they have different intrinsic activities at each site (Table 37.4). Equipotent IV doses for analgesia also are listed in Table 37.4. All the agonist–antagonists behave as partial agonists, with lower efficacy than that of the pure agonists; thus, there is a ceiling for both the analgesic and ventilatory-depressant effects. These agents offer no major benefits compared with the pure agonists for use during balanced anesthesia. Even extremely large doses will not produce the intensity of analgesia produced by fentanyl or morphine, and they are less effective in reducing MAC of the volatile anesthetics.

The subjective effects of buprenorphine are similar to morphine. The κ -opioid agonists nalbuphine and butorphanol have been described as producing “apathetic sedation,” and patients generally do not experience mood elevation like that seen with morphine. After analgesic doses, patients often appear extremely sedated, yet they are able to carry on conversations. The lack of euphoric effects makes these analgesics much less desired by opioid addicts, which is thought to be a key factor in their lower abuse liability. Butorphanol may be used as a premedicant because it produces sedative effects in doses lower than those routinely used for analgesia. Unlike the benzodiazepines, it produces very little anterograde amnesia.

Table 37.4. Agonist–antagonist opioid receptor effects and equianalgesic doses

Drug	μ -Opioid receptor	κ -Opioid receptor	Analgesic dose, mg ^a
Buprenorphine	Partial agonist	Antagonist	0.3
Butorphanol	Antagonist	Partial agonist	2
Nalbuphine	Antagonist	Partial agonist	10

^a Equivalent to morphine, 10 mg.

Because these opioids are partial agonists, the ventilatory-depressant effects are limited in intensity, reaching a maximum after about 30 mg of nalbuphine or about 4 mg of butorphanol. Severe ventilatory depression still is possible in sensitive individuals, such as those with concomitant CNS or pulmonary disease or those receiving other depressant drugs. Buprenorphine has limited ability to cause ventilatory depression. This is important because it has high affinity for μ -opioid receptors, and complete reversal using naloxone may be difficult. Reversal cannot be achieved with another agonist-antagonist.

Nalbuphine and butorphanol do not cause significant elevation of intrabiliary pressure, whereas buprenorphine may cause mild biliary effects. The agonist-antagonists appear to have small effects on smooth muscle in the intestine and bladder, and they cause less constipation than the pure agonists. The cardiovascular effects of buprenorphine and nalbuphine are similar to those of morphine. Butorphanol also may increase pulmonary artery pressure, but heart rate and blood pressure usually decrease slightly.

Nalbuphine and buprenorphine are strong μ -opioid antagonists, and they may be used for this purpose. Reversal of agonist effects with an agonist-antagonist has never been demonstrated to be safer or more reliable than reversal with a pure antagonist such as naloxone. Administration of an opioid antagonist to an opioid-dependent patient will precipitate withdrawal; therefore, agonist-antagonist agents should be avoided in such patients.

Antagonists

Naloxone

Naloxone acts as a competitive antagonist at all opioid receptors, but it has greatest affinity for μ -opioid receptors. Small doses of naloxone reliably reverse or prevent the effects of pure opioid agonists and most mixed agonist-antagonists. The block is reversible, so it can be overcome by additional agonist. Given by itself to an opioid-naïve person, naloxone is nearly devoid of clinically demonstrable effects.

Naloxone is widely distributed and rapidly achieves effective concentrations in the CNS. Plasma and brain concentrations decrease rapidly because of redistribution. The drug is cleared rapidly by hepatic biotransformation. The terminal half-life is 1 to 2 hours. The onset of antagonist effect is extremely rapid, but the duration of action is quite brief. A total IV dose of 0.4 mg will usually antagonize morphine for less than 1 hour, and increasing the dose does not increase the duration appreciably. With the exception of remifentanyl, the duration of naloxone is shorter than the opioids it is used to antagonize.

The presence of excessive opioid effects is a common problem in the postoperative setting. Small doses of naloxone (0.04 mg in an adult, repeated every few minutes) can be given intravenously, usually with dramatic improvement. In many cases, there is partial reversal of analgesia as well, but careful

dosing can minimize this effect. Patients who receive naloxone need continued observation, and possibly repeated doses. Postoperative ventilatory compromise is frequently caused by a combination of factors, and therapy with naloxone does not eliminate the need to search for and treat conditions such as residual paralysis, bronchospasm, and airway edema.

Opioid reversal may sometimes have important hemodynamic consequences. Increases in systemic pressure, heart rate, and plasma levels of catecholamines may occur. This may be because of the sudden onset of pain, but these effects have been reproduced experimentally in the absence of painful stimuli. There have been several case reports of fulminant pulmonary edema, dysrhythmias, and even death in young, previously healthy individuals given naloxone. In one case, the dose of naloxone was only 0.1 mg. The etiology of this is not known.

Naltrexone

Naltrexone is available for oral administration or as a depot injection given monthly. The main clinical use of naltrexone is in the treatment of opioid addiction and alcoholism. Naltrexone blocks the euphoriant effects of opioids and decreases drug craving, thus helping prevent relapse. In the event a patient on naltrexone requires opioid treatment for acute pain, naltrexone antagonism is competitive and may be overcome with high doses of morphine or fentanyl.

N-methylnaltrexone

N-methylnaltrexone (MNTX) is a new quaternary analogue of naltrexone. The permanently charged molecule does not cross the blood-brain barrier and achieve significant concentrations in the CNS. It is given subcutaneously as a treatment for opioid-induced bowel dysfunction (OBD). In healthy volunteers and patients given morphine, IV MNTX reversed depression of gastric emptying and intestinal motility but did not interfere with analgesia.

Alvimopan

Alvimopan is another permanently charged new opioid antagonist that does not achieve significant concentrations in the CNS. It is poorly absorbed after oral administration and does not reverse opioid analgesia. Alvimopan is given orally for the treatment of postoperative ileus.

Muscle relaxants

Torin D. Shear and J. A. Jeevendra Martyn

Neuromuscular block (NMB) refers to the interference with nerve signal transmission at the neuromuscular junction (NMJ) resulting in skeletal muscle paralysis. Several pharmacologic agents are clinically available to produce this paralysis and are collectively known as muscle relaxants. These relaxants block the action of the neurotransmitter acetylcholine (ACh), which initiates muscle contraction. Muscle relaxants are conveniently subdivided into two categories according to the mechanism of action at the NMJ: *depolarizing neuromuscular blockers* and *nondepolarizing neuromuscular blockers*. Both classes of drug block the action of ACh at the nicotinic ACh receptor on skeletal muscle.

Clinically, neuromuscular blocking drugs (NMBDs) facilitate tracheal intubation, mechanical ventilation, and optimization of surgical conditions by producing skeletal muscle paralysis. The pharmacologic effect of NMBDs can be monitored using electrical stimulation of peripheral nerves and assessment of the evoked twitch response. Neuromuscular paralysis can be reversed with the careful titration of anticholinesterase drugs and, more recently, by direct binding of the drug.

Neuromuscular junction

The NMJ comprises a presynaptic motor nerve terminal and a postsynaptic skeletal muscle membrane (Fig. 38.1). Between the presynaptic nerve terminal and the postsynaptic membrane is the synaptic cleft. ACh is stored in the nerve terminal in special organelles called vesicles. ACh receptors (AChRs) cluster in the highly folded motor endplate opposite the nerve terminal.

In the adult NMJ, there are approximately 5 million AChRs. These are nicotinic cholinergic receptors that form transmembrane ion channels permeable to sodium and calcium (into the cell) and potassium (out of the cell). The AChRs are formed by a five-subunit glycoprotein weighing about 250,000 Da. This pentameric protein consists of two α subunits and one each of β , δ , and ϵ subunits in the adult NMJ. Also located on the postsynaptic membrane is acetylcholinesterase.

Alterations in the conventional AChR subunits have been described in denervated muscle, leading to increased membrane permeability associated with hyperkalemic cardiac arrest following administration of depolarizing NMBDs. These immature receptors are expressed in extrajunctional areas of the

skeletal muscle membrane in response to many pathologic states, including muscle denervation. More recently, another isoform, the α_7 AChR, consisting of five α_7 subunits, has been described following denervation.

Normal muscle contraction occurs in a predictable manner. In response to nerve stimulation, an action potential is generated, causing voltage-dependent N-type calcium channels, which are located in the nerve terminal, to open. The ensuing rapid influx of calcium generates an increase in the intracellular calcium concentration in the nerve terminal. This causes ACh-filled synaptic vesicles to fuse with the cell membrane, releasing ACh into the synaptic cleft. ACh molecules bind to nicotinic AChRs on the motor endplate, thereby changing membrane permeability to sodium, calcium, and potassium. This causes an increase in the transmembrane potential from -90 mV to -45 mV. The motor endplate action potential is then propagated throughout the skeletal muscle via sodium channels, leading to muscle contraction.

Neuromuscular blockers

All NMBDs bind to the AChR and antagonize the action of ACh. The NMBDs are quaternary ammonium compounds and, like ACh, bind to the α subunit of AChRs. Nondepolarizing NMBDs can be subdivided based on duration of action or structure (steroid vs. benzylisoquinoline). The evoked twitch response to depolarizing and nondepolarizing NMB differs. Depolarizing block is characterized by a dose-dependent decrease in twitch height without fade during repetitive stimulation. Nondepolarizing block is characterized by fade during repetitive stimulation, the inability to maintain tetanus, and by posttetanic potentiation.

Depolarizing NMBDs

Depolarizing NMBDs are agonists at the nicotinic AChR. They mimic the action of ACh by binding to the AChR and causing skeletal muscle contraction through depolarization of the motor endplate. Persistent endplate depolarization prevents further muscle contraction. Succinylcholine (SCh) is currently the only depolarizing NMBD in clinical use. SCh structurally consists of two ACh molecules linked by methyl groups. It is unique in its rapid onset and short duration. The dose of SCh

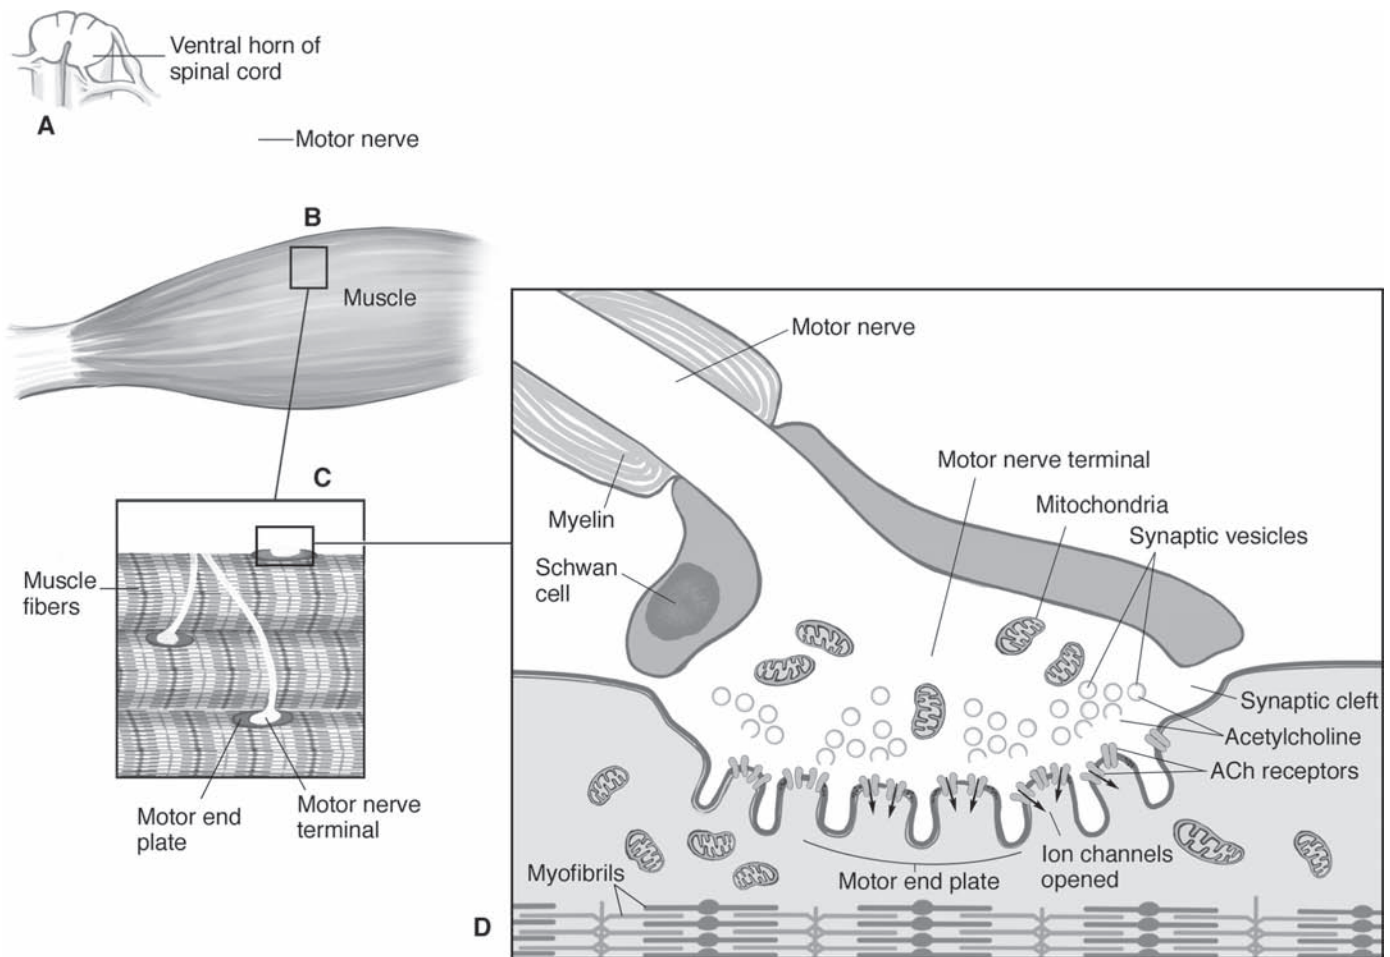

Figure 38.1. Structure of the adult NMJ with the three structures that constitute the synapse: the motor neuron (i.e., nerve terminal), muscle fiber, and Schwann cell. **(A)** The motor nerve originates in the ventral horn of the spinal cord or brainstem. **(B)** As the nerve approaches its muscle fibers, it divides into branches that innervate many individual muscle fibers. **(C)** Each muscle receives only one synapse. **(D)** The nerve terminal, covered by a Schwann cell, has vesicles clustered about the membrane thickenings as well as mitochondria and microtubules. A synaptic cleft separates the nerve from the muscle. The muscle surface is corrugated, and dense areas on the shoulders of each fold contain ACh receptors. Acetylcholinesterase, proteins, and proteoglycans that stabilize the NMJ are present in the synaptic clefts.

has been extensively studied during its long history of clinical use, and ranges from 0.6–1.5 mg/kg. Although studies demonstrate adequate intubating conditions with doses as low as 0.6 mg/kg, a dose of 1 mg/kg is most commonly used.

Rapid onset of skeletal muscle paralysis occurs in 30 to 60 seconds, and paralysis lasts 5 to 10 minutes. With an initial bolus dose of SCh (e.g., 1 mg/kg), phase I neuromuscular block occurs. Higher bolus doses or a prolonged infusion will cause phase II block. Phase I block is the typical depolarizing block and is manifested as a decrease in twitch height without fade in response to peripheral nerve stimulation. As the block resolves, there is an increase in twitch height. During phase II block, the evoked twitch response is similar to that seen during nondepolarizing block in that fade occurs (Fig. 38.2).

SCh is metabolized by plasma butyrylcholinesterase (also known as pseudocholinesterase or plasma cholinesterase), and the NMB produced by SCh is prolonged in patients with plasma butyrylcholinesterase deficiency. A history of prolonged paralysis after general anesthesia or family history of such should

raise concern. Butyrylcholinesterase activity can decrease in states such as burns and liver disease. Genetic variations of butyrylcholinesterase also occur. Normal plasma butyrylcholinesterase can be inhibited by the local anesthetic dibucaine. An *in vitro* assay using dibucaine measures the atypical genetic variations. In normal patients, dibucaine will inhibit 80% of enzyme activity with the corresponding *dibucaine number* of 80. Heterozygous atypical plasma butyrylcholinesterase occurs in about 4% of the population with the corresponding dibucaine number between 30 and 65. Homozygous atypical plasma butyrylcholinesterase occurs in about 0.04% of the general population and corresponds to a dibucaine number of 20. That is, atypical genetic variant plasma butyrylcholinesterase, that does not metabolize SCh, is inhibited less effectively by dibucaine.

Other genetic variants have been described. In addition, plasma butyrylcholinesterase may be inhibited by exogenous compounds such as organophosphates (e.g., insecticides, chemical warfare agents, and echothiophate, a drug used topically

Figure 38.2. Illustration of train-of-four stimuli following administration of neuromuscular blockers. **(A)** With incremental doses of SCh, the twitch height decreases. All four twitches are decreased by the same height. **(B)** During nondepolarizing relaxation, increasing doses result in a decrease of twitch height and a lower second, third, and fourth twitch compared with the first (the twitch amplitude fades during train-of-four stimulation).

in the eye to treat glaucoma), anticholinesterase agents (e.g., neostigmine, pyridostigmine, edrophonium), and monoamine oxidase inhibitors.

Since its introduction in 1951, the pharmacodynamic advantages of SCh have been invaluable in facilitating intubation in and out of the operating room. Its desirable properties allow rapid muscle relaxation of short duration. In contrast, SCh has many undesirable and occasionally lethal adverse effects.

Myalgias secondary to skeletal muscle depolarization are more pronounced in young, muscular individuals. Many clinical trials have evaluated pharmacologic therapies to prevent and or treat this adverse effect. Pretreatment with a nonsteroidal anti-inflammatory agent or a small dose of a nondepolarizing NMBD may be effective.

Hyperkalemia may occur after the administration of SCh. Normal patients typically experience a 0.5 to 1 mEq/L increase in plasma potassium concentration after SCh. Patients at risk for developing life-threatening hyperkalemia after SCh are listed in [Table 38.1](#). Up-regulation and spread of the immature isoform as well as proliferation of the α_7 AChR throughout the muscle membrane plays a role in hyperkalemia following SCh administration. These isoform changes are seen in pathologic states listed in [Table 38.1](#).

Dysrhythmias induced by SCh include sinus bradycardia, junctional rhythm, and, more commonly in children, sinus arrest. Sinus arrest in children can be prevented by pretreatment with atropine. These cardiac effects are secondary to the agonistic action of SCh at parasympathetic nerves.

Table 38.1. Risk factors for the development of hyperkalemia after the administration of depolarizing NMBDs

Upper or lower motor neuron defect
Prolonged chemical denervation (e.g., muscle relaxants, magnesium, clostridial toxins)
Direct muscle trauma, tumor, or inflammation
Thermal trauma
Disuse atrophy
Severe infection

SCh may also can produce other adverse effects, including elevated intracranial pressure and increased intraocular pressure. Both these effects may be mitigated by a higher dose of an intravenous induction agent and pretreatment with a small dose of a nondepolarizing NMBD.

Nondepolarizing NMBDs

Nondepolarizing NMBDs are often subdivided based on their duration of action (short, intermediate, or long acting) or chemical structure (benzylisoquinoline or steroid). NMBDs from the two different chemical classes will act synergistically and prolong the duration of action compared with either drug alone. Drugs from the same chemical class will act in an additive manner. Pancuronium, vecuronium, and rocuronium are steroids. Atracurium, cisatracurium, and mivacurium are benzylisoquinolines. Nondepolarizing NMBDs are competitive antagonists of ACh at the NMJ and bind to the α subunits of the AChR. Unlike SCh, nondepolarizing drugs do not cause depolarization of the postsynaptic muscle membrane.

Long-acting NMBDs

Pancuronium, a steroid, is the longest-acting NMBD available clinically. Its prolonged effect is a result of the action of the parent compound and its active metabolite, 3-hydroxypancuronium, produced in the liver. Pancuronium and its metabolite are eliminated equally in the urine and bile. The initial dose is 0.06 to 0.1 mg/kg, with a maintenance dose of 0.01 mg/kg every 25 to 60 minutes after the initial dose. The time to 25% twitch recovery is 80 to 100 minutes. Hepatic disease can double the terminal half-life and prolong neuromuscular recovery time. Because of its vagolytic properties, tachycardia, increased cardiac output, and hypertension may occur.

Because of pancuronium's prolonged neuromuscular effect, residual paresis may occur in the postanesthesia care unit. Studies comparing the incidence of postoperative residual paresis between long-acting NMBDs and intermediate-acting agents show a decreased risk of residual paresis when shorter-acting relaxants are used. For this reason, the use of pancuronium may be more appropriate when postoperative intubation is planned.

Intermediate-acting NMBDs

Most NMBDs currently in use fit into the intermediate-acting class. Vecuronium, rocuronium, atracurium, and cisatracurium are the intermediate-acting agents.

Table 38.2. Onset and duration of action of rocuronium on laryngeal adductors at varying doses

Dose, mg/kg	Onset at laryngeal adductor muscles, sec	Duration (T1 + 25%), min
0.4	92 ± 29	NA
0.8	96 ± 29	25 ± 9
1.2	54 ± 30	43 ± 13

Data from Wright PM, Caldwell JE, Miller RD. Onset and duration of rocuronium and succinylcholine at the adductor pollicis and laryngeal adductor muscles in anesthetized humans. *Anesthesiology* 1994; 81:1110–1115.

Vecuronium

Vecuronium is an intermediate-acting steroid NMBD used for both intubation and surgical muscle relaxation. The intubating dose is 0.1 mg/kg, with good intubating conditions within 2 to 3 minutes. Maintenance doses of 0.01 to 0.015 mg/kg may be given 25 to 40 minutes after the initial dose. If SCh is used for intubation, a lower initial dose of 0.04 to 0.06 mg/kg is adequate. The time to 25% twitch recovery is approximately 25 to 30 minutes, with a half-life of 51 to 80 minutes. Vecuronium undergoes both renal and hepatic elimination, with 80% excretion in the bile. The active metabolite, 3-desacetyl vecuronium, has half the potency of the parent compound. During prolonged administration, as in the intensive care setting, metabolite accumulation may cause prolonged recovery from paralysis, especially in the presence of renal failure. Vecuronium has little effect on the cardiovascular system.

Rocuronium

Rocuronium is an intermediate-acting steroidal NMBD whose rate of onset is directly related to the dose. Therefore, with larger initial doses (e.g., 1.2 mg/kg), intubating conditions can be achieved within 60 seconds (Table 38.2). It can be used as an alternative to SCh for rapid-sequence intubation. When compared with SCh, the onset of rocuronium at the adductor pollicis, in doses >1 mg/kg, is similar. Larger doses of rocuronium also significantly increase the duration of action. Repeat dosing for maintenance of paralysis is 0.1 to 0.2 mg/kg. Metabolism occurs in the liver to 17-desacetyl rocuronium, which has 5% to 10% of the activity of the parent compound. The terminal half-life is 60 to 70 minutes. More than 70% of the elimination occurs via the liver, with 30% eliminated renally.

Sugammadex is a novel investigational selective relaxant binding agent. It is a modified γ -cyclodextrin derivative that causes chemical encapsulation of rocuronium as well as vecuronium. Published data show that increasing doses of sugammadex reduced the mean recovery time of rocuronium from 122 minutes (spontaneous recovery) to less than 2 minutes in a dose-dependent manner. Signs of recurrence of paralysis did not occur. It has failed to achieve US Food and Drug Administration approval because of concerns regarding the incidence of hypersensitivity reactions.

Atracurium

Atracurium is an intermediate-acting benzyloquinoline NMBD. It has four chiral centers, and there are theoretically 16 isomers. The clinical preparation is a mixture of 10 of these isomers. The intubating dose is 0.4 to 0.5 mg/kg, with good intubating conditions achieved in 2 to 3 minutes. However, it causes histamine release when given rapidly, thereby resulting in hypotension. It undergoes both Michael elimination (commonly referred to as Hofmann elimination) and ester hydrolysis, with a time to 25% recovery of 25 to 30 minutes. The metabolite laudanosine can cross the blood–brain barrier and has central nervous system–stimulating properties (convulsions). It is cleared both by the liver and kidneys. Adverse clinical effects of this metabolite are uncommon.

Cisatracurium

Cisatracurium is an intermediate-acting benzyloquinoline NMBD. It is one of the isomers of atracurium and is the isomer with the largest ratio of NMB activity to histamine-releasing activity. It is approximately two to three times more potent than atracurium. Adequate conditions for intubation are achieved in 3 to 5 min with an intubating dose of 0.15 to 0.2 mg/kg. Cisatracurium undergoes Michael elimination to laudanosine, although the levels of laudanosine are less than those seen in atracurium. Its action and metabolism are not affected by renal or hepatic disease. The terminal half-life is 26 to 28 minutes, and the time to 25% recovery is 50 to 60 minutes.

Factors altering NMBD pharmacology

Various medications potentiate the clinical pharmacologic effects of NMBDs (Table 38.3). In addition, various disease states antagonize or potentiate the effects of NMBDs (Table 38.4).

Renal disease

In the presence of impaired renal function, renal clearance will be reduced. Prolonged recovery is not typically seen after a single bolus dose, because redistribution terminates the drug effect. However, after multiple bolus doses or a continuous

Table 38.3. Effect of various medications on the neuromuscular junction

Decreases synthesis of ACh	Impairs release of ACh by block of presynaptic calcium channels	Postsynaptic block of the AChR (by allosteric binding)

Demyelinating lesions	Hypokalemia
Peripheral neuropathies	Hypermagnesemia
Denervation states	Certain neuromuscular diseases
Infection	Acidosis
Immobilization	Acute intermittent porphyria
Muscle trauma	Eaton-Lambert syndrome
	Myasthenia gravis
	Renal failure
	Hepatic failure

infusion, the relaxant effect of drugs cleared by the kidney (especially pancuronium) will be prolonged. Atracurium and cisatracurium do not undergo renal clearance; thus, their duration of action is largely independent of renal function. In the presence of decreased metabolism of SCh (e.g., homozygous butyrylcholinesterase deficiency), the termination of its effect depends on renal elimination.

Hepatic disease

Following multiple bolus doses or a continuous infusion of rocuronium, vecuronium, or pancuronium, prolonged paralysis will occur in patients with significant hepatic dysfunction. However, because liver failure is often associated with fluid retention and/or ascites, a larger volume of distribution may be present. This larger volume of distribution may increase the initial dose needed to achieve the desired clinical effect. The duration of a single bolus dose is typically unchanged, because redistribution terminates the drug effect. A decreased synthesis of plasma butyrylcholinesterase may occur with decreased liver function, potentially prolonging the duration of SCh.

Diseases of the neuromuscular junction

Myasthenia gravis is an autoimmune disorder resulting in a decrease in the number of AChRs at the NMJ. This decrease in receptor number causes an increased sensitivity to nondepolarizing NMBDs. In addition, the decreased number of receptors requires an increased dose of SCh to effectively depolarize skeletal muscle. Eaton-Lambert syndrome is a paraneoplastic disorder in which antibodies bind to presynaptic voltage-gated calcium channels. This decreases ACh release at the NMJ, causing increased sensitivity to both nondepolarizing and depolarizing NMBDs.

Infection

Severe infection and immobilization in the intensive care unit can cause resistance to nondepolarizing NMBDs and a hyperkalemic response to SCh. This is secondary to up-regulation of AChRs. Infection with *Clostridium botulinum*, or administration of a large therapeutic dose of botulinum toxin, may lead

to a denervated state, resulting in a hyperkalemic response to SCh. Therapeutic exposure to botulinum toxin, in which only a single area or muscle is injected (i.e., forehead or for torticollis or blepharospasm), does not increase the risk of hyperkalemia. Animal data indicate that clostridial infection may lead to increased sensitivity to nondepolarizing NMBDs. This is an exception to the usual response, where resistance to nondepolarizing NMBDs is usually seen when AChRs are increased.

Drug interactions

Drugs that alter liver cytochrome P450 (CYP) will alter the pharmacokinetics of NMBDs cleared by the liver, specifically the steroidal NMBDs. Several studies have demonstrated increased elimination of vecuronium with the concomitant use of anticonvulsants (phenytoin, phenobarbital, carbamazepine) secondary to induction of CYP. In contrast, vecuronium activity was prolonged after inhibition of CYP by cimetidine. Other medications interact with muscle relaxants at the level of the NMJ by decreasing ACh synthesis, impairing the release of ACh or binding the α subunit of the AChR, and/or blocking the ion channel (see Table 38.3).

Data regarding the use of anti-inflammatory glucocorticoids and their interaction with NMBDs are contradictory. One study in humans found a prolonged effect of vecuronium in patients given concomitant glucocorticoids, whereas another study found no effect of acute glucocorticoid therapy on nondepolarizing muscle relaxants. Given this contradiction, care should be taken when administering NMBDs to patients on chronic glucocorticoid therapy.

Reversal of neuromuscular blockade

Thor C. Milland and Neelakantan Sunder

When the need for muscular relaxation has passed, one may either await spontaneous return or administer one of several agents to hasten the return of neuromuscular function. Adequate muscle strength is a prerequisite for protective airway reflexes to prevent aspiration, as well as to maintain adequate spontaneous ventilation to prevent hypoxemia and hypercarbia. If mechanical ventilation is to be continued postoperatively for longer than the duration of action of the neuromuscular blocking agents used, reversal is most often omitted.

Depolarizing neuromuscular blockers

Succinylcholine, a depolarizing neuromuscular blocker, has the most rapid metabolism of any neuromuscular blocking drug. Most of this agent is metabolized by the circulating enzyme plasma butyrylcholinesterase (also known as pseudocholinesterase or plasma cholinesterase), even before it reaches the neuromuscular junction (NMJ). If this enzyme is phenotypically normal, the duration of neuromuscular blockade is short, with full spontaneous recovery within 4 to 10 minutes. Several medications can decrease butyrylcholinesterase activity, including metoclopramide, oral contraceptives, esmolol, some cytotoxic drugs, anticholinesterase agents, monoamine oxidase inhibitors, and echothiophate (a glaucoma agent). Individuals heterozygous or homozygous for a range of mutations in the butyrylcholinesterase gene may have increased duration of blockade, ranging from modest prolongation to up to 4 to 8 hours. There is no medication that increases the rate of recovery from succinylcholine neuromuscular blockade.

Nondepolarizing neuromuscular blockers

The neuromuscular blockers that are typically reversed are the nondepolarizing agents. These neuromuscular blockers are competitive antagonists of acetylcholine (ACh) at the NMJ. The return of normal transmission of excitation–contraction coupling at the NMJ depends on the reestablishment of the ability of ACh to bind to its receptor. Several factors either prolong or decrease the duration of neuromuscular blockade.

The major factors that influence the reversal of neuromuscular blockade are (1) concentration of ACh in the synapse, (2) concentration of neuromuscular blocker at the ACh receptor, (3) removal of the neuromuscular blocker from the synapse,

and (4) metabolism and/or excretion of the neuromuscular blocker from the body. Numerous factors can potentiate neuromuscular blockade, including volatile anesthetics, acidosis, hypothermia, and drugs such as aminoglycosides and polypeptide antibiotics. Electrolytes also have an influence on neuromuscular blockade, with hypokalemia and hypermagnesemia prolonging it and hypercalcemia antagonizing it.

Removal of neuromuscular blockers from the synapse occurs primarily by diffusion away from the synapse to the interstitial fluid, and then to the bloodstream. For most, hepatic metabolism ensures that a gradient favorable to their diffusion away from the synapse will be maintained. Cisatracurium is a notable exception, most of it being degraded by Michael (commonly referred to as Hofmann) elimination, and therefore largely independent of organ function. The primary route of elimination of neuromuscular blockers is via hepatic metabolism and/or renal excretion.

Assessment of neuromuscular blockade

The degree of neuromuscular blockade present, as well as its assessment, is of crucial importance in determining reversal strategy. There is a nonlinear relationship between the time to return of muscular function and depth of neuromuscular blockade when reversal agents are administered. Peripheral nerve twitch monitoring with the train-of-four (TOF) pattern of stimulation is used most commonly. Either the number of twitches observed or the ratio of the amplitude of the first twitch to the fourth twitch (TOF ratio) indicate the degree of neuromuscular blockade present. When TOF is used, the simplest method to assess neuromuscular blockade is visual or tactile assessment of the number of twitches present.

Without a quantitative measurement of twitch amplitude, TOF is inherently an inaccurate method. A single twitch remaining on the TOF represents approximately 90% blockade. If four twitches are visible, the degree of blockade is about $\leq 25\%$. TOF monitoring without accurate quantization of twitch amplitude should not be used to assess the degree of spontaneous recovery or the success of reversal, as there may be a clinically significant neuromuscular blockade in the absence of a manual or visually perceptible difference between the first and fourth twitches.

The preferred method to assess the degree of recovery or the success of reversal is to use the double-burst pattern of stimulation. The double-burst consists of a series of two short 50-Hz tetanic stimuli separated by 0.75 seconds. A difference in the ratio of the first and second responses is determined more easily visually or with the palpating finger. However, lack of apparent difference following a double-burst stimulus is still no guarantee that the patient has a clinically insignificant degree of NMB.

Another method to assess degree of recovery or the success of reversal is to elicit sustained tetanus for 5 seconds at 100 Hz without fade in degree of muscular contraction (in anesthetized patients, because it is painful) or eliciting a sustained head lift for 5 seconds (in awake patients). Following administration of tetanus, there will be posttetanic potentiation of the TOF and double-burst, so these methods of assessment then become less accurate. Other clinical methods include leg lift, grip strength, response to verbal communication, and adequate ventilatory parameters (tidal volume 3–5 ml/kg, maximum inspiratory force –20 mm Hg).

Monitoring site

To assess the degree of neuromuscular blockade, the twitch-monitoring site is important. The larynx, diaphragm, and other central muscles are more rapidly affected by neuromuscular blockers and also have a quicker recovery. Stimulation of the facial nerve with observation of the orbicularis oculi muscle is closely correlated with laryngeal adductor paralysis, and is a good indicator of intubating conditions. However, it is often difficult to differentiate between direct versus evoked responses when the facial nerve is used. For recovery from neuromuscular blockade, the ulnar nerve and adductor pollicis muscle provide the best correlation with the tone of the muscles involved in protective airway reflexes. Furthermore, when adduction of the thumb is used as the response, there is no interference from direct stimulation.

Although spontaneous movement and respiratory activity are also measures of return of neuromuscular function, they are inherently inaccurate, and a twitch monitor should be used whenever possible. It is important to remember that in hemiplegic patients, peripheral nerve twitch monitoring should be done on the normal side, as monitoring on the weak side may lead to an overdose of neuromuscular blockers because of an exaggerated response on the weaker side due to the presence of extrajunctional receptors.

When to reverse

When considering reversal of neuromuscular blockade with an inhibitor of acetylcholinesterase, two important factors should be considered: (1) the time elapsed since the last dose of the neuromuscular blocker and (2) the dose of neuromuscular blocker administered. Although administration of neostigmine during profound neuromuscular blockade will indeed result in shortening of the interval before a TOF ratio of 0.9 is achieved, waiting until the TOF ratio is > 0.1 will result in a far speedier

reversal. If reversal is attempted at a deeper degree of block, residual blockade is likely. A good practice is to reverse the neuromuscular blockade when at least two twitches (TOF) are detectable.

Spontaneous recovery

If the route of spontaneous recovery of neuromuscular blockade is chosen, it is important to allow sufficient time for recovery to occur. Even then, it is important to realize that despite apparent adequate muscular tone, as gauged by nonquantitative methods of measurement such as sustained head lift for 5 seconds, leg lift, or grip strength, a significant amount of residual paralysis may still be present. This subclinical paralysis may cause a significant compromise of protective airway reflexes. In addition, these clinical signs are subject to significant interobserver variability, which significantly decreases their reliability. Even when a TOF ratio of 0.9 is set as the limit of adequate reversal of neuromuscular blockade, 13% of patients will still have pharyngeal dysfunction. Given this evidence, many anesthesiologists feel it is prudent to reverse neuromuscular blockade prior to extubation in all patients who have received nondepolarizing neuromuscular blockers.

Agents for neuromuscular blockade reversal

Various pharmacologic agents are available to reverse neuromuscular blockade. These agents produce their effect by increasing the amount of ACh available to compete with the NMB at the NMJ by inhibiting acetylcholinesterase, the enzyme that degrades ACh. This mechanism for reversal will be effective as long as there is not such a surplus of neuromuscular blocker at the synapse that it is impossible to overcome the blockade by the levels of ACh achieved. In overdose, acetylcholinesterase inhibitors can themselves cause paradoxical weakness due to the production of a depolarizing block from the excess of ACh present at the NMJ. Acetylcholinesterase inhibitors also prolong the effect of succinylcholine by inhibition of butyrylcholinesterase.

Neostigmine, edrophonium, pyridostigmine

Anticholinesterase agents available for clinical use at present are neostigmine, edrophonium, and pyridostigmine. Neostigmine is the most potent and widely used neuromuscular blockade reversal agent because its pharmacokinetics closely matches that of the commonly used neuromuscular blockers. Its onset is within 5 minutes, and its duration is about 1 to 2 hours.

Pyridostigmine is slower in onset and longer in duration compared with neostigmine. It is sometimes used in the reversal of deep neuromuscular blockade. Edrophonium is more rapid in onset than neostigmine (approximately 2 minutes) and shorter in duration ($\ll 1$ hour). Because of its short duration, there is the possibility of re paralysis, especially with longer-acting neuromuscular blockers.

All anticholinesterase drugs are metabolized in the liver and excreted in the urine. However, in the presence of hepatic or

renal disease, their doses usually do not need to be adjusted, because the neuromuscular blockers are also metabolized hepatically or excreted renally.

Although the aforementioned anticholinesterase agents are quaternary ammonium compounds, physostigmine, also an anticholinesterase agent, is a tertiary ammonium compound and is lipid soluble. It is the only anticholinesterase agent that can cross the blood–brain barrier into the central nervous system (CNS). Therefore, CNS symptoms of anticholinergic toxicity (due to scopolamine or atropine) can be reversed with physostigmine.

Adverse effects of acetylcholinesterase inhibitors

When neuromuscular blockade is reversed by acetylcholinesterase inhibitors at the NMJ, the acetylcholinesterase enzyme is inhibited at all cholinergic synapses, resulting in increased ACh at both nicotinic and muscarinic receptors. Although the nicotinic receptor at the NMJ is the targeted receptor, ACh is also the neurotransmitter at the nicotinic receptors in autonomic ganglia as well as at the muscarinic receptors at parasympathetically innervated organs. The increase in ACh leads to bradycardia, hypersalivation, and bronchoconstriction. Severe parasympathetic overstimulation may lead to the so-called SLUDGE (salivation, lacrimation, urination, defecation, gastrointestinal upset, emesis) or cholinergic syndrome. These effects are seen least following the use of edrophonium.

Anticholinergics

To offset the aforementioned cholinergic effects, a muscarinic antagonist (vagolytic/anticholinergic) is usually given in combination with the anticholinesterase agent (Table 39.1). The three commonly used anticholinergic drugs are scopolamine, atropine, and glycopyrrolate, of which the latter two are used in neuromuscular blockade reversal. Scopolamine and atropine are tertiary amines and can cross the blood–brain barrier, whereas glycopyrrolate is a quaternary amine and does not cross the blood–brain barrier. The anticholinergic drugs competitively block the effect of ACh at the muscarinic receptors.

Glycopyrrolate has a longer duration (1–2 hours) and a slower onset of action compared with atropine. This makes it well suited for use in conjunction with neostigmine. Atropine occasionally may cause a paradoxical bradycardia in lower doses

Table 39.1. Typical combinations of acetylcholinesterase inhibitors and vagolytic agents

Combination	Dose, mg/kg
Neostigmine/glycopyrrolate	Neostigmine: 0.04–0.07 Glycopyrrolate: 0.005–0.01
Edrophonium/atropine	Edrophonium: 0.5–1 Atropine: 0.01
Pyridostigmine/glycopyrrolate	Pyridostigmine: 0.2–0.35 Glycopyrrolate: 0.005–0.01

Table 39.2. Effects of anticholinergic agents on various organ systems

Antisialagogue effect	Drying of secretions, rise in body temperature
Cardiovascular ^a	Tachycardia, shortening of PR interval
CNS ^b	Sedation, amnesia, stimulation/depression
Respiratory	Inhibition of secretion of respiratory mucosa, bronchodilation
Gastrointestinal	Decreased intestinal motility, increased risk of aspiration as lower esophageal sphincter tone is decreased
Renal	Urinary retention
Ophthalmic	Pupillary dilation and cycloplegia ^c

^a Atropine produces the highest cardiovascular effects and scopolamine the least.

^b Glycopyrrolate does not cross the blood–brain barrier and does not produce CNS effects. Scopolamine produces the most CNS effects.

^c Cycloplegia is the inability to accommodate to near vision.

(<0.5 mg). All muscarinic antagonists are antisialagogues and inhibit perspiration (Table 39.2), both of which are desirable characteristics in the setting of imminent extubation and hypothermia, often the case at the end of an operative procedure. Heart transplant patients, despite having a theoretic parasympathetic denervation of the transplanted organ, may suffer pronounced bradycardia or asystole if an acetylcholinesterase inhibitor is administered, regardless of the concurrent administration of a vagolytic agent.

Administration of a centrally acting anticholinergic agent such as scopolamine may lead to the so-called central anticholinergic syndrome characterized by excitation, delirium, and hyperpyrexia. Physostigmine, a cholinesterase inhibitor, may be used to treat the central anticholinergic syndrome.

Sugammadex

Sugammadex, formerly known as Org 25969, is a cyclodextrin whose mechanism of reversal is by encapsulation of rocuronium or vecuronium. (It is much less active against pancuronium.) As acetylcholinesterase inhibitors and antimuscarinic agents are not administered, the adverse effects attributable to these agents are absent. Sugammadex possesses several unique characteristics that may drastically change the practice of neuromuscular blockade and its reversal.

Return of a TOF ratio of 0.9 within 1 minute of intravenous administration of sugammadex (8 mg/kg) has been demonstrated. In addition, although a higher dose is required for reversal with increasing depth of neuromuscular blockade, this agent can be used immediately after the blockade is established. The adverse effect profile is benign; the most noteworthy effect was signs of insufficient depth of anesthesia after sugammadex administration in 20% of patients in a dose-finding study. The therapeutic range is wide, with up to a 10-fold overdose being tolerated without incident. The ability to rapidly reverse profound neuromuscular blockade may offer an alternative to succinylcholine and may be beneficial for rescue in a certain subset of patients in a “can’t ventilate, can’t intubate” scenario.

Although approved for use in Europe, sugammadex has failed to achieve US Food and Drug Administration approval due to concerns regarding the incidence of hypersensitivity reactions.

Perioperative pulmonary aspiration prophylaxis

John P. Broadnax and B. Scott Segal

Pulmonary aspiration of gastric contents is a complication that causes significant trepidation among anesthesia providers. Indeed, the first clearly anesthesia-related death was probably the result of aspiration. Pulmonary aspiration involves the regurgitation of gastric contents and their subsequent entrance into the respiratory tract, which may lead to acute lung injury mediated by particulate matter and the acidic nature of gastric contents. Aspirated particulate matter may lead to a focal inflammatory and foreign body reaction. The low pH of gastric contents causes diffuse acid-mediated damage. Animal models suggest that aspiration of material with pH < 2.5 is associated with pulmonary morbidity, whereas more alkaline material causes little or no injury. The volume required to cause injury is controversial. Early data suggesting 0.4 ml/kg (or approximately 25 ml in a 70-kg adult) was sufficient probably overestimated the risk; more recent, larger studies suggest 1 ml/kg in the lung (not merely in the stomach) is required.

Together, the twin insults of acid and particulate matter can act synergistically, leading to increased pulmonary damage. Acutely, pulmonary aspiration may lead to aspiration pneumonia. After the initial insult, pulmonary aspiration may later evolve into aspiration pneumonia, respiratory failure, or acute respiratory distress syndrome.

The overall risk of pulmonary aspiration of gastric contents during general anesthesia is actually quite low, on the order of one to five in 10,000 anesthetic procedures. In the setting of modern pulmonary care, the aspiration of gastric contents is fortunately associated with minimal morbidity and negligible mortality. The incidence of aspiration is slightly greater in the obstetric and pediatric patient populations, but overall morbidity and mortality are not increased. Studies in trauma patients indicate a much higher incidence of aspiration.

The first step in preventing pulmonary aspiration is to identify patients who are at an increased risk for this complication. Several risk factors for pulmonary aspiration have been identified: increased gastric pressure, increased gastric regurgitation, and laryngeal incompetence. The specific entities that predispose patients to these conditions are outlined in [Table 40.1](#).

Traditionally, pregnancy and obesity have been thought to be associated with an increased risk of aspiration due to associated decreased gastric emptying. However, these assumptions appear to be untrue in both the obese and the nonlaboring parturient.

To minimize the risk associated with pulmonary aspiration, surgical patients are required to be nil per os (NPO) prior to undergoing general anesthesia. The current American Society of Anesthesiologists (ASA) NPO guidelines recommend patient fasting of 2 hours after clear fluids, 4 hours after breast milk for neonates and infants, and 6 hours after infant formula, nonhuman milk, or a light meal (ASA 1999). Many anesthesiologists favor a more conservative fast of 8 hours, or NPO after midnight the day of surgery.

Several anesthetic techniques have been proposed to reduce the risk of pulmonary aspiration in high-risk patients. Rapid sequence intubation and the application of cricoid pressure are widely used in anesthetic practice. Neither, however, has been shown to reduce the incidence of aspiration or affect the morbidity or mortality from pulmonary aspiration. Nonetheless, most anesthesiologists consider such techniques to be the standard of care for patients known to have elevated risk of pulmonary aspiration.

Pharmacologic approaches to reducing the risk of aspiration include the preoperative administration of nonparticulate antacids, histamine H₂ antagonists, proton pump inhibitors (PPIs), and prokinetic agents. [Table 40.2](#) summarizes suggested aspiration prophylaxis drugs, doses, and routes of administration.

Table 40.1. Risk factors for perioperative pulmonary aspiration

Increased gastric volume	Increased gastric regurgitation	Decreased laryngeal competence
Delayed gastric emptying	Gastroesophageal reflux disease	General anesthesia
Diabetic gastroparesis	Decreased lower esophageal sphincter tone	Depressed level of consciousness
Labor	Esophageal obstruction	Head injury
Pain/stress	Zenker's diverticulum	Stroke
Gastric hypersecretion	Achalasia	Neuromuscular disorders
Overfeeding	Extremes of age	Muscular dystrophies
Recent meal	Esophageal/upper abdominal surgery	
	Esophagectomy	
	Increased intra-abdominal pressure	

Table 40.2. Suggested aspiration prophylaxis drugs, doses, and routes of administration

Drug	Dose	Route of administration
Citric acid/sodium citrate	30 ml	PO
Metoclopramide	5–15 mg	PO/IV/IM
Rabeprazole	20 mg	PO/IV
Omeprazole	20–40 mg	PO/IV
Pantoprazole	40–120 mg	PO/IV
Lansoprazole	15–30 mg	PO/IV
Esomeprazole	20–40 mg	PO/IV
Nizatidine	150–300 mg	PO/IV/IM
Famotidine	20–40 mg	PO/IV/IM
Cimetidine	400–800 mg	PO/IV/IM
Ranitidine	75–150 mg	PO/IV/IM

IM, intramuscular; IV, intravenous; PO, oral.

Nonparticulate antacids administered immediately preoperatively significantly raise gastric pH. The most commonly used solution is sodium citrate or a citrate/citric acid buffer. These agents have a very rapid onset of action but a relatively short-lived gastric acid-neutralizing effect.

Histamine H₂ antagonists and PPIs have been used to increase gastric pH. Both pharmacologic classes act by limiting parietal cell acid secretion in the stomach. Histamine H₂ antagonists exert their effect by antagonizing the action of histamine on gastric parietal cells via competitive inhibition. PPIs bind to and block the action of the H⁺,K⁺-ATPase pump on parietal cells. Both methods effectively increase gastric pH when administered appropriately preoperatively. Their onset of action is slower but they last considerably longer than antacids.

Metoclopramide is a dopamine receptor antagonist with prokinetic properties due to peripheral cholinergic agonism. Its effects include increased gastric contractions, relaxation of the pyloric sphincter, and increased small bowel peristalsis. Metoclopramide is administered preoperatively to increase gastric emptying, thereby theoretically reducing the risk of perioperative aspiration because of decreased gastric volume. Its onset time after intravenous administration is approximately 20 minutes. In emergency settings, it may help reduce the risk of aspiration at extubation, even if it has no effect at induction.

Although each of these agents has proven to be effective in achieving the goals of reducing gastric volume and increasing gastric pH, none has been shown to affect the morbidity or mortality from perioperative pulmonary aspiration. In large part, this may be the result of insufficient power given the rare incidence of perioperative pulmonary aspiration and associated morbidity and mortality. Therefore, routine prophylaxis with these agents for all patients is not recommended. Despite the paucity of outcome data, however, these agents likely are useful in patients at high risk for pulmonary aspiration or in whom the consequences of such an event would be poorly tolerated.

Perioperative antiemetic therapies

John P. Broadnax and B. Scott Segal

Introduction

Postoperative nausea and vomiting (PONV) has been a perpetual problem since the introduction of ether anesthesia. It has often been referred to as the “big little problem” (Kapur 1991). Although this condition rarely results in significant mortality, the morbidity has a significant effect on the patient’s perioperative experience and perception. PONV may lead to incisional suture dehiscence, aspiration, and delayed postoperative patient discharge. In several studies, patients identified their primary perioperative concern as PONV, even greater than pain. Over the past few decades, a substantial amount of research has been dedicated to this topic, leading to better mechanistic understanding and development of rational solutions. This chapter reviews the pharmacology of antiemetic drugs. The assessment of PONV risk and strategies for rational use of these drugs are discussed in [Chapter 54](#).

Physiology of PONV

Nausea and vomiting are the results of a complex integration of inputs from various physiologic systems ([Fig. 41.1](#)). It is the manifestation of the stimulation of the salivary center, respiratory center, and pharyngeal, gastrointestinal (GI), and abdominal muscles. These centers receive their stimulatory input from the central vomiting center, which has been classically postulated to be located in the lateral reticular formation of the medulla. More recent evidence suggests it is not a single anatomic center but a group of closely integrated areas in the brainstem. This central vomiting center is responsible for integrating and coordinating the complex processes involved in vomiting. The vomiting center receives input from the chemoreceptor trigger zone (CTZ), the vestibular apparatus, the cerebral cortex, and the visceral afferent nerves from the GI tract. The CTZ, also located in the brainstem (in the area postrema at the floor of the fourth ventricle) lies outside the blood–brain barrier and thus is uniquely positioned to receive blood-borne chemical emetogenic stimuli. The stimulation of dopamine, opioid, histamine, acetylcholine, neurokinin-1, or serotonin type-3 receptors in these centers initiates the cascade that leads to emesis. These receptors are the targets of the various antiemetic therapies, and it is through them that they enact their antiemetic effects.

Rational administration of antiemetic therapy

The preoperative identification of independent risk factors followed by the use of a risk-dependent stratification management model should form the foundation of a rational, evidence-based approach to the prophylaxis and treatment of established nausea and vomiting in the postoperative setting. Please refer to [Chapter 54](#) for a detailed discussion of this topic.

Number needed to treat and number needed to harm

Comparison of the efficacy and side effects of antiemetic drugs is complex, and few head-to-head comparisons are available. Instead, it is common to compare a given drug with placebo. The apparent effect of the tested drug depends on its effectiveness or harmfulness as well as the incidence of PONV or side effects in the placebo-treated group. A common way to standardize this comparison across studies and drugs is to compute the number needed to treat (NNT) or number needed to harm (NNH). This number is simply the reciprocal of the absolute difference in risk in the treatment and placebo groups. For example, if 25% of the drug-treated group experiences PONV, compared with 50% of the placebo-treated patients, then the absolute risk reduction is 25%, and the NNT is $1/(0.5 - 0.25) = 4$.

Pharmacology of antiemetic drugs

Anticholinergics

Anticholinergics presumably produce their antiemetic effects via inhibition of postganglionic muscarinic receptors in the central nervous system. They prevent cholinergic transmission from the vestibular nuclei and reticular formation to the central vomiting center. The most effective antiemetic in this drug class is scopolamine. As a tertiary amine, scopolamine crosses the blood–brain barrier to exert its central anticholinergic effects. Scopolamine is available as either a parenteral solution or a transdermal patch delivery system. Transdermal scopolamine premedication has been shown to decrease the incidence of vomiting following general anesthesia when applied the evening before surgery or 4 hours before the end of anesthesia. Early

Figure 41.1. The neurobiology of PONV.

application of the patch is necessary because of its 2- to 4-hour delay in onset of an antiemetic effect. Conversely, a single patch may provide up to 72 hours of antiemetic treatment.

A meta-analysis of randomized studies (Kranke et al. 2002) found the NNT with scopolamine to prevent postoperative vomiting was 5.9 patients. Transdermal scopolamine also has been shown to decrease nausea and vomiting caused by epidural and intrathecal morphine. It may find particular benefit in outpatient surgery, because its anti-motion sickness effect is prominent. Side effects are mild but common; the NNH is 5.6 for visual disturbances such as blurry vision and 12.5 for dry mouth. Other common side effects include sedation, memory disturbance, confusion, constipation, and urinary retention. Table 41.1 shows currently used PONV prophylaxis drugs, as well as their suggested doses and time of administration.

Serotonin-3 antagonists

The antiemetic properties of many classic antiemetics initially were attributed solely to dopaminergic antagonism (see later), but serotonin receptor antagonism later was discovered to also partially play a role in this effect. This discovery led to the

research and eventual development of the serotonin-3 (5-HT₃) antagonists. These drugs act via antagonism of 5-HT₃ receptors in the CTZ and the vagal afferents in the GI tract. They have been shown to be effective in both the prophylaxis and treatment of PONV. The first 5-HT₃ antagonist to be marketed in the United States and the most studied drug in the class is ondansetron. Its efficacy has been documented in numerous randomized placebo-controlled trials (Tramer et al. 1997). The NNT for prevention of nausea is 6 to 7, compared with 5 for prophylaxis against vomiting, indicative of the class’s superiority in preventing vomiting over nausea. The optimal timing of administration is at the end of surgery (Sun et al. 1997).

Other 5-HT₃ antagonists include dolasetron, granisetron, tropisetron, and ramosetron (the latter two are not available in the U.S.). When used in equipotent doses, 5-HT₃ receptor antagonists are equally effective in the prevention of PONV (Naguib et al. 1996).

The side effect profile of the 5-HT₃ antagonists includes constipation, with an NNH of 23; headache, with an NNH of 36; elevated liver enzymes, with an NNH of 31; and more rarely, dizziness, electrocardiogram abnormalities, and flushing. The lack of sedation with drugs of this class makes them particularly suitable for use in ambulatory surgery. Recently, the FDA withdrew approval of intravenous dolasetron for chemotherapy-induced nausea and vomiting because of the risk of dose-dependent QT interval prolongation. All 5-HT₃ antagonists prolong the QT interval to some extent, but the risk with dolasetron seems to be highest. Because the dose for PONV is so much lower than that for chemotherapy patients, the risk in the perioperative period is still relatively small. Another part of the new FDA warning is that dolasetron should not be given to patients with congenital long QT syndrome or with hypokalemia or hypomagnesemia.

Table 41.1. Suggested PONV prophylaxis drugs, doses, and times of administration

Drug	Dose	Time of administration ^a
Dexamethasone	4–5 mg IV	Induction of anesthesia
Dimenhydrinate	1 mg/kg IV, 25–50 mg PO	Undetermined
Dolasetron	12.5 mg IV	End of surgery
Droperidol	0.625–1.25 mg IV	End of surgery
Granisetron	0.35–1.5 mg IV	End of surgery
Haloperidol	0.5–2 mg IM/IV	? / End of surgery
Prochlorperazine	5–10 mg IM/IV	End of surgery
Promethazine	6.25–25 mg IV	Induction of anesthesia
Ondansetron	4 mg IV	End of surgery
Scopolamine	Transdermal patch	Preoperatively
Aprepitant	40 mg PO	Preoperatively

^a The stated times of administration are based on the best currently available evidence; however, significant controversy remains regarding the optimal timing of perioperative antiemetic administration.

IM, intramuscularly; IV, intravenously; PO, orally.

Data from Gan T, Meyers T, Apfel C. Consensus guidelines for managing postoperative nausea and vomiting. *Anesth Analg* 2003; 97:62–71.

Glucocorticoids

Dexamethasone is the most extensively evaluated and frequently used glucocorticoid in the prophylaxis and treatment of PONV. The mechanism by which glucocorticoids exert their antiemetic effect is unknown. Dexamethasone has been shown to be effective for both the immediate and late onset of PONV. Its effects on late-onset PONV appear to be more pronounced. The NNT for early-onset PONV is 7.1, compared with 3.8 for

later-onset PONV (Henzi et al. 2000). To provide prophylaxis for both early- and late-onset PONV, dexamethasone should be administered relatively early in the immediate perioperative period. For example, dexamethasone was demonstrated to be more effective at preventing PONV during the first 2 hours following surgery when given before induction of anesthesia, as opposed to at the end of surgery; however, administration at either time was effective in preventing late-onset symptoms from 2 to 24 hours postoperatively (Wang et al. 2000). Most studies on dexamethasone have focused on doses of 8 to 10 mg, but some data suggest that lower doses of 2.5 to 5 mg may be effective as well. Given the short duration of therapy for PONV, long-term adverse effects of glucocorticoids, such as reduction in bone mineral density, diabetes, and cataracts, have not been reported (Henzi et al. 2000).

Dopaminergic antagonists

The butyrophenones most often used as antiemetics are droperidol and haloperidol. These drugs act via antagonism of the dopamine D₂ receptor in the CTZ and in the postremal area. Although both drugs have shown efficacy in PONV, droperidol is more frequently used in anesthetic practice. Droperidol doses as low as 0.625 mg have been shown to be effective in the prophylaxis of PONV (Henzi et al. 2000a). Doses <1 mg are more effective for the prevention of nausea than of vomiting; however, doses between 1 and 2.5 mg improve antiemetic efficacy. Droperidol's efficacy is similar to that of ondansetron for PONV prophylaxis, with an NNT of approximately 5 (Tramer 2001).

On November 26, 2001, the US Food and Drug Administration (FDA) issued a “black box” warning for droperidol regarding the potential for QT interval prolongation and cardiac arrhythmias that may result in torsades de pointes and sudden cardiac death. Continuous cardiac rhythm monitoring for 2 to 3 hours is recommended for any patient receiving droperidol at the approved (labeled) dose of ≥ 2.5 mg. Although the aforementioned cardiac morbidity is a well-documented effect seen with high doses of droperidol, questions have been raised regarding its relevance at the lower doses (0.625–1.25 mg) used for PONV prophylaxis and treatment.

Of the numerous cases reported to the FDA involving droperidol-associated QT prolongation, arrhythmia, or cardiac death, only 10 cases involved droperidol administered at a dose of ≤ 1.25 mg. Droperidol was not conclusively found to be causally related to the deaths in any of the reported cases. Because of the lack of submitted data, the FDA has declined to comment on the efficacy or safety of droperidol at these lower doses. Also of note, the FDA has reiterated the importance of off-label drug use in medical practice and neither restricts physicians' discretionary use of approved drugs nor regulates the off-label use of approved drugs (Ludwin et al. 2008; Rappaport 2008).

The second class of antiemetic dopaminergic antagonists is the phenothiazines. Their antiemetic effects are primarily via antagonism of the dopamine D₂ receptor in the CTZ.

Phenothiazines also antagonize histamine H₁ receptors. Prochlorperazine, an agent in this class of medications, has been shown to be an effective antiemetic when administered at the end of surgical procedures. Caution should be taken when using prochlorperazine in the perioperative period because of its profound antagonism of α -adrenoceptors.

Antihistamines

Antihistamines exert their antiemetic effects via antagonism of the histamine H₁ and muscarinic receptors in the vestibular system. The most effective antiemetic antihistamines used frequently in anesthetic practice are members of the ethanolamine, piperazine, and phenothiazine families.

Dimenhydrinate, an ethanolamine, appears to have antiemetic efficacy similar to that of the 5-HT₃ receptor antagonists, dexamethasone and droperidol. A meta-analysis of randomized controlled trials showed the NNT for nausea and vomiting prophylaxis to be approximately 5 within 48 hours after surgery. The optimal timing and dose response for administration could not be calculated because of insufficient data (Kranke et al. 2002). Also of note, dimenhydrinate is pharmacologically similar to diphenhydramine, as it is composed of the salts of diphenhydramine and 8-chlorotheophylline.

The most used antiemetic antihistamines in the piperazine family are cyclizine and hydroxyzine. Hydroxyzine also has been found to be a favorable option because of its other properties, including anxiolysis and potentiation of opioid analgesia.

Another commonly used antiemetic with significant antihistamine activity is promethazine. Promethazine is chemically a phenothiazine; however, it does not block dopamine receptors at the usual clinical doses. Promethazine therefore exerts most of its antiemetic effects via histamine H₁ and muscarinic receptor antagonism.

Antihistamines share a similar side effect profile, which tends to be the limiting factor in their perioperative use. These side effects include sedation, dry mouth, constipation, confusion, blurred vision, delirium, urinary retention, and tachycardia. In particular, sedation limits their popularity for outpatient surgery.

Neurokinin-1 receptor antagonists

Substance P has been implicated in the pathogenesis of PONV via both central and peripheral mechanisms. Substance P is a ligand of the neurokinin-1 (NK₁) receptor, which may be found centrally in the CTZ and vomiting center, as well as peripherally in the vagal afferents of the GI tract. The first NK₁ receptor agonist approved for clinical use by the FDA in the United States was aprepitant. This drug was shown to be superior to ondansetron in preventing vomiting up to 48 hours postoperatively and equivalent in reducing the incidence of nausea and need for rescue antiemetics in the first 24 hours (Gan et al.

2007). Aprepitant should be given within 3 hours prior to induction of anesthesia.

Other antiemetics

The current available data suggest that several drugs traditionally used for PONV prophylaxis are relatively ineffective for that purpose. Metoclopramide, at least at the standard clinical dose of 10 mg, has no anti-nausea effect and is only minimally effective in prophylaxis against vomiting (Henzi et al. 1999). Other agents that have shown poor clinical efficacy for PONV include ginger root and the cannabinoids.

Nonpharmacologic strategies

Nonpharmacologic approaches to PONV prophylaxis have been explored as inexpensive and noninvasive alternatives and adjuncts to traditional treatments. These therapies also confer the additional benefit of allowing patients to avoid the numerous side effects involved with pharmacologic treatments. Therapies such as acupuncture, transcutaneous electrical nerve stimulation, acupoint stimulation, and acupressure have shown some antiemetic efficacy when used prior to surgical procedures. The NNT for these procedures has been estimated to be approximately 5 (Lee and Done 1999). Other nonpharmacologic therapies shown to be effective in at least limited settings include intravenous hydration, high supplemental inspired fractional oxygen content, and inhalation of isopropyl alcohol vapor.

Conclusion

Although significant advances have been made in antiemetic therapy, PONV continues to be a problem for patients and anesthesiologists alike. There likely is no “magic bullet” that will eliminate PONV, the most common anesthetic side effect. The keys to overcoming it are to continue to refine methods for identifying high-risk patients, to continue to find ways to reduce baseline risk factors, to optimize multimodal prophylactic combination regimens, and to continue the research and development of novel antiemetic agents and strategies.

COX inhibitors and α_2 -adrenoceptor agonists

Benjamin Parish and Mark Dershwitz

Cyclooxygenase (COX) inhibitors are nonopioid drugs that reduce pain (analgesic) and fever (antipyretic). All except acetaminophen also reduce inflammation. Commonly used COX inhibitors include aspirin, acetaminophen, ibuprofen, ketorolac, and celecoxib. A major advantage of COX inhibitors over opioids is that COX inhibitors do not produce sedation, ventilatory depression, or tolerance. Adverse effects, however, limit their use. The following section considers the pharmacology of the parenteral COX inhibitor ketorolac.

Ketorolac

Indications

In 1990, ketorolac was the first parenteral COX inhibitor approved for use for postoperative pain. It is used for short-term management (<5 days in adults) of moderate to severe acute pain. It is not indicated for use in children (<17 years) or for chronic pain conditions.

Mechanism of action

Ketorolac's primary mechanism of action is thought to be competitive and reversible inhibition of the enzyme COX, resulting in the inhibition of prostaglandin synthesis, as shown in Fig. 42.1. There are two isozymes of COX: COX-1 is a constitutive enzyme that participates in the protection of the gastrointestinal (GI) mucosa from acid damage, in the activation of platelets, and in the regulation of renal blood flow; COX-2 is an inducible enzyme that participates in the mediation of inflammation, pain, and fever. Ketorolac is a racemic mixture of the "S" active form and the "R" inactive form. The active form inhibits both COX-1 and COX-2 (as do aspirin and ibuprofen). Selective COX-2 inhibitors, such as celecoxib, are selective for the COX-2 isozyme. The therapeutic effects of these medications are additive, as are their adverse effects (except that celecoxib has little effect on the GI mucosa and on platelets).

Pharmacokinetics

Ketorolac can be administered orally, intramuscularly (IM), or intravenously (IV). Its bioavailability is 100% following oral administration. The recommended dosage for postoperative

pain management is 30 mg IM or IV every 6 hours, with a maximum daily dose of 120 mg. The dose should be halved in persons over 65 years of age, in persons with renal insufficiency, or in adults weighing <50 kg. The onset of analgesia is slow, occurring about 30 minutes following IV and in about 60 minutes following IM administration. Oral ketorolac may be given at 10 mg every 6 hours. The duration of therapy should not exceed 5 days.

Ketorolac is metabolized by the liver, and the metabolites are excreted primarily in the urine. About 40% of an administered dose is metabolized, whereas the remainder is excreted unchanged.

The comparative doses of ketorolac and other COX inhibitors are shown in Table 42.1.

Alternative to opioids

Although potency ratios are difficult to measure, a 30-mg dose of ketorolac is approximately equipotent to 4 mg of morphine. Using ketorolac as an alternative to opioids avoids the adverse effects of sedation and ventilatory depression. Most patients also will experience less nausea and vomiting. For these reasons, ketorolac has become particularly popular in ambulatory surgery, in which its use may permit shorter patient discharge times. When given in combination with opioids, the opioid requirement likely will be lower. The adverse effect profile of ketorolac is summarized in Table 42.2.

Table 42.1. Doses of COX inhibitors

Drug	Dose, mg	Interval, h	Maximum daily dose, mg
Ketorolac	30 IV/IM	6	120
	10 PO	6	40
Acetaminophen	500–1000	4–6	4000
Aspirin	500–1000	4–6	4000
Ibuprofen	200–800	4–6	2400
Naproxen	500 initially, then 250	6–8	1500
Celecoxib	200–400 initially, then 100–200	12–24	400

PO, orally.

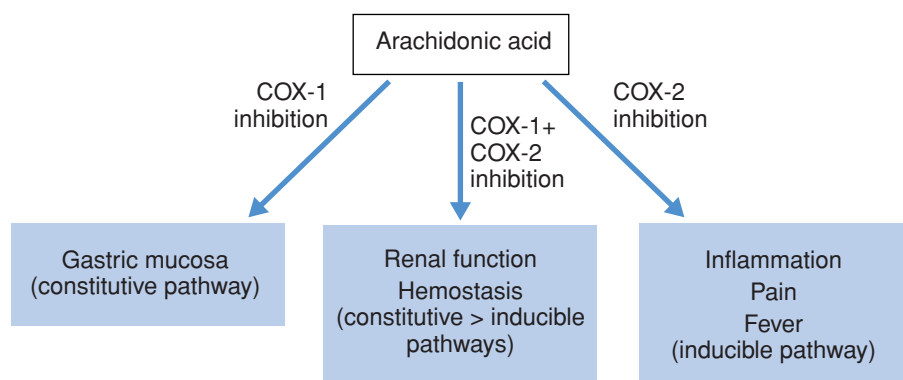

Figure 42.1. Mechanism of action of the COX inhibitors. Ketorolac, aspirin, and ibuprofen inhibit both COX-1 and COX-2, whereas celecoxib is a selective COX-2 inhibitor.

Special populations

Elderly patients

The dose of ketorolac should be halved in persons over 65 years of age. Such patients are also at higher risk for experiencing adverse effects, especially GI ulceration.

Pediatric population

Ketorolac is contraindicated in children <17 years of age.

Pregnancy

Ketorolac is contraindicated during labor and delivery and for nursing mothers. Inhibiting prostaglandin synthesis may decrease uterine blood flow and contractions. Ketorolac is excreted in breast milk.

Drug interactions

Because the effects of ketorolac are additive with other COX inhibitors, their concurrent administration is not recommended. Ketorolac may reduce the natriuretic effect of furosemide and thiazide diuretics in some patients, leading to increased edema. Administration of ketorolac with angiotensin-converting enzyme inhibitors may cause renal impairment, especially in volume-depleted patients. The effects of ketorolac on GI bleeding are synergistic with warfarin and

heparin; therefore, ketorolac should not be used in the presence of coagulation disorders or in patients on anticoagulant therapy.

α_2 -Adrenoceptor agonists

Currently, there are two α_2 -adrenoceptor agonists used in clinical practice. Dexmedetomidine is a useful adjunct in anesthesiology and critical care medicine. Clonidine, although not used by anesthesiologists as often as dexmedetomidine, has profound effects in anesthetic management.

The primary effect of the α_2 -adrenoceptor agonists is to decrease sympathetic outflow from the central nervous system (CNS), leading to a decrease in heart rate and blood pressure. There is a significant sedative effect that is not accompanied by ventilatory depression. Analgesia and a decreased requirement for opioid analgesics also occur.

Although these medications cannot produce general anesthesia, they may be useful as anesthetic adjuvants. Dexmedetomidine decreases the minimal alveolar concentration of halothane by 95% in animals, whereas clonidine does so by up to 50%. In contrast to benzodiazepines, α_2 -adrenoceptor agonists do not produce reliable amnesia.

Ventilatory effects

At doses used to provide sedation, there is a minimal reduction in minute ventilation secondary to decreased tidal volumes.

Table 42.2. Adverse effects of ketorolac

System	Effect	Patient restrictions	Notes
Renal	Renal papillary necrosis	Elderly patients, preexisting renal disease, hypovolemia	
Hematologic	Inhibition of platelet aggregation	Coagulation disorders, use of anticoagulants	Unlike aspirin, platelet inhibition disappears 24–48 h after discontinuation
GI	Ulceration	Peptic ulcer disease, bleeding or perforation	
Respiratory	Bronchospasm	Aspirin-sensitive asthma cross-reactivity	Indirect stimulation of leukotriene pathway
Cardiovascular	Inhibition of platelet aggregation	Myocardial infarction, thrombotic events, stroke	Contraindicated following cardiac surgery
Hepatic	Liver necrosis, hepatitis	Impaired hepatic function	
Reproductive	Decreased uterine contractions	Pregnant women	Also decreases uterine blood flow

However, the ventilatory response to carbon dioxide remains intact.

Cardiovascular effects

Through its centrally acting sympatholytic effects, there are frequent decreases in heart rate, blood pressure, and cardiac output. If the initial bolus of dexmedetomidine is given too rapidly, there may be a paradoxical increase in blood pressure. This is thought to be a result of agonist effects at vascular α_1 -adrenoceptors.

CNS effects

As mentioned previously, α_2 -adrenoceptor agonists produce sedation and analgesia. When given in combination with opioids, the requirement for opioid is lessened. Their amnestic effect is much less reliable than with benzodiazepines.

Clonidine has been used in nerve blocks with varying results. Some studies have suggested improved onset and quality of the block, whereas others have documented prolongation of the block. The mechanism of action is unknown.

Use of dexmedetomidine

Dexmedetomidine is approved for sedation in the intensive care unit and for procedural sedation, including for awake fiberoptic intubation. The usual loading dose is 1 $\mu\text{g}/\text{kg}$ given over 10 minutes. Maintenance doses are typically 0.1 to 1 $\mu\text{g}/\text{kg}/\text{h}$.

The therapeutic goal of diuretics is to reduce edema by decreasing total body water. Diuretics may also be used to alter electrolyte or osmotic levels. Essentially all diuretics interfere with sodium ion (Na^+) reabsorption in some way at various segments of the nephron. They achieve this by increasing sodium chloride (NaCl) output, which results in a net NaCl loss and, therefore, water loss along with it. Fig. 43.1 shows sites of diuretic action along the nephron.

Proximal convoluted tubule diuretics

The proximal convoluted tubule is the primary site for Na^+ reabsorption and seems a likely site for effective diuretic action. However, the number of downstream reabsorption sites limits the effectiveness of any diuretic targeting this region. Carbonic anhydrase inhibitors are the only commonly used diuretics that particularly target this region, although they are rarely used primarily as diuretics. They work by blocking the enzyme carbonic anhydrase, which acts to help reabsorb bicarbonate in the proximal tubule. The net effect is reduction of bicarbonate ion (HCO_3^-) reabsorption, which instead remains in the filtrate (metabolic acidosis). To maintain electrochemical neutrality, Na^+ (the most abundant cation) accompanies HCO_3^- out of the proximal tubule. The thick ascending limb (TAL) of the loop of Henle is capable of reabsorbing increased loads of NaCl . As a result, a large amount of the Na^+ is reabsorbed there, accounting for the relatively weak diuretic effect of acetazolamide. In the distal tubule, Na^+ is exchanged for potassium (K^+), with a net result of a small increase in the excretion of HCO_3^- , K^+ , and water.

Acetazolamide occasionally is used for the treatment of glaucoma, as it inhibits the production of aqueous humor by the ciliary body, resulting in lowered intraocular pressure. It also is used for the treatment of acute mountain sickness (AMS). Its precise mechanism of action in ameliorating the symptoms of AMS is unclear, although it is presumed to counter the hyperventilation-induced respiratory alkalosis that results from exposure to the hypoxia of high altitude. Acetazolamide is contraindicated in patients with sickle cell anemia, sulfonamide allergy, or diabetes.

Osmotic diuretics

Osmotic diuretics act primarily at the loop of Henle. Examples of osmotic diuretics include mannitol, glycerin, and, occasionally, glucose. Mannitol and glycerin are freely filtered into the tubular fluid but are inert, and are not reabsorbed from the filtrate. In the proximal tubule, Na^+ is reabsorbed, resulting in an increase of filtrate osmolality due to the increasing concentration of mannitol. The increased oncotic pressure opposes water reabsorption from the filtrate and results in increased excretion of water as well as Na^+ . Osmotic diuretics also increase the serum osmolarity following their administration, which results in net water extraction from the extravascular to the intravascular compartment. This effect is commonly observed when osmotic diuretics are administered to decrease intracranial volume/pressure. Although the increase in intravascular volume is transient, it may cause congestive cardiac failure in a minority of patients. Mannitol is the most rapidly acting and commonly used osmotic diuretic. There is some evidence that mannitol may have some renal protective activity (increases renal vasodilation), although the evidence is mixed. Glucose is also freely filtered, but it undergoes significant reabsorption by proximal tubular sodium-glucose transport proteins. Excess glucose due to severe hyperglycemia (above the capacity of proximal tubular reabsorption) also may result in an osmotic diuresis (dehydration in diabetics).

Loop diuretics

Loop diuretics act by blocking the Type 2 Na-K-Cl cotransporter (NKCC2) in the thick ascending limb of the loop of Henle. Inhibition of this cotransporter decreases reabsorption and results in increased luminal Na^+ and Cl^- . Additionally, the active Na^+ uptake in the TAL is responsible for establishing and maintaining the medullary osmolarity gradient critical for filtrate concentration. By these effects, loop diuretics decrease maximal urine concentration. This class of diuretics is the most potent and causes excretion of up to 20% of the filtered Na^+ . The loop of Henle is also the primary site for reabsorption of Ca^{++} and Mg^{++} , whose reabsorption is inhibited by excess luminal

Figure 43.1. Sites of diuretic action along the nephron.

Na^+ . Therefore, Ca^{++} (as in the treatment of hypercalcemia) and Mg^{++} are excreted along with Na^+ , K^+ , and water.

Because of their potency, loop diuretics may cause significant electrolyte loss, consequently hypokalemia and other electrolyte deficiencies are common with their use. Loop diuretics are often used in neurosurgical settings as a means to lower intracranial pressure. Used together with mannitol, their effect in lowering intracranial volume is synergistic. The likely mechanism for this may be their diuretic effect, but some component also may result from their vasodilatory effect, particularly in the splanchnic circulation. Dilutional hyponatremia (or syndrome of inappropriate antidiuretic hormone hypersecretion [SIADH]) can be corrected with furosemide, as excess water excretion increases the sodium plasma concentration. A small dose of furosemide may be given intravenously to differentiate prerenal from renal failure, as in the former it will lead to an increase in urine output.

Furosemide, bumetanide, and ethacrynic acid are commonly used loop diuretics. Dosages may need to be increased in the presence of reduced renal blood flow so that these agents can reach their target site. Adverse effects of loop diuretics include electrolyte loss, hyperuricemia (gout), dyslipidemia,

dehydration and metabolic alkalosis, postural hypotension, syncope, and ototoxicity (tinnitus, vertigo, or deafness).

Ascending limb and distal convoluted tubule diuretics

The thiazide and thiazide-like diuretics act at the cortical TAL and distal convoluted tubule (DCT) to inhibit Na^+ and Cl^- transport. Only 5% to 7% of sodium is normally reabsorbed here, so inhibition in this region provides a less overall diuretic effect. Additionally, if the glomerular filtration rate (GFR) is already diminished (e.g., in renal insufficiency), less fluid will reach the distal tubule, so inhibition may have minimal effect. Diuretics such as the loop diuretics, which act more proximally in the tubule, can result in a compensatory increase of reabsorption in the distal tubule. Thiazide diuretics can block this compensatory response and therefore can be coupled with loop diuretics to provide potent diuresis. In the United States, thiazides are recommended as a first-line treatment for hypertension. They reduce the plasma volume (diuresis), decrease cardiac output, and cause peripheral vasodilation. Thiazide diuretics also inhibit the enzyme carbonic anhydrase to some

extent. Adverse effects include dehydration and metabolic alkalosis, hypokalemia, hypocalcemia, hyperuricemia (gout), hyperlipidemia, impaired glucose tolerance (diabetes), and impotence.

Metolazone, a thiazide-like diuretic, is the diuretic usually selected for combination therapy with loop diuretics. It is a quinazoline diuretic with the same mechanism of action, but much greater affinity for the DCT Na^+ channel. Metolazone is generally the only DCT diuretic effective in severe renal insufficiency. In addition, metolazone also has an antihypertensive effect, the exact mechanism of which is not clear.

Collecting duct diuretics

Diuretics that act at the collecting duct generally are called *potassium-sparing diuretics*, because they tend to avoid the potassium wasting that characterizes the loop and thiazide diuretics. These agents include the aldosterone antagonist spironolactone and the distal tubule Na^+ channel antagonists amiloride and triamterene. Blockade of these pathways results in decreased Na^+ uptake in exchange for K^+ and H^+ . These are generally weak diuretic agents, because more than 90% of the filtered load is reabsorbed prior to the distal tubule and only a small amount of Na^+ is reabsorbed in the terminal distal tubule and collecting duct.

Spironolactone competes with aldosterone for its receptors. It is commonly used orally to treat ascites and heart failure and has an antiandrogen effect that may result in gynecomastia and menstrual irregularities. Some studies have shown that its potassium-sparing effect can delay the development of Alzheimer's disease. In contrast to spironolactone, amiloride and triamterene are noncompetitive inhibitors of aldosterone. They inhibit Na^+ reabsorption and K^+ secretion by closing sodium channels. With all three drugs, hyperkalemia and metabolic acidosis may result in patients with renal insufficiency or in those on angiotensin-converting enzyme inhibitors.

Another diuretic that acts at the collecting duct (in addition to other locations) is atrial natriuretic peptide (ANP). ANP is released from atrial myocardial cells in response to increased intravascular volume. It is a direct vasodilator that also binds to receptors in the medullary collecting duct and increases intracellular cyclic guanosine monophosphate cGMP, which in turn

decreases Na^+ channel activity. There is some evidence that ANP may also bind to receptors in the proximal convoluted tubule and inhibit Na^+ reabsorption. The net result is decreased Na^+ reabsorption and increased solute excretion accompanied by water excretion, with little effect on K^+ excretion. ANP also inhibits renin secretion and increases GFR by decreasing afferent and increasing efferent glomerular constriction. ANP appears to be a relatively weak diuretic, able to achieve only moderate diuresis. Its activity is inhibited by lowered arterial pressure or increased afferent arteriolar constriction. Brain natriuretic peptide is a similar molecule released from brain and myocardial tissue. Its levels (normally less than 20% of the natriuretic peptide fraction) are significantly increased in congestive heart failure and can be useful in differentiating between edema due to heart failure versus other etiologies. ANP levels are not significantly altered under anesthesia.

Drug interactions

Martha Cordoba-Amorocho and Jie Zhou

Anesthesiology involves the administration of multiple drugs. The goal of combining medications is to produce the best therapeutic effects with the fewest adverse effects. Anesthesiologists also care for patients with multiple underlying conditions for which they are taking medications, sometimes as part of complex therapeutic regimens. Drug combinations are a useful and unavoidable part of anesthetic practice; however, they may be a source of significant morbidity.

Drug interactions result when the effect of one drug is altered by the concurrent administration of another. To minimize unexpected or dangerous effects, it is important to know the way drugs interact with each other. The mechanisms of drug interactions may be one of three types: *pharmaceutical*, *pharmacokinetic*, or *pharmacodynamic*.

Pharmaceutical interactions

A pharmaceutical interaction is a chemical or physical interaction between drugs that occurs before they are administered or absorbed systemically. Some examples of pharmaceutical interactions include the following:

- The precipitate that forms when thiopental (a weak acid) mixes with succinylcholine (a weak base), either in a syringe or within intravenous tubing
- The precipitate that forms when thiopental mixes with vecuronium
- The precipitation of bupivacaine when bicarbonate is added
- The inactivation of catecholamine solutions (e.g., norepinephrine, epinephrine) when alkalized by sodium bicarbonate; this situation may occur during resuscitation of a patient
- The interaction of desflurane with dry soda lime or Baralyme[®] to produce carbon monoxide; this situation may occur when oxygen is left flowing through the absorber canister overnight

Pharmacokinetic interactions

Pharmacokinetic interactions are a much more common source of adverse effects in anesthesia. A pharmacokinetic interaction occurs when one drug alters the absorption, distribution, metabolism, or elimination of another.

Absorption

An alteration in absorption may occur because of the direct chemical interaction between drugs in the body or because one drug affects the physiology of the absorption of another drug. Examples of drug-induced alterations in the absorption of another drug include:

- The chelation by tetracycline of the polyvalent cations (calcium, magnesium, or aluminum) contained in antacids
- The delay in gastric emptying produced by opioids and anticholinergics, thereby reducing the absorption of orally administered medications because the primary site for the absorption of most medications is the small intestine
- The increase in the speed of gastric emptying produced by metoclopramide that may increase the rate of diazepam absorption
- The decrease in the rate of absorption, and the increase in the duration of action, of local anesthetics produced by epinephrine
- The rapid uptake of nitrous oxide that may increase the alveolar concentration of a second volatile anesthetic (the “second gas effect”)
- The administration of medications that increase the gastric pH (e.g., antacids, histamine H₂ antagonists, proton pump inhibitors) that may reduce the absorption of medications that are weak acids (e.g., aspirin)

Distribution

An alteration in distribution may occur because of a variation in hemodynamics, drug ionization/lipid solubility, or plasma protein binding. Some examples of drug-induced alterations in the distribution of another drug include:

- The decrease in cardiac output caused by intravenous and volatile anesthetics that increases the concentration and the effects of other drugs in the cardiovascular system and central nervous system (CNS).
- The decrease in cardiac output that also increases the end-tidal concentration of volatile anesthetics.
- The diffusion of some medications (e.g., fentanyl, meperidine) back into the stomach from the bloodstream. The medications then become ionized and trapped in the

gastric acid and are reabsorbed when the environment becomes alkaline in the small bowel. This process may produce a secondary increase in their blood concentrations.

- The occurrence of hypoproteinemia in cases of hepatic cirrhosis or nephrotic syndrome that decreases the amount of drug bound to circulating proteins. Conversely, surgery, burns, myocardial infarction, trauma, and malignancies increase α_1 -acid glycoprotein. Many drugs that are weak bases (e.g., bupivacaine, lidocaine, and meperidine) bind to α_1 -acid glycoprotein.
- The displacement of highly protein bound drugs (e.g., warfarin, phenytoin) by other drugs (e.g., a cyclooxygenase [COX] inhibitor).

Metabolism

Drugs are eliminated from the body by several processes. Many drugs increase or decrease the metabolism of others by the liver or other organs. Some examples of drug-induced alterations in the metabolism of another drug include:

- The inhibition of plasma butyrylcholinesterase (also known as pseudocholinesterase) by inhibitors of acetylcholinesterase (e.g., neostigmine, edrophonium, pyridostigmine) that may prolong the effect of succinylcholine.
- The inhibition of plasma butyrylcholinesterase that may also increase the toxicity of ester local anesthetics by decreasing their rate of metabolism in the circulation.
- The potentiation of indirect-acting sympathomimetics (e.g., ephedrine, amphetamine) by monoamine oxidase inhibitors (MAOIs; e.g., phenelzine, tranylcypromine, isocarboxazid, selegiline). MAOIs increase the amount of presynaptic transmitter available to be released. A typical clinical dose of ephedrine may then produce a severe hypertensive crisis.
- The production of serotonin syndrome (excitation, hyperpyrexia, hypertension, profuse sweating, rigidity) by the interaction of an MAOI and a medication that has serotonin reuptake-inhibiting activity (e.g., meperidine, methadone, dextromethorphan).

Many anesthetic drugs undergo oxidative metabolism by one of the isoforms of cytochrome P450 (CYP). A wide range of chemical compounds may interact with CYP, resulting in either an increase or decrease in activity.

Based on the fraction of a drug metabolized in a single pass through the liver, drugs may be classified as “high extraction” or “low extraction.” The metabolism of high-extraction drugs (e.g., morphine, fentanyl, sufentanil, lidocaine) is decreased by drugs or maneuvers that decrease cardiac output and/or hepatic blood flow (e.g., β -blockade, vasoconstrictors, halothane, hypotension, upper abdominal surgery). The metabolism of low-extraction drugs (e.g., alfentanil, diazepam) is affected by medications that induce or inhibit drug metabolism.

Some examples of inducers of CYP are phenobarbital, phenytoin, rifampin, carbamazepine, ethanol, and the polycyclic aromatic hydrocarbons present in cigarette smoke and charred meat. In contrast, some examples of drugs that inhibit CYP are cimetidine, antifungal agents (e.g., fluconazole, ketoconazole, itraconazole), macrolide antibiotics (e.g., erythromycin, clarithromycin, but not azithromycin), antiretroviral protease inhibitors (e.g., ritonavir, indinavir), verapamil, and grapefruit juice.

The list of potential drug interactions due to the induction or inhibition of CYP is enormous. An excellent and frequently updated list of clinically relevant drug interactions as a result of these mechanisms may be found at <http://www.drug-interactions.com>.

Elimination

Alteration in drug elimination may involve changes in renal clearance or in pulmonary excretion. For certain cellular barriers, such as in the stomach, placenta, or renal tubules, the pH on either side of the barrier is very different. Many drugs are weak acids or bases that are partially ionized at physiologic pH. Because it is only the un-ionized fraction that diffuses across such barriers, small alterations in pH may have a large effect on the degree of ionization and therefore the rate of transport as a result of diffusion. For example, an increase in urinary pH may cause phenobarbital or aspirin to become trapped in the urine because its rate of tubular reabsorption decreases.

Organic anions and cations are actively secreted by different transporters in the renal tubules. Various anions or cations may compete for their respective transporter systems. Examples of drugs eliminated by the anion system are aspirin, β -lactam antibiotics (penicillins, cephalosporins), and many diuretics. Probenecid is an inhibitor of the anion transporter and may decrease the rate of elimination of drugs dependent on that transporter for their elimination. The cation system transports atropine, isoproterenol, neostigmine, and meperidine.

Pharmacodynamic interactions

A pharmacodynamic interaction occurs when one drug alters the sensitivity of a target receptor or tissue to the effect of another drug. These interactions can be classified as *additive*, *antagonistic*, or *synergistic*.

Additive interactions occur when drugs with the same mechanism of action are administered concurrently. Examples of such additive interactions include:

- Rocuronium and vecuronium, two aminosteroid nondepolarizing muscle relaxants
- Two volatile anesthetics, or nitrous oxide with a volatile anesthetic
- The additive CNS toxicity produced by lidocaine and tetracaine

Table 44.1. Claimed effects and potential toxic effects of herbal preparations

Name	Common use	Potential toxicity
Ephedra	Energy building, weight loss, antitussive, bacteriostatic	Hypertension, tachycardia, dysrhythmias; stroke, seizure. Effects potentiated by agents with MAOI activity
Echinacea	Respiratory and urinary infections, promote wound and burn healing	Hepatotoxicity Decreased glucocorticoid effects Macrophage and natural killer cell activation
Garlic	Hyperlipidemia, hypertension, antiplatelet, antioxidant, and antibiotic effects	Increased risk of perioperative bleeding, potentiation of anticoagulant effects; risk of interactions with cardiovascular medications, MAOIs, hypoglycemics
Ginger	Antinausea, antispasmodic; respiratory ailments; motion sickness	Increased risk of perioperative bleeding, potentiation of anticoagulant effects; hyperglycemia
Ginkgo	Circulatory stimulant; dementia, Alzheimer's disease; asthma, angina	Increased risk of perioperative bleeding, potentiation of anticoagulant effects; neurotoxicity, decreased seizure threshold, decreased efficacy of anticonvulsants; interaction with MAOIs
Ginseng	Energy building	Elevates digoxin concentration by 75%; interaction with MAOIs
Goldenseal	Diuretic, antiinflammatory, laxative, hemostatic	Oxytocic, paralysis, edema, hypertension
Kava	Anxiolytic	Hepatotoxicity; potentiates barbiturate and benzodiazepine effects
Licorice	Peptic ulcer disease, respiratory infections	Hypertension, hypokalemia, edema; reduction in ADH, aldosterone and plasma renin activity
St. John's wort	Depression, anxiety, insomnia	Decreased digoxin concentrations; prolonged general anesthesia, sedation; induction of CYP and P-glycoprotein (i.e., numerous drug interactions)
Valerian	Sedative, anxiolytic	Potentiates barbiturate and benzodiazepine effects
Vitamin E	Antiangiing; prevention of stroke, blood clots, and atherosclerosis; promotes wound healing	Increased risk of perioperative bleeding, potentiation of anticoagulant effects

ADH, antidiuretic hormone.

There are multiple mechanisms that produce antagonistic drug reactions. Examples of antagonistic drug interactions include:

- Two medications with opposite physiologic effects administered concurrently (e.g., phenylephrine and nitroglycerin)
- A partial agonist or a competitive antagonist given concurrently with a full agonist that decreases the effect of the full agonist (e.g., the partial μ -opioid agonist buprenorphine concurrently with the full agonist fentanyl)
- A medication that increases agonist concentration overcoming the action of a competitive antagonist (e.g., using neostigmine to reverse the effect of vecuronium)

Synergistic drug interactions are very important clinically when small doses of two or more drugs produce greater than additive effects. Some examples of synergistic drug interactions include:

- The concurrent administration of an aminosteroid and a benzylisoquinoline muscle relaxant (e.g., vecuronium and cisatracurium)
- The potentiation of opioid analgesia by COX inhibitors (e.g., morphine and celecoxib)
- The potentiation of nondepolarizing muscle relaxants by volatile anesthetics (e.g., vecuronium and isoflurane)
- The potentiation of nondepolarizing muscle relaxants by aminoglycoside antibiotics (e.g., vecuronium and gentamicin)

- The potentiation of the ventilatory depressant effect when an opioid is administered concurrently with a benzodiazepine (e.g., fentanyl and midazolam)
- The decrease in the minimum alveolar concentration of a volatile anesthetic when an opioid is administered concurrently (e.g., isoflurane and fentanyl)
- The decrease in the required dose of a hypnotic when an opioid or a benzodiazepine is given preoperatively (e.g., propofol and fentanyl)
- The potentiation of the effects of an opioid or a benzodiazepine by a centrally acting α_2 -adrenoceptor agonist (e.g., fentanyl and dexmedetomidine)

Cardiovascular medications and drug interactions

Some patients are particularly prone to experiencing drug interactions. Patients who are chronically ill and/or elderly are at high risk because of the number of medications they consume. The severity of the underlying disease state(s) may also place these patients at higher risk.

Most cardiovascular medications should not be discontinued prior to surgery, so it becomes important to predict how they will interact with the medications administered during anesthesia. Fortunately, most of the interactions with cardiovascular medications are simply extensions of the known pharmacologic effect of these agents:

- α -Adrenoceptor antagonists: hypotension, vasodilation, reflex tachycardia

- β -Adrenoceptor antagonists: hypotension, decreased contractility, bradycardia, atrioventricular (AV) block
- Calcium channel antagonists: hypotension, vasodilation; with verapamil only: decreased contractility, bradycardia, AV block
- Vasodilators: hypotension, vasodilation, reflex tachycardia
- Angiotensin-converting enzyme inhibitors and angiotensin antagonists: hypotension, vasodilation, hyperkalemia
- Diuretics: hypovolemia, hypokalemia, vasodilation

Herbal preparations and drug interactions

An increasing number of patients are taking herbal preparations, vitamins, or other over-the-counter preparations in addition to their medications. Although these preparations may have some benefits, adverse effects are often associated with their use. Unfortunately, some patients may not report the use of these alternative medications. During the preoperative assessment, anesthesiologists should specifically ask patients about their use of these agents.

Herbal preparations are classified as dietary supplements and are exempt from the safety and efficacy requirements that prescription and over-the-counter medications must fulfill. Different brands or even batches of the same herbal preparation may not contain the same amount of the active compound, or any active compound at all. Some of the claimed efficacious effects and potential toxic effects of herbal preparations are listed in Table 44.1. Herbal medications with the greatest impact on hemostasis are garlic, ginkgo, and ginseng. However, presently, mandatory discontinuation of the herbals is not recommended before surgery or anesthesia.

Anesthesiologists should also be aware of medications with narrow therapeutic indices. Such medications are risky in overdose, and drug interactions that increase their concentrations or effects are particularly hazardous. Table 44.2 lists some commonly used medications with a narrow therapeutic index. Additional topics related to alternative medicine and anesthesia are covered in Chapter 177.

Allergic reactions

Karan Madan and David L. Hepner

An allergic or hypersensitivity reaction is an immunologic response to stimulation by an antigen. Anesthesiologists frequently encounter allergic reactions while managing patients in the perioperative period. Patients are exposed to multiple medications, including antibiotics, anesthetic agents, sedatives and hypnotics, neuromuscular blocking (NMB) agents, polymers such as protamine, blood products, and environmental agents such as latex. All of the aforementioned agents can cause mild to severe (anaphylactic) allergic reactions. The incidence of life-threatening reactions has been reported to be approximately one in 3500 to 13,000 anesthetics. Although anaphylaxis is a rare intraoperative event, most drugs used during the perioperative period have been associated with severe allergic reactions. Muscle relaxants and latex are the most common agents that may lead to anaphylaxis, and prevention is the most important component to decrease the incidence of anaphylaxis.

Pathophysiology

When an individual is exposed to an allergen for the first time, sensitization takes place. This process involves a fixation of IgE to human mast cells and basophils, preparing these cells for activation on reexposure to the allergen. IgE-mediated activation of human mast cells leads to the solubilization and swelling of the secretory granules, as well as fusion of multiple granules and their membranes with the plasmalemma. This initiates a signal transduction cascade that culminates in the increase of intracellular calcium and the release of preformed mediators such as histamine, proteases (tryptases), proteoglycans, and platelet-activating factor.

Phospholipid metabolism, the main component of the lipid mediator pathway, then leads to the generation of potent inflammatory leukotrienes (LTC_4 , LTD_4 , LTE_4 , and LTB_4) and prostaglandins (PGD_2) (Fig. 45.1). Histamine, PGD_2 , and LTC_4 are potent vasoactive mediators implicated in vascular permeability changes, flushing, urticaria, angioedema, hypotension, and bronchoconstriction. Leukotriene B_4 mediates leukocyte-endothelial cell adhesion and chemotaxis. In addition, there is generation and release of cytokines involved in the perpetuation of the reaction, including tumor necrosis factor- α (TNF- α), interleukin (IL)-4, IL-5, IL-6, IL-13, and granulocyte macrophage colony-stimulating factor (GM-CSF).

The immunologic pathways, as a result of mast cell activation, are summarized in Fig. 45.2. Mediator release leads to several responses, including adherence and chemotactic leukocyte responses, proliferation of fibroblast and collagen production, activation of the coagulation cascade, and changes in venous and capillary permeability, including constriction and dilatation.

Types of hypersensitivity reactions

Immune-mediated allergic reactions are classified according to their mechanism (Table 45.1). Whereas anaphylaxis is a type I IgE-mediated hypersensitivity reaction involving mast cells and basophils, contact dermatitis is a type IV T-lymphocyte cell-mediated delayed-type hypersensitivity reaction. Other immune-mediated reactions include type II reactions, in which IgG, IgM, and complement mediate cytotoxicity, and type III reactions, in which immune complex formation and deposition lead to tissue damage. Anaphylactoid reactions (i.e., non-allergic anaphylaxis) occur through a direct non-immune-mediated release of mediators from mast cells or basophils or as a result of direct complement activation. However, they present with clinical symptoms similar to those of anaphylaxis.

Figure 45.1. Lipid mediator generation. PG, prostaglandin; TX, thromboxane; LT, leukotriene; HPETE, hydroperoxyeicosatetraenoic acid.

Figure 45.2. Mast cell activation and responses.

Clinical presentation

The onset of anaphylaxis may be delayed by a few minutes to 2 to 3 hours, depending on the route of exposure. After parenteral administration, the onset of anaphylaxis is usually immediate. Dermatologic manifestations include urticaria, itching over the skin and eyes, rash, warmth, and swelling of the face. Conscious patients may complain of dizziness, chest tightness, difficulty breathing, and coughing. In addition, wheezing, tachypnea, laryngeal stridor, and cyanosis may be observed, with the potential to progress to glottic, epiglottic, and pharyngeal edema accompanied by acute respiratory distress. In an anesthetized patient, the first sign of an anaphylactic reaction may be respiratory (bronchospasm) or cardiovascular collapse (sudden massive hypotension). This is the result of the end-organ response to vasoactive mediators leading to bronchospasm, laryngeal edema, reduced effective intravascular volume, and decreased systemic vascular resistance, resulting in shock.

In the latest epidemiologic survey of anaphylactic and anaphylactoid reactions occurring during anesthesia in France and published in the English literature (January 1999–December 2000), anaphylactic reactions were diagnosed in 518 cases (66%), whereas 271 cases (34%) were attributed to anaphylactoid reactions. The most common causes of anaphylaxis were NMB agents (59%), latex (17%), and antibiotics (15%). Anaphylactic reactions to colloids (4%), hypnotics (3%), opioids (1%), and other agents (1%) also were reported. These incidences are illustrated in Fig. 45.3.

Table 45.1. Types of hypersensitivity reactions (Gell and Coombs classification)

Type	Description
I (immediate)	Atopy, urticaria, anaphylaxis
II (cytotoxic)	Autoimmune hemolytic anemia, heparin-induced thrombocytopenia, hemolytic transfusion reactions
III (immune complex mediated)	Serum sickness, Arthus reaction, acute hypersensitivity pneumonitis
IV (delayed cell mediated)	Contact dermatitis, tuberculin-type hypersensitivity, chronic hypersensitivity pneumonitis

Muscle relaxants

Muscle relaxants are the most common agents responsible for intraoperative anaphylaxis. Because environmental contact with cosmetics and disinfectants may lead to sensitization to NMB, anaphylactic reactions to NMB may occur without previous exposure. Females are more likely than males to develop an allergic reaction to NMB agents. Rocuronium (43%) and succinylcholine (23%) were the most frequently incriminated NMB agents. Cross-reactivity between NMB agents was observed in 75% of cases of anaphylaxis; antibodies to NMB agents seem to persist for years. Therefore, cross-reactivity with other NMB agents should be assessed through skin tests in order to propose a safe alternative for further procedures when anaphylaxis to a definite NMB agent has been documented. Rocuronium and vecuronium account for 80% of the sales of nondepolarizing muscle relaxants in the United States. An analysis done in 2005 revealed that in the United States, there was no difference in the incidence of anaphylaxis between the two drugs. However, reports from abroad have found a higher incidence of anaphylaxis with rocuronium.

Figure 45.3. Incidence of allergic reactions by agent.

Latex allergy

Allergy to latex was first recognized in 1979 as a result of the use of “universal precautions” promoted by the Centers for Disease Control and Prevention to decrease the spread of HIV and hepatitis B and C viruses. This effort resulted in a 25-fold increase in the use of latex-containing surgical gloves, causing it to emerge as the second most common cause of anaphylaxis in surgical suites (17% of cases) over the following two decades. Health care workers, who come in contact with latex in the form of gloves or other latex-containing medical equipment, may become sensitized to latex. Other high-risk groups include non-health care workers with occupational exposure to latex, patients with an atopic background, and children with spina bifida or genitourinary abnormalities who have undergone multiple surgeries. In addition, some fruits, such as bananas, avocados, and kiwis, contain proteins that cross-react with latex.

Latex-mediated reactions include irritant contact dermatitis (most common reaction), allergic contact dermatitis (type IV), and type I IgE-mediated hypersensitivity reactions (anaphylaxis). Whereas *latex sensitization* is the presence of IgE antibodies to latex without clinical manifestations, *latex allergy* refers to any immune-mediated reaction associated with clinical symptoms that may include urticaria, rhinitis, and conjunctivitis. Latex-specific IgE can be detected in the patient’s serum by radioallergosorbent test (RAST) or enzyme allergosorbent test. No standardized antigens for skin testing are commercially available in the United States. Most health care facilities have institutional guidelines for precautions used during management of patients with known latex allergy that must include the use of non-latex-containing gloves and other medical equipment, particularly in patients with IgE-mediated hypersensitivity reactions. There are no data that support the use of pharmacologic prophylaxis (i.e., histamine H₁ and/or H₂ antagonists and/or steroids) prior to a surgical procedure.

Antibiotics

Prevention of postoperative surgical infections has increased preoperative antibiotic use. In the general population, antibiotics, particularly the β -lactams, are the most common drugs causing anaphylaxis, accounting for about 75% of anaphylaxis-related deaths in the United States. Antibiotics that share the β -lactam ring include penicillins, cephalosporins, carbapenems, and monobactams. Although cross-reactivity between cephalosporins and penicillins has been reported, with an incidence between 8% and 10%, recent data suggest the actual incidence is lower. Taking a detailed history of the reaction to penicillin will remove most of the questionable cases of penicillin allergy, which usually are related to nonimmunologic adverse effects. In addition, most of the reported reactions of cross-sensitivity between cephalosporins and penicillins consist of rashes that are not immunologic in origin. Furthermore, earlier generations of cephalosporins contained trace amounts of penicillin; therefore, patients with an allergy to penicillin were more likely to experience an anaphylactic

reaction. It is also important to understand that patients who have a definite allergic reaction to a specific antibiotic are more likely to develop anaphylaxis upon exposure to any other antibiotic. More recently, side chain structure attached to the beta-lactam ring has been identified as an important component in determining the allergenicity of the molecule. Because first-generation cephalosporins and cefamandole share a similar side chain with penicillin and amoxicillin, a higher incidence of allergic reactions to first generation cephalosporins and cefamandole is likely to occur in those with a history of penicillin allergy. In contrast, second- and third-generation cephalosporins have different side chains from penicillin and amoxicillin and are unlikely to cross-react with penicillin. There is an increasing trend toward using cephalosporins in patients without a convincing history of penicillin allergy.

It is important to distinguish between a chemically mediated response that may be prevented upon further exposure, such as red man syndrome due to a too-rapid administration of vancomycin, and a true allergic or anaphylactic reaction. Allergic reactions to antibiotics may present as urticaria, pruritus, erythema, angioedema, rhinitis, bronchospasm, hypotension, cardiac arrhythmias, or full-blown anaphylaxis.

Colloids

Albumin, dextran, hetastarch, and gelatin are colloids commonly used in the operating room. Gelatin is the colloid most likely to cause an allergic reaction (although gelatin-based intravenous fluids are not available in the United States). Gelatins and dextrans are more likely than albumin or hetastarch to cause an allergic reaction, with the latter being the colloid least likely to cause an allergic reaction. IgE-mediated anaphylaxis has been proven by demonstrating IgE antibodies and positive intradermal tests against gelatins. Increased circulating IgG dextran-reactive antibodies are found in most adults with dextran anaphylaxis. Enzyme-linked immunosorbent assay (ELISA) is used for detecting hetastarch- and dextran-reactive antibodies (IgG and IgM) in human sera. Although there is no known cross-reactivity among the different groups of colloids, those that belong to the same group, such as Haemaccel (Piramal, Mumbai, India) and Gelofusine (B. Braun, Bella Vista, NSW, Australia), which are both gelatins, have been shown to have cross-reactivity.

Individuals with prior drug allergies are more likely to develop anaphylaxis, with males more likely than females to develop an allergic reaction. Egg allergy does not appear to be a contraindication to the use of albumin, because the principal egg protein, ovalbumin (45 kDa), is different from human serum albumin (67 kDa).

Hypnotics

Cases of propofol-induced bronchoconstriction and allergy have been reported. Although large doses of propofol inhibit histamine-induced contraction in isolated human airway smooth muscle, some reports have suggested that propofol may

cause histamine release in healthy and atopic patients and may induce bronchospasm. Propofol is currently formulated in a lipid emulsion vehicle containing 10% soybean oil, 1.2% egg lecithin, and 2.25% glycerol. True allergic reactions to propofol likely are secondary to the two isopropyl groups. Most cases of drug allergy to propofol are IgE mediated, and specific IgE-RIA and intradermal skin tests have been reported. The egg lecithin component of the lipid vehicle is highly purified egg yolk. Ovalbumin, the principal protein of eggs, is present in the egg white. Current evidence suggests that patients allergic to eggs likely will not develop anaphylaxis when exposed to propofol.

An anaphylactoid reaction to thiopental is seen in one in 30,000 anesthetics. Although some of these reactions may be a result of the release of histamine, others are true IgE-mediated anaphylactic reactions.

Opioids

The incidence of allergic reactions to opioids is one in every 100,000 to 200,000 anesthetics. Some opioids (e.g., morphine, meperidine) cause the direct release of histamine, leading to dermatologic manifestations such as urticaria, itching, and vasodilation. Large doses of morphine used during cardiac anesthesia did not show any increased incidence of bronchospasm or angioedema. Anaphylactoid reactions to codeine and morphine have been reported; however, skin tests were negative when affected patients were tested.

Local anesthetics

Although allergy to local anesthetics is frequently reported by patients and there are case reports of such reactions, it is extremely rare to encounter a true IgE-mediated allergic reaction to local anesthetics, especially in the amide class. The most common immune-mediated reaction to local anesthetics is a delayed hypersensitivity (type IV) reaction or contact dermatitis. The metabolism of amide local anesthetics primarily is in the liver, whereas that of esters is via plasma cholinesterases. Para-aminobenzoic acid (PABA) is the main metabolite of ester local anesthetics implicated in causing allergic reactions. Preservatives such as methylparaben, propylparaben (both metabolized to PABA), and metabisulfite are often added to multiple-dose vials of local anesthetics. Many reactions attributed to local anesthetics are actually a result of reactions to PABA. It is also important to distinguish an allergic reaction from more common reactions due to anxiety or epinephrine, as are seen frequently preoperatively and in dentists' offices. Cross-reactivity exists among the ester local anesthetics and is unusual among amides. There is no cross-reactivity between amide and ester local anesthetics. Skin and antigen-challenge testing may be used to identify local anesthetics that are safe for a particular patient, but it should be done with preservative-free solutions.

Blood products

Urticarial reactions are seen in 0.5% of all transfusions with frozen plasma. Because there is a small amount of plasma in all

blood products, allergic reactions to plasma contained in units of red blood cells and platelets may occur as well. The reaction may present as itching, swelling, or a rash. These symptoms can be avoided by pretreating patients with previous severe urticarial reactions with diphenhydramine. In addition, it is recommended that such patients be transfused with saline-washed red cells. The prophylactic use of acetaminophen prior to transfusion is controversial, because it has potential toxicity and studies have not shown that it prevents transfusion reactions.

True anaphylactic reactions to blood products are infrequent, except in patients with IgA deficiency, who may have been previously sensitized by either a transfusion or a prior pregnancy.

Radiocontrast agents

Most reactions to nonionic contrast agents are minor events such as flushing or skin rashes and are not immune in origin. The incidence of anaphylactoid reactions is 1% to 2% during infusion of radiocontrast agents, and these reactions occur as a result of nonspecific histamine release. The incidence of repeat reactions on reexposure to radiocontrast material is 17% to 35%, and the severity of these reactions may be reduced by premedication with antihistamines and glucocorticoids. Premedication has not been proven to prevent these reactions.

Protamine

Protamine, a histone derived from salmon sperm, is used to reverse the effects of heparin. Exposed patients may develop an allergic reaction to protamine in 0.4% to 0.8% of cases, with the risk increased in patients previously exposed to protamine. Some forms of insulin, such as NPH and protamine zinc insulin, contain protamine; therefore, diabetic patients exposed to them may have an increased risk for a protamine reaction. Although antigenic crossover is possible in patients with fish allergies, and some vasectomized men have IgG antibodies to protamine, recent reports have failed to demonstrate an association between protamine allergy and vasectomy, infertility, or fish allergy.

Protamine reactions include IgE- and IgG-mediated hypersensitivity, complement activation, nonimmunologic histamine release, and augmentation of thromboxane, which may lead to urticaria, systemic hypotension, and an elevation in pulmonary artery pressure with pulmonary vasoconstriction. Although cutaneous testing will identify IgE-mediated sensitivity, protamine-specific IgE and IgG antibodies can be measured by solid-phase immunoassay, ELISA, and RAST.

Treatment of allergic reactions

The first step in treating an anaphylactic reaction (Table 45.2) consists of withdrawing the drug likely to be the cause of the reaction, interrupting the effects of the preformed mediators, and preventing more mediator release. An immediate assessment of airway, breathing, and circulation (ABC), in addition to early administration of epinephrine, is mandatory

Table 45.2. Treatment of anaphylaxis

Withdrawal of agent
 Assessment of airway, breathing, circulation
 Early administration of epinephrine
 Oxygen supplementation
 Intravenous fluids
 Histamine H₁ and H₂ antagonists, bronchodilators, hydrocortisone

to avoid airway compromise and cardiovascular collapse. Epinephrine, in doses of 5 to 10 µg IV (0.2 µg/kg), is used in the treatment of mild to moderate hypotension, and is titrated to effect. Doses of 0.1 to 0.5 mg IV are used in the presence of cardiovascular collapse. In addition, it is important to decrease or discontinue anesthetic agents likely to cause vasodilation, such as inhalational agents, as well as any medications with negative inotropic effects. Recently, the concept of anaphylactic shock refractory to epinephrine has been introduced. If incremental doses of epinephrine fail to restore the cardiovascular collapse associated with severe cases of anaphylaxis, norepinephrine, metaraminol, arginine vasopressin or glucagon for patients taking β-blockers should be utilized.

Other important steps in the treatment of anaphylaxis include airway support with 100% oxygen to compensate for the increased oxygen consumption, IV crystalloid replacement (2–4 L) to compensate for the peripheral vasodilatation, histamine H₁ antagonists (diphenhydramine, 0.5–1 mg/kg), histamine H₂ antagonists (ranitidine, 150 mg, or cimetidine 400 mg IV), bronchodilators (nebulized albuterol and/or ipratropium bromide), and glucocorticoids (hydrocortisone) to decrease airway swelling and prevent recurrence of symptoms.

There are no randomized controlled trials that address the treatment of anaphylaxis, and clinical treatment protocols for anaphylaxis are based on our understanding of its cellular mechanism, animal experiments, and clinical presentation. Immediate discontinuation of the offending agent and administration of epinephrine are the cornerstones of treating anaphylaxis.

Pharmacology of Local Anesthetics

Pradeep Dinakar and Gary R. Strichartz, editors

Mechanism of action and pharmacokinetics

Peter Gerner and Pradeep Dinakar

Overview

Local anesthesia is defined as the temporary or permanent loss of sensation in localized areas of the body by either chemical or physical modalities. The chemical modalities include the use of local anesthetic agents, which reversibly inhibit the generation and propagation of nerve impulses in excitable tissues, producing a transient loss of sensory, motor, and autonomic functions.

Chronology of discovery of local anesthetics

In 1860 Neimann isolated and described the chemical structure of cocaine. Koller introduced cocaine as the first local anesthetic clinically in 1884, but the development of dependence and addiction with prolonged use and local irritant properties paved the way for development of newer and related drugs that were less toxic and less addictive. Procaine was the first clinically relevant local anesthetic, introduced in 1905, which formed the prototype of the modern local anesthetics. Changes in the benzoic acid moiety resulted in chlorprocaine and tetracaine initially. This was followed by a change in the linkage from ester to amide, resulting in the introduction of lidocaine in 1948. Lidocaine was soon succeeded by the introduction of bupivacaine, levobupivacaine, mepivacaine, and ropivacaine. The chronology of introduction of local anesthetics into clinical practice and the intermediate chain type, which formed the basis of local anesthetic classification, is shown in [Table 46.1](#).

Chemical structure of local anesthetics

Local anesthetics have a lipophilic benzene ring, a hydrophilic tertiary amine separated by an ester or amide linked intermediate chain. The link which contains either the ester or amide linkages formed the basis of the local anesthetic classification into amino-ester-linked or amino-amide-linked local anesthetics ([Table 46.2](#)). The amino-amide local anesthetics were far superior to the early amino-ester local anesthetics in that chemically they were more stable in solution and at higher temperatures. Structural variations in the amino-ester linkage further classified the amino-ester local anesthetics into aminoacyl and aminoalkyl amides. The newer aminoacyl-amide local anesthetics also had the advantages of being longer acting among all anesthetics, associated with fewer allergic reactions compared

to the ester anesthetics, and exhibiting stereo selectivity, which reduced cardiac side effects.

Pharmacodynamics of local anesthetics

Type of nerve fibers affected

Axons differ in their size and structure. The larger the diameter of an axon, the faster is the speed of propagation of the action potential along that axon. A greater degree of myelination also yields faster transmission of electrical impulses by insulating the axon membrane and allowing the “action current” to move more efficiently to the subsequent, uninsulated regions called nodes of Ranvier. Thus, based on the fiber size and myelination, the nerve fibers are classified into type A, B, or C ([Fig. 46.1a](#)). This process by which depolarization travels rapidly from one uninsulated region to another along the axon is called *saltatory conduction* ([Fig. 46.1b](#)). Sensitivity to blockade is determined by axonal diameter, degree of myelination, and various other physiologic factors as described below ([Table 46.3](#)).

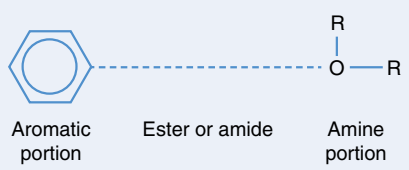

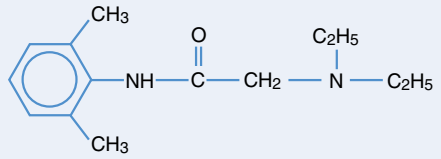

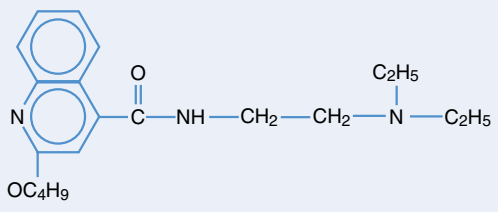

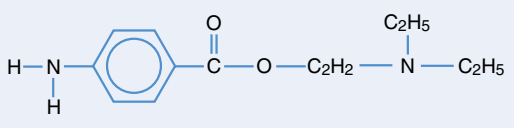

Role of sodium ion channel conformational states on blockade

The generation and propagation of impulses in nerve axons that carry afferent (sensory) and efferent (motor, sympathetic) information require the flow of specific ionic currents through channels in the plasma membrane. Many of these channels open and close depending on the electrical potential across the cell membrane. The major determinant of depolarization and

Table 46.1. Chronology of clinical use of local anesthetics

Anesthetic agent	Type of linkage	Year of introduction
Cocaine	Ester	1884

Myelination	+++	+++	++	+	–
Function	Motor, proprioception	Touch, pressure, proprioception	Pain, Temperature, Touch, Motor	Autonomic	Pain, Temperature, Touch

impulse propagation is the influx of sodium (Na^+) ions through specific voltage gated sodium channels located in the nerve axons. Local anesthetic agents reversibly bind to and block these sodium channels and reduce the sodium currents across the channels (see Fig. 46.2), thereby preventing the initiation and propagation of action potentials.

The sodium ion conformational state, which depends on the depolarization–repolarization cycle, could be in a resting, open, or inactivated state. The local anesthetics have a minimal effect on the resting states and have the greatest affinity to the open state followed by the inactivated state. Thus local anesthetics create a “state dependent block” by showing greatest affinity to the open Na^+ channels (Fig. 46.3).

Although local anesthetics may interfere with other channels (K^+ and Ca^{2+}), their interaction with sodium channels is clinically most relevant. Additional mechanisms of local anesthetic action include the nonspecific expansion of the neuronal lipid membrane to compress and thus affect the function of various ion channels and alteration of neuronal membrane surface charge. Also, local anesthetic drugs directly interact with specific neuronal membrane receptors (nicotinic acetylcholine-activated receptors, the substance P receptor, and many of the G protein–coupled receptors). These alternative actions may contribute to local anesthesia actions, particularly at synapses in the spinal cord and also play a role in local anesthetic toxicity.

Differential blockade

Local anesthetics differ in their ability to block autonomic, sensory, and motor action potentials on nerves in different parts of

Figure 46.2. Decrease in amplitude of Na^+ currents by local anesthetic drugs (bupivacaine).

the body. The reason for this differential blockade is unclear and many theories exist with some clinical correlation. Fiber size, which was thought to play a role in differential blockade, has not been shown to play a significant role in a clinical setting. C fibers (unmyelinated) are the most sensitive to the local anesthetic action and A fibers (myelinated) the least sensitive. This is the reason for analgesia seen prior to the loss of pressure and touch sensations. Other theories on efficacy of the local anesthetics relating to the anatomical arrangement and location of the nerve fibers, vasodilating properties of the individual local anesthetics, and differential effects on other ion channels have been proposed as some of the causes. Bupivacaine has the most favorable sensory-to-motor differential blockade and is widely used in obstetric analgesia and chronic pain procedures, where preservation of motor function is essential. If the local anesthetic concentration is increased to a sufficiently high level, all local anesthetics will cause complete blockage of all modalities.

Systemic actions of local anesthetic agents

Various chronic pain syndromes, including neuropathic pain syndromes and fibromyalgia, show a favorable response to the systemic administration of local anesthetics. Intravenous lidocaine infusion is an approved pain treatment modality in refractory pain conditions, and the mechanism of its systemic action is unclear. Presumed sites of action are the activated sodium channels on the central and peripheral nervous system, the dorsal root ganglia, and the sympathetic nervous system.

Pharmacokinetics of local anesthetics

Absorption of local anesthetics

Local anesthetics are rapidly absorbed from mucous membranes (conjunctiva), whereas absorption from intact skin requires time and increased dosage. Local anesthetics are frequently applied directly on or near their target via the injection techniques of regional anesthesia, where their pharmacodynamic effects are directly related to tissue concentrations in the immediate vicinity of injection. Plasma levels of local anesthetic rarely bear a relationship to their desired effects; however, plasma levels are directly related to systemic toxicity. Peak plasma levels of local anesthetic reach the highest concentrations after direct intravenous or intra-arterial injection and are lowest after subcutaneous injection (intravenous > tracheal >

Figure 46.3. Conformational change of Na⁺ ion channel from active to inactive and resting state. LA, local anesthetic.

intercostal > caudal > epidural > brachial plexus > sciatic > subcutaneous). Following injection, local anesthetics absorbed into the circulation are taken up first by the highly perfused organs (brain, heart, liver, kidney, lung), and then by less well-perfused tissues (muscle and fat).

Metabolism and clearance

Metabolism and clearance of amide-type local anesthetics (Table 46.4) depend on liver function (hydroxylation and *N*-dealkylation by microsomal cytochrome P-450) and may be limited in any disease state that reduces hepatic blood flow or liver function (e.g., liver disease, congestive heart failure). An increase of α_1 -acid glycoprotein and other plasma proteins (e.g., due to cancer, trauma, inflammatory disease) may lead to slower hepatic metabolism and slower clearance, as more drug is bound to proteins. However, dissociation rates from plasma proteins are relatively rapid compared with clearance rates and have only modest effects on overall biotransformation. Metabolites of prilocaine and benzocaine can cause methemoglobinemia.

Ester-type local anesthetics are hydrolyzed by plasma pseudocholinesterase enzymes to an alkylamine and para-aminobenzoic acid (PABA). Thus, patients with genetically abnormal pseudocholinesterase levels are at increased risk for toxic side effects. In addition, PABA may cause allergic reactions in some patients; allergy to ester-type local anesthetics is far more common than allergy to amide local anesthetics. Benzocaine, a local anesthetic commonly used to

produce topical anesthesia in the upper airway, exists only in the uncharged form. It passes rapidly through the skin and is rapidly hydrolyzed in plasma, leading to potentially high levels of PABA. To a limited degree, the liver also extracts and metabolizes ester-type compounds (especially cocaine). Termination of action of intrathecally administered ester-type local anesthetics (tetracaine) is by systemic absorption into the blood, as cerebrospinal fluid lacks the esterase enzymes. Renal disease has little effect on the pharmacokinetics of local anesthetics.

Role of pH

Local anesthetics are weak bases that pass through the phospholipid membrane into the cell when they are in their uncharged

Table 46.4. Pharmacokinetics of local anesthetics most often used clinically

Mepivacaine	7.7	5.5

^a Depends on temperature and ionic condition.

lipid-soluble form. However, once inside the cell, they are rapidly converted to the charged form, which more effectively blocks the sodium channel. The Henderson-Hasselbach equation relates the pH to the dissociation constant (pK_a) and the relative concentrations of uncharged base (B) and charged base (BH⁺). Given the reaction, B + H⁺ ↔ BH⁺, the pH determines the ratio of B and BH⁺.

$$\text{pH} = \text{pK}_a + \log_{10}[\text{B}]/[\text{BH}^+].$$

pK_a is the pH at which 50% of the local anesthetic is uncharged ([B] = [BH⁺]). As shown in Table 46.5, the pK_a values for commonly used local anesthetics lie within the range between about 8 and 9. For amide local anesthetics, the pK_a usually correlates with the speed of onset. In general, it is thought that drugs with a pK_a closer to the pH in the tissue surrounding the nerve (physiologic pH) have faster block onset, as there are more local anesthetic molecules available in the neutral (uncharged) form, which is largely responsible for traversing the membranes that ensheath the nerve.

Sodium bicarbonate is often added to increase the pH of these local anesthetic solutions, thus increasing the concentration of nonionized lipophilic free-base. This increases the rate of membrane permeation of the drug and its speed of onset. Clinically, the addition of 1 mEq of sodium bicarbonate to each 10 ml of commercially prepared 1.5% to 2% lidocaine solution (0.1 mEq to each 10 ml bupivacaine) produces a significantly faster onset of anesthesia and more rapid spread of sensory block. Excessive alkalinization, particularly of more

Table 46.6. Advantages of adding epinephrine to local anesthetic drugs

Has weak local anesthetic property of its own

LAD, local anesthetic drug.

concentrated local anesthetic solutions, will cause the local anesthetic to precipitate from solution.

Effect of lipid solubility

Lipid solubility is also an important factor in determining the speed of onset of action. Although higher lipid solubility would be expected to promote drug entry into membranes by increasing the diffusion rate, very high lipophilicity results in a dominant absorption of the drug into the membrane, with concomitantly slow dissociation and net transport across the membrane. Very lipid-soluble drugs, such as etidocaine, have both a slow onset of action and an extraordinarily long duration. Lipid solubility is directly proportional to potency of the drug, because of hydrophobic binding to the Na⁺ channel.

Role of additives

Commonly used additives to local anesthetic drugs include opioids and vasoconstrictors. Opioids such as fentanyl are added to supplement analgesia. Epinephrine (5 µg/ml, or 1:200,000) is the vasoconstrictor most commonly added to local anesthetic drugs. Advantages of adding epinephrine are listed in Table 46.6. Addition of epinephrine in patients with coronary artery disease and hypertension should be done with caution, as direct intravascular injection will produce tachycardia and hypertension. Epinephrine should not be added to local anesthetic drugs when peripheral nerve blocks are performed in tissues with inadequate collateral blood circulation (wrist, ankle, digits, penis) or when intravenous regional anesthesia is administered.

Clinical applications of local anesthetics

Pradeep Dinakar and Peter Gerner

Overview

The clinical application of local anesthetic agents depends on the type of local anesthetic, stereoselectivity, clinical potency, and the side effect profile. Local anesthetic potency is based on a multitude of factors including time of onset of action, duration of action, and type of regional anesthetic block.

Clinical characteristics of local anesthetics

Type of local anesthetics

Clinically used local anesthetics, as described in Chapter 46, may be classified as amino-amides (lidocaine, mepivacaine, prilocaine, bupivacaine, levobupivacaine, and ropivacaine), or amino-esters (procaine, chlorprocaine, tetracaine, and cocaine). This classification is based on the type of linkage, which is either an amide or an ester, that links the lipophilic benzene ring with the hydrophobic tertiary amine (see Table 46.2).

Amide and ester local anesthetics differ in their chemical stability, metabolism, and allergic potential. Amides are extremely stable, whereas esters are relatively unstable, particularly in neutral or alkaline solution. Amide compounds undergo enzymatic degradation in the liver, whereas the ester compounds are hydrolyzed in plasma by the pseudocholinesterase enzymes. Cocaine, an ester, is an exception, as it is metabolized predominantly by the liver. The metabolites of esters include para-aminobenzoic acid (PABA), which can occasionally induce allergic-type reactions. Allergies to amides are extremely rare.

Stereochemistry

Local anesthetics are available as individual enantiomers and racemic mixtures. An *enantiomer* is one of two stereoisomers of a given molecule that cannot be superimposed. Enantiomers differ only in their ability to rotate the plane of polarized light, and thus are named for the direction of that polarization, levorotatory (left) or dextrorotatory (right). A *racemic mixture* contains equal amounts of the two enantiomers. The two enantiomers can have significantly different chemical and physiologic properties that are of clinical importance.

Potency of local anesthetics

Local anesthetics differ in their potency based on onset of action, duration of action, lipid solubility, vasodilating property, and the type of regional block.

The uncharged form of a local anesthetic is more likely to cross the cell membrane than the charged (protonated) form, thus the proportion of the local anesthetic that is in the uncharged form will significantly impact the speed of onset of action. Local anesthetics (bases) are poorly soluble in water but can be dissolved in hydrophobic organic solvents. Therefore, most local anesthetics are commercially formulated as the more soluble hydrochloride salts, accounting for their low (acidic) pH (see Table 46.5). Hence, speed of onset of local anesthetics depends on their pKa and the pH of the anesthetic solution which influences the ratio of the unprotonated and protonated forms. Low pKa of an agent and high pH of the solvent are most favorable for rapid onset of action. Other favorable factors include high lipid solubility, low vasodilating property, and higher dose of local anesthetic (Table 47.1).

Table 47.1. Maximum recommended doses of local anesthetics^a

Drug	Onset ^b	Maximum dose for plain solution, mg/kg	Maximum dose with epinephrine, mg/kg ^c
Lidocaine	Rapid	5	7
Mepivacaine	Rapid	5	7
Chlorprocaine	Rapid	10	15
Prilocaine	Rapid	7 ^d	8 ^d
Ropivacaine	Slow	3	3
Bupivacaine	Slow	2.0	2.5
Levobupivacaine	Slow	2.5	3
Procaine	Slow	8	10

^a The maximal recommended dose of local anesthetics is influenced by various factors (see text) and should be adjusted for each injection site.

^b Onset times vary significantly with the injection site – for example, all the above commonly used local anesthetics have fast onset when used for infiltration anesthesia, but most are very slow topical anesthetics.

^c The maximal adult recommended dose of epinephrine is 250 µg per dose; for children, 3 µg/kg per dose.

^d The maximal recommended adult dose of prilocaine is 600 mg because of clinically significant methemoglobinemia.

Table 47.2. Tissue infiltration^a

Drug	Volume for 70-kg person, ml	Usual duration, min
Lidocaine 0.5%–1%, plain	70–35	30–60
Lidocaine 0.5%–1%, with epinephrine (1:200,000–1:400,000) ^b	100–50	60–120
Mepivacaine 0.5%–1%, plain	70–35	45–90
Mepivacaine 0.5%–1%, with epinephrine (1:200,000–1:400,000) ^b	100–50	120
Bupivacaine 0.25%–0.5%, plain	56–28	180
Bupivacaine 0.25%–0.5%, with epinephrine (1:200,000–1:400,000) ^b	70–35	180
Levobupivacaine 0.25%–0.5%	70–35	120
Levobupivacaine 0.25%–0.5%, with epinephrine (1:200,000–1:400,000) ^b	84–42	120
Ropivacaine 0.2%–0.5%	105–42	120

^a Do not exceed the maximum dosage listed in Table 47.1.

^b Caution: The maximal *adult* recommended dose of epinephrine is 250 µg per dose; for children, the maximum dose is 3 µg/kg per dose.

The duration of action varies for each local anesthetic agent. Bupivacaine, levobupivacaine, and ropivacaine have one of the longest durations of anesthesia. This is followed by lidocaine, mepivacaine, and prilocaine. Procaine and chlorprocaine have the shortest durations (Table 47.2).

The duration and onset of action are also affected by the type of regional block. Peripheral nerve/plexus blocks have a slow onset of action but last the longest given their relative tissue

Table 47.3. Minor nerve blocks^{a,b}

Drug	Volume, ml	Usual duration, min
Lidocaine 1%–2%, plain	5–10	60–120
Lidocaine 1%–2%, with epinephrine (1:200,000–1:400,000) ^c	5–10	120–180
Chlorprocaine 2%–3%, plain	5–10	15–30
Chlorprocaine 2%–3%, with epinephrine (1:200,000–1:400,000) ^c	5–10	30–60
Mepivacaine 1%–1.5%, plain	5–10	60–120
Mepivacaine 1%–1.5%, with epinephrine (1:200,000–1:400,000) ^c	5–10	120–360
Bupivacaine 0.25%–0.5%, plain	5–10	180–480
Bupivacaine 0.25%–0.5%, with epinephrine (1:200,000–1:400,000) ^c	5–10	240–960
Levobupivacaine 0.25%–0.5%	5–10	180–480
Levobupivacaine 0.25%–0.5%, with epinephrine (1:200,000–1:400,000) ^c	5–10	240–960
Ropivacaine 0.2%–0.5%	5–10	120–480

^a Single nerve, such as ulnar or radial, and blocks below the knee.

^b Of note, most minor nerve blocks are performed without the addition of epinephrine. Epinephrine is contraindicated in blocks of the digits or penis, as is plain cocaine, because tissue ischemia may result. Also, do not exceed maximum dosage listed when blocking several nerves simultaneously.

^c Caution: The maximal *adult* recommended dose of epinephrine is 250 µg per dose; for children, the maximum dose is 3 µg/kg per dose.

Table 47.4. Major nerve blocks^{a,b}

Drug	Volume, ml	Usual duration, min
Lidocaine 1%–2%, plain	50–30	60–180
Lidocaine 1%–2%, with epinephrine (1:200,000–1:400,000) ^c	50–30	120–240
Mepivacaine 1%–1.5%, plain	50–30	60–180
Mepivacaine 1%–1.5%, with epinephrine (1:200,000–1:400,000) ^c	50–30	180–300
Levobupivacaine 0.25%–0.5%, plain	50–30	180–270
Levobupivacaine 0.25%–0.5%, with epinephrine (1:200,000–1:400,000) ^c	50–30	360–1440
Ropivacaine 0.5%–0.75%, plain or with epinephrine (1:200,000–1:400,000) ^c	50–30	360–720

^a Several nerves or a plexus.

^b Do not exceed maximum dosage listed in Table 47.1.

^c Caution: The maximal *adult* recommended dose of epinephrine is 250 µg per dose; for children, the maximum dose is 3 µg/kg per dose.

avascularity and large block volume required (Table 47.3 and Table 47.4). Intrathecal, epidural, and subcutaneous blocks have a much faster onset of action but have a much shorter duration of action (Table 47.5 and Table 47.6).

Local anesthetic toxicity

Local anesthetics are the mainstay of regional anesthesia and pain management; however, their toxicity is a major limitation to their use. Because of the constant concern about systemic or local neurotoxicity, clinicians have to use the lowest concentrations/dosages of local anesthetics possible, thereby effectively limiting the full potential of these agents, lowering the success rate, and shortening the duration of block.

Table 47.5. Epidural anesthesia^a

Drug	Volume, ml	Usual duration, min
Chlorprocaine 2%–3%, plain or with epinephrine (1:200,000)	30–15	30–60
Lidocaine 1%–2%, plain	25–15	45–60
Lidocaine 1%–2%, with epinephrine (1:200,000)	25–15	60–75
Mepivacaine 1%–2%, plain	25–15	45–75
Mepivacaine 1%–2%, with epinephrine (1:200,000)	25–15	60–180
Bupivacaine 0.25%–0.75%, plain	20–10	90–240
Bupivacaine 0.25%–0.75%, with epinephrine (1:200,000)	25–10	120–300
Levobupivacaine 0.25%–0.75%,	25–10	Same as plain
Levobupivacaine 0.25%–0.75%, with epinephrine (1:200,000)	30–10	bupivacaine
Ropivacaine 0.2%–1.0%, plain or with epinephrine (1:200,000)	20–10	90–300

^a Do not exceed the maximum recommended dose listed in Table 47.1. Administration in fractionated doses of 3–5 ml is recommended.

Table 47.6. Spinal anesthesia: commonly used agents/doses

Drug	Dose, mg	Usual duration, min
Procaine 5%–10%	80–160	30–75
Lidocaine 1%–2%	20–100	30–90
Mepivacaine 1.5%–4%	20–80	30–90
Bupivacaine 0.5%–0.75%	5–18	75–300
Levobupivacaine	Same as bupivacaine	
Ropivacaine 0.5%–1%	8–18	75–300

Direct local toxicity (direct neurotoxicity and nerve degeneration) may occur at clinically used concentrations and cause permanent nerve lesions. This is particularly disabling, as its frequency is greater in the spinal cord than in peripheral nerves, potentially causing damage to the nerves of the cauda equina (cauda equina syndrome, which manifests with varying neurologic deficits depending on the nerves affected, including incontinence, impotence, and paresthesia in the buttocks, perineal area, and legs), and even paraplegia. *Transient neurologic symptoms* (TNS) have been reported after spinal anesthesia with almost every local anesthetic agent, especially lidocaine. The cause is thought to be direct irritation of one or more spinal nerves, characterized by burning pain in the lower extremities and the buttocks. Symptoms usually resolve over 3 to 5 days (Table 47.7).

Systemic toxicity may occur as a result of vascular absorption or accidental intravascular injection of local anesthetics. Systemic toxicity usually is heralded by restlessness, twitching, metallic taste, and seizures. Severe systemic toxicity manifests as generalized seizures and cardiac arrhythmias, which can progress to ventricular tachycardia and asystole at higher blood levels. Usually, much higher blood levels of local anesthetic (about three times) are required to cause cardiotoxicity than to cause neurotoxicity. Lidocaine and bupivacaine (approved by the US Food and Drug Administration in 1947 and 1963, respectively) are still the two most widely used local anesthetic agents. Bupivacaine is more cardiotoxic than lidocaine, in part

Table 47.7. Symptoms and signs of local anesthetic toxicity

Central nervous system	Transient neurologic symptoms, cauda equina syndrome, dizziness, perioral and tongue numbness, blurred vision, tinnitus, restlessness, agitation, slurred speech, seizures, unconsciousness
Respiratory system	Decreased ventilatory drive to hypoxia, apnea, depression of respiratory center in the medulla
Cardiovascular system	Decreased myocardial automaticity, contractility—bradycardia, ventricular arrhythmias, heart block, hypotension, cardiac arrest
Hematologic system	Decreased platelet aggregation, increased fibrinolysis, decreased embolic events
Prolonged action of	Muscle relaxants, opioids
Action prolonged by	Propranolol, cimetidine – decreased hepatic blood flow

because it binds to and dissociates more slowly from sodium channels than lidocaine. Two homologues of bupivacaine, ropivacaine (less lipid soluble) and levobupivacaine (stereoisomer of bupivacaine), are believed to be less toxic than racemic bupivacaine. However, neither is dramatically less toxic, as evidenced by similar dosage guidelines and recurring case reports of their toxicity, including fatalities.

In recent years, the administration of intravenous intralipid solution, termed *lipid rescue*, has shown some promise of reducing systemic local anesthetic toxicity. Specifically, the intravenous administration of a 20% intralipid solution in a dose of 1.5 ml/kg as an initial bolus, followed by 0.25 ml/kg/min for 30 to 60 minutes has been shown to improve the survival of animals with bupivacaine-induced asystole.

Currently, there is no therapy for permanent nerve damage from local anesthetics, either in the spinal cord or the peripheral nervous system. Minor reactions to local anesthetic agents may resolve spontaneously, probably by repair of neuronal damage. The best approach is to adopt practices that minimize the risk of systemic local anesthetic toxicity. Administering local anesthetic in small, incremental doses while frequently assessing the patient for signs or symptoms of toxicity is prudent. If the restlessness, twitching, metallic taste or seizures appear, further administration of any local anesthetic should be halted and oxygen/airway management provided immediately. Seizures are most often transient, but persistent seizures can be treated with thiopental, propofol, or midazolam. In the event of cardiac arrest, cardiopulmonary resuscitation and standard treatment of any apparent arrhythmias, including direct cardiac defibrillation should be instituted. Lipid rescue should be considered if standard resuscitation measures fail. Prompt efforts to institute cardiopulmonary bypass can be life-saving.

Clinically used local anesthetics

Amino-amide local anesthetics

Lidocaine

Lidocaine, the first widely used local anesthetic, is available for infiltration as well as peripheral (including intravenous regional anesthesia of Bier block), spinal, and epidural blocks. It has a rapid onset of action, moderate duration of action limited by its vasodilating properties, and a favorable side effect profile. Its use for spinal anesthesia has declined because of concerns about neurotoxicity and transient neurologic symptoms. It can be applied topically as an ointment or jelly, or nebulized as an aerosol to anesthetize the upper airway. Intravenous injection of lidocaine to achieve low plasma levels (<5 µg/ml) results in systemic analgesia; this is due to lidocaine's action in the central nervous system (CNS) as well as its effect on peripheral nerves or cutaneous nerve endings. Clinically, lidocaine has been administered as an infusion to treat chronic neuropathic pain and can predict the efficacy of oral sodium channel blocking drugs, such as mexiletine.

Lidocaine causes vasodilation at most concentrations. Thus, the addition of epinephrine can significantly reduce the absorption of lidocaine by nearby vasculature, allowing more of the initially administered dose to rapidly enter the neural compartment, thereby prolonging the duration of action by as much as 50%. Experimentally, intravenous lidocaine profoundly suppresses both increased peripheral neuronal “firing” induced by injury and inflammation and central sensitization of wide dynamic range neurons in the dorsal horn of the spinal cord.

Prilocaine

Prilocaine has a clinical profile similar to that of lidocaine and is used for infiltration, peripheral nerve blocks, and spinal and epidural anesthesia. Because prilocaine causes significantly less vasodilation than lidocaine, addition of epinephrine is not necessary to prolong the duration of action. This may be advantageous when epinephrine is contraindicated. Prilocaine shows the least systemic toxicity of all the amide local anesthetics; therefore, it is useful for intravenous regional anesthesia. However, because it causes methemoglobinemia (>500 mg dose) because of its metabolite, *o*-toluidine, it largely has been abandoned for regional anesthetic use.

Mepivacaine

The anesthetic profile of mepivacaine is also similar to that of lidocaine, but its duration of action is slightly longer. However, it is not as effective when applied topically. Although toxicity appears to be less than that with lidocaine, the metabolism of mepivacaine is prolonged in the fetus and newborn. Consequently, mepivacaine is not used for obstetric anesthesia. Vasodilation is mild, but adding epinephrine can attain significant prolongation of action.

Bupivacaine

Bupivacaine provides prolonged and intense sensory analgesia, often outlasting the motor block. For epidural analgesia and anesthesia, bupivacaine usually is used at concentrations from 0.25% to 0.5%, with a 2- to 5-hour duration of action. Peripheral nerve blocks are also performed with these concentrations, depending on the amount of motor block sought. The block may last for 12 to 24 hours. Intrathecal use provides approximately 2 to 3 hours of anesthesia and 4 to 6 hours of analgesia. Other clinical uses include tissue infiltration with 0.25% concentration, useful in “trigger point” injections for treating myofascial pain. Epinephrine is sometimes added as a marker for intravascular injection and to prolong the duration of action because of its decreased vascular absorption. However, as vasoconstriction has less impact on the duration of more hydrophobic agents, epinephrine is more commonly added to agents that are more hydrophilic, such as lidocaine.

Many reports of sudden cardiac arrest with bupivacaine injection were associated with considerable morbidity and mortality. This agent’s high affinity for the local anesthetic receptor protein and its high lipid solubility may be the main causes. By consensus, the 0.75% concentration of bupivacaine

is not used in obstetrics because of the associated mortality/toxicity.

Levobupivacaine

Levobupivacaine is the *S*-enantiomer of bupivacaine, which is a racemic mixture containing equal amounts of the *R* and *S* enantiomers. Compared with bupivacaine, the CNS and cardiovascular toxicity of levobupivacaine is considerably reduced, allowing a larger dose to be given. The clinical profile and potency of levobupivacaine appear similar to those of bupivacaine. Levobupivacaine is particularly useful when large doses are required, as for plexus blocks.

Ropivacaine

Concerns about the cardiotoxicity of bupivacaine led to the development of ropivacaine. Ropivacaine can be administered in larger doses than bupivacaine before early signs of toxicity develop. The clinical profile of ropivacaine is similar to that of bupivacaine, but ropivacaine is less lipid soluble and less potent than bupivacaine. Epidural application may allow for even greater sensory block without significant motor block. An intrinsic vasoconstricting effect (also true for levobupivacaine) may augment the duration of action and reduce the incidence of cardiotoxicity.

Amino-ester local anesthetics

Procaine

Procaine was used mainly for infiltration and spinal blocks in the last century, before lidocaine use became popular (Table 46.2). Low potency, slow onset (probably a result of its high dissociation constant [pK_a]), and short duration of action all limit the use of procaine. Allergic reactions are possible because of the production of the metabolite PABA (see Figure 47.1).

Chloroprocaine

Because of its relatively low potency and extremely low toxicity, relatively high concentrations of chloroprocaine can be used. This agent also has an extremely short plasma half-life because it is metabolized very rapidly by cholinesterase. Reports of CNS

Figure 47.1. Metabolism of a typical ester local anesthetic.

toxicity are extremely unusual. Chloroprocaine is thought to have the lowest CNS and cardiovascular toxicity rates of all agents in current use. Chloroprocaine is used commonly for epidural anesthesia. It also is used for peripheral blocks in combination with other long-acting, slow-onset local anesthetics, for the combined effect of rapid onset and prolonged duration. In obstetrics, epidural chloroprocaine, with or without bicarbonate, is used to rapidly attain surgical levels of anesthesia in preparation for cesarean section. Another advantage in obstetrics is that there is virtually no transmission of chloroprocaine to the fetus. Epidurally administered chloroprocaine may, however, interfere with the action of epidurally administered amide anesthetics or opioids.

There is controversy regarding the use of chloroprocaine related to reports of persistent, serious neurologic deficits associated with accidental massive subarachnoid injection. Initially, the agent itself was thought to be implicated. Subsequent evaluation suggests that the preservative, antioxidant bisulfite, may by itself produce the phenomenon. However, after elimination of bisulfite, several reports of back pain appeared. Moreover, renewed interest led to a report suggesting that bisulfite actually may have been neuroprotective in an animal model.

Tetracaine

Tetracaine is a slow-onset, potent, intermediate- to long-acting ester-type local anesthetic. Even longer duration of action can be achieved when it is administered with a vasoconstrictor such as epinephrine; however, it is quite toxic. Animal studies suggest that tetracaine might cause neurotoxicity at high doses and may cause cauda equina syndrome with repeated spinal dosing. It is used mainly topically or sometimes for spinal anesthesia. Tetracaine is highly lipid soluble, and a significant amount may get absorbed when used on mucous membranes or wounded skin.

Cocaine

Cocaine, the only naturally occurring local anesthetic used clinically, is also the only local anesthetic that causes intense vasoconstriction. Thus, it is used as a topical anesthetic, such as in anesthetizing the cornea or the nasal airway before endotracheal intubation. Cocaine inhibits the neuronal reuptake of catecholamines and therefore may cause hypertension, tachycardia, dysrhythmias, and other serious cardiac effects.

Benzocaine

Benzocaine has a slow onset and short duration of action and is both minimally potent and minimally toxic. Its clinical use is limited to topical anesthesia to anesthetize mucous membranes – for example, to anesthetize the oral and pharyngeal mucosa before fiberoptic endotracheal intubation. Excessive use of benzocaine is associated with methemoglobinemia.

Mixture of local anesthetics

The rationale for mixing local anesthetics is an attempt to benefit from their respective pharmacokinetics: a quick onset with the short-acting drug while prolonging anesthesia with

the long-acting drug. However, the beneficial effects of local anesthetic agent mixtures may be overstated. For example, bupivacaine provides a clinically acceptable onset of action as well as prolonged anesthesia. In addition, catheter techniques for many forms of regional anesthesia make it possible to extend the duration of action of rapid- and short-acting agents such as chloroprocaine and lidocaine. Most importantly, one should be cautioned against the use of maximum doses of two local anesthetics. Toxicities of these agents are independent; the toxicities should be presumed to be additive, or even synergistic/supra-additive.

Topical local anesthetics

Eutectic mixture of local anesthetic

Eutectic mixture of local anesthetic (EMLA) cream is a mixture of lidocaine and prilocaine, each at a concentration of 2.5%. It is a eutectic mixture because it has a melting point below room temperature and therefore exists as a viscous liquid rather than a solid powder. EMLA should be applied to intact skin surfaces, because application to breached skin surfaces may lead to unpredictably rapid absorption. It provides dermal analgesia by the release of the lidocaine and prilocaine from the cream into the skin, which leads to blockade of pain transmission originating from the free nerve endings. The onset, quality, and duration of dermal analgesia depend primarily on the duration of skin application. Although there is considerable interpatient variation, EMLA cream should be applied under an occlusive dressing for about 1 hour to provide adequate analgesia for insertion of an intravenous catheter. The maximum recommended duration of exposure is 4 hours, although exposures of up to 24 hours have not led to toxic plasma levels of local anesthetics.

For intravenous catheter placement or the drawing of blood, roughly 2.5 g of the cream should be applied over a 25-cm² area of skin, about 1 hour before the procedure. Caution must be taken in children or very small adults, as plasma levels of lidocaine and prilocaine depend on patient size and the rate of systemic drug elimination. A large application area, a long duration of application, and impaired elimination may result in high blood values of the local anesthetics.

Lidocaine patch (5%)

The lidocaine patch (Lidoderm; Endo Pharmaceuticals, Newark, DE) was approved by the US Food and Drug Administration in 1999 for the treatment of pain associated with postherpetic neuralgia, a chronic neuropathic pain condition. The patch is a topical delivery system intended to deliver low doses of lidocaine to superficially damaged or dysfunctional cutaneous nociceptors in an amount sufficient to produce analgesia but not mechanosensory block. Its recommended dosing is an application of up to three patches to intact painful skin areas for 12 hours per day.

Pharmacokinetic studies have demonstrated that clinically insignificant plasma levels are achieved with this formulation. The levels are one tenth of those required to produce cardiac

activity and 1/32 of those required to produce toxicity. However, patients often report pain relief even during the 12 hours between patch applications, although lidocaine plasma half-life is much shorter. This suggests that some cumulative benefit results from prolonged delivery of the drug.

Administration of general anesthesia

Introduction

The primary goal of anesthesia is to provide patient comfort and safety during surgery or to facilitate the surgical procedure itself. Anesthesia can be general, regional, and local, depending on the needs of the patient and surgeon. In this chapter, we will discuss general anesthesia.

General anesthesia is a reversible drug-induced state of unconsciousness with hypnosis, amnesia, analgesia, and elimination of the patient response to the painful stimuli, sometimes accompanied by paralysis.

Preoperative preparation

Preoperative evaluation

Preparation for administration of general anesthesia is affected by whether the surgery is elective or emergency, the extent of the procedure, and the patient's comorbidities. [Table 48.1](#) summarizes the steps usually involved in preoperative preparation.

For elective procedures, a preoperative visit to the hospital's pre-admitting test center several days before surgery can have tremendous value. This is an opportunity to evaluate the patient for comorbidities, perform necessary tests and consults, discuss the anesthesia plan with the patient, and address the patient's concerns. Anesthesia information leaflets provided preoperatively have been shown to have a significant effect on patient satisfaction and are a way to evaluate comorbidities, decrease patient anxiety, and prevent an unnecessary cancellation of surgery.

Decisions regarding specific preoperative tests and procedures should be individualized and depend on information obtained from patient's medical record, history and physical examination, and the type and invasiveness of the planned procedure. For example, a patient with renal failure may need dialysis before the procedure, a patient with an implantable cardioverter-defibrillator may need the device turned off, or a hypovolemic patient may need fluid resuscitation before induction to minimize hemodynamic instability. Of course, in an emergency situation, time for preparation is scarce. The most important aspects of the preoperative evaluation include a problem and medication list, allergies, NPO (nothing by mouth) status, chest examination, and airway evaluation.

Preparing anesthesia equipment

There are basic steps that need to be addressed before each anesthesia case, including anesthesia machine checkout, preparation of appropriate equipment for intubation, basic ASA (American Society of Anesthesiologists) monitors, and medications. In trauma centers, it is necessary to have a dedicated trauma room available at all times for emergent cases. This room should be checked on a daily basis and contain medications, intravenous (IV) fluids, a rapid infusion device, and other equipment ready to be used. Obstetric centers should have a dedicated emergency cesarean section room.

Preparing the patient

Discussion of the anesthetic plan with the patient or guardian will help address his or her concerns and help ease the patient's anxiety. An informed consent should also be obtained at this time, although it may not always be possible in emergent cases. In such a situation, the attempt to obtain informed consent and the reasons for proceeding without it should be clearly documented in the chart before the surgical procedure is undertaken. The anesthesiologist should also become familiar with the surgical plan.

Table 48.1. Preoperative preparation

Preoperative preparation step	Considerations
Evaluating the patient	History and physical Laboratory tests NPO status Airway evaluation Anesthetic plan
Preparing anesthesia equipment	Anesthesia machine Monitors Fluid warmer Emergency medications
Preparing the patient	Discussion of anesthetic plan Obtaining consent Preoperative medication Line placement
Assessing need for blood products	Type and screen, cross-match, contact blood bank

IV access

Adequate and reliable IV access is an important part of preparation for anesthesia and surgery. In surgeries with significant risk of bleeding or fluid loss, at least two large-bore IV lines (≥ 16 -gauge) are necessary. If a reliable peripheral IV line is not available, central line placement should be considered. When obtaining access, it is important to pay attention to patient-specific factors, such as history of radical mastectomy or previous arteriovenous fistula.

Premedication

Relief of anxiety and pain is an important aspect of premedication. Reassurance and appropriate interaction with the patient are effective ways to relieve patient anxiety. One may use a benzodiazepine or an opioid premedication, with midazolam and fentanyl being the most commonly used agents for this purpose. Occasionally, clonidine and other medications are used as well. In the case of an emergency surgery or underlying gastroesophageal reflux, H_2 -receptor blockers and metoclopramide may be given by slow intravenous infusion. Metoclopramide is a useful tool to promote gastric emptying, but it must be administered slowly, over 3 to 4 minutes. If given as a rapid bolus injection, it often results in severe anxiety or panic attack. If an awake fiber-optic intubation is part of the anesthetic plan, glycopyrrolate may be used to decrease airway secretions, and airway topicalization with local anesthetic and phenylephrine or oxymetazoline spray, if the nasotracheal route is planned, may be performed. Sometimes β -blockers are administered preoperatively to control heart rate, especially in patients with ischemic heart disease.

Blood products

Blood product availability is important any time there is possibility of significant bleeding. Before surgery is begun, there should be clear documentation that the blood or blood products previously requested to be put on reserve are indeed available. There should be clear communication with the blood bank whenever the emergency release of blood products is necessary.

Monitoring plan

The decision for additional monitoring is usually made during the preoperative evaluation and sometimes may evolve during surgery. In addition to basic ASA monitoring required for all patients undergoing general anesthesia, the following may be necessary:

Arterial line: Indications include significant blood loss and fluid shifts, as well as underlying comorbidities that can result in hemodynamic instability. An indwelling arterial line is a convenient way to draw arterial blood gases. An arterial line is also indicated when the surgery itself is associated with rapid changes in blood pressure, for example, resection of a pheochromocytoma or clipping of an intracranial aneurysm.

Central venous pressure line and pulmonary artery catheter: Indications may include patients with significant cardiac or renal disease undergoing major surgery, large fluid shifts and blood loss, and the possibility of significant change in peripheral vascular resistance and cardiac output. With the advent of portable ultrasound devices to aid in insertion of a central venous catheter, these devices should be used whenever possible to decrease the incidence of inadvertent carotid artery puncture or cannulation.

Transesophageal echocardiogram (TEE): TEE may be used in cardiovascular surgery or in patients with reduced cardiac function undergoing major surgery. It is increasingly being used instead of a pulmonary artery catheter in cardiac surgery. An evaluation by TEE may be required to obtain the most precise information to guide surgical interventions (e.g., myocardial revascularization, valvular competence, and repair of congenital heart defects), pharmacologic support, or fluid administration in the perioperative period.

Esophageal Doppler monitor (EDM): The EDM is a promising noninvasive technique to estimate left ventricular preload and cardiac output. An esophageal probe is inserted into the lower esophagus. Blood flow in the descending aorta is calculated from the area under the velocity–time curve and the aortic cross-sectional area.

Foley catheter: Urine output monitoring is necessary whenever there is a risk of significant bleeding, fluid shifts, long surgical time, or preexisting renal impairment. A Foley catheter is also employed for abdominal hysterectomy and other major gynecologic procedures to monitor urine output in case a ureter is inadvertently transected during the procedure. If suspected, the surgeon will ask the anesthetist to administer methylene blue, which appears in the Foley bag within minutes. If irrigation fluid in the surgical field turns blue after the methylene blue is given, it indicates that a ureter or the bladder may have been lacerated.

Bispectral index (BIS) monitor (or other depth-of-anesthesia monitors): This monitor has become popular with increasing scientific and media attention about awareness under anesthesia. The utility of electroencephalogram monitoring remains controversial. Patients at high risk for awareness under anesthesia include those undergoing cardiac surgery, trauma surgery, or obstetric surgery under general anesthesia, and those with unusually high anesthetic requirements.

Induction of anesthesia

Application of appropriate monitoring, measuring of preinduction vital signs, and preoxygenation should precede induction of anesthesia. In emergency and trauma cases, additional preinduction considerations may include full-stomach precautions, possibility of alcohol and drug intoxication, and cervical spine and hemodynamic instability. [Table 48.2](#) outlines common induction-related issues and considerations.

Table 48.2. Induction of anesthesia

Induction-related issue	Considerations
Choice of anesthetic agent	Intravenous Intramuscular Inhalational
Stages of anesthesia	Guedel's stages of anesthesia (Table 48.3)
Airway management	Endotracheal tube Laryngeal mask airway Fiberoptic intubation Management of a difficult intubation
Positioning	Nerve and soft tissue injury Hemodynamic changes

Choice of anesthetic agents

Inhalation induction, using only inhalational agents, is often chosen for induction of general anesthesia in children and occasionally in adults when IV access is difficult to obtain prior to induction. An inhalational induction is also used, with an IV in place, when the airway is compromised and the goal is to maintain spontaneous respiration throughout the induction until the airway can be secured with an endotracheal tube. Most commonly, sevoflurane is used as it is thought to be relatively non-irritating to the airway, although other agents, such as isoflurane and halothane also have been used successfully. Table 48.3 outlines Guedel's four stages of general anesthesia. Guedel's stages were formulated around the time of World War II to aid medical corps and nursing personnel in administering ether because it was the only induction agent used at the time. When using the newer inhalational agents, it is more difficult to appreciate the stages, especially when an IV induction agent, such as propofol, is used along with them.

IV induction agents are considered the principal route of anesthetic induction, especially in adults and in emergency cases. In emergency cases, induction is usually performed in rapid sequence (see later) and with in-line neck stabilization in trauma cases. In hemodynamically unstable patients, etomidate or ketamine may be a better choice. Muscle relaxants are used to improve intubating conditions. With the exception of

rapid-sequence induction, the ability to ventilate the lungs is usually assessed prior to the administration of a muscle relaxant.

Rapid-sequence induction refers to induction in which the IV injection of a drug to produce unconsciousness is followed immediately by a neuromuscular blocking drug that produces a rapid onset of skeletal muscle paralysis (e.g., succinylcholine). Mask ventilation is traditionally avoided until the patient's airway is secured with an endotracheal tube. In addition, cricoid pressure may be applied from the beginning of induction until the correct placement of the endotracheal tube is confirmed. The goal of these maneuvers is to reduce the risk of aspiration during induction. Therefore, rapid-sequence induction is typically performed in patients with significant reflux disease, bowel obstruction, or a full stomach, and in trauma patients and pregnant patients. All are considered a high risk for aspiration.

Intramuscular induction agents, mainly ketamine, occasionally are used in combative, mentally challenged patients. Detailed information about different induction agents can be found in Chapter 34.

Airway management and anesthetic techniques

The decision to use mask ventilation, laryngeal mask airway, or an endotracheal tube (orotracheal vs. nasotracheal) depends on the risk of aspiration, necessity of muscle relaxation, length of surgery, and patient positioning. Regardless of the primary plan of airway management, anesthesiologists must always be prepared for the need to perform an endotracheal intubation. This requires precise preoperative evaluation of the airway and readiness to deal with potentially difficult intubations. A difficult intubation cart should be readily available. Discussion regarding management of a difficult intubation is presented elsewhere in the text. Hemodynamic effects of laryngoscopy may be significant and severe degrees of arterial oxygen desaturation may occur if the anesthesiologist is unable to insert quickly an endotracheal tube. It is always advisable to pre-oxygenate before attempting endotracheal intubation, especially when a difficult airway is suspected or encountered.

Table 48.3. Guedel's stages of general anesthesia with ether as the sole agent

Guedel's clinical criteria, simplified						
Stage	General description	Respiratory pattern	Eyeball activity	Pupil size	Eyelid reflex	Risk of vomiting, laryngospasm
I	Analgesia	Slow, regular	Baseline	Baseline	Present	
II	Delirium Excitement Unconsciousness	Irregular	Markedly increased	Reactive to light, may be dilated	Present, starts to disappear	Increased
III	Surgical anesthesia	Regular, then progresses to complete paralysis	Decreases progressively, then ceases	Gradual dilation	None	
IV	Respiratory paralysis Cardiovascular collapse	Complete paralysis	None	Complete dilation	None	

Positioning

Proper patient positioning requires particular attention from the anesthesia team to avoid pressure on the peripheral nerves and soft tissues. This is especially important in the prone, lateral, and lithotomy positions. Hemodynamic effects of positioning may be significant as well. In a patient with an arteriovenous fistula, it is important to avoid excessive pressure and to confirm its patency.

Maintenance

Maintenance of anesthesia is achieved with either IV or inhalational agents, or a combination thereof. Close attention to the patient's vital signs, ventilation, the surgical field, and blood loss is an important aspect of care during this time. Communication with the surgical team also is important. For example, excessive pressure on the diaphragm might be the reason for bradycardia, or if it is challenging to catch up with blood loss, the surgeon may be able to temporarily stop the procedure and prevent ongoing bleeding by applying direct pressure on the vessels.

The total IV anesthesia (TIVA) technique uses only IV drugs for the induction and maintenance of anesthesia. Drugs used for this technique may include hypnotics such as propofol, opioids such as fentanyl and remifentanyl, and sometimes a muscle relaxant. No inhalational agents are used for this type of anesthesia. TIVA is the main route of administration of anesthesia in patients susceptible to malignant hyperthermia (MH). This mode of anesthesia may be associated with less postoperative nausea and vomiting. A detailed description of this technique is discussed in [Chapter 49](#).

Inhalational anesthetic techniques are widely used and are an alternative to TIVA. These agents, except for nitrous oxide (N₂O), are not safe to use in MH-susceptible patients. Desflurane is a potential airway irritant, and caution is advised when using it in patients with reactive airway disease.

Opioids and N₂O (65%–75%) are safe agents in MH-susceptible patients. The likelihood of intraoperative awareness with the pure opioid/N₂O method is greater than with other general anesthetic techniques. Use of depth-of-anesthesia monitoring is advised along with a propofol by infusion or intermittent boluses to help ensure an adequate anesthetic depth. A bispectral anesthesia depth monitor is of particular value in such situations. N₂O is contraindicated in surgery for bowel obstruction, pneumothorax, or in pneumoencephalograms due to its tendency to diffuse into closed air spaces, and is relatively contraindicated in patients with severe pulmonary hypertension.

Fluid management

In calculating fluid requirements under anesthesia, one needs to consider the fluid deficit from NPO status, maintenance fluid requirements, additional fluid requirements secondary to blood and other fluid loss, and metabolic state. Other fluid losses include evaporative loss (depending on the size of the incision),

losses through the gastrointestinal and respiratory systems, and third space loss. The maintenance fluid requirement is calculated based on weight: 4 ml/kg/h for the first 10 kg of weight, 2 ml/kg/h for >10 kg up to 20 kg of weight, and 1 ml/kg/h thereafter. For example, the maintenance fluid requirement for a 70-kg man is 110 ml/h. Fluid deficit is calculated based on the maintenance fluid requirement times the number of hours the patient has been NPO. Replacement of blood by crystalloid is roughly calculated by a ratio of 1:3 and for colloid by the ratio of 1:1. This means that every milliliter of blood loss should be replaced with 3 ml of crystalloid or 1 ml of colloid. When the decision is made to replace blood with packed red blood cells (PRBC), the ratio is 1:2 because the hematocrit of PRBC is twice that of whole blood. Crystalloid versus colloid replacement of fluid loss has long been debated. There is no consensus regarding the current outcome data, as each method has its advantages and disadvantages.

Blood components may be necessary during surgery if blood loss exceeds the allowable amount or if there is continuous loss and the patient remains unstable. With rapid blood loss, measured hematocrit may not be accurate. The threshold for blood transfusion also depends on the patient's age and coexisting diseases. In the case of massive transfusion, the administration of platelets and fresh frozen plasma may be necessary. Detailed information about transfusion and fluid management may be found in Sections XI and XII of this textbook.

Pain management

The ASA practice guidelines recommend using two analgesic agents that have a single route but act by different mechanisms, allowing better analgesic response with equal or fewer adverse effects. Examples include the administration of epidural opioids with local anesthetics or clonidine, or administration of IV opioids in combination with ketorolac or ketamine. Multimodal pain management is a growing trend in acute postoperative pain management. It has been shown that nociceptive neurons are involved primarily in the attraction of opioid-containing leukocytes during early stages of inflammation. Compared with patient-controlled IV analgesia, epidural analgesia may result in significantly decreased migration of β -endorphin-containing leukocytes to the injured site 24 hours after surgery. Regional anesthesia such as epidural, peripheral nerve block, single dose, or continuous nerve block may improve postoperative pain control and reduce the inflammatory response. Acupuncture also has been shown to reduce the analgesic requirement by up to 21%. Clonidine has been used for postoperative pain control, with dose-dependent side effects of hypotension and sedation. Nonsteroidal anti-inflammatory drugs, opioids, ketamine, and clonidine all have been used in multimodal pain management.

Intraoperative problems

Airway difficulties, hypotension, arrhythmias, anaphylaxis, and emergence have been shown to cause the most serious intraoperative anesthesia problems. A trained anesthesiologist will

have an armamentarium of “mental algorithms” to quickly approach these serious problems and also to resolve less serious but common intraoperative problems.

Table 48.4 provides an overview of common intraoperative problems that may occur during anesthesia. Table 48.5 is a more elaborate algorithmic approach to intraoperative hypoxemia. Neither of these tables represents an exhaustive presentation of the topics.

In the following sections, selected intraoperative problems are discussed.

Hypotension

Hypotension is very common during induction. Anesthetics cause a dose-dependent decrease in blood pressure as a result of pharmacologically induced myocardial depression, decreased systemic vascular resistance (SVR) from lowered sympathetic outflow, or both. Compounding this hypotensive tendency is the possibility that the patient may be dehydrated and may have reduced preload.

The usual, initial approach to dealing with intraoperative hypotension is to treat it immediately with a single dose of a short-acting pressor such as phenylephrine, 40 to 80 μg IV, ephedrine, 5 to 10 mg IV, to lighten the anesthesia if feasible; and to infuse fluid boluses.

The use of pressors and fluids is often the only temporizing measure until the source of hypotension is identified and resolved. Besides the anesthetic, other causes include surgical procedure itself (e.g., bleeding, retractors compressing the inferior vena cava), the patient’s medical condition necessitating the surgical procedure (e.g., septic shock, ruptured aortic aneurysm, trauma), or co-morbidities (e.g., heart failure).

It is also important to recognize that spinal or epidural anesthesia should not be used in patients with hemorrhagic hypotension from acute blood loss, such as a gunshot wound to the lower extremity. In such patients, the onset of a sympathetic block from the regional anesthetic may cause pooling of blood in the lower extremities, thereby decreasing venous return to the heart (preload) and exacerbating the hypotension. In extreme cases, pulseless electrical activity and death can result.

Hypertension

Hypertension also is commonly encountered. Most brief hypertensive episodes are benign and are related to a sudden increase in surgical stimulation. Thus, the best first option is simply to deepen anesthesia with an IV bolus of propofol and to increase the concentration of a volatile inhaled anesthetic. Administration of an opioid medication such as fentanyl also may be appropriate.

If inadequate anesthetic depth likely is not the contributor to hypertension, practitioners generally consider the use of short-acting antihypertensive medication (e.g., nitroglycerin, 40 μg IV bolus), especially when the hypertensive episode may be catastrophic (e.g., bleeding intracranial aneurysm).

Infusion of a short-acting antihypertensive drug (e.g., nitroglycerin, nitroprusside, or esmolol) may be needed to control blood pressure throughout the surgical procedure. The agent should be infused via a stopcock near the hub of the venous intracatheter. That way, the dead space of the IV line is low, meaning changes in medication infusion rates will reach the patient quickly. Nitroprusside administration requires the use of intra-arterial monitoring because reduction of systolic pressure occurs so rapidly that severe hypotension can result within 2 to 3 minutes, and if undetected could be dangerous.

If it becomes evident that the hypertension will persist well into the postoperative period, longer-acting antihypertensive medications (e.g., hydralazine IV, labetalol IV) may be considered. However, there is a tendency to overtreat hypertension until the cumulative overdosage is evident and the patient is hypotensive.

Hypoxemia

Hypoxemia deserves special emphasis. When it occurs during anesthesia, diagnosis and therapy must be done expeditiously. Uncorrected hypoxemia leads to anaerobic metabolism and metabolic acidosis from lactic acid. This adversely affects the biochemistry of the cell and may indeed be irreversible, leading to organ damage or death. See Table 48.5 for a good approach to intraoperative hypoxemia. The brain is at extreme risk from severe hypoxia lasting longer than 4 to 8 minutes, the reason being that cerebral neuronal function is almost entirely dependant on the aerobic metabolism of glucose. Sustained periods of anoxia carry a high probability of irreversible brain damage.

Failure to ventilate

Failure to ventilate may occur at any stage during an anesthetic. At induction, it can occur when the anesthetist is unable to ventilate by mask or to insert an endotracheal tube during a rapid intubation for a full stomach. In severe cases, insertion of a laryngeal mask airway may restore the ability to ventilate. In any such event, the ASA Difficult Airway Algorithm should be familiar to every anesthesiologist and followed in such situations. During the anesthetic itself, after an airway is established, ventilation can be lost because of a disconnection, a leak in the circuit or tube or from an obstruction, or the endotracheal tube itself becoming dislodged. This constitutes an emergency and immediate threat to the patient. The surgical team should be informed immediately; they may be able to help quickly by reconnecting the circuit if it is in the surgical field.

The commonest site of disconnection is where the 15-mm polyethylene adapter connects to the tracheal tube or the circuit. If the ventilator or capnography alarm indicates failure to ventilate, the entire length of the circuit and tube should be inspected or palpated. The connections from the machine to the circuit’s inspiratory and expiratory limbs (called 22-mm adapters) should be checked; they also are common sites of disconnection.

Table 48.4. Common intraoperative problems and differential diagnoses

Problem	Differential diagnosis	Remarks
Hypotension	Hypovolemia Vasodilatation from medication	The most common cause is blood loss or preoperative fasting and dehydration. Any opioid, sedative, or anesthetic may reduce central sympathetic outflow and cause vasodilation. Virtually every anesthetic induction or heavy sedation will be accompanied by this finding.
	Sepsis or SIRS	During surgery for an infectious process, sudden decreases in blood pressure are often from sepsis or SIRS.
	Low cardiac output	Many anesthetics decrease cardiac output; congestive heart failure or myocardial infarction may do this also.
	Severe bradycardia Severe tachycardia	This may cause low cardiac output, resulting in hypotension. If atrial fibrillation or flutter conduction to the ventricle becomes too fast, hypotension may result.
	Pneumothorax	This is uncommon but may spontaneously arise during positive pressure ventilation with or without anesthesia.
	Hypertension	Pain or surgical stimulus Essential hypertension Tourniquet or cuff
Lightening anesthesia		Has blood loss, an empty vaporizer or medication infusor, or rapid drug clearance made the patient "light"?
Preeclampsia		Perhaps the most common cause of acute peripartum hypertension. May be accompanied by seizures, proteinuria, acute renal injury, acute liver failure, thrombocytopenia, or coagulopathy.
Hypervolemia		In the setting of hypertension, it is possible to overfill or overtransfuse and predispose to pulmonary edema and congestive heart failure acutely.
Pheochromocytoma		Patients have been known to have an occult tumor secreting epinephrine or norepinephrine, but this is rare.
Hyperadrenocorticalism		Patients who are cushingoid, hypertensive, or hypokalemic may have this.
Hypoxemia	Low FiO ₂ Hypoventilation	Increase FiO ₂ immediately while searching for the cause. May be the result of opioids, benzodiazepines, muscle relaxants, or inhalation agents, which decrease respiratory drive and/or muscle strength.
	Disconnection of circuit Atelectasis	The commonest cause of serious hypoxemic accidents. A result of patients being intubated and receiving positive pressure ventilation. Consider gentle recruitment maneuvers.
	Mucus plugging Right main stem intubation	Suction and recruitment maneuvers. Maximum depth for tracheal tubes measured from teeth (on average): females, 21 cm; males, 23 cm. May visualize with bronchoscope.
	Pulmonary thromboembolism	Significant pulmonary embolism leads to sudden drop in end-tidal CO ₂ , and hypoxemia that does not improve on 100% FiO ₂ , accompanied by tachycardia and hypotension.
	Pulmonary edema	May be secondary to fluid overload, diastolic dysfunction, systolic dysfunction, or myocardial infarction.
	Venous air embolism	Also causes drop in end-tidal CO ₂ , and an increase in end-tidal N ₂ .
	Failure to ventilate	Kinked tube
Biting on tube Disconnection of tube from circuit or adapter Complete obstruction from mucus or tissue		Especially during "light" anesthesia or emergence. Still the commonest cause of severe hypoxia during general anesthesia. May occur very rapidly in infants and children whose endotracheal tubes are narrow; worse when no humidification is used. May need to replace tube very quickly. Encountered more often in the ICU setting.
Hole in tube or punctured cuff		Laser airway surgery and tracheostomies are particularly common settings for this problem. Beware of the risk of airway fire in tracheostomy and laser airway surgery!
High peak airway pressures		Kinked tube Biting on tube
	Bronchospasm	First approach usually is to deepen anesthesia, then consider neuromuscular blockade; administer β-agonists, inhaled or IV corticosteroids, and methylxanthines (e.g., aminophylline) occasionally.
	Mucus plugging (smaller tubes, copious mucus production, and nonhumidified gases predispose)	Patients with COPD, asthma, cystic fibrosis, tracheostomy, pneumonia, or otherwise excessive secretions may have plugging of significance. It may require replacement of the endotracheal tube but usually improves with suctioning and humidification of anesthetic gases.
	Pneumothorax (although this may happen in any anesthetic, predisposing surgeries include thyroidectomy, mastectomy, tracheal procedures, nephrectomy, and the use of high PEEP)	This causes increased peak airway pressures if the pneumothorax is extreme. Likewise, a complete inability to ventilate may be caused by a pneumomediastinum or a pneumothorax.
	High mean airway pressures	Bronchospasm
Stacking or auto-PEEP of mechanical breaths		This happens when the expiratory phase is not long enough to allow exhalation. Slow the respiratory rate.

Table 48.4 (continued)

Problem	Differential diagnosis	Remarks
Hypocarbica	Dynamic airway obstruction Pneumothorax Obesity or chest wall restriction of excursion ARDS	May be from airway neoplasm or mediastinal mass. Other things would be observable first: hypotension, hypoxia. Fairly common and may be difficult to treat. Common cause of high mean pressures in ICU patient with respiratory failure.
	Hypothermia Massive pulmonary embolus Hyperventilation	Most evident in severe hypothermia. A sudden drop in expired CO ₂ should make one think of this. Patients who are anxious (awake) or mechanically hyperventilated (anesthetized) may have this.
Hypercarbia	Leak in CO ₂ sampling tubing	This also may cause an abnormal shape of the capnograph waveform or envelope.
	Hyperthermia Malignant hyperthermia	Metabolic rate increases 15% for every 1°C. Uncoupling of calcium metabolism in mitochondria from a rare (1:15,000) genetic defect in the ryanodine receptor of the calcium channel.
	Hypoventilation	May be from opioid medication, residual neuromuscular blocking drug, or weakness from a variety of reasons.
	Increased “dead space” Increased diffusion gradient in lung Increased metabolic rate from feedings	From a variety of causes: long endotracheal tube, lung disease, etc. From COPD, interstitial lung disease, ARDS, pulmonary edema, or previous chemotherapy. Feeding patients with COPD often makes it difficult to liberate (wean) them from mechanical ventilation in the ICU.
Hypothermia	Administration of unwarmed fluid or blood products Anesthetic effects on hypothalamus	Ideally, all fluids should be warmed by an FDA-approved device. No microwave or ad hoc fluid heating methods are safe! Every general anesthetic causes impaired central thermoregulation due to its effect on the hypothalamus.
	Conductive, radiative, evaporative losses Massive blood loss TURP or other irrigation with unwarmed fluid	Wet drapes or sheets; exposed skin or body cavities, or nonheated breathing circuits. Very difficult to keep patients warm after 1 blood volume has been lost. Use FDA approved warming devices only! Surprisingly few urology suites use warmed TURP/TURBT irrigation. Hypothermia is common after TURP/TURBT.
Hyperthermia	Malignant hyperthermia	Specific therapy for MH: dantrolene IV plus other measures. If MH is suspected, call for help and consult.
	Fever from SIRS, sepsis, or transfusion reaction Stroke Neuroleptic malignant syndrome	Use acetaminophen or ibuprofen in addition to a cooling blanket. Sudden extreme hyperthermia (> 105°F) may be from a stroke to the hypothalamus. Relatively uncommon side effect that may develop after use of an antipsychotic medication, e.g., chlorpromazine, haloperidol, olanzapine, escitalopram.
	Excessive warming	Use the air-warming blanket at room temperature setting to cool the patient.
Bradycardia	Increased vagal tone	Spinal anesthesia causes sympathectomy and may lead to profound bradycardia or even asystole. Surgical stimulus on the gut or bladder (or other organs) may feed back and cause vagal tone to increase.
	Hypoxia	Occurs with severe hypoxia and is a bad prognosticator. Correct hypoxia immediately if possible.
	Increased SVR with intact baroreceptor reflex	In patients with an intact baroreceptor reflex, increased systemic vascular resistance causes increased blood pressure, which in turn causes reflex bradycardia. Phenylephrine may induce this, especially in young patients.
	β-Blockers Degenerative fibrosis of nodal tissue Calcium channel blockers	A common cause. This is actually considered the most common cause of bradyarrhythmias; it occurs in all settings, not just the operating room. Diltiazem is most likely to cause heart rate decreases and is used for this purpose in atrial fibrillation and flutter.
Sinus tachycardia	Reversal of neuromuscular blockade with cholinesterase inhibitors such as edrophonium or neostigmine	Usually, coadministration of an anticholinergic medication such as atropine or glycopyrrolate is standard practice, so this happens rarely. However, edrophonium may be used alone to try to convert SVT or slow heart rate, or in a common test for myasthenia gravis (Tensilon test).
	Sick sinus syndrome Myocardial infarction Third-degree heart block	May require temporary or permanent pacemaker. Especially if the right coronary artery and sinus node are involved in the infarction The ECG rhythm strip will provide the diagnosis.
	Pressors or inotropes Increased pain or surgical stimulus	Ephedrine, epinephrine, norepinephrine, isoproterenol. The commonest cause at the start of the surgical procedure; suggests insufficient anesthesia.
	Myocardial infarction Malignant hyperthermia	The commonest dysrhythmia associated with MI. Tachycardia in MH follows an observed increase in CO ₂ production, and it precedes hyperthermia.
	Atropine, scopolamine, or glycopyrrolate given β-Adrenergic agonists	These are given for drying (antisialagogues), heart rate control (vagolytics) or nausea control (antiemetics). Bronchodilators, tocolytics, decongestant medications, and anorexigenics (diet medications) may do this.

Note and disclaimer: Any table such as this one must necessarily be incomplete and imperfect.

ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; ECG, electrocardiogram; ENT, ear, nose, throat; FiO₂, fraction of inspired oxygen; FDA, US Food and Drug Administration; MI, myocardial infarction; PEEP, positive end-expiratory pressure; SIRS, systemic inflammatory response syndrome; SVT, supraventricular tachycardia; TURBT, transurethral resection of bladder tumor; TURP, transurethral resection of the prostate.

Table 48.5. Steps to consider immediately and a few minutes after sudden hypoxemia in the operating room

Immediately	In a minute or so	In 3–5 minutes
Inform all caretakers Ventilate by hand; assess compliance and chest excursion Ensure 100% FIO ₂ delivery. Look for disconnection: circuit, tube, 15-mm connector. Check expired gases for ETCO ₂ . Examine capnograph waveform Inspect the tube and circuit for kinking, biting, obstruction Inspect tube for excessively deep insertion: 21 cm (females); 23 cm (males). Palpate the cuff in the sternal notch while inflating and deflating it. Withdraw it if it is in too far.	Suction the tracheal tube with a thin catheter to remove secretions and assess patency or obstruction Perform direct laryngoscopy to verify tube placement in the trachea Reassess compliance and chest excursion If in doubt, replace tracheal tube under direct laryngoscopy Try bronchodilator inhaler empirically Apply recruitment maneuvers to open alveoli	Perform bronchoscopy through the tube Apply PEEP Obtain arterial blood gases Try alternate means of obtaining SaO ₂ Obtain chest radiograph to rule out atelectasis or pneumothorax Consider TTE or TEE

ETCO₂; end-tidal CO₂; FIO₂, fraction of inspired oxygen; PEEP, positive end-expiratory pressure; SaO₂ – arterial oxygen saturation; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

Removable plastic plugs, sampling tube fittings, cracks, and holes also should be checked for leaks, and the circuit should be checked for manufacturing defects. Next, the large rubber seals of any carbon dioxide (CO₂)-absorbent canister fittings on the anesthesia machine should be assessed, because these may become dislodged slightly when the canisters are replaced, resulting in a leak. Another source of a gross leak in the anesthesia circuit is the insertion point of the CO₂ sensor. Typically, the hole at the machine where the sensor inserts has a width of several centimeters. If the sensor falls out, it will result in an enormous leak with inability to ventilate. Although uncommon, this can generally be avoided by a thorough leak check of the anesthesia circuit prior to induction and by making certain that the sensor is firmly plugged in.

After these measures have been used and the leak diagnosed and corrected, the anesthesiologist should verify that the patient is receiving adequate ventilation. Checking the CO₂ trace may be insufficient to ensure that ventilation is optimal. The anesthesiologist should auscultate the breath sounds while giving breaths by hand and restoring mechanical ventilation. This gives valuable information as to inspiratory pressures required and the presence of rales or wheezing. The inspiratory pressure valve should also be viewed to quantitate the pressures required to ventilate. A bag–valve oxygen supply (e.g., Ambu bag) should be available on each anesthesia machine to connect to the endotracheal tube or mask in the event of circuit or machine failure that is not immediately repairable.

Obstruction of the circuit or tracheal tube or a sudden increase in airway peak pressure

One cause of obstruction of the circuit or tracheal tube or a sudden increase in airway peak pressure is concretions of dried mucus that can accumulate and, over time, completely obstruct a large adult-size tracheal tube. This phenomenon is even more common in pediatric patients, whose tracheal tubes are smaller. Humidification may reduce the risk of obstruction, but

may not prevent it entirely. When it does happen, replacement of the tracheal tube with a new one may be the only way to restore patency if suctioning with a catheter down the tube is insufficient.

More common is biting on or kinking the tracheal tube. To prevent kinking, use of an armored (embedded metallic spring) tube at the beginning of the procedure is effective. Armored tubes are especially valuable in prone and sitting cases where the endotracheal tube may be subject to torsion. A patient biting on the tube during maintenance of anesthesia usually is a sign of light anesthesia and should be treated quickly by deepening anesthesia, inserting (gently) a bite block, and/or giving a dose of neuromuscular blocking drug (10 to 20 mg of succinylcholine is sufficient to relax the jaw within 30 to 60 seconds in such a situation).

Other, less likely causes of sudden obstruction to ventilation are severe, sudden coughing or bronchospasm, pneumomediastinum causing tracheal obstruction, and tension pneumothorax. Bronchospasm is treated with bronchodilators, whereas coughing can be decreased with muscle relaxants and deeper anesthesia. Tension pneumothorax and pneumomediastinum are likely to be accompanied by severe hypotension. Needle or tube thoracocentesis is the first, emergent step for these complications.

Arrhythmias

Studies have demonstrated that approximately 50% of serious intraoperative arrhythmias are anesthesia related. The majority consist of extreme bradycardia or asystole, often resulting from spinal anesthesia with a high level, widespread sympathetic block and overriding vagal tone. Such an event usually responds to atropine (1 mg IV), IV ephedrine, and even a brief period of external cardiac massage to get the drug circulating in the event of asystole. Laparoscopy can result in sudden severe bradycardia or even asystole when the trocar pierces the peritoneum, causing an intense vagal stimulus. Again, atropine 0.2–1 mg IV (depending on severity of bradycardia) is usually

effective in this situation and typically restores heart rate to 60 or greater within 45 to 90 seconds. Sudden onset of sinus tachycardia with hypertension commonly is a sign of insufficient depth of anesthesia (see earlier). Sudden onset of tachycardia with hypotension may be an ominous sign indicating an immediate life-threatening event, such as venous air embolus (e.g., intracranial surgery), pulmonary embolus (e.g., patient with known deep vein thrombosis), or myocardial ischemia with a sudden drop in cardiac output. Please refer to [Chapter 155](#) on arrhythmias [Part 28](#) and to the Advanced Cardiac Life Support algorithms ([Chapter 153](#)) to review the differential diagnosis of arrhythmias in detail.

Allergy problems

Severe anaphylactoid or anaphylactic reactions occur in a small but significant percentage of cases. Often, the adverse allergic reaction to a specific drug is not known prior to the anesthetic. One study demonstrated that a severe allergic reaction to neuromuscular blocking drugs occurred in one in 3000 cases of general anesthesia. If the allergy is unknown, prevention is difficult, but early diagnosis and prompt and aggressive treatment may prevent morbidity. An anaphylactic reaction is a life-threatening event, calling for immediate vigorous fluid administration to combat cardiovascular collapse, IV epinephrine, H₂-blockers, and corticosteroids.

Emergence and extubation

Preparation for emergence includes reversal of muscle relaxants and discontinuation of inhalational and IV anesthetics. The patient should meet the criteria for extubation before the endotracheal tube is removed. The decision to extubate depends on the patient's ability to ventilate and oxygenate, the provider's ability to mask ventilate or reintubate if necessary upon extubation, and the impact on the patient if the extubation fails. Tracheal extubation may be complicated by laryngospasm, aspiration, hypoventilation, or negative pressure pulmonary edema. The premature removal of an endotracheal tube during the second stage of anesthesia may be particularly dangerous.

Criteria for extubation include stable vital signs, adequate ventilation and adequate reversal of muscle relaxant (4/4 twitches on the train-of-four and sustained 100 Hz tetanus), and an awake and cooperative patient. A good clinical measure of adequate reversal of neuromuscular blockade is the patient's ability to perform a sustained head lift for 5 to 10 seconds. Occasionally, the anesthesiologist may choose "deep" extubation to prevent coughing and bucking during emergence. This technique is particularly useful in a patient with significant reactive airway disease, but may not be advisable in a patient with difficult intubation.

Common problems during emergence from general anesthesia include residual neuromuscular blockade and delayed emergence (see [Chapter 52](#)).

Residual neuromuscular blockade may be demonstrated by the use of the transcutaneous peripheral nerve stimulator, which will show posttetanic fade or significant blockade on train-of-four stimulation (see section immediately above). If maximal anticholinesterase medication has been given, the proper treatment is conservative: passive or forced-air warming, correction of metabolic acidosis, and ensuring amnesia as recovery of muscle strength occurs. Mechanical ventilation with varying degrees of support is needed in the postanesthesia care unit (PACU) or intensive care unit (ICU). Great care must be taken in such situations to ensure that the patient is adequately ventilated and not experiencing dyspnea. Dyspnea from inability to breathe adequately or spontaneously is a frightening sensation and, if possible, the patient should be asked if he or she feels that he or she is "getting enough air while being mechanically ventilated." In such cases, additional sedation may be indicated along with careful settings on the ventilator to ensure adequate ventilation.

Delayed emergence, that is, delayed regaining of consciousness following the end of an anesthetic administration, is almost always from residual anesthetic effect and is longer if surgery lasts longer. The patient is supported with mechanical ventilation, and reassuring the family (and other caretakers) is key. Drugs such as scopolamine may cause delayed emergence and distort the pupil examination. Of course, CT scanning frequently is done to reassure caretakers that no intracranial event has occurred. Neurologic consultation usually is not necessary, but patience is. Pressure points should be padded carefully, and the eyes and airway cuff should be cared for as if a prolonged anesthetic were taking place.

Agitation occasionally occurs in patients on emergence and is more common in young patients who have received general anesthesia with an inhalational agent. The anesthesiologist should rule out physiologic causes of agitation, including hypoxia, hypercarbia, a full bladder, and pain. Clonidine has been used to reduce the incidence of emergence agitation in children, but it also may delay awakening from anesthesia.

Mortality and morbidity

Overall mortality from general anesthesia is approximately one in 200,000. Morbidity related to anesthesia includes dental injury, soft tissue and nerve injury, awareness under anesthesia, and postanesthesia respiratory and cardiac complications. Administration of anesthesia has become far safer during the past 30 years, owing to improved monitoring techniques and the widespread adoption of safety standards modeled after those in the airline industry. Claims for death and brain damage decreased between 1975 and 2000. From 1986 to 2000, adverse respiratory events decreased, whereas adverse cardiovascular events increased. By 1992, respiratory- and cardiovascular-damaging events occurred in approximately the same proportion (28%), a trend that continued through 2000. The overall downward trend did not seem to be affected by the

use of pulse oximetry and end-tidal carbon dioxide monitoring, which began in 1986.

There is emerging evidence that the choice of anesthetic technique may influence patients' long-term outcome, especially following surgery for certain types of cancer. The perioperative inflammatory response to surgical stress, but also to anesthetics, appears to influence particularly the cell-mediated immune response, which plays a pivotal role in scavenging cancer cells spilled into the circulation during surgery. Two small retrospective studies suggest less frequent cancer recurrence after removal of the primary tumor when regional anesthesia was used for analgesia rather than systemic opioids. Currently, larger prospective trials are under way to further explore the potentially significant impact anesthesia might have on long-term patient outcome.

Transport

The decision to transport to the PACU versus ICU depends on the need to keep the patient intubated after surgery, hemodynamic stability, significant comorbidities, and the need for frequent checks. Transfer with or without supplemental oxygen to the PACU depends on the type and length of surgery and anesthesia, as well as the patient's comorbidities. Monitoring for transport depends on the patient's stability and the length of travel. If oxygen is to be administered during transport, it is essential that the tank be checked prior to leaving the operating room. An "E" tank, most commonly used for transport, holds 660 liters when fully pressurized at 2000 p.s.i. At a 6L/min flow, a full tank will last 110 minutes; that is, just under two hours. The reserve times are directly proportional to the gauge pressure; that is, 1000 p.s.i. allows 55 minutes at 6L/min. This is of great importance when a patient is taken to the PACU or SICU (surgical intensive care unit) at the end of the anesthetic. An E-cylinder with 250 p.s.i. will only last about 15 minutes at 6L/min. This can be disastrous if an elevator is caught between floors during transit to the SICU.

Reporting to the accepting team either in the PACU or ICU by the anesthesia team is an important component of perioperative care. This report should include the patient's medical history, preoperative and intraoperative medications, ease of intubation, any problems in the operating room, intraoperative blood loss, and fluid management. A postoperative visit is a standard of practice, if feasible, in order to elicit any postoperative complications and patient satisfaction.

Total intravenous anesthesia (TIVA)

Amit Gupta and J. Lance Lichtor

Introduction

Total intravenous anesthesia (TIVA) may be defined as a technique of general anesthesia using a combination of agents given solely by the intravenous (IV) route and in the absence of all inhalational agents, including nitrous oxide.

The IV route has been used to administer drugs for hundreds of years. The administration of anesthesia solely by the IV route using chloral hydrate was documented as early as the 1870s. In 1934, thiopental was introduced into clinical practice, and IV induction of anesthesia became popular. However, only in more recent years has TIVA become possible and practical; there are two reasons for this. First, only drugs with a rapid onset and shorter recovery profiles, such as propofol and the newer synthetic, short-acting opioids, are suitable for maintenance of anesthesia with IV infusion. Second, advances in computer technology have allowed the development of easier-to-use infusion delivery systems.

Indications and advantages

TIVA is indicated for any general anesthetic provided a well-functioning IV is in place. With TIVA, there is no operating room pollution by nitrous oxide or potent inhalation agents. After TIVA, patients have been shown to feel better and report a more pleasant anesthetic experience, in part because of less postoperative nausea and vomiting (PONV). In an ambulatory setting, these patients may be able to leave the recovery room earlier, reducing costs of stay. However, it has also been noted that the combination of certain IV drug infusions (e.g., propofol and dexmedetomidine) without the use of a depth-of-anesthesia monitor, may result in gross overdose and delayed awakening. Initial reports also showed that postoperatively, patients experience less pain with TIVA compared with maintenance with isoflurane.

For individuals with a personal or family history of malignant hyperthermia TIVA is frequently chosen because the use of inhalational agents is generally contraindicated for this disorder (Chapter 110).

Intravenous hypnotic drugs

Modern hypnotic drugs suitable for TIVA include propofol, midazolam, ketamine, etomidate, and dexmedetomidine. Most commonly, a hypnotic drug is combined with an opioid.

Table 49.1 provides suggested dosages for hypnotic agents used in TIVA.

Propofol has become the hypnotic drug of choice for the TIVA technique. It has a short context-sensitive half-time that is prolonged only to a minor extent as the infusion duration increases (Fig. 49.1). This allows for fast awakening, even after several hours of continuous administration. It should be noted that the time to recovery also depends on other factors (see Chapter 36). Propofol can be used by itself, with no other drugs. It causes a decrease in peripheral vascular resistance and mean arterial blood pressure (30%), but these hemodynamic side effects can be attenuated with slow injection and careful titration to effect. When used for maintenance of anesthesia, propofol is associated with less PONV than inhalation anesthesia. For example, in a study of 5161 patients, propofol reduced nausea and vomiting by 19% compared with a volatile anesthetic (Fig. 49.2).

In contrast to propofol, the context-sensitive half-time of thiopental increases rapidly following all but the shortest infusions owing to cumulation (Fig. 49.1). This property renders it unsuitable for maintenance of anesthesia. Midazolam is also rarely used as a maintenance infusion since significant and prolonged psychomotor impairment often occurs following the administration of larger doses.

Etomidate has many unfavorable side effects, such as PONV, phlebitis, excitatory movements, venous irritation, and adrenal cortical suppression, limiting its use in TIVA. When dexmedetomidine is included as an adjunct to propofol and an opioid, PONV is decreased as a result of a decreased use of intraoperative opioids. In addition, dexmedetomidine can help reduce central sympathetic outflow, a property that

Table 49.1. Suggested dosages for anesthetic agents used in general anesthesia

Agent	Loading dose, mg/kg	Maintenance infusion rate
Midazolam	0.15–0.35	–
Propofol	1–3	50–200 µg/kg/min
Thiopental	3–6	–
Etomidate	0.2–0.4	–
Ketamine	1–2	5–10 µg/kg/min
Dexmedetomidine	1 µg/kg	0.2–1.0 µg/kg/h

Figure 49.1. Context-sensitive half-time values of hypnotic drugs, shown as a function of infusion duration. Adapted from Figure 36.4.

enhances sedation, analgesia, anxiolysis, and amnesia, reducing the requirements and associated side effects of other drugs.

Analgesics for TIVA

Analgesia during IV anesthesia may be provided by opioids, ketamine, or local anesthetics.

The opioid analgesic chosen for TIVA must have a fast onset and be easily titratable. Fentanyl is the most commonly used opioid. It can be administered by intermittent boluses or as an infusion, and provides good postoperative pain control. However, the context-sensitive half-time of fentanyl

Figure 49.2. Postoperative nausea and vomiting (PONV). PONV occurs least after a propofol anesthetic with either air or nitrous oxide that also includes one or more antiemetics. Illustrated is the incidence of PONV when different anesthetics and different numbers of prophylactic antiemetic treatments are administered.

Table 49.2. Suggested opioid dosages for TIVA

Agent	Loading dose, $\mu\text{g}/\text{kg}$	Maintenance infusion rate	Additional boluses
Alfentanil	25–100	0.5–2 $\mu\text{g}/\text{kg}/\text{min}$	5–10 $\mu\text{g}/\text{kg}$
Sufentanil	0.25–2	0.005–0.025 $\mu\text{g}/\text{kg}/\text{min}$	2.5–10 μg
Fentanyl	4–20	0.03–0.17 $\mu\text{g}/\text{kg}/\text{min}$	25–100 μg
Remifentanyl	1–2	0.025–1 $\mu\text{g}/\text{kg}/\text{min}$	0.1–1.0 $\mu\text{g}/\text{kg}$

increases markedly with prolonged infusion owing to cumulation at higher dosages. This effect may result in delayed recovery after prolonged administration. Other opioids suitable for TIVA include alfentanil and sufentanil. Remifentanyl has gained popularity for the administration of TIVA because it has a short onset time, high metabolic clearance, and short context-sensitive half-time, which is independent of the duration of infusion. This desirable property is a function of its rapid enzymatic degradation in all patients, regardless of ethnicity or coexisting hepatic or renal impairment. When postoperative analgesia is desired, a longer-acting analgesic such as fentanyl or morphine should be administered.

Ketamine is a dissociative anesthetic with sedative, hypnotic, and analgesic properties. Ketamine can be used with continuous infusions of propofol as an adjunct to help reduce the opioid requirement.

Approximate opioid bolus doses, maintenance infusion rates, and additional maintenance doses are listed in Table 49.2.

Drug interactions and TIVA

In recent years, advances in computer technology and pharmacokinetic modeling have allowed us to gain a better understanding of individual drugs as well as the interactions between drugs when administered by the IV route. The context-sensitive half-times of the intravenous opioids given by infusion are shown in Figure 49.3.

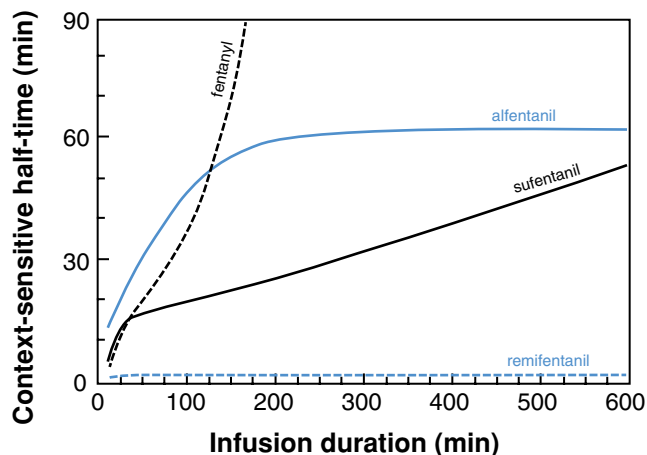

Figure 49.3. Context-sensitive half-time values of opioid drugs, shown as a function of infusion duration. Among the opioids, remifentanyl is associated with the most rapid return to consciousness. Adapted from Figure 36.4.

Infusion delivery systems: manual-controlled infusion and target-controlled infusion

Two types of infusion devices can be distinguished: manual-controlled infusion (MCI) and target-controlled infusion (TCI) systems.

MCI is a continuous IV infusion with a syringe pump programmed for use with any drug used for TIVA; the anesthesiologist sets the pump's rate. These systems are widely used in operating rooms and intensive care units across the United States to administer various drugs as continuous infusions. These infusion systems are commonly referred to as *infusion pumps*.

TCI devices are now available worldwide, except in the United States. This worldwide availability primarily reflects the widespread approval of the Diprifusor (AstraZeneca, Wilmington, DE) for the administration of propofol. The anesthesiologist enters the patient's age and weight and sets the initial target blood concentration. He or she also estimates the target drug concentration based on the patient's physiologic state. The device then achieves and maintains the target concentration, with no further intervention required by the anesthesiologist. If signs of inappropriate anesthetic depth are manifested, the anesthesiologist has to adjust the set point up or down to achieve the appropriate depth of anesthesia.

Randomized trials have explored the differences in quality of anesthesia, adverse event rate, and drug cost between the two types of delivery systems (TCI vs. MCI) when administering propofol. The comparative effectiveness of the two systems remains controversial. A recent systematic review by the Cochrane Collaboration comparing the two systems did not demonstrate an advantage of either delivery system in clinical practice. The authors therefore concluded that there is not sufficient evidence to recommend the use of TCI versus MCI in clinical anesthetic practice.

This may be not surprising if one considers that the described TCI systems do not take into account many factors that influence the optimal IV dose, such as the type of operation (superficial, intra-abdominal), preexisting diseases (hepatic, renal, cardiac), and intraoperative interventions (laryngoscopy, skin incision). Anesthesiologists are very well aware that the appropriate depth of anesthesia remains a moving target that requires constant adjustments – a challenge that has not been resolved by the TCI systems on the market.

Open-loop versus closed-loop control systems

Currently, all TCI devices on the market are “open-loop” control systems, meaning that the anesthesiologist must recognize changes in the required depth of anesthesia and then adjust the target concentration appropriately (as described earlier).

“Closed-loop” control systems are in development. These systems will measure feedback signals from the patient, such as evoked potential and/or bispectral index (BIS). Based on the feedback signals, these systems will automatically adjust the target concentration, without the intervention of the

anesthesiologist. These closed-loop control systems are purely investigational at this time but most likely will be part of the future technological advances in the field of anesthesia.

Limitations of TIVA

Although there is some controversy concerning TIVA and intraoperative awareness, the incidence of awareness with TIVA probably is no different than that of inhalation anesthesia. During TIVA, direct drug concentration measurements are not available and the relationships between infusion rates and adequate effect-site concentrations are not easy to establish. However, in one study, 11,785 patients were questioned for explicit recall on three occasions after anesthesia. Although TIVA was used for only about 3% of all patients, no patients who received TIVA reported recall. In that study, all the patients who did report unpleasant effects during or after wakefulness had been paralyzed. In another study of 1000 patients who specifically received TIVA with propofol, alfentanil, and paralysis, the incidence of recall (0.2%) was similar to that found in other studies. Depth-of-anesthesia monitors have been shown to reduce, but not eliminate, the incidence of recall (Chapter 30). Another study showed that intraoperative recall is possible even with a BIS value below 60. The most common reasons for intraoperative awareness are related to technical problems such as infusion pump malfunctions or disconnections. Other potential limitations of the TIVA technique include significant cumulation of the infused drugs after prolonged infusions, leading to delayed awakening, and the side effects of propofol administration, including pain on injection and postoperative fatigue and confusion. Finally, prolonged infusion of propofol may result in significant expense.

Monitored anesthesia care

Shubjeet Kaur

Introduction

The use of monitored anesthesia care (MAC) as an anesthetic technique for the care of patients both in the operating room and in a procedural setting continues to increase. Currently, MAC is the first choice in an estimated 10% to 30% of all surgical procedures in the operating room.

Monitored anesthesia care

The American Society of Anesthesiologists (ASA) defines MAC as a “specific anesthesia service for a diagnostic or therapeutic procedure.” The standards of anesthesia care are no different from those of general or regional anesthesia. MAC includes a preprocedure assessment, intraoperative care, and postprocedure anesthesia management. The anesthesiologist either provides the anesthesia himself or herself or supervises another anesthesia care provider (resident, nurse anesthetist).

During MAC, an anesthesiologist may administer medications that produce analgesia, anxiolysis, amnesia, or hypnosis. The anesthesiologist is always responsible for monitoring the patient’s vital functions. Often, analgesia is provided by the surgeon via local anesthesia or nerve blocks on the surgical field. Sometimes the anesthesiologist may not need to administer any medications at all.

An important component of successful MAC is that the anesthesiologist providing this service is responsible for anticipating, diagnosing, and treating any medical problems that may arise during the procedure. MAC may need to be converted to a general anesthetic at a moment’s notice. Therefore, the anesthesia care provider must be able to ensure adequate airway support and ventilation.

Moderate sedation/analgesia (formerly known as “conscious sedation”) by nonanesthesiologists

It is important to have a clear understanding of the differences between MAC and moderate sedation/analgesia: MAC is provided by a fully trained anesthesia care provider and adheres to the same standard as any other choice of anesthetic (as outlined earlier). Therefore, during MAC cases, at least two independently functioning healthcare providers are present: the health

care provider performing the procedure and the anesthesiologist/nurse anesthetist. This is in contrast to moderate sedation/analgesia cases, in which the physician performing the procedure is also directing and supervising the provider administering the sedation.

Although anesthesiologists have specific training to provide sedation and analgesia, in most institutions these services often are provided by nonanesthesiologists for various reasons, including scheduling issues, convenience, lack of availability of anesthesiologists, and cost.

To improve patient safety, most institutions have developed policies and procedures for moderate sedation/analgesia with the help of the anesthesiologists. An ASA task force has published practice guidelines for sedation and analgesia by nonanesthesiologists to assist anesthesiologists in the process of developing these institutional policies. The ASA practice guidelines define four levels of sedation that represent a continuum (Table 50.1). At one end of the spectrum is “minimal sedation,” which may progress to “moderate sedation/analgesia (conscious sedation)” to “deep sedation/analgesia,” and finally to “general anesthesia.”

Moderate sedation/analgesia (formerly known as “conscious sedation”) is defined as a medically controlled state of depressed consciousness that allows protective reflexes to be maintained, retaining the patient’s ability to maintain a patent airway and to respond to verbal and physical stimulation. A “conscious sedation” case therefore should never exceed the level of moderate sedation. Sedation beyond moderate sedation may lead to airway compromise and the immediate need for airway intervention to avoid adverse patient outcome.

Most institutions exclude high-risk patient groups from undergoing moderate sedation/analgesia (e.g., patients with morbid obesity, chronic pain issues, sleep apnea, severe cardiac, pulmonary, hepatic, renal, central nervous system disease) and require anesthesiologists to provide MAC or general anesthesia for these patient groups.

Sedation with propofol is classified as deep sedation by the ASA practice guidelines. Therefore, most institutions exclude propofol and sometimes other medications from being used by nonanesthesiologists in an attempt to avoid adverse patient outcomes. In addition, institutions often require nonanesthesiologists to undergo training in monitoring, resuscitation skills, and

Table 50.1. Continuum of depth-of-sedation definitions

Parameter	Minimal sedation (anxiolysis)	Moderate sedation/analgesia (conscious sedation)	Deep sedation/analgesia	General anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal or tactile stimulation ^a	Purposeful response following repeated or painful stimulation ^a	Unarousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

^a Reflex withdrawal from a painful stimulus is *not* considered a purposeful response.

From ASA. Continuum of Depth of Sedation Definition of General Anesthesia and Levels of Sedation/Analgesia. (Approved by ASA House of Delegates on October 13, 1999 and amended on October 27, 2004.)

medication knowledge before they are given privileges to provide moderate sedation/analgesia.

Indications for MAC

Choosing MAC as the anesthetic technique over regional techniques or general anesthesia depends on various considerations, such as the type of procedure; the patient's medical condition, including the patient's mental status; specific positioning requirements during the procedure; and the surgeon's and patient's preference. Examples of procedures that are usually well tolerated under MAC are breast biopsy, indwelling central venous catheter placement, eye operations, minor plastic surgery, diagnostic cystoscopy, hysteroscopy, dilatation and curettage (D&C), creation of AV fistula for dialysis access, insertion of pacemaker or ICD, many interventional radiology cases, and upper and lower gastrointestinal endoscopic procedures.

Communication with the surgeon and the patient about the advantages and limitations of MAC prior to the start of the procedure facilitates the successful conduction of a MAC anesthetic.

Preprocedure evaluation

A thorough preprocedure evaluation must be completed, an anesthetic plan formulated, and informed consent obtained for every patient scheduled for MAC. The patient must be informed that although a MAC anesthetic is planned, there is always a possibility that it may get converted to a general anesthetic in order to complete the procedure safely. A detailed medical history and focused physical examination with emphasis on airway evaluation must be performed, along with a review of current medications and any drug allergies. The patient's medical condition should be optimized prior to the planned procedure, and the indicated laboratory workup and diagnostic studies should be ordered. ASA fasting guidelines should be used and are the same as those for a general anesthetic.

Monitoring

The standards for basic monitoring apply to all patients under the care of an anesthesiologist, regardless of whether the anesthetic is general, regional, or MAC.

The continuous presence of a qualified anesthesia provider (an anesthesiologist or, in the case of medical direction, a certified registered nurse anesthetist/anesthesia resident) is a requirement for the conduct of MAC (monitoring standard I as defined by the ASA). There is no substitute for a vigilant anesthesia caregiver. Continuous observation of the patient, along with verbal communication, provides a wealth of information in a dynamic clinical situation. In addition, every patient must have the following parameters continually monitored: oxygenation, ventilation, circulation, and body temperature (basic anesthetic monitoring standard II as defined by the ASA).

Techniques for MAC

Patient safety and operating conditions that facilitate timely and satisfactory completion of the procedure are the key goals from the provider's perspective. Generally, the following end points must be met: analgesia, sedation/comfort, anxiolysis, and early discharge/return to baseline function. In addition to verbal reassurance and preemptive communication with the patient, a variety of medications may be used to achieve the aforementioned end points. The surgeon will commonly inject local anesthetic to provide analgesia. The anesthesiologist is in a position to advise the surgeon about the maximum allowable dose to prevent local anesthetic toxicity and be constantly vigilant for symptoms and signs of toxicity. The anesthesia provider must be prepared to manage this potential complication immediately.

Systemic agents used for MAC

The ideal drug used during MAC should have a quick onset of action, minimal side effects, a high therapeutic index, short duration of action, and rapid elimination (noncumulative). The aim is to have a rapid return to baseline status and to facilitate early discharge. Some key pharmacologic concepts with which the anesthesiologist should be familiar are ESET (effect site equilibration time), therapeutic index, and context-sensitive half-time (see Part 6 in this book). Drugs may have a synergistic or additive effect, and there may be considerable interpatient variability. Various techniques ranging from intermittent boluses to multiple concurrent continuous infusions of drugs

Table 50.2. Commonly used intravenous agents in MAC

Desired end point	Drug group	Commonly used agents
Sedation	Benzodiazepines	Midazolam
	α_2 -Agonists	Dexmedetomidine
Hypnosis	Hypnotics	Propofol
Analgesia	Opioids	Fentanyl
		Alfentanil
		Remifentanil
Amnesia	Nonopioids	Ketamine
	Benzodiazepines	Midazolam

to achieve the goals of providing sedation and analgesia have been described. Table 50.2 provides a summary of common intravenous (IV) agents used to achieve the different end points of MAC; Table 50.3 provides examples of dosing regimens of these drugs.

The most important pharmacologic principle in this setting is “titration to effect.” To help prevent overdosing, titration involves ensuring that the drug administered into the IV tubing is actually being delivered into the patient’s circulation, and also waiting for the peak effect prior to redosing. Heightened caution is especially important in the elderly and in patients who have multiple comorbid conditions. The changing level of stimulation and the concurrent use of multiple drugs may result in undesirable end points in spite of using a conservative approach. The anesthesiologist may have to temporarily support the patient’s airway and ensure adequate ventilation.

Benzodiazepine and opioid antagonists

Sometimes pharmacologic agents may have to be given to reverse the unintended side effects of administered drugs such as benzodiazepines and opioids. Flumazenil is a specific competitive benzodiazepine antagonist that can reverse the sedation as well the ventilatory depression produced by benzodiazepines. It can be titrated in increments of 0.2 mg IV at 60-second intervals (total dose of 1 mg IV) until the desired level of consciousness is achieved. Naloxone is an opioid antagonist that reverses all opioid effects, including ventilatory depression and analgesia. It is titrated in 20- to 40- μ g IV increments. It produces peak effects in 1 to 2 minutes, and titration is essential to avoid severe pain in patients. Sudden, complete

Table 50.3. Typical dosing regimens for MAC

Drug	Induction bolus dose	Maintenance infusion rate, μ g/kg/min	Maintenance intermittent boluses
Midazolam	0.5–5 mg	–	0.5–2 mg
Propofol	10–80 mg	10–75	10–50 mg
Fentanyl	25–50 μ g	0.01–0.03	25–50 μ g
Alfentanil	20–50 μ g	0.25–1	20–50 μ g
Remifentanil	10–25 μ g	0.025–0.1	10–25 μ g
Ketamine	10–50 mg	2–10	10–50 mg
Dexmedetomidine	1.0 μ g/kg over 10–20 min	0.2–1.0 μ g/kg/h	10–30 μ g

Table 50.4. Benzodiazepine and opioid antagonists

Factor	Flumazenil	Naloxone
Antagonist	Benzodiazepines	Opioids
Dose	0.2 mg IV	40 μ g IV
	Repeat 0.2 mg every 1 min maximum	Repeat to effect every 1–2 min
	1 mg IV	
Duration of action	30–60 min	30–45 min
Side effects	Seizures	Reversal of analgesia
	Agitation/confusion	Nausea and vomiting ¹
	Acute anxiety	Hypertension, tachycardia, ventricular dysrhythmias
	Sweating or shivering	Pulmonary edema
	Blurred vision	
	Headache	

¹ Dependent upon the prior dose of opioid and the dose of naloxone; an antagonist like naloxone might be very effective in treating opioid-induced nausea and vomiting.

antagonism of opioid effects may cause hypertension, tachycardia, ventricular dysrhythmias, and pulmonary edema. Table 50.4 lists these two antagonist agents and provides a brief summary of the key pharmacologic features.

Discharge criteria

Postprocedure, a patient who has undergone MAC has to be monitored under the care of a registered nurse who has the clinical skills and core competencies required in a postanesthesia care unit (PACU) until discharge criteria are fulfilled. The anesthesiologist should be immediately available to address any patient management issues during the recovery phase. Return to baseline mental status, minimal pain, vital signs within 20% of preprocedure values, and control of nausea and vomiting must be achieved prior to discharge. A responsible adult must be available to escort the patient home and observe the patient for any unexpected events in the postprocedure period. A patient who has undergone MAC must be provided the same standard of postprocedure care given to patients who underwent a regional or general anesthetic.

Outcomes and safety of MAC

MAC sometimes is requested for patients who are considered “too sick” to have a general anesthetic. In addition, anesthesiologists are being asked to provide this care in settings remote from the operating room with greater frequency. Some of the factors that contribute to adverse outcomes are the use of multiple drugs, inadequate monitoring, and lack of timely resuscitation efforts. Combining a benzodiazepine with an opioid may result in frequent episodes of hypoxemia and apnea. Administering propofol with opioids produces a synergistic or additive effect and diminishes the ventilatory response to hypercarbia. A recently published Closed Claims analysis revealed that “respiratory depression after absolute or relative overdose of a combination of sedative and/or opioid drugs was the most common specific damaging event in claims

associated with Monitored Anesthesia Care.” In addition, “nearly half of these claims were judged preventable by better monitoring, including capnography, improved vigilance, or audible alarms.” In this claims analysis, although death or permanent brain damage was present with similar frequency whether the claim was filed for a MAC or general anesthetic, patients undergoing MAC were found to be sicker and older than those who had a general anesthetic. The authors concluded that the use of capnography as a monitor for ventilation may enhance patient safety. Current ASA practice guidelines state that “continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure or equipment.”

Conclusion

MAC is a safe anesthetic technique when it is chosen for the right procedure in a patient who has been medically optimized. It allows the anesthesiologist an opportunity to provide a more intimate level of care and reassurance to patients than can be given during most general anesthetics. Patients undergoing MAC deserve the same level of vigilance and care before, during, and after the procedure. One might say that MAC should

stand for *maximum anesthesia caution*, not *minimal anesthesiology care*.

Patient positioning and common nerve injuries

Christian D. Gonzalez

Introduction

Although monitoring vital signs is an important part of the anesthesiologist's responsibility perioperatively, it is far from being the sole task. As advocates of patient safety, anesthesiologists are also involved in setting and monitoring the patient's position during surgery.

Because nerve injuries resulting from patient malpositioning may lead to serious morbidity, the American Society of Anesthesiologists (ASA) published a practice advisory for the prevention of peripheral neuropathies associated with positioning in the perioperative period. Furthermore, a task force was created aiming at practice improvement based on limited available scientific data. In this chapter, we discuss the most common patient positions during surgery; explore how patient positioning may lead to adverse outcomes, particularly nerve injuries; and review the current guidelines for preventing nerve injuries due to malpositioning.

Preparation

Planning the intraoperative patient position begins in the preoperative visit. At this time, the anesthesiologist should have an understanding of the procedure and the patient's expected position during surgery. This knowledge helps determine which structures are at high risk of injury. Any existing nerve injury should be documented carefully, with emphasis on focal motor or sensory deficits. Examples include a history of hand numbness, radicular pain in the extremities, and chronic back pain. There are other aspects of the medical history that are important risk factors associated with adverse outcomes due to positioning. The ASA task force enumerated six risk factors:

- Preexisting neurologic symptoms
- Body habitus
- Diabetes mellitus
- Peripheral vascular disease
- Alcohol dependency
- Arthritis

Thus, a thorough knowledge of the patient's medical history is vital in assessing the risk of nerve injury due to positioning. In addition, during the preoperative visit, the practitioner should discuss with the patient any potential risks of nerve injury. The patient's position during surgery is a joint decision between the

surgeon seeking to facilitate surgery and the anesthesiologist assessing for risk of injury. After induction of anesthesia and once a sterile field has been created, the patient's position is final.

Monitoring

After the patient has been positioned in the operating room, the anesthesiologist must make one final position check before the sterile field is created: All pressure points must be cushioned and vulnerable joints well supported. The patient under general anesthesia should look as if sleeping comfortably.

There are many instances during surgery in which patient movement or change in position might occur, potentially leading to adverse outcomes. For example, the surgeon might lean on the patient's arm or face, the Trendelenburg position might be too steep, or the patient's arm might fall off the arm board. Constant monitoring, quick assessment, and possible correction of these changes are of the utmost importance in preventing adverse outcomes. General preparation and monitoring of the patient's position are indeed essential to prevent nerve injury. However, specific knowledge of different surgical positions, and the risks associated with them, is equally important.

Common positions and their related injuries

Supine position

The supine position is the most common position during surgery (Fig. 51.1). The arms may be abducted or adducted

Figure 51.1. Supine position.

Figure 51.2. Arm positioning: olecranon, ulnar nerve, and surrounding structures.

depending on the type of surgery and the surgeon's preference. When the arm is in the *abducted* position, the ASA task force recommends that the angle be $\leq 90^\circ$. In fact, multiple studies have demonstrated that arm abduction beyond 90° is associated with brachial plexus injury. In the abducted position, the ASA recommends placing the forearm so that the olecranon process rests on the padded board, minimizing pressure on the ulnar nerve (Fig. 51.2). However, for some patients this position may be uncomfortable. Furthermore, upper-extremity supination may cause brachial plexus stretching. The decision to pronate or supinate often is made by the anesthesiologist based on the patient's comfort, before induction of anesthesia. The ASA task force generally advises that the forearm be supinated or placed in a neutral position. When the *adducted* position is selected, care must be taken to avoid arm compression by any external device (e.g., metal side rails) and to ensure appropriate padding. The forearm should be placed in a neutral position.

The most common nerve injury following surgery is ulnar neuropathy. There is evidence that placement of the arm in a nonsupinated position may contribute to the development of ulnar neuropathy. Although classically this injury was believed to always be the result of compression of the ulnar nerve at the level of the elbow, more recent nerve conduction studies have proved this belief incorrect. Current data indicate that the patient's susceptibility to injury, in the form of preexisting illness or other risk factors, may play a more important role. It is important to note that 40% of the general, asymptomatic population has anatomic variations of the ulnar nerve at the elbow. For this reason, it is important to pad generously around the medial epicondyle.

Although less common, other nerve injuries may occur in the supine position. Relaxation of the paravertebral spine muscles secondary to anesthesia may cause the loss of normal lumbar lordosis. If the patient has chronic low back pain secondary to herniated disks, listhesis, or other abnormalities of the spine, there is a likelihood that the patient may suffer from nerve root compression or radiculopathy. Radial nerve injury also may occur, most often as a result of external pressure on the nerve as it traverses the spiral groove of the humerus in the lower third of the arm. At this point, it is most sensitive to injury

secondary to pressure. Caution should be exercised to avoid any external pressure on the patient's arms, especially in the presence of metal side frames. Finally, focal alopecia also has been documented with the supine position. It can be prevented by moving the patient's head every 2 hours or using a foam pad.

Prone position

Potential pressure points in the prone position (Fig. 51.3) include the cheek, ear, acromion process, breasts (women), genitalia (men), patella, and toes. In the prone position, the head may be tilted to one side; however, this may worsen any pre-existing cervical spine pathology. It is recommended that for any patient with cervical spine pain or cerebral vascular disease placed in the prone position, specialized padding be used to keep the head in the neutral position. However, care must be taken not to cause pressure buildup on the face, especially the eyes, as this may lead to retinal ischemia. The arms may be placed at the patient's sides or flexed at the elbow and shoulder and placed on arm boards alongside the patient's head. Pads or rolled towels may be used to support areas of the arms suspended. A pillow usually is placed under the lower legs to alleviate pressure on the toes and feet. If the arms are to be placed above the patient's head, a preoperative examination should rule out thoracic outlet syndrome, which might lead to brachial plexus injury. If the arms are to be placed alongside the patient's body, attention must be given to placing the padding above the elbow to prevent equipment or personnel-related pressure over

Figure 51.3. Prone position.

Figure 51.4. Lateral decubitus position.

the ulnar nerve. The patient may require a chest roll to allow for diaphragmatic excursion.

Lateral decubitus position

Potential pressure points in the lateral decubitus position include the ear, acromion process, ribs, ilium, greater trochanter, medial and lateral condyles, and malleolus (Fig. 51.4). The lateral decubitus position also places the patient at an increased risk for brachial plexus injury. Typically, the bottom arm is placed in an arm board and the top arm is supported by a pillow or other supporting devices parallel to the lower arm. An axillary roll helps prevent damage to the brachial plexus. However, if the axillary roll is displaced or misplaced, pressure over the head of the humerus may result in a brachial plexus injury secondary to compression. Stretching of the brachial plexus of the nondependent upper extremity can be limited by aligning the cervical and thoracic spine and keeping the head in the neutral position. Care must be taken to avoid pressure over the axilla, which may cause compression of the brachial plexus and nerve damage. Proper head support also prevents straining of the spinal facet joints. The patient's head can be supported by a pillow, keeping the head in normal anatomic alignment with the rest of the body. The patient's bottom leg should be flexed, and a pillow should be placed between the legs.

Lithotomy position

The use of the lithotomy position is associated with multiple peripheral nerve injuries (Fig. 51.5). The nerves at increased risk for injury are the femoral, common peroneal, sciatic, saphenous, and obturator nerves. Reducing the risk of injury to these nerves is accomplished by proper padding over susceptible areas. These vulnerable nerve sites should be clear of hard surfaces or metal braces.

If shoulder braces are used, the patient is at a higher risk for injury. The use of these braces has become more controversial, and there is now evidence that they are associated with brachial plexus injury, likely as a result of the weight of the torso compressing the plexus. A patient with a history of lumbosacral spine pathology also is at an increased risk for worsening symptoms. The best way to prevent further injury is

Figure 51.5. Lithotomy position.

to have the patient try the position while awake and report any discomfort.

Trendelenburg position

The Trendelenburg (or “head-down”) position (Fig. 51.6) is common, especially during laparoscopic surgery. In this position, the patient may be at a high risk for brachial plexus injury, especially if pressure is placed on the shoulders to prevent the patient from sliding in the cephalad direction.

Sitting position

Potential pressure points in the sitting position include the scapulae, ischial tuberosities, back of the knees, and calcaneus. Common nerve complications of the sitting position include excessive neck flexion leading to spinal cord ischemia, and sciatic nerve injury from excessive lower-extremity extension.

Subsequent care of nerve injury

Intraoperative positional nerve injuries manifest immediately when the patient wakes from surgery. A delayed diagnosis is not uncommon, however, and may be secondary to the postoperative patient being intubated, sedated, casted, or not ambulatory. The deficit is usually most severe immediately after surgery

Figure 51.6. Trendelenburg position.

and often improves with time. The anesthesiologist should be informed as soon as possible of any adverse outcomes in the perioperative period. In case of suspected nerve damage, a detailed history should be taken and a focused physical examination performed. Sensory or motor changes should be noted and compared with the preoperative assessment.

If nerve injury is suspected after the initial assessment, a neurology consultation should be obtained for further examination and testing. The hiatus for a neurology consult should be within the first 2 weeks postinjury. Testing within this time-frame is important to determine the temporal nature of the nerve injury. Electromyography (EMG) may show no changes within the 2-week time period if the injury is acute. If the injury is chronic (preexisting), the EMG may be abnormal within that period. If testing is done beyond that, EMG may be positive for both acute and chronic injuries. Thus, the combination of initial testing within the first 2 weeks and repeated testing after this period will allow determination of whether the nerve injury occurred during surgery or was preexisting. The operative position used should be reviewed carefully by the surgeon and anesthesiologist. Any erythema or other skin changes indicative of prolonged pressure should be documented. The alternative diagnosis of an inflammatory (noncompressive) neuritis can be ruled out if the neurologic deficit is present immediately after surgery, because neuritis often takes several days to develop. Some practitioners also test the opposite limb to determine whether there are any unrecognized abnormalities that might predispose the patient to injury.

If a diagnosis of acute peripheral neuropathy is made, the patient should be reassured that most symptoms resolve within the first 6 weeks. Symptoms will resolve faster if the nerve injury causes only a sensorial deficit. Studies show that up to 80% of patients have no residual symptoms 6 months after the injury. Persisting pain can then resolve within the year. However, after

1 year, only a minority will get better within 24 months and after that the symptoms will more than likely be permanent. If the symptoms do not improve within 6 weeks, or if there is disruption of daily living activities, the patient should be referred to a pain management specialist. Although interventions such as nerve blocks will not hasten overall recovery, pain relief can allow more aggressive physical therapy. This is particularly important because physical therapy decreases the incidence and severity of complex regional pain syndrome and allows faster recovery of function.

Managing the Transition from Anesthesia

Robert M. Knapp, editor

Emergence from anesthesia

Michael P. Storey and Richard D. Urman

Emergence from anesthesia is a critical time for the patient and the anesthesia provider. As surgery comes to a close, a patient emerging from anesthesia requires the full attention and focus of the anesthesia provider. At the end of anesthesia and surgery, the patient should typically be awake or easily arousable, be able to protect the airway, maintain adequate ventilation, and have his or her pain adequately controlled. Time to emergence from anesthesia varies, depending on many patient factors as well as the type and length of surgery and the type of anesthetic administered.

Delayed emergence

Delayed emergence or awakening is common after prolonged surgery and anesthesia. Although no specific definition of delayed awakening exists, it is commonly described as the case in which a patient takes longer to awaken from a specific circumstance than a clinician would expect. The causes of delayed awakening from anesthesia are listed in [Table 52.1](#).

Residual drug effects

Most often, delayed awakening may be attributed to the residual effects of drugs. The speed of emergence from a volatile anesthetic primarily depends on the patient's alveolar ventilation and the anesthetic's blood/gas solubility. Less soluble agents, such as nitrous oxide and desflurane, are eliminated faster than more soluble agents, such as isoflurane. In addition, hypoventilation will result in prolonged emergence. Finally, as a case lengthens, the anesthesia provider must factor in the anesthetic agent's total tissue uptake that is related to the drug's solubility, the concentration being delivered, and duration of administration. End-tidal gas monitoring is now used routinely, and it is important to ascertain that it is working properly. Using a bispectral index monitor may provide an estimate of the level of consciousness if an unexpected delay is encountered.

Table 52.1. Causes of delayed awakening from anesthesia

Residual drug effects
Respiratory failure (hypercarbia and reduced oxygen delivery)
Cardiovascular complications
Metabolic derangements
Neurologic complications

The anesthesia provider should always suspect a drug overdose or error, as well as the possibility of an increased sensitivity to a particular drug. This may be particularly true of elderly and chronically ill patients and patients with impaired drug metabolism because of underlying liver, kidney, or enzymatic deficiency. It is important to assess for the possibility of an overdose of the commonly used medications, such as benzodiazepines, opioids, and neuromuscular blockers.

For intravenous (IV) anesthetic agents, immediate recovery generally depends on redistribution from the brain to less vascular organs, muscle, and fat. Propofol is rapidly metabolized in the liver, with a short terminal half-life and minimal accumulation over time. Thiopental, a formerly popular induction agent, is metabolized at a slower rate and has a longer terminal half-life than propofol. As a result, it may demonstrate cumulative effects following higher doses.

Respiratory failure

Respiratory failure may lead to delayed emergence. Hypoventilation may lead to hypercarbia that can cause sedation and even unconsciousness (i.e., carbon dioxide [CO₂] narcosis) when profound. Respiratory failure may be a result of a preexisting condition such as chronic obstructive pulmonary disease but also may be the result of persistent paralysis from neuromuscular blockers, respiratory depression following opioids, or airway obstruction. In this case, a blood gas measurement may be helpful.

Cardiovascular complications

Cardiovascular causes of delayed emergence, such as heart failure, cardiac arrhythmias, or hypotension, may result in inadequate delivery of blood and oxygen to the brain. The hypotension should be reversed (by IV fluids or blood products and/or vasopressors, as appropriate) and the underlying rhythm and contractility issues treated appropriately.

Metabolic causes

Hypoglycemia may occur in patients taking insulin or oral hypoglycemics. It is more common in infants and in patients with liver failure. Hyperglycemia may occur in diabetic patients, possibly leading to diabetic ketoacidosis or diabetic coma.

Table 52.2. Stages of anesthesia

Stage	Description
I	Amnesia, induction of anesthesia to loss of consciousness
II	Delirium, excitation, potential for vomiting, laryngeal spasm, hypertension, tachycardia, uncontrolled nonpurposeful movements, dilated pupils
III	Surgical anesthesia, constricted pupils, regular respiration, adequate anesthetic depth, prevention of hypotension and tachycardia, absence of movement
IV	Overdosage; shallow or no respiration; dilated, nonreactive pupils; hypotension

Serum glucose should be checked if an abnormal glucose level is suspected. Serum electrolytes should be checked to detect a sodium, potassium, calcium, or magnesium imbalance.

Severe hypothermia may lead to reduced consciousness. Body temperature in the low 30°C range may lead to respiratory depression, potentiate the central nervous system effects of anesthetic drugs, reduce the minimum alveolar concentration of inhalational anesthetics, potentiate muscle relaxants, and slow metabolism of other drugs.

Neurologic complications

It also is important to rule out neurologic causes of delayed awakening, such as increased intracranial pressure, cerebral hemorrhage, and air or fat embolism. If a neurologic cause is suspected, a neurologic consultation should be ordered and the patient should remain intubated until all the potential causes are explored.

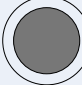

Extubation

Near the end of emergence, the anesthesia provider must decide when to remove the airway device – generally an endotracheal tube (ETT) or a laryngeal mask airway (LMA). If the ETT or LMA is removed too early, the patient may not adequately breathe or protect the airway. If the patient is still in stage II of anesthesia (see Tables 52.2 and 52.3), the patient may develop laryngospasm or not be able to support his or her airway. However, if the ETT or LMA is in place when the patient is fully conscious, it may cause severe discomfort to the patient.

Extubation criteria

Extubation criteria are listed in Table 52.4. Ideally, the patient should be able to perform simple actions on command, such as eye opening, hand grasping, or holding his or her head off the operating table for at least 5 seconds. Additionally, the anesthesia provider should assess for other useful extubation criteria, such as a regular respiratory pattern, a respiratory rate of <30 breaths per minute, tidal volumes of at least 5 ml/kg, positive end-expiratory pressure (PEEP) requirements ≤ 5 cm H₂O, and a negative inspiratory force > -20 cm H₂O. It is also important to ensure that the patient is not hypoxic or hypercarbic (end-tidal CO₂ < 50 mm Hg). A vital capacity > 10 ml/kg indicates

Table 52.3. Effects of anesthesia at different stages

Stage	Pupil	Pulse	Blood pressure	Respiration
I (induction)		Fast	Baseline	Normal
II (excitement)		Fast	High	Automatic and regular
III (surgical)		Slow	Baseline	Intercostal muscle paralysis
IV (overdose)		Weak, thready	Low	Diaphragmatic paralysis

that the patient's coughing should be able to clear secretions and help maintain airway patency.

For extubation to be attempted, the patient should be breathing 100% oxygen with a high flow rate. The increased flow rate will help expedite the removal of residual anesthetic gases from the patient and the anesthesia circuit. If the anesthesia provider believes extubation can be performed successfully, the patient's oropharynx should be gently suctioned to remove any secretions from above the cuff of the ETT. After suctioning, the ETT cuff should be fully deflated, the reservoir bag squeezed, and the breathing tube gently removed from the trachea. The purpose of squeezing the reservoir bag is to create a positive pressure, thereby helping to blow any remaining secretions above the ETT cuff upward, instead of allowing them to fall onto the vocal cords. The anesthesia mask should then be attached to the anesthesia circuit and placed on the patient to ensure he or she is breathing adequately after extubation. After it has been determined that the patient can maintain a patent airway and adequate oxygenation while breathing spontaneously, supplemental oxygen may be delivered via a simple face mask or nasal cannula may be used during transport to the postanesthesia care unit (PACU).

Airway complications during emergence

Upper airway obstruction

Upper airway obstruction in a patient emerging from anesthesia may occur for a variety of reasons. Possible causes include

Table 52.4. Extubation criteria

Negative inspiratory force > -20 cm H ₂ O
Tidal volume > 5 ml/kg
PaO ₂ 65–70 mm Hg on FiO ₂ $< 40\%$
Respiratory rate < 30 /min
Vital capacity > 10 ml/kg
PaCO ₂ < 50 mm Hg
PEEP < 6 cm H ₂ O

secretions, glottic edema, and foreign bodies such as teeth or dentures, secretions, blood, or vomit. The most common cause of upper airway obstruction is the tongue. Airflow is blocked when the tongue falls back into a position that occludes the pharynx, resulting in a partial or total obstruction. Common signs and symptoms of upper airway obstruction include snoring, intercostal and suprasternal retractions, paradoxical respirations, and use of the accessory muscles of respiration. To relieve an upper airway obstruction, a patent airway must be established. This can often be accomplished simply by stimulating the patient, repositioning the head, or using the “head tilt, chin lift” technique or a jaw thrust. At times, an airway adjunct such as a nasal or oral airway may be needed.

Laryngospasm

Laryngospasm is a true life-threatening emergency. Laryngospasm occurs with stimulation of the superior laryngeal nerve, when the vocal cords spontaneously close and remain closed. This may be the result of light anesthesia, irritating gas in the airway, or a mechanical cause such as instrumentation in the airway or secretions falling onto the vocal cords. Signs and symptoms of laryngospasm include the inability to ventilate the patient, acute respiratory distress, absent breath sounds, severe agitation, and oxygen desaturation.

Laryngospasm must be treated immediately. Suctioning of the oropharynx and positive pressure ventilation with 100% oxygen should be initiated at once. Maintaining PEEP may be helpful. Performing a jaw thrust while applying positive pressure with a tight-fitting anesthesia mask and inserting an oral or nasal airway also may be helpful. These maneuvers often are enough to break intermittent or complete laryngospasms. However, if they fail, 10 to 20 mg of IV succinylcholine may be administered to aid in breaking the laryngospasm.

Laryngeal edema may cause swollen vocal cords to approximate and, as a result, allow little air to pass; it is characterized by a high-pitched inspiratory noise. Laryngeal stridor is often confused with a partial airway obstruction. Initially, treatment should include suctioning the oropharynx or performing a “head tilt, chin lift” or jaw thrust. If the patient still remains stridorous, additional options include placing an oral or nasal airway and, finally, attempting continuous positive airway pressure (CPAP) with a tight-fitting anesthesia mask. If stridor still does not resolve, it most likely is laryngeal in nature. Treatment in this case consists of racemic epinephrine (0.5 ml in 2 ml normal saline) via a nebulizer. These measures are usually adequate. However, if the patient is still struggling to breathe, heliox with a maximum fraction of inspired oxygen content (FiO_2) of 35% may be instituted. When heliox is administered, an $\text{FiO}_2 > 35\%$ may be ineffective because of the increasing density of the gas mixture with increasing FiO_2 . In addition to heliox, mild sedation and anxiolysis may be beneficial.

Bronchospasm

Bronchospasm is caused by increased bronchial smooth muscle tone. A bronchospastic patient experiences closure of the

small airways, resulting in “tight” breathing. Patients with reactive airway disease and smokers are at greater risk than others for bronchospasm. These patients may be treated prior to induction and emergence with a β_2 -agonist bronchodilator such as albuterol. Bronchospasm also may be the result of aspiration, secretions, airway instrumentation, or reaction to medications. Any mechanical triggers of bronchospasm, such as oropharyngeal secretions, should be removed or alleviated. Patients are then usually treated with β_2 -agonists via a nebulizer or inhaler. If the bronchospasm is life threatening, epinephrine may be administered endotracheally or IV.

Pulmonary aspiration

Aspiration during emergence may result in severe hypoxemia and morbidity. An actively vomiting patient should be vigorously suctioned in a head-down tilt. Aspiration of gastric contents may lead to adult respiratory distress syndrome, hypoxia, atelectasis, bronchospasm, infection, or chemical pneumonitis. Aspiration is treated by alleviating the hypoxemia, maintaining airway patency, and supporting hemodynamic status. Antibiotics should be given only in response to culture-proven pneumonia. Some patients who have aspirated gastric contents may need to remain intubated postoperatively to prevent hypoxemia.

Pulmonary edema

Pulmonary edema is characterized by engorgement of the perivascular and peribronchial interstitial tissues and by alveolar edema. During emergence, it is often the result of one of two causes.

Negative pressure pulmonary edema occurs when a patient creates a strong negative pressure within the chest. This often results from an attempt to take a large-volume breath through a small ETT or to breathe against a closed glottis. Negative pressure pulmonary edema may result in severe hypoxemia. Supportive treatment, including reintubation, is often necessary.

Pulmonary edema that is cardiac in nature may occur during emergence and extubation. Treatment of cardiogenic pulmonary edema also begins with supplemental oxygen therapy. Occasionally patients may need to be reintubated or placed on CPAP to maintain oxygenation. Therapy such as furosemide diuretics and fluid restriction also may be beneficial to the patient postoperatively.

Hypoventilation

Hypoventilation is a common finding after general anesthesia, especially if opioids have been given. Depression of respiratory drive, inadequate reversal of paralytics, pain from surgery, and neuromuscular disease also may result in hypoventilation. Hypoventilation is often defined as a $\text{PaCO}_2 > 45$ mm Hg, although it often is clinically apparent only when the PaCO_2 rises above 60 mm Hg and the arterial pH is < 7.25 . A prominent sign of hypoventilation is a decreased respiratory rate and tidal volume. There may or may not be a concurrent decrease in

Table 52.5. Common causes of emergence delirium

Physiologic		Pharmacologic
Hypoxemia	Gastric dilation	Ketamine
Hypercapnia	Bladder distention	
Electrolyte imbalance	Pain	Benzodiazepines
Alcohol withdrawal	Hypothermia	Metoclopramide
Intracranial injury	Sensory overload	Atropine, scopolamine
Sepsis	Sensory deprivation	Inhalational anesthetics

oxygen saturation, especially if the patient had been ventilated with a high concentration of oxygen. Treatment should be aimed at the underlying cause, such as treating opioid overdose with naloxone in titrated doses and fully reversing neuromuscular blocking drugs. Adequate ventilation should be assured either by assisting the patient's respirations or through positive pressure ventilation.

Emergence delirium

Emergence delirium or agitation may be caused by a variety of factors, both physiologic and pharmacologic (Table 52.5). It often occurs in very young or in elderly patients. Emergence delirium is characterized by severe disturbances in attention, orientation, perception, arousal, and intellectual function. It is often associated with fear and agitation, occasionally requiring the use of restraints to prevent injury to the patient or care

providers. Periods of excitement or agitation may be followed by periods of lethargy and inappropriate behavior.

Arterial hypoxemia or hypercapnia should be ruled out as a cause of agitation, as should possible pharmacologic or physiologic causes. Benzodiazepines may be useful for sedating and calming patients. Other useful agents include physostigmine, haloperidol, analgesics, and α_2 -agonists (e.g., dexmedetomidine). Fortunately, most incidences of emergence delirium are time limited and resolve prior to the patient's discharge from the PACU.

Postoperative complications in the PACU

Ala Nozari and Edward A. Bittner

Patients are often admitted to a postanesthesia care unit (PACU) for recovery after procedures that require anesthesia or sedation. It is essential that specially trained personnel are immediately available to supervise the postprocedural care of these patients, particularly if they have complicating medical problems or have undergone challenging surgical procedures. Complications in the PACU are common (Fig. 53.1). Anticipation, identification, and timely management of postoperative problems lead to decreased perioperative morbidity and mortality, improve the overall care, and enhance patient satisfaction.

The American Society of Anesthesiologists (ASA) has published standards for postoperative care (Table 53.1). These standards provide five general principles intended to ensure safe postoperative recovery.

Patients admitted to the PACU should be monitored and assessed as follows:

- Respiratory: respiratory rate, oxygen saturation, airway patency
- Cardiovascular: heart rate, blood pressure, electrocardiogram (ECG)
- Neuromuscular strength
- Pain
- Mental status
- Nausea or nausea/vomiting (see Chapters 41 and 54)
- Temperature
- Urine output
- Surgical site bleeding or drainage

Airway obstruction

Complete or partial airway obstruction is among the most common perioperative complications and without treatment, it may lead rapidly to life-threatening hypoxemia. Pharyngeal obstruction caused by posterior tongue displacement or soft tissue collapse can be managed successfully with simple maneuvers such as a chin lift, jaw thrust, and lateral decubitus positioning. Nasopharyngeal or oropharyngeal airways may be helpful but are not always tolerated by awake patients. Laryngeal or subglottic edema is often treated with head-up positioning and nebulized epinephrine and steroids, but it may require emergency reintubation or tracheostomy.

Laryngospasm may be precipitated by the presence of an airway irritant such as blood or secretions, or by the insertion of an oropharyngeal airway or other foreign bodies. Unrelieved laryngospasm may lead to the development of negative pressure pulmonary edema. Jaw thrust and positive pressure ventilation may be helpful, but occasionally a small dose of succinylcholine or intravenous (IV) anesthetic may be required to relieve the spasm.

Other common postoperative complications that may result in complete or incomplete airway obstruction include direct laryngeal trauma, extrinsic airway compression from an expanding neck hematoma, and vocal cord paralysis caused by recurrent laryngeal nerve injury. Unilateral vocal cord paralysis results in hoarseness, with the ipsilateral vocal cord fixed in a paramedian position, whereas bilateral paralysis results in airway occlusion and requires emergent intubation or a surgical airway.

Exacerbation of obstructive lung disease is frequent in the postoperative course of patients with preexisting disease and may require treatment for bronchospasm and airway inflammation, as well as correction of hypoxemia and hypercapnia.

Hypoxemia

Common causes of hypoxemia ($\text{PaO}_2 < 60$ mm Hg) in the early postoperative period include hypoventilation and atelectasis. Hypoventilation may be caused by respiratory muscle weakness, decreased ventilatory drive, or exacerbation of chronic pulmonary disease. Incomplete reversal of neuromuscular blockade, more commonly observed in patients who receive long-acting muscle relaxants such as pancuronium, may result in generalized weakness with uncoordinated movements, shallow breathing, atelectasis, and hypoxemia.

Inadequate analgesia, gastric distention, restrictive surgical dressings, and obesity may increase the work of breathing and contribute to the development of respiratory failure and hypoxemia. Residual anesthetics and ventilatory depression from opioids and benzodiazepines also may cause significant hypoventilation with carbon dioxide retention, respiratory acidosis, and hypoxemia.

A cerebrovascular accident should be ruled out in a patient with hypoventilation and altered mental status.

Figure 53.1. Major PACU complications by percentage of occurrence, from a prospective study of 18,473 patients. Reproduced with permission. (From Hines R, et al. Complications occurring in the postoperative care unit: a survey. *Anesth Analg* 1992; 74:503–509.) ROMI, rule out myocardial infarction.

Aspiration is an infrequent cause of perioperative hypoxemia but may result in severe morbidity. Inhalation of sterile acidic gastric contents may cause aspiration pneumonitis, whereas contents colonized with pathogenic bacteria may cause pneumonia. Symptoms depend on the type and volume of the material aspirated and include bronchospasm, tachypnea, hypoxemia, tachycardia, and hypotension. Aspiration of large volumes may require bronchoscopy to remove particulate matter from the tracheobronchial tree, administration of bronchodilators, and mechanical ventilation for correction of hypoxemia and hypercapnia. Empiric antibiotic treatment is not recommended. Steroids have not been shown to be beneficial.

Pulmonary edema caused by left ventricular dysfunction or mitral valve disease (cardiogenic pulmonary edema) or

increased pulmonary capillary permeability (noncardiac pulmonary edema) may hinder gas exchange and lead to significant hypoxemia. Supplemental oxygen, diuretics, and vasodilators may reverse the course of the disease, but mechanical ventilation with positive end-expiratory pressure may be required in some cases. A cardiology evaluation may be indicated if myocardial ischemia or valvular disease is a contributing factor.

Pulmonary embolism is another cause of hypoxemia. It is associated with significant perioperative morbidity and mortality. The most common cause of pulmonary embolism is a venous thrombosis, usually originating in a leg or pelvic vein. Thrombosis is triggered by venous stasis, hypercoagulability, and inflammation of the vascular wall.

Other common materials that can form emboli include fat that escapes into the blood from a long bone fracture or mobilized during orthopedic surgery, and amniotic fluid embolized into the pelvic veins during a tumultuous childbirth.

Symptoms of pulmonary embolism include dyspnea, pleuritic pain, hypoxemia, and, in severe cases, cardiovascular compromise or collapse. As thrombolysis and aggressive anticoagulation often are contraindicated in the early postoperative period, treatment generally is only supportive. However, an inferior vena cava filter may be beneficial in preventing further embolism.

Pneumothorax should always be considered in patients with respiratory distress or hypoxemia, particularly after thoracic or upper abdominal procedures, tracheostomy, or central line placement. Auscultation of the lungs will reveal decreased or absent breath sounds over the affected lung, but chest radiography often is required to confirm the diagnosis.

Tension pneumothorax causes rapid deterioration in gas exchange and marked hemodynamic instability and requires immediate decompression.

Table 53.1. ASA standards for postoperative care

- I All patients who have received general anesthesia, regional anesthesia, or monitored anesthesia care shall receive appropriate postanesthesia management.
- II A patient transported to the PACU shall be accompanied by a member of the anesthesia team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.
- III Upon arrival to the PACU, the patient shall be reevaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.
- IV The patient's condition shall be evaluated continually in the PACU.
- V A physician is responsible for discharge of the patient from the PACU.

From the ASA Standards for Postanesthesia Care. Available at: <http://www.asahq.org/publicationsAndServices/standards/36.pdf>. Accessed August 2008.

Hypotension

Hypotension is a common postoperative complication, and hypotension may result from intravascular volume depletion or decreased cardiac output or vascular tone. Perioperative hemorrhage, inadequate fluid replacement, and fluid sequestration are common causes of intravascular volume depletion, and assessment requires consideration of the patient's preoperative volume status, type and duration of surgery, and intraoperative blood loss and fluid replacement. Administration of a fluid bolus is considered a safe maneuver for the initial assessment of a patient's intravascular volume status. Nevertheless, echocardiography may be required if hypotension persists despite seemingly adequate fluid replacement.

Myocardial ischemia and infarction and dysrhythmias are common causes of decreased cardiac output and should always be considered in the hypotensive patient. If present, they should be treated immediately. Systemic vasodilation due to rewarming, systemic inflammation and sepsis, neuraxial blockade, or residual anesthesia also may cause systemic hypotension by decreasing vascular tone and impairing venous return. Diagnosis of the specific etiology is crucial, although vasoconstrictors such as phenylephrine or norepinephrine may be used for symptomatic treatment.

Cardiac dysrhythmia

Cardiac dysrhythmias, common causes of decreased cardiac output and hypotension in the postoperative period, are most likely to occur in patients with underlying structural heart disease. However, sinus tachycardia, the most common cardiac dysrhythmia in the immediate postoperative period, is usually benign and resolves when its underlying etiology, such as pain, anxiety, anemia, hypovolemia, or hypoxia, is treated. Nevertheless, in patients at risk for myocardial ischemia, the rate should be controlled by correcting the underlying cause. Pharmacological management of tachycardia (e.g., with β -blockers or calcium channel blockers) should not be attempted until the aforementioned treatable etiologies are excluded.

Atrial fibrillation, a common dysrhythmia, has the potential for serious consequences in the postoperative period. Unstable patients with a rapid ventricular rate require urgent cardioversion, whereas rate control can be achieved in stable patients with β -blockers, calcium channel blockers, or amiodarone.

Bradycardia without hypotension is benign and requires no treatment. In a patient with symptomatic bradycardia, anticholinergics may improve atrioventricular nodal conduction, but epinephrine, isoproterenol, or ventricular pacing may be required to increase the ventricular rate. Electrolyte imbalances, acid-base abnormalities, hypoxia, and pharmacologic effects of drugs such as digoxin should be ruled out. Complete heart block may develop in patients with preexisting conduction disease and often will result in hypotension and inadequate organ perfusion. A cardiologist should be consulted to assist in the management of patients with dysrhythmias associated with hemodynamic compromise.

Myocardial ischemia

ECG changes are common after anesthesia and surgery, resulting from the effects of anesthetics and other administered drugs, increased sympathetic tone, hypothermia, and electrolyte imbalances. Changes in P- or T-wave morphology, intraventricular conduction, or ST segments may occur in the absence of a cardiac abnormality or ischemia. Perioperative myocardial ischemia and infarction often occur within the first 2 days following surgery and may be difficult to diagnose in the PACU, as residual anesthesia and analgesia may mask chest pain, and pain perception may be altered because of the competing stimulus of surgical pain.

ECG and serial markers of myocardial injury should be examined if myocardial ischemia is suspected, and measures to enhance the myocardial oxygen supply/demand ratio (oxygen administration, rate control, aspirin, and nitrates) should be implemented immediately. Early consultation with a cardiologist should be considered, particularly in a hemodynamically unstable patient or a patient with evidence of ongoing myocardial ischemia who may require invasive monitoring and reperfusion therapy (e.g., thrombolysis, percutaneous angioplasty).

Pacemaker and implantable cardioverter–defibrillator dysfunction

Permanent pacemakers and implanted cardiac defibrillators (ICDs) deserve special consideration in the perioperative period. The patient's medical history and pacemaker dependency and possible perioperative complications should be discussed with the operating room team and the patient's cardiologist. Electrocautery used during surgery may increase the pacing rate or inhibit the pacing function, convert a pacemaker to "noise reversion" mode, or damage the lead–tissue interface or the pacemaker or ICD circuitry. ECG monitoring is essential in the postoperative setting, and all patients with a pacemaker or ICD should remain in a monitored setting postoperatively until the device is interrogated to confirm proper functioning.

Hypertension

Hypertension, a common postoperative problem, frequently is observed in patients who did not receive their regular antihypertensive medications preoperatively and is more commonly present after neurosurgical, vascular, and cardiac procedures. If uncontrolled, postoperative hypertension can potentially precipitate surgical bleeding and lead to end-organ damage, including myocardial ischemia and dysrhythmias, congestive heart failure, cerebral bleeding, and edema.

Reversible causes of hypertension, such as pain, anxiety, hypoxemia, and hypercarbia, should be treated before antihypertensive treatment is initiated. The decision to treat hypertension should take into consideration the patient's baseline blood pressure, coexisting diseases, and perceived risk of complications. Short-term treatment in the PACU is achieved using IV

agents such as β -blockers (e.g., esmolol, metoprolol), vasodilators (e.g., hydralazine), or labetalol (that is both a β -blocker and vasodilator). For persistent or refractory hypertension, continuous infusion of a vasodilator such as nitroglycerin or nitroprusside may be needed.

Oliguria and urinary retention

Oliguria, defined as urine output < 0.5 ml/kg/h, may be a sign of acute renal failure, with the risk for significant perioperative morbidity and mortality. Acute renal failure may be broadly categorized as prerenal, renal, or postrenal.

Prerenal failure is the result of reduced renal perfusion, usually related to hypovolemia or hypotension. In prerenal failure, renal function is impaired, but there is no parenchymal damage. Administration of an IV fluid bolus may be helpful in the assessment of the fluid status, but more extensive workup, including echocardiography, may also be required.

Postrenal failure is caused by an obstruction to urine flow. Assessing the urinary catheter for kinking or obstruction (by irrigation) or catheter migration is important to exclude those causes, but obstruction of the bilateral urinary tracts also may cause postrenal failure and may require diagnosis with ultrasound or CT imaging of the kidneys.

Acute tubular necrosis refers to necrosis of kidney tubules and is used to describe the clinical syndrome of reversible acute intrinsic renal failure that follows an episode of renal ischemia or exposure to nephrotoxins such as organic solvents, aminoglycoside antibiotics, radiologic contrast media, and myoglobin. Analysis of urine and plasma osmolality and electrolytes, acid–base status, and urine microscopy is helpful in the assessment of the etiology, but an ultrasound scan of the kidneys, urography, or renal biopsy may be required for definitive diagnosis. Consultation with a nephrologist may be indicated.

Delirium

Postoperative delirium, the most commonly encountered serious mental disturbance in the postoperative period, may present as reduced awareness, apathy, or drowsiness, although restlessness, hyperactivity, and agitation are more commonly associated signs. Elderly patients and those with a history of organic brain disease or mental disorders are at particular risk. Ruling out physiologic causes of delirium, such as hypoxemia, hypotension, and hypoglycemia, should be the first priority in management.

Other common causes include postoperative pain, bladder distention, and electrolyte and acid–base disturbances. Anticholinergics, opioids, and benzodiazepines are medications commonly associated with postoperative delirium. Physostigmine may be helpful if centrally acting anticholinergic drugs are the suspected cause. The catatonic effect of droperidol or haloperidol may be beneficial by protecting the patient from physical harm, although it does not improve the disordered thinking of delirium.

Pain

Most patients experience pain in the PACU, with approximately 20% describing the pain as severe. Adequate postoperative analgesia should always begin in the operating room and continue into the PACU (see [Chapter 144](#)). Opioids remain the mainstay of postoperative analgesia, with patient-controlled analgesia being preferred over intermittent boluses (see [Chapter 37](#)). Intravenous patient-controlled analgesia results in greater patient satisfaction compared with intermittent analgesia administered by nursing staff and should be promptly initiated in the PACU when indicated.

COX inhibitors are effective complements but have potential side effects, such as nephrotoxicity, decreased platelet aggregation, and gastrointestinal bleeding (see [Chapter 42](#)). Regional or peripheral sensory blockade is an effective alternative for patients in whom opioids are contraindicated.

Temperature abnormalities

Hypothermia remains a common problem in the postoperative period, despite an increasing body of evidence supporting intraoperative temperature control and advances in warming technology. Even mild hypothermia is associated with adverse postoperative complications, including myocardial ischemia, arrhythmias, coagulopathy, and wound infection. Warm blankets usually are sufficient therapy for patients with mild hypothermia, although forced-air warming devices are more efficient. Pharmacologic control of shivering may sometimes be achieved with a small dose of meperidine (e.g., 12.5–25 mg).

Significant hyperthermia is relatively uncommon in the immediate postoperative period. Mild elevation in body temperature, however, is not infrequently associated with the inflammatory response that accompanies surgery. Although infection is always a concern in the postoperative patient with hyperthermia, it is less likely than other etiologies to be the cause, unless bacteremia is provoked by the procedure or the patient had a preexisting infection. Febrile reaction to a medication or blood product should always be considered. Less common causes of postoperative hyperthermia include hyperthyroidism, malignant hyperthermia, and neuroleptic malignant syndrome. Treatment should be targeted toward the most likely etiology, although symptomatic treatment with acetaminophen may be helpful for patient comfort and to minimize the metabolic demands of fever.

Fluid administration in PACU

The use of colloid solutions or crystalloids for perioperative fluid resuscitation continues to generate significant debate. A possible advantage of colloids is related to their potential for effective and prolonged intravascular volume expansion. Regardless of the type of fluid administered, goal-directed perioperative fluid management has been shown to have a positive impact on outcome and to shorten the hospital stay.

Similar to the controversy over the ideal perioperative fluid management, the blood transfusion threshold for patients has been extensively debated in the literature. Recent reports that blood transfusion may adversely affect outcomes in critically ill patients support the application of a more conservative perioperative transfusion policy. Hence, it is recommended that clinicians consider the risk and benefit for each patient when deciding whether to use a volume replacement strategy that may involve blood component therapy.

Hemorrhage

Postoperative bleeding requires rapid evaluation to differentiate poor surgical hemostasis, potentially requiring an immediate reoperation, from a diffuse coagulopathy. Surgical and nonsurgical bleeding often coexist. Ongoing hemorrhage in the postoperative patient is an emergency requiring immediate treatment. Risk factors for postoperative hemorrhage, such as anticoagulation therapy and surgical complications, should prompt close monitoring in the postoperative period.

Saturated dressings, increased drain output, decrease in hemoglobin level, hypotension, tachycardia, or decreased urine output can guide the clinician in assessing the bleeding patient, but internal bleeding is not always obvious and may not be identified until the patient is severely compromised. Coordination among the surgical and anesthesia teams, the operating room staff, and the blood bank is essential.

Adequate IV access should be established immediately and the availability of appropriate blood products ensured. Thrombocytopenia, hypothermia, and loss of coagulation factors are common causes of coagulopathy in these patients, but preexisting medical conditions, such as liver failure and bone marrow suppression, and specific surgical or nonsurgical complications, such as disseminated intravascular coagulation and consumption coagulopathy, also should be considered.

Management of postoperative nausea and vomiting

Robert M. Knapp

Introduction

Postoperative nausea and vomiting (PONV) is common following anesthesia; the overall occurrence rate is 20% to 30%. Much of the variability reflects the fact that some patients are more prone to PONV than others and that some anesthetic agents are more prone to inducing PONV than others. Identifying patients with PONV-related traits, as well as those who receive PONV-inducing agents, allows identification of subgroups of patients whose PONV risk runs as high as 70%.

Patients dislike PONV; however, this does not mean that they all dislike it equally or that they all fear it as the worst possible postoperative experience. Attempts to quantify how much patients dislike PONV have mostly involved measuring how much they claim to be willing to pay to avoid having it after surgery. The numbers are not entirely reliable, however. The dollar values given by individual patients cover enormous spreads, and the group median values vary widely from study to study. Also, it turns out that the values change when the study population is broken down into subgroups based on factors such as age, sex, level of preoperative anxiety, or household income.

Furthermore, even though preoperative questionnaires tend to rank PONV as the postoperative event most concerning to patients, those who actually experienced both pain *and* PONV felt otherwise. For example, adults who experienced postoperative pain increased the dollar value they had previously placed on pain relief. They did *not*, however, change the value they placed on PONV treatment after having PONV. Similarly, children who experienced PONV were more likely to view pain as their primary concern, even if better pain control meant a higher risk of vomiting.

Definition of PONV

PONV refers to both nausea and vomiting. Strictly speaking, the two are different. Nausea is a conscious sensation of an urge to vomit, whereas vomiting is a reflexive expulsion of gastric contents. The two symptoms seem to be intimately related, however, and the same measures generally are used to relieve both. For this reason, PONV is usually referred to and treated as a single entity.

For treatment purposes, PONV is classified as either early or late. Early PONV occurs up to 6 hours after surgery. Late PONV

generally occurs up to 24 hours following surgery, although some studies expand this definition to 48 hours. Differentiating between 24 and 48 hours generally reflects an attempt to differentiate the treatment effects of different drugs.

Mechanisms of PONV

PONV is often described as multifactorial, because the list of neurotransmitters known or at least suspected to influence PONV includes histamine, opioid, acetylcholine, muscarine, neurokinin-1, serotonin, and dopamine. Stimulation of several specific nerves, particularly the vestibular-cochlear, vagus, and glossopharyngeal nerves, also may play a role. Because of the multiple possible neurotransmitters involved, the optimal management of PONV may require drugs that interact with multiple receptors.

How is PONV managed?

The management of PONV involves three steps. First, the patient's risk of having PONV is estimated preoperatively. Second, appropriate drugs are given intraoperatively to reduce this risk. Finally, those who experience PONV nonetheless are treated in the postanesthesia care unit (PACU). Occasionally, the anesthetic regimen itself is adjusted to affect PONV risk.

Estimating the risk

A given patient's risk of having PONV is increased by each "risk factor" that can be applied. Risk factors are certain traits or exposures that predispose some people toward having PONV. The four most prominent risk factors in use today are (1) a previous history of PONV, (2) a history of not smoking, (3) female gender, and (4) use of perioperative opioids. Increasing duration of surgery and certain types of surgery are also associated with elevated risk. In addition, the act of having anesthesia of any kind introduces risk, with some agents producing somewhat more risk than others.

In the most popular risk estimation algorithm in use today, the following is an approximate guide to estimating overall PONV risk: The simple fact of having any sort of anesthesia introduces its own small degree of risk, approximately 10%. (This approximately doubles with the use of a volatile agent with nitrous oxide [N₂O]). Next, the four primary risk factors each

add approximately 10–20% to the risk level. The mean overall risk with one, two, three and four risk factors is approximately 20%, 40%, 60%, and 80%, with less precision in the estimates of the highest risk group (see the studies by Apfel et al. for more detail). In practice, the precise estimates are less important than the overall classification of risk to low (0–1 risk factors), moderate (2 factors), and high (3–4 factors). In addition, if the operation itself has a known association with PONV, or the duration seems significant, many anesthesiologists would consider the patient to be at least at moderate risk.

Reducing the risk

Reducing the risk of PONV is almost entirely a matter of giving medications that are known to reduce the baseline risk. It is important to remember that risk reduction, rather than risk elimination, is the expected result. Also, the results from any one drug are only modest under the best of circumstances – no medication is a complete preventive. In fact, the most effective medications stop or prevent one patient in four or five *at best* from having PONV. Given this, the primary strategy for reducing the incidence of PONV is to give the number and combination of drugs that obtain the most effective decrease in baseline risk. To maximize effectiveness, the medications selected should provide some degree of relief beyond the immediate recovery period and should also address the fact that PONV can be triggered from many different sites. The medications given should reflect a spread of durations as well as a spread of mechanisms of action.

Numerous regimens have been studied for the prophylaxis of PONV. Direct comparisons between them are complicated by differences in the studied patient population and therefore baseline risk. Moreover, many trials have focused on newer agents in preference to older drugs (which may be far less expensive but also less likely to attract funding for large studies). Several algorithms have been suggested based on the estimated PONV risk and most share a common framework. For the lowest risk patients, no prophylaxis is recommended. For those of low to moderate risk, one or two drug regimens are suggested. The most popular such regimens are a serotonin antagonist alone, or the combination of dexamethasone and a serotonin antagonist. Although the data supporting timing of administration are sparse, most authorities recommend steroids be given early in the case, and anti-serotonin agents just prior to emergence. As noted earlier, there are likely other regimens of similar efficacy, although none has been studied as extensively nor compared head-to-head with this combination. For high-risk patients, a three- or four-drug regimen (with drugs from different classes) is commonly recommended. In addition, efforts to reduce anesthetic-related factors contributing to PONV risk are indicated (see “Adjusting the anesthetic regimen”). Reasonable alternatives to dexamethasone include scopolamine patches and perhaps the neurokinin-1 receptor antagonists, though the latter are very expensive. Low-dose butyrophenones (droperidol, haloperidol) are very effective alternatives or supplements

to serotonin antagonists and likely do not significantly increase the risk of dangerous dysrhythmias such as torsades de pointes. Metoclopramide is likely effective only in higher doses and not as effective as serotonin antagonists.

Treating PONV in the PACU

Comparatively little research has been directed at the treatment of established PONV. Treating PONV in the PACU is partly an extension of prophylactic regimens and partly an extension of older regimens passed on by oral tradition. The medications used in current prophylactic regimens also may be used as treatments for PONV. The most important caveat is that if they already were given as prophylaxis, the medications are unlikely to have much treatment effect if repeated in the PACU. However, medications such as low-dose butyrophenones droperidol 0.625 mg intravenously (IV); and haloperidol, 1 mg IV, may be overlooked as prophylactics so are then available for PACU therapy. Some medications, such as dexamethasone and transdermal scopolamine, are not well suited for PACU therapy because of their prolonged time to onset.

Medications that block the histamine H₁ receptor, such as promethazine and hydroxyzine, are commonly used as antiemetics. Promethazine has been studied and found to be more efficacious than a repeat dose of ondansetron given for PONV in the PACU. The dose most commonly given is 6.25 mg IV, which has shown the same efficacy as doses of 12.5 and 25 mg. If serotonin antagonists have not been used for prophylaxis, very low doses (e.g., ondansetron 1 mg) may be effective.

Principles for PACU treatment are as follows:

1. Do not repeat drugs already given for prophylaxis.
2. Consider drugs with good antiemetic properties that have not already been given, such as a low-dose butyrophenone.
3. When implementing a prophylactic regimen, and if considering a 5-hydroxytryptamine 3 (5-HT₃) antagonist such as ondansetron, consider reserving it for rescue.
4. Older drugs given on the basis of tradition, such as promethazine, 6.25 mg IV, may have a significant antiemetic effect.

Adjusting the anesthetic regimen

In any patient with elevated risk of PONV, it is prudent to minimize the contribution of the anesthetic to this risk.

Volatile agents/N₂O

Both volatile agents and N₂O are widely thought to increase the incidence of PONV. However, determining the effect of omitting N₂O is complicated by the requirement to substitute another agent, sometimes potent volatile anesthetics, which may themselves contribute to PONV risk. A meta-analysis of 24 trials found that omitting N₂O reduced the risk by 27% overall, with an NNT of 13. However, the effect was highly dependent on the baseline risk of PONV. In studies in patients with lower than average risk, the effect of omitting N₂O was not statistically

significant; in those with above average baseline risk the effect was stronger and the NNT was 5. The authors also cautioned that the NNT for intraoperative awareness was 46 compared to anesthetics in which N₂O was used, limiting the overall benefit of its omission. In separate meta-analyses of trials comparing propofol, with or without N₂O, to inhaled anesthetics with or without N₂O, little benefit was found in substituting propofol for N₂O. The NNT was 9 when propofol was used for induction only, and 6 when used for maintenance, relative to other techniques. The early prevention (0–6 hr after surgery) of nausea was the strongest effect of propofol. TIVA (with propofol) had a NNT of 6 when compared to general anesthesia, including N₂O. General anesthesia with both volatile anesthetics and N₂O produced more PONV than the other techniques.

Propofol

Propofol is often described as being protective against PONV. There are three clinical contexts in which this claim is made: propofol infused as a general anesthetic, propofol used as a bolus induction agent, and propofol given in small amounts as a rescue drug used to treat PONV in the PACU.

In the general anesthetic context, propofol is almost universally said to protect against PONV, and by a significant amount. However, the preceding analysis of PONV risk with volatile/N₂O anesthesia shows that the difference between volatile and propofol techniques is not very great. The second context, propofol used as a bolus induction agent was shown by meta-analysis to cause nearly no significant reduction in PONV. Only in patients with a relatively high baseline risk of PONV was there any discernable effect, and the NNT was 9.

Finally, propofol given in subhypnotic doses, 20 mg every 5 minutes as needed according to one study, appears to have a good antiemetic effect, although the duration is uncertain.

Neostigmine

The effects of neostigmine on PONV are somewhat controversial. One meta-analysis found that neostigmine at dosages over 2 mg was associated with an increased risk. However, a later review found no association between neostigmine and PONV at any dose.

Clinical summary for providing PONV prophylaxis

A reasonable strategy for PONV prophylaxis is as follows:

1. Estimate the risk. Get a sense of whether the patient appears to be at low or medium to high risk for PONV. The presence of only one of the common risk factors establishes a low sense of risk, unless there are additional considerations, such as the likelihood that the patient will receive a significant amount of postoperative opioids or is undergoing a surgery associated with a high PONV rate. The risk should then be considered at least moderate. Two risk factors establish a moderate sense of risk, particularly

in the presence of a volatile-based general anesthetic or for a surgical procedure that either is associated with PONV or is of longer duration. More than two risk factors should by themselves indicate a moderate to high risk.

2. Give prophylaxis according to the sense of risk. A low sense may merit a wait-and-see approach (no drugs) or baseline prophylaxis (two drugs). A moderate to high sense merits full prophylaxis (three or four drugs).
3. Use dexamethasone as the foundation drug (unless it is inappropriate for the patient). Dexamethasone works well with others and has a relatively long duration. Transdermal scopolamine is a cost-effective alternative; aprepitant is a very costly one.
4. When using a serotonin antagonist, combine it with a longer acting drug, generally give it near the end of surgery, and consider giving it in the PACU. Once it is given, there is no effect from a second dose. Finally, when PONV rescue is needed in the PACU, ondansetron is an excellent choice.

Cognitive changes after surgery and anesthesia

Joshua C. Vacanti, Gregory J. Crosby, and Deborah J. Culley

It has long been recognized that patients subjected to the stress of surgery are at risk for the development of a host of neurologic impairments postoperatively. These may result from well-known metabolic or physiologic derangements that occur intraoperatively. Conversely, patients who undergo seemingly uneventful surgery routinely develop cognitive dysfunction that cannot easily be attributed to any clear operative event. In the acute phase, cognitive dysfunction presenting as transient confusion is commonly referred to as *postoperative delirium*. It is typified by an acute fluctuating course that may begin at emergence from anesthesia, during recovery in the postanesthesia care unit, or more typically after discharge to the floor. More concerning is the fact that a small subset of patients appear to suffer from long-term cognitive changes following surgery; this constellation of changes in a patient's cognitive function is generally referred to as *postoperative cognitive dysfunction*.

Although postoperative changes in cognition have not yet been as thoroughly researched as other areas in anesthesia, such as postoperative nausea and vomiting, the significance of these pathologies in terms of physical, emotional, and monetary cost may be enormous. The postoperative patient who suffers from delirium also suffers from an increased risk of self-injury, extended hospital stays, and a higher incidence of placement in long-term care facilities, all of which increase the cost of health care. These additional costs add to the financial burden of the US health care system by adding billions of dollars in payments per year. The potential impact of long-term postoperative cognitive dysfunction on society extends well beyond the health care industry, and the societal contributions are likely to be even more burdensome.

Postoperative delirium

Delirium is the most common form of cognitive impairment in hospitalized patients. Although delirium may occur at any age, it is especially common in hospitalized elders; 40% of elderly medical patients and 10% to 40% of elderly surgical patients become delirious during their hospital stay. In fact, delirium is the most common perioperative morbidity in elders. Delirium is an acute transient organic brain syndrome characterized by disturbances of consciousness and cognition that develop over a relatively short period (hours to days) and wax and wane over the course of the day. The *Diagnostic and Statistical Manual of*

Mental Disorders (DSM-IV) criteria for delirium include a disturbance of consciousness with altered awareness of the environment, inability to sustain or shift attention, and a change in cognition or development of perceptual disturbances that are not better explained by preexisting, established, or evolving dementia. The Confusion Assessment Method (CAM) and its variant for intubated, nonverbal patients in the intensive care unit, the CAM-ICU, are widely used at the bedside to diagnose delirium. They both have the benefits of ease, speed, reliability, and validity (Table 55.1).

Delirium is generally divided into three types: hyperactive, hypoactive, and mixed. Agitation, irritability, restlessness, and aggression characterize the hyperactive form, whereas hypoactive delirium is typified by somnolence and psychomotor

Table 55.1. Confusion Assessment Method^a

CAM diagnostic algorithm – the diagnosis of delirium requires the presence of features 1 and 2 and the presence of feature 3 or 4

Feature 1: acute or fluctuating course

This feature is usually obtained from a family member or nurse and is shown by positive responses to the following questions: Is there evidence of an acute change in mental status from the patient's baseline? Did the (abnormal) behavior fluctuate during the day, i.e., did it tend to come and go, or increase and decrease in severity?

Feature 2: inattention

This feature is shown by a positive response to the following question: Did the patient have difficulty focusing attention, e.g., was he or she easily distractible or did he or she have difficulty keeping track of what was being said?

Feature 3: disorganized thinking

This feature is shown by a positive response to the following question: Was the patient disorganized or incoherent, e.g., did he or she engage in rambling or irrelevant conversation, an unclear or illogical flow of ideas, or unpredictable switching from subject to subject?

Feature 4: altered level of consciousness

This feature is shown by any answer other than "alert" to the following question: Overall, how would you rate this patient's level of consciousness? (Alert [normal], vigilant [hyperalert], lethargic [drowsy, easily aroused], stuporous [difficult to arouse], comatose [unarousable].)

^a The CAM diagnostic algorithm is a short test used by clinicians to differentiate delirium from other cognitive impairments. Through correlation with DSM-IV criteria for delirium, the CAM diagnostic algorithm has a reported sensitivity of 94% to 100% and a specificity of 90% to 95%. From Inouye SK, van Dyck CH, Alessi CA, et al. Clarifying confusion: The confusion assessment method. A new method for detection of delirium. *Ann Intern Med* 1990; 113:041–8.

Table 55.2. Risk factors for delirium^a

Nonmodifiable factors	Modifiable factors
Age > 70 y	Metabolic/physiologic derangements
Preexisting cognitive impairment	Hypoxemia
History of delirium	Hypercarbia
History of depression	Hypoglycemia
Multiple comorbidities	Hypoalbuminemia ^b
Poor functional status	Perioperative anemia ^b
Genetic factors – apo E4	Electrolyte disturbances
Type of surgery	Hypothermia
Major orthopedic	Occult infection
Cardiac	Occult cerebrovascular event
Thoracic	Iatrogenic causes ^c
Vascular	Pain
Emergency	Acute systemic disturbances
	Urinary retention, fecal impaction

^a Patients with any of the nonmodifiable factors demonstrate an increased risk for the development of delirium postoperatively and should be identified during the preoperative assessment. Patients who develop delirium after surgery should be evaluated for any of the modifiable factors and treated accordingly.

^b Linked to the development of postoperative delirium, although perioperative correction has not been demonstrated to improve the clinical course of delirium.

^c Anticholinergics (with the exception of glycopyrrolate), benzodiazepines, and antidopaminergic agents are the most commonly implicated agents.

slowing. Because delirious patients who are hypoactive look sedated and are not bothersome to hospital staff, the delirium frequently goes undetected. A common misconception is that delirium is transient and harmless. In fact, delirium may last days to weeks. It is associated with a longer hospital stay (and cost) and a greater chance of requiring discharge to a post-acute care nursing facility; and patients with delirium have a higher 1-year mortality than those who do not develop it in the hospital.

Conditions contributing to delirium can be divided into nonmodifiable and modifiable factors (Table 55.2).

Age greater than 70 years, preexisting cognitive impairment, a history of delirium, depression, multiple comorbidities, poor functional status, and the apolipoprotein (apo) E4 genotype are important predictors. The type of surgery is also important, with major orthopedic, cardiac, thoracic, vascular, and emergency surgery carrying the greatest risk. Among the modifiable factors, metabolic and physiologic derangements are common causes of confusion. Hypoxemia, hypercarbia, and hypoglycemia are readily identifiable and potentially life-threatening causes of postoperative delirium and should be treated without delay. There is also evidence that low serum albumin concentration or hematocrit values are associated with development of postoperative confusion, but it is not established that correction of these abnormalities alters the clinical course of the delirium. The role of intraoperative hypotension in development of delirium is unclear, with some studies indicating elders maintained at a mean arterial blood pressure of 45 to 55 mm Hg are no more likely to develop postoperative delirium than those whose

mean arterial pressure is maintained between 55 and 70 mm Hg. Electrolyte disturbances, mild hypothermia, subclinical infection, and an occult neurologic event such as a stroke should also be considered.

Anesthetic agents and drugs used in conjunction with surgical anesthesia have been implicated in postoperative delirium. Anticholinergic agents may be best avoided in elders. The aged brain has a relative cholinergic deficiency, and these drugs, with the exception of glycopyrrolate, which does not cross the blood–brain barrier, increase the risk of postoperative delirium, presumably by further reducing cholinergic neurotransmission. In susceptible elderly patients, even small dosages of drugs with anticholinergic effects may produce symptoms of confusion, agitation, and disorientation. If these symptoms occur, physostigmine, a centrally active acetylcholinesterase inhibitor, may be useful in partially reversing the symptoms.

Benzodiazepines are also problematic. They have prolonged effects in the elderly and sometimes produce paradoxical disinhibition and agitation.

Antihistamines given for their antiemetic effects, such as diphenhydramine, hydroxyzine, and promethazine, all have significant central anticholinergic effects. Antagonism of dopamine may exacerbate symptoms in patients at risk for postoperative delirium.

What is curious and surprising is that the type of anesthesia used does not seem to affect delirium risk. Specifically, there is no benefit of spinal or epidural anesthesia in elders in terms of the risk of developing delirium perioperatively and no indication that delirium is more likely with the use of nitrous oxide or a particular volatile agent.

Pain is an important and underrecognized contributor to delirium in the postoperative period. Elderly, cognitively intact patients with inadequately treated postoperative pain are nine times more likely to develop delirium than those whose pain is controlled. The specifics of pain treatment are less important than the quality of pain control. Indeed, in the postoperative period, low but not high opioid use is a factor in the development of delirium. This is relevant because studies show that cognitively impaired patients receive only 30% to 50% as much opioid as cognitively intact patients. This suggests that suboptimal pain management in demented and delirious patients may contribute further to their cognitive deterioration. Meperidine is an exception to this rule and should probably be avoided in geriatric patients. It has been associated with the development of postoperative delirium, presumably because of accumulation of toxic metabolites or its anticholinergic activity.

The key to managing postoperative delirium is to avoid it by identifying patients at greatest risk, correcting metabolic or physiologic abnormalities that may contribute, and selecting anesthetic adjuvants carefully and using them sparingly and deliberately. There is also evidence that a preoperative geriatric consultation and perioperative use of visual aids, environments, and cognitive and physical activities designed specifically for at-risk patients may reduce the incidence of delirium significantly. Once delirium occurs, it is important to look aggressively

for treatable causes (e.g., hypoxia, electrolyte disturbances, drug effects, infection) and to correct them before embarking on pharmacotherapy. Pharmacologic treatment of delirium is controversial, and one should resort to it only after treating remediable medical conditions. Haloperidol remains the mainstay of pharmacologic treatment of agitated delirium but may produce extrapyramidal side effects. Sedating a delirious patient with lorazepam or another benzodiazepine is inadvisable because these agents have themselves been implicated in development of delirium and may produce a paradoxical reaction of agitation and disinhibition in elders. Thus, whenever pharmacologic treatment of delirium is considered, it is wise to abide by the geriatrician's adage: "start low, and go slow."

Postoperative cognitive dysfunction

Postoperative cognitive dysfunction (POCD) is operationally defined as a subtle and long-lasting impairment in cognitive function after surgery and anesthesia. First described more than 50 years ago, it has only recently been accepted as a legitimate and common perioperative morbidity, especially in the elderly. POCD is present in 25% to 40% of elderly patients in the first week after noncardiac, nonneurologic surgery and even in 10% to 14% 3 months postoperatively. In contrast, only about 3% of age-matched controls (not hospitalized, no surgery) decline over the same interval. Postoperative cognitive impairment is not unique to the elderly. The incidence is similar in young, middle-aged, and aged patients during the first postoperative week, but it persists only in elders. Besides advanced age, important patient- or procedure-specific risk factors include low educational level, history of a previous stroke, the type of surgery (lower incidence with minor ambulatory surgery), duration of anesthesia, prolonged hospital stay, and postoperative infectious and respiratory complications (Table 55.3). Genetic predisposition may play a role, but the only study thus far looked at apo E4, a susceptibility gene for Alzheimer's disease, and no association with POCD was found.

Unlike delirium, which is a clinical diagnosis, POCD is defined by performance on various neuropsychological tests. One problem this creates is that not all studies adhere to the

same test batteries and statistical criteria, leading to variability in the reported incidence of POCD. In fact, standardization of the definition of POCD and improvement in conventional methods for identifying it are needed for the field to advance. Another issue is that although patients with preexisting cognitive impairment or dementia would seem more likely to be at risk for POCD, these patients have been excluded from studies to date – so the true incidence of POCD may be higher.

The cognitive domains most often affected are memory and/or executive function. Particularly in those with dysfunction in both of these domains, POCD is associated with limitations in activities of daily living. Moreover, POCD at the time of hospital discharge and 3 months later is associated with higher 1-year mortality. Thus, POCD occurs in at least one third of patients in the first week after surgery, lasts 3 months or more in some elderly persons, and is associated with functional limitations and greater 1-year mortality. The encouraging news is that patients seem to recover completely within 1 to 2 years or less, but this optimism is based on follow-up of only a small subgroup.

The key question is, what causes POCD? The answer is that no one is certain. Surprisingly, intraoperative hypotension (mean arterial pressure < 60% for ≥ 30 minutes) and hypoxemia (oxygen saturation of hemoglobin ≤ 80 for > 2 minutes) are not predictors of cognitive decline 3 months postoperatively in elders. Surgery and/or general anesthesia may, however, contribute to POCD by more subtle and insidious means. Surgery induces a robust peripheral inflammatory response, and there is an associated inflammatory response in the cerebrospinal fluid (CSF) and brain. Because inflammatory cytokines interfere with neural events involved in memory and, in high concentrations, produce neurotoxicity and neurodegeneration, surgery may impair cognition and contribute to POCD via inflammation. General anesthesia also may be involved. Of course, the most profound change in cognition in the perioperative period occurs during general anesthesia, and evidence from animal studies shows that general anesthesia without surgery caused impaired spatial learning for days to weeks in aged rats. These data imply either that the neurobiological machinery of memory is altered in an enduring way by anesthesia itself or that damage occurs. There is some support for both concepts, with reports that general anesthesia leads to persistent changes in gene expression in the brain of old animals and that common volatile anesthetics promote formation and/or reduce clearance of amyloid β , a protein implicated in the pathogenesis of Alzheimer's disease, and change its physical properties to augment its neurotoxic qualities. The roles of inflammation and anesthesia in POCD remain unclear, however, because inflammatory markers in the CSF return to normal within days of surgery. Clinical studies find no difference between regional and general anesthesia regarding the risk of prolonged POCD and do not identify previous general anesthesia as a risk factor for development of Alzheimer's disease. This issue has garnered considerable attention recently, but more work is necessary

before the etiology, neurobiology, and clinical significance of POCD are fully understood.

The uncertainty about the mechanisms of POCD makes it difficult to recommend specific prevention or treatment strategies. Other than recognizing that elders are often cognitively fragile and treating them accordingly, there presently is no scientific basis for recommending (or avoiding) a particular anesthetic agent or technique on the basis of concerns about POCD. This may change quickly with ongoing research.

The aged brain is different from the young brain in many respects, making elders more vulnerable to perioperative cognitive complications such as delirium and persistent POCD. These perioperative cognitive morbidities are a major challenge for the anesthesiologist and perioperative physician because they may lead to prolonged hospital stay and poor postsurgical functioning, and appear to be associated with increased 1-year mortality. The specific features of hospitalization, surgery, and anesthesia that contribute to these cognitive morbidities are not well defined, making prevention and treatment difficult. With the population aging, the challenge for the decades ahead is to better understand the role of surgery and anesthesia in causation of these complications so that perioperative physicians can tailor care for the elderly patient with the aged brain in mind.

Anatomy of the vertebral column and spinal cord

Assia Valovska

Osseous anatomy

The spinal column consists of both the vertebral column and the spinal cord. It comprises 33 vertebrae (Table 56.1) and has characteristic curves in the lumbar and thoracic regions, which give it a “double S” shape (Fig. 56.1). A lordosis is an anteriorly convex curve, seen in the cervical and lumbar region, and kyphosis is a posteriorly convex curve, seen in the thoracic and sacral sections of the spinal column. The natural curves of the spinal column may influence the spread of medications injected in the subarachnoid space. The bony vertebral column fulfills several functions (Table 56.2).

Vertebral arch and body

Each vertebra has an anterior part or body and a posterior part or vertebral arch (Fig. 56.2). The vertebral arch has two pedicles and two laminae, and together they enclose a foramen, the *vertebral foramen*. All the vertebral foramina constitute the spinal canal, which houses the spinal cord and nerve roots. Each vertebral arch supports seven processes:

- One spinous process, a midline structure arising between the two laminae, a place for attachment of muscles and ligaments.
- Two transverse processes, laterally at the junction of the laminae and the pedicles.
- Four articular processes – two superior, projecting upward, and two inferior, projecting downward – that participate in each zygapophyseal joint above and below. The pedicles of two adjacent vertebrae form the intervertebral foramina on each side, through which nerve roots exit the spinal column.

Cervical vertebrae

The vertebral bodies of the cervical spine are the smallest and have horizontal spinous processes, permitting an easy midline approach for performing neuraxial blockade. Each transverse process has a foramen. The first six foramina transversaria give passage to the vertebral artery and vein and a plexus of sympathetic nerves.

The atlas (the first cervical vertebra [C1]) lacks a body and spinous process and consists of an anterior and posterior arch

Table 56.1. Vertebral groups according to region

Cervical	7 vertebrae in the neck (C1–7)
Thoracic	12 vertebrae in the upper back corresponding to each pair of ribs (T1–12)
Lumbar	5 vertebrae in the lower back (L1–5)
Sacral	5 vertebrae fused together, forming the sacrum (S1–5)
Coccygeal	4 vertebrae fused together to form the coccyx

and two lateral masses containing the facets. The ring of the atlas is divided by the transverse atlantal ligament into a small anterior part receiving the odontoid process of the axis, and a larger posterior part housing the spinal cord. Inflammatory and arthritic changes in this ligament in patients with rheumatoid arthritis, diabetes mellitus, or trisomy 21 may lead to overt or occult subluxation of the two vertebral bodies and present a challenge at intubation. The axis (C2) has a distinct process, the odontoid (or dens axis) that represents the fusion of the bodies of the atlas and the axis. It rises perpendicularly toward the atlas and forms the pivot on which the C1 rotates to enable head rotation. The spinous process is short and bifid. The seventh vertebra (C7) has a prominent spinous process.

Thoracic vertebrae

The thoracic vertebrae are intermediate in size and increase in size from cephalad to caudad. All transverse processes, except the 11th and 12th vertebrae, have facets for articulation with the tubercles of the ribs. The laminae are thick and overlap the subjacent vertebrae like tiles on a roof. The facet joints are nearly horizontal. The spinous processes are very long, are steeply inferiorly directed, and overlap from the fifth to the eighth vertebrae. The paramedian approach to neuraxial anesthesia may be preferred to avoid the slanted spinous process.

Table 56.2. Functions of the vertebral column

Protection	Encloses the spinal cord and nerve roots
Base	Attachment place for ligaments, tendons, muscles
Structural support	Supports the head, shoulders, chest; connects the upper and lower body
Mobility	Ensures flexibility of the upper body by enabling flexion, extension, rotation

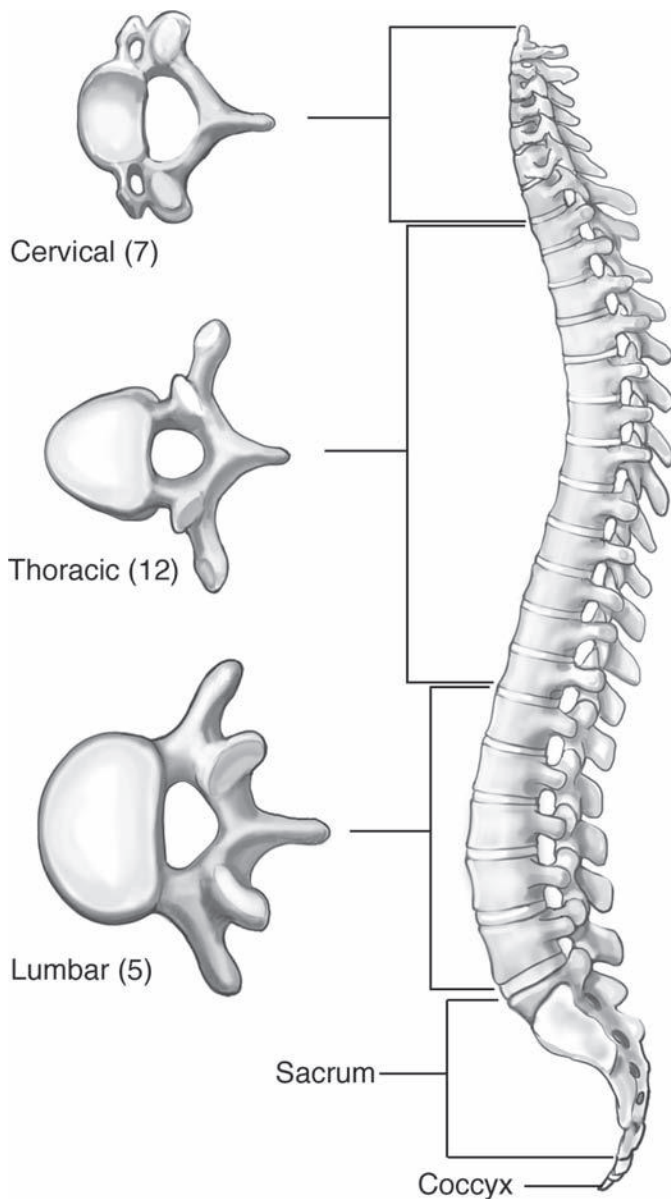

Figure 56.1. The vertebral column.

Lumbar vertebrae

The vertebrae in the lumbar region have longer and wider pedicles and horizontal spinous processes. The vertebral bodies are thick and almost square. The lowest lumbar vertebra, L5, articulates with the sacrum.

Sacral vertebrae

The sacrum comprises five bones fused together in a triangular shape. The spinal canal extends into the sacrum, and the sacral nerves exit the canal through bony foramina. The lamina of S5, and partially that of S4, normally does not fuse and comprises the sacral hiatus. The coccyx is made up of four or five vertebrae fused together. All the segments lack pedicles, laminae, and spinous processes.

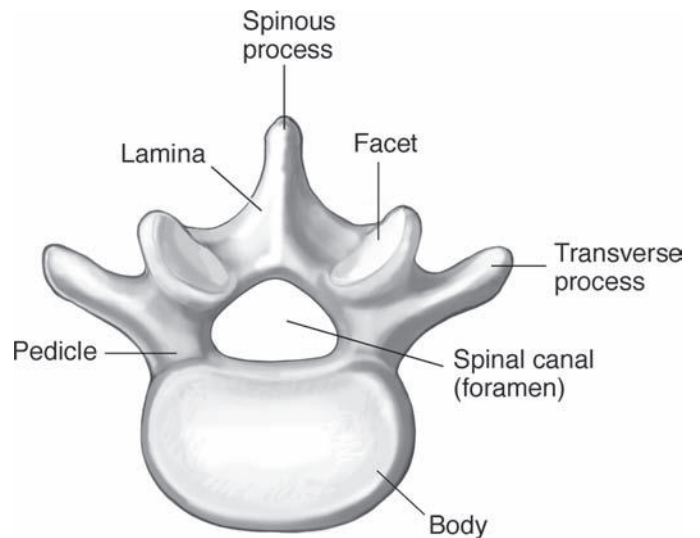

Figure 56.2. A typical lumbar vertebra.

Intervertebral discs

The intervertebral discs are structures composed of three main components: a strong avascular annulus fibrosus, that encloses the soft nucleus pulposus, and a cartilaginous endplate (Fig. 56.3). The outer layer is richly innervated by multiple nerves and is a source of some chronic back pain.

Joints

Each vertebra joins the ones above and below it with several different types of joints. The atlanto-occipital joint is a condyloid joint between the atlas of the vertebral column and the occipital bone of the skull. The atlantoaxial articulation is a pivot joint between the atlas and the odontoid process of the axis.

Figure 56.3. Intervertebral disc in relation to vertebral body.

Figure 56.4. Ligaments of the spinal column. (A) Lateral view. (B) Transverse view.

The uncovertebral joints (Luschka's joints) articulate each cervical vertebral body to the one immediately below it. The costovertebral and costovertebral joints are articulations between the ribs and the vertebral bodies or transverse processes of the thoracic spine. The facet or zygapophyseal joints are formed by the inferior and superior processes of adjacent vertebral bodies.

Ligaments

The ligaments of the spine provide stability and protection from injury while allowing flexion, extension, and rotation. They are typically traversed during neuraxial anesthesia techniques. There are five main ligamentous structures seen throughout the spine (Fig. 56.4).

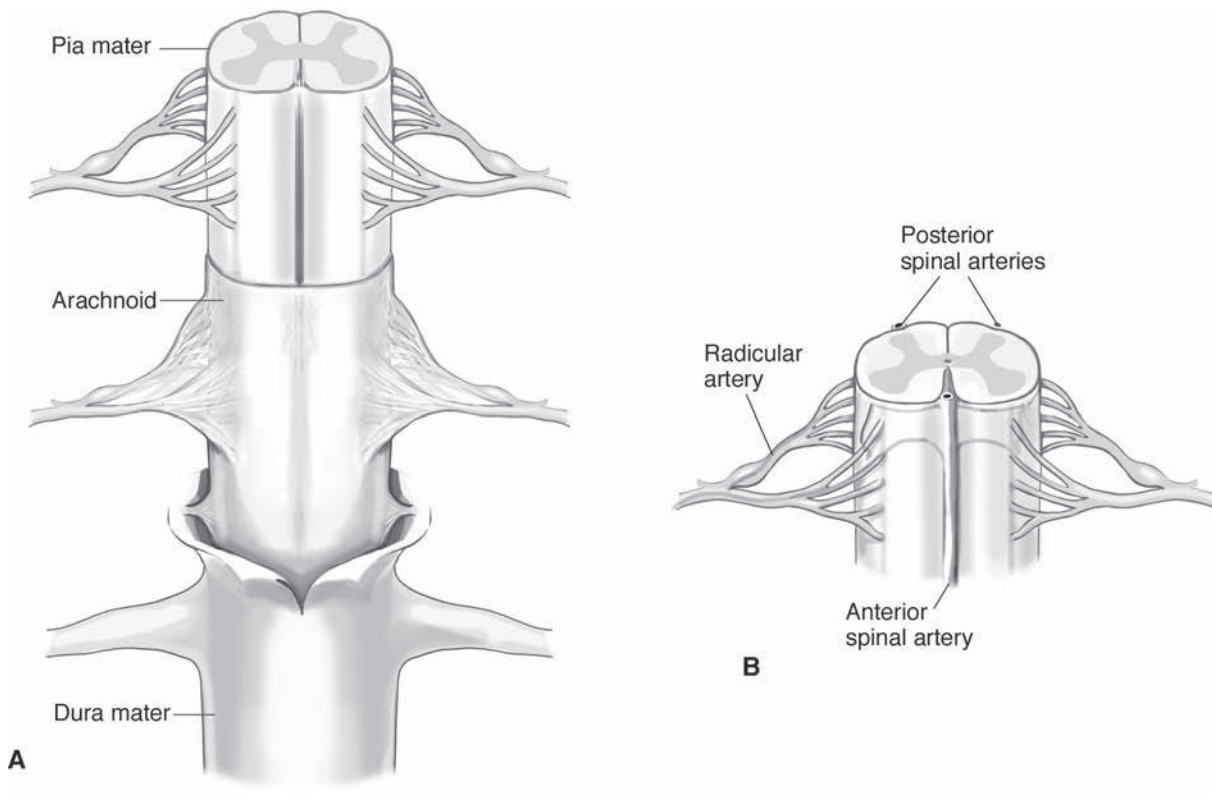

Figure 56.5. Spinal cord anatomy. (A) Coverings of the spinal cord. (B) Arterial supply of the spinal cord.

The anterior longitudinal ligament extends throughout the whole length of the spine and adheres to the anterior surface of the vertebral body and annulus fibrosus. The posterior longitudinal ligament runs along the posterior surface of the vertebral bodies and adheres to the annulus fibrosus but not to the vertebra. The supraspinous ligament connects the tips, and the interspinous ligament connects the bases of the spinous processes.

The ligamentum flavum defines the dorsolateral margins of the spinal canal from the base of the skull to the pelvis and classically is portrayed as a single ligament. In reality, there are two ligamenta flava, that join in the middle, forming an acute angle with a ventral opening. The distance from skin to ligamentum flavum ranges from 3–8 cm in most patients. The thickness of the ligament differs at different vertebral levels, ranging from 1.5 mm at the cervical level to 6.0 mm in the lumbar area. Penetration of the ligamentum flavum with the tip of an epidural needle is thought to be the cause of loss of resistance in identifying the epidural space. However, investigations have demonstrated that the ligament frequently exhibits incomplete fusion, with gaps being more frequent at cervical and thoracic levels and less frequent at lumbar levels.

Spinal cord anatomy

The spinal cord is located in the vertebral canal and extends from the foramen magnum caudad to the first or second lumbar vertebra. The spinal cord gives rise to the eight cervical, 12 thoracic, five lumbar, and five sacral nerves and one coccygeal spinal nerve. The spinal nerves comprise the sensory nerve roots that enter the spinal cord at each level, and the motor roots that emerge from the cord at each level. C1–7 nerves emerge above their respective vertebrae. C8 emerges between the C7 and T1 vertebrae. The remaining nerves emerge below their respective vertebrae.

The spinal cord terminates with the conus medullaris that is attached to the coccyx by the filum terminale. This is surrounded by the cauda equina (lumbar and sacral nerve roots). The dural sac ends at the S2 level, whereas the spinal cord ends at L1 in adults and L3 in children. Performing spinal anesthesia below these levels is necessary to avoid needle trauma to the cord.

The spinal cord is covered by three membranes known as meninges (Fig. 56.5). The outermost layer is the dura mater, a tough fibrous sheath closely applied to the inner layer of bone surrounding the spinal canal. The epidural space is a potential space between the dura and the bone (see Chapter 58 for details).

Beneath the dura mater is a thin and delicate membrane called the arachnoid mater. Normally, the arachnoid mater is closely applied to the dura, but between them exists a potential space, the subdural space, that is the result of separation within the meninges. Beneath the arachnoid mater and intimately applied to the spinal cord is the pia mater. Cerebrospinal fluid is contained between the arachnoid mater and the pia

Figure 56.6. Dermatomes of human body.

mater in the subarachnoid space. The pia mater continues caudally as the filum terminale through the dural sac and attaches to the coccyx.

Arterial supply and venous drainage

The spinal cord is supplied by a single anterior spinal artery and two posterior spinal arteries. The anterior spinal artery enters the anterior median fissure of the spinal cord and supplies the anterior two-thirds of the cord. The posterior spinal arteries supply the posterior one-third of the spinal cord. The blood to the roots, as well as the cord, is segmentally supplied by radicular arteries. Usually, a few large segmental radiculospinal

Table 56.3. Important dermatome levels

C6–median nerve	1st digit (thumb)	T6–7	Xyphoid process
C7–radial nerve	2nd and 3rd digits	T10	Umbilical level
C8–ulnar nerve	4th and 5th digit	T12	Pubic symphysis
T4	Nipple level	L1	Inguinal ligament
T5	Inframammary fold	L4	Knee level

arteries are noted, including the artery of Adamkiewicz (or artery of the lumbar enlargement), that is larger than the others. In 75% of cases, it originates between T9 and T12, almost always on the left, and supplies the lower one-third of the cord. Injury to this artery may result in anterior spinal artery syndrome. This is also referred to as *Beck's syndrome* and consists of weakness, urinary and fecal incontinence, and loss of temperature and pain sensation below the level of injury with relative sparing of position and vibratory sensation.

Veins draining the spinal cord have a distribution similar to that of the arteries. The internal vertebral venous plexus (Batson plexus) is in the epidural space and consists of four interconnecting longitudinal vessels, two anterior and two posterior. Increased intra-abdominal pressure or obstruction of the inferior vena cava distends the epidural venous plexus. The epidural veins engorge during pregnancy and with uterine contraction and pushing efforts. Epidural veins connect to the

azygous vein, potentially delivering local anesthetic inadvertently injected intravascularly directly to the heart.

Dermatomes and myotomes

A dermatome is an area of skin associated with a pair of dorsal roots from the spinal cord. Dermatomal maps (Fig. 56.6) portray sensory distributions for each level and provide information about the spread of a neuraxial block. The term *myotome* is used to describe the muscles served by a single spinal nerve. It is the motor equivalent of a dermatome. Table 56.3 shows important dermatome levels frequently used in assessing neuraxial blocks.

Spinal anesthesia

Ivan T. Valovski and Assia Valovska

Spinal anesthesia is produced by injection of a local anesthetic drug into the subarachnoid space creating a conduction blockade of the spinal nerves and resulting in a rapid, dense, and predictable state of anesthesia.

Indications

Spinal anesthesia is an ideal choice for surgeries below the level of the umbilicus. Examples include low abdominal, inguinal, genitourinary, gynecologic, rectal, and lower-extremity surgeries. Spinal anesthesia is not widely used for upper abdominal procedures because of the need for a very high level of block that may increase the risk of cardiovascular and respiratory complications. A low spinal anesthetic or “saddle block” can be used for perineal or perianal surgery (Table 57.1).

Contraindications

Contraindications to spinal anesthesia are absolute and relative (Table 57.2). Patient refusal is the only absolute contraindication. Spinal anesthesia may be discussed with the reluctant patient and the surgeon and the risks and benefits of the procedure fully understood by the patient. However, patients should not be coerced into accepting the technique.

The presence of active infection at the site of needle insertion may predispose the patient to spread of the infection into the epidural and subarachnoid spaces. Fever alone is not an absolute contraindication, provided appropriate antibiotic therapy is initiated before dural puncture and the patient has shown a response to therapy. Spinal anesthesia, especially higher thoracic levels, will block multiple preganglionic sympathetic nerve fibers, and if the patient is hypovolemic, this may result in severe hypotension; therefore, correction of preoperative hypovolemia is advised.

The major concern regarding full anticoagulation is the development of spinal bleeding leading to hematoma formation. In patients with severe cardiac disease (especially severe stenotic defects) a high thoracic block may result in refractory hypotension and cardiac arrest because of an inability to increase cardiac output. Neuraxial anesthesia may be considered as an option in these patients if a lower level of blockade is adequate for the surgery. There is little evidence that

Table 57.1. Level of spinal anesthesia required for common surgical procedures

Spinal level required	Surgical procedure
T4–5 (nipple)	Upper abdominal surgery, cesarean section
T6–8 (xiphoid)	Lower abdominal surgery, appendectomy, gynecologic surgery, ureteral surgery
T10 (umbilicus)	TURP, vaginal delivery
L1 (inguinal ligament)	Thigh surgery, lower limb surgery
L2–3 (knee and below)	Foot surgery
S2–5 (perineal)	Perineal surgery, hemorrhoidectomy

TURP, transurethral resection of the prostate.

spinal anesthesia may worsen preexisting neurologic disease, but some anesthesiologists avoid it because of medicolegal considerations. Advantages and disadvantages of spinal anesthesia are summarized in Table 57.3.

Physiologic responses to spinal anesthesia

Injection of local anesthetic into the subarachnoid space produces a multitude of physiologic responses that depend on the patient’s preexisting medical conditions, height of the block, and the medications and doses used (see Chapter 47).

Neural blockade

Small-diameter C-fibers (conducting pain impulses) are located to a greater extent in spinal nerve roots and the periphery of

Table 57.2. Contraindications to spinal anesthesia

Absolute	Relative	Controversial
Patient refusal	Bacteremia Preexisting neurologic deficit Stenotic valvular lesions Spinal column deformities Anticoagulation or coagulopathy Hemorrhagic diathesis Elevated intracranial pressure	Chronic back pain Severe headache Back surgery with instrumentation Complex or prolonged surgery

Table 57.3. Advantages and disadvantages of spinal anesthesia

Advantages	Disadvantages
Cost-effectiveness	Difficult needle placement
High patient satisfaction	Inability to obtain CSF
Preserved protective reflexes	Hypotension
Decreased risk of aspiration	PDPH
Less bleeding	Urinary retention
Rapid return of bowel function	Infection
Decreased incidence of DVT	Possible conversion to general anesthesia
Less incidence of nausea	Failed spinal
Decreased postoperative pain	
Lower incidence of cognitive impairment	

DVT, deep vein thrombosis; PDPH, postdural puncture headache.

the spinal cord; thus, they are more easily accessible to the local anesthetic. This might explain why sensory anesthesia occurs more rapidly than motor blockade (block from first to last: sympathetic > temperature > sensory > motor). Classically, the level of sympathectomy is said to be about two levels above the sensory loss level, but more recent data suggest the degree of sympathetic blockade may be at, below, or above the level of sensory loss.

Cardiovascular response

Sympathetic outflow from the spinal cord originates from T1 to L2, whereas the parasympathetic outflow is primarily craniosacral. Sympathetic fibers from T1–4 (cardioaccelerator fibers) increase the cardiac rate. Blocking these fibers causes cardiac sympathetic denervation and a decrease in heart rate, as well as a decrease in cardiac contractility and cardiac output. Systemic effects of spinal anesthesia include dilatation of arteries and venous capacitance vessels, leading to decreased systemic vascular resistance; decreased venous return; decreased cardiac output; and ultimately, hypotension. Spinal blockade at lower levels produces less hemodynamic change and is better tolerated by hypovolemic patients, elderly patients, or those with cardiac disease.

Respiratory response

In healthy patients, spinal anesthesia has no major effects on ventilation, even with a high spinal block. This is because spinal anesthesia does not alter the ventilatory response to carbon dioxide. In addition, phrenic nerve function is usually preserved. Spinal anesthesia may cause paralysis of intercostal and abdominal muscles that may affect patients with preexisting pulmonary disease and decrease their ability to cough. A high spinal level may not be a good choice for patients with severe pulmonary disease.

Gastrointestinal response

Spinal anesthesia may cause nausea and vomiting in a significant number of patients because of unopposed

parasympathetic visceral activity. Consequently, parasympatholytics (e.g., atropine, glycopyrrolate) and sympathomimetics (e.g., ephedrine, phenylephrine) may be helpful in treating these symptoms. In addition, spinal anesthesia may cause a decrease in hepatic blood flow proportional to the decrease in mean arterial blood pressure.

Renal response

Spinal anesthesia tends to decrease renal blood flow as a result of arterial hypotension. However, the kidneys autoregulate to maintain renal blood flow.

Neuroendocrine response

The body's response to surgical trauma includes localized production of inflammatory mediators and activation of somatic and visceral afferent nerve fibers. These responses lead to an increase in the activity of adrenocorticotropic hormone, cortisol, epinephrine, norepinephrine, vasopressin, and the renin-angiotensin-aldosterone system. Spinal anesthesia suppresses part of this neuroendocrine response to a greater degree than general anesthesia.

Thermoregulation

Spinal anesthesia inhibits normal thermoregulation. There is loss of heat due to peripheral vasodilation as a result of sympathectomy.

Spinal anesthetic agents

The most common local anesthetics used for spinal anesthesia are lidocaine, tetracaine, and bupivacaine (Table 57.4). Mepivacaine and ropivacaine, though more commonly used in peripheral nerve blocks or epidural anesthesia, may be used for spinal anesthesia, although this is not a labeled use in the United States. Since procaine is associated with a slow onset and short duration of spinal anesthesia, it is rarely used. Chlorprocaine is not approved for spinal anesthesia and formerly was felt to be neurotoxic, although it has been used successfully in some studies.

The usual doses, onset time, and duration of action of various local anesthetics are shown in Table 57.4. Lidocaine once was the most popular local anesthetic for spinal anesthesia, but its use has declined significantly because of its association with transient neurologic symptoms. Bupivacaine and tetracaine are popular choices for longer surgery. While epinephrine has minimal effects on the duration of bupivacaine, epinephrine or phenylephrine significantly prolong the duration of tetracaine anesthesia.

Preparation for spinal anesthesia

Informed consent is an absolutely necessary part of patient preparation. It involves discussing the risks and benefits of

Table 57.4. Drugs used for spinal anesthesia

Drug and concentration	Dose, mg	Onset, min	Duration (plain drug ^a), h	Duration (drug + epinephrine, 0.2 mg ^b), h
Procaine (5%)	100–150	3–5	<1	<1.5
Lidocaine (1.5% with dextrose 7.5%, 2% plain ^c)	50–100	3–5	1–2	1.5–2.5
Bupivacaine (0.75% with dextrose 8.25%, 0.5% plain ^c)	8–15	5–10	1.5–3	2–4
Tetracaine (0.5%)	6–16	5–10	1.5–3.5	3–5

^a Times are approximate; dextrose-containing solutions spread over more dermatomes and thus a given dose will provide shorter duration of anesthesia than plain solutions.

^b Motor block is extended more than sensory block, particularly for dextrose-containing solutions.

^c Plain lidocaine and bupivacaine solutions are not approved in the United States for spinal anesthesia.

the procedure as well as alternative techniques to spinal anesthesia.

Physical examination

Routine physical examination, including airway examination, is performed prior to administering spinal anesthesia. Patients should be questioned about a history of bleeding problems. The lumbar spine should be examined, and rash, infection, prior lumbar surgery, or severe spine deformities should be documented if present. In addition, any history of a neurologic condition or existing neurologic deficit should be documented.

Laboratory tests

Specific tests that should be considered prior to administering spinal anesthesia are usually determined by the patient's history and physical examination. If the patient reports a history of coagulopathy or easy bleeding and bruising, then prothrombin time (PT), partial thromboplastin time (PTT), and platelet count may be useful.

Premedication

Midazolam, 1 to 2 mg intravenously IV immediately, or diazepam, 5 to 10 mg orally 1 hour prior to administering spinal anesthesia, may be used to allay the patient's anxiety. An opioid may be used to help relieve pain during patient positioning.

Intravenous preloading

Patients receiving spinal anesthesia must have an IV cannula placed. Anesthesiologists commonly infuse 500 to 1000 mL of crystalloid fluid immediately before the spinal anesthetic, to mitigate the effects of sympathectomy.

Monitoring

Blood pressure may fall precipitously following induction of spinal anesthesia. Therefore, spinal anesthesia must be administered in an environment in which the ASA monitoring standards are achieved (see Chapter 24). Warning signs of falling blood pressure include pallor, sweating, nausea, and feeling generally unwell.

Equipment

Spinal needles generally fall into two categories: those that cut the dura and those designed to spread the dural fibers (Fig. 57.1).

The Whitacre and Sprotte needles have a rounded or pencil-point tip, no cutting edges, and a side hole proximal to the tip. The Quincke–Babcock needle is the “traditional” needle design. It is a cutting-type needle with sharp edges, medium bevel length, sharp point, and an end hole located on the cut bevel.

Needle size and tip design have been shown to correlate with the incidence of postdural puncture headache (PDPH). Smaller-gauge needles (25–27 G) have a lower incidence of PDPH than larger-gauge needles (22 G). Pencil-point needles (e.g., Whitacre, Sprotte) have a lower incidence of PDPH compared with cutting-type needles (e.g., Quincke) of similar or even smaller diameter.

Techniques

Landmarks

The iliac crests are palpated, and if a line is drawn at this level perpendicular to the spinal column it will generally intersect the L4–5 interspace or the L4 body. However, imaging studies

Figure 57.1. Common tip designs for spinal needles: Quincke, Whitacre, and Sprotte needles.

Figure 57.2. Neuraxial anesthesia in the sitting position. The patient sits on the edge of the bed and is supported by an assistant or a specially designed stand. Note the direction of the needle, shown on the right.

indicate poor correlation between anesthesiologists' landmark-predicted interspace and the anatomically verified interspace. The injection site is then prepared with a skin antiseptic and draped. If accidentally introduced into the spinal space, antiseptic solutions may cause chemical meningitis. The skin is anesthetized at the level chosen using 1% lidocaine, and the spinal needle is then inserted directly (Quincke needle), or through a larger introducer needle (Whitacre or Sprotte needle).

Positioning

Spinal anesthesia can be administered in the sitting (Fig. 57.2), lateral decubitus (Fig. 57.3), or prone positions. The lateral decubitus and sitting positions are most commonly used. Oxygen by face mask or nasal cannula may be administered, especially if a sedative has been given.

Figure 57.3. Neuraxial anesthesia in the lateral decubitus position. The patient lies on his or her side with the back slightly rounded and the knees flexed toward the abdomen. An assistant holds the patient at the neck and behind the knees. Note the direction of the needle, shown on the right.

Sitting position

The sitting position is a popular position for spinal anesthesia, and is also chosen when low lumbar or sacral levels of anesthesia are needed. This position allows easier identification of lumbar structures, especially in obese patients or patients with scoliosis. The patient is positioned at the edge of the bed with the legs hanging or supported by a foot rest. He or she is asked to bend forward and arch the lower back posteriorly (reversing the lumbar lordosis); assuming this position allows “opening” of the interspaces and easier access to the subarachnoid space. An assistant or a specially designed support device then supports the patient. Once the spinal injection is performed, the patient is positioned for surgery. If a hyperbaric solution is used, spread of the local anesthetic solution can be facilitated by tilting the operating table to the side as needed, or to a Trendelenburg (head-down) position to increase cephalad spread of the local anesthetic.

Lateral decubitus position

The lateral decubitus position allows administration of more sedation and is less dependent than the sitting position on a well-trained assistant. The patient is placed close to the edge of the table in a comfortable position with a pillow underneath the head and sometimes between the knees. The hips and knees are flexed and knees drawn up to the chest. The neck is flexed toward the knees to provide maximum anterior flexion of the spinal column. The hips and shoulders should be perpendicular to the surface of the table. If a hyperbaric solution is used, the surgical site is often placed dependently if the planned surgery is unilateral. If the surgical site is placed nondependently, then a hypobaric or isobaric anesthetic solution may be used.

Prone position

The prone position (Fig. 57.4) is usually reserved for patients undergoing rectal, perineal, or lumbar surgery. The patient is placed in the desired position, often with jackknife modification, and this position is maintained during surgery. Most often, the operative site is caudad to the level of injection; therefore, the prone position is well suited to the use of hypobaric anesthetic solutions. An isobaric solution will also provide satisfactory sacral anesthesia.

Approach

Lumbar puncture can be performed using either a midline or a paramedian approach.

Figure 57.4. Patient position for neuraxial anesthesia in the prone position.

Figure 57.5. Spinal anesthesia via the midline and paramedian approaches. (A) Transverse view. (B) Posterior view.

Midline approach

In the midline approach, the spinal needle is inserted and advanced between the upper and lower spinal processes in the midline, taking into account the minimal cephalad angulation of the spinal processes in the lumbar area (Fig. 57.5). If the needle is angled and advanced correctly, it will pierce through the supraspinous and interspinous ligaments, and then the ligamentum flavum. After entering the epidural space, it pierces the dura to reach the subarachnoid space. At any time, bone may be encountered, and this should be used as an indication as to where in the interspace the needle could be. Superficial contact with bone usually indicates spinal process, whereas deeper contact implies contact with the lamina. When the ligamentum flavum is encountered, there is an increase in needle resistance, followed by decreased resistance (“pop”) when the subarachnoid space is entered. The stylet is then removed. Correct position in the subarachnoid space is confirmed by spinal fluid flowing through the needle hub.

Paramedian approach

In some patients with difficult anatomy, such as kyphoscoliosis or severe arthritis, the paramedian approach (Fig. 57.5) may be the technique of choice. In the presence of severe scoliosis, the approach should be from the concave rather than the convex side of the curvature. With this technique, the needle insertion point is approximately 1–1.5 cm lateral and 1–1.5 cm caudal to the inferior edge of the superior spinal process of the chosen interspace. A longer needle may be needed for this approach. The needle is advanced with an angle of 10° to 15° off the sagittal plane and 45° cephalad. If the lamina is contacted, the needle is redirected and “walked off” the lamina in a slight medial

and cephalad direction. With this approach, the interspinous ligament has been bypassed and the needle encounters the ligamentum flavum before entering the spinal space.

Taylor approach

The lumbosacral approach is useful in patients who have had lumbar spine fusions. The point of needle insertion is about 1 cm caudal and 1 cm medial from the posterior superior iliac spine. In this technique, a 5-inch spinal needle is directed upward, medially, and anteriorly at an angle that approximates the angle of the dorsal aspect of the sacrum. The needle is then advanced so that its point enters the lumbosacral space between the sacrum and the last lumbar vertebra at the L5–S1 interspace.

Factors affecting spinal block

In the past, numerous factors were thought to affect the spread of spinal local anesthetic, including the patient’s body habitus, technique of injection, characteristics of the spinal fluid, and the anesthetic solution. In clinical practice, only baricity, patient posture, and perhaps total dose of anesthetic have any important effects.

The *baricity* of a local anesthetic solution refers to the density of the solution compared with the density of human CSF. Hyperbaric solutions contain glucose and have a specific gravity greater than 1.008 and therefore tend to migrate toward dependant areas. Hypobaric anesthetic solutions have a specific gravity less than 1.003 and are prepared by mixing local anesthetic with preservative-free water. Hypobaric anesthetic solutions tend to move opposite the dependant areas. Isobaric anesthetic solutions (specific gravity same or close to CSF) will stay near the site of injection, with minimal spread.

Despite a long tradition of calculating spinal anesthetic dose based on desired level of anesthesia and patient height, there is little direct evidence for the influence of either parameter, except at the extremes. Most adult patients will achieve a midthoracic level with any reasonable dose of hyperbaric solution (unless the patient remains in the sitting position while the block “sets”), and an upper lumbar or low thoracic level with an isobaric solution. The curves of the spine in the supine position make the midthoracic spine the most dependent point, thus solutions denser than CSF (hyperbaric) will reach these levels. The position of this curve is independent of height, so the latter rarely is a clinically significant determinant of anesthetic level. At extremes of height, the level may vary modestly, although this may be the result of altered spinal curves rather than height per se. Controlling the position of the most dependent point in the spine by patient positioning or tilting the bed can influence this distribution.

It may seem logical that a greater dose or volume of solution would block more spinal segments, but there is little evidence that this is true. The effect of baricity so overwhelms other effects, including dose, that the small effect that may be caused by the drug dose is clinically meaningless. Isobaric injections may show some modest dose or volume dependency, and any block will be more intense and last longer when a larger dose is used.

Adverse effects of spinal anesthesia

Cardiovascular effects

The most common cardiovascular effects after spinal anesthesia are hypotension and bradycardia. Cardiac arrest (asystole) is a rare but more serious complication.

Hypotension, the most common complication of spinal anesthesia, is the result of venous and arterial vasodilation from sympathectomy, resulting in reduced venous return, cardiac output, and systemic vascular resistance. The incidence of hypotension following spinal anesthesia is estimated to be about 10%–40%. Hypotension, if severe, should be treated with appropriate administration of IV fluids and careful administration of vasoactive drugs, such as ephedrine (5–10 mg IV bolus) or phenylephrine (40–80 μ g IV bolus).

Bradycardia is caused by widespread sympathetic blockade, leading to unopposed vagal tone. Risk factors for bradycardia during spinal anesthesia include a baseline heart rate less than 60 bpm, age younger than 50 years, American Society of Anesthesiologists status I, use of β -blockers, a high spinal level, and a prolonged PR interval. Bradycardia during spinal anesthesia may be associated with hypotension and hypoxemia, but also may occur independently. It may be related to surgical manipulations, peritoneal traction and decreased venous return, or reflex bradycardia (Bezold-Jarisch reflex). In cases of severe bradycardia that compromise myocardial oxygen supply, further deterioration may follow. Consequently, severe or symptomatic bradycardia should be treated aggressively with

glycopyrrolate, atropine, or ephedrine. Epinephrine should be used if other agents are not effective.

Neurologic effects

The incidence of serious neurologic complications is reported to be 0.5 per 10,000 spinal anesthetics. The most common neurologic complications are described in the following text.

Aseptic meningitis is usually benign and presents within 24 hours of spinal anesthesia. Clinically, nuchal rigidity and photophobia may be present, accompanied by a fever. CSF cultures are negative for bacteria but may show abundant polymorphonuclear leukocytes. Infectious meningitis should always be in the list of differential diagnoses and needs to be ruled out, especially if fever is present. Aseptic meningitis requires only symptomatic treatment and usually resolves within a few days.

Postdural puncture headache (PDPH) is thought to be caused by persistent CSF leak through the dural puncture site. Age (young > older), gender (female > male), the size and type of the needle, orientation of the bevel (parallel > perpendicular to the long axis of the body for cutting needles), and pregnancy all are risk factors for developing PDPH. Management of PDPH is discussed in [Chapter 58](#).

Transient neurologic symptoms (TNS) were first described in 1993 and originally termed transient radicular irritation. It presents with pain in the lower back, limbs, buttocks, thighs, or calves after uncomplicated spinal anesthesia. The pain may last for 5 to 10 days. There are no associated motor or sensory deficits with TNS. Somatosensory evoked potential, electromyography, and nerve conduction studies do not show any abnormalities. TNS is more common after the lithotomy position, in obese patients, and in outpatient operations. Although TNS may develop after injection of any local anesthetic, the highest incidence has been found after administration of lidocaine. There is no association of TNS with gender, age, needle type, difficulty with block placement, or paresthesia during needle placement. The first line of therapy is patient reassurance and analgesics such as COX inhibitors if the pain is severe.

Nerve damage is a rare complication of spinal anesthesia, with an incidence of fewer than one in 10,000 cases. Spinal nerve roots may be damaged directly from the needle contact, and this is usually preceded by paresthesias or pain during placement. Under no circumstances should the needle be advanced or injection continued if the patient complains of pain or paresthesia.

Meningitis may rarely follow spinal anesthesia, particularly if there is a breach of sterile technique or if the patient has severe untreated bacteremia. The incidence is estimated to be approximately one in 50,000. Oral commensal organisms have been isolated in some cases, implying the source may be the anesthesiologist's mouth. Careful attention to sterile precautions, including universal use of a mask and sterile gloves, pretreatment of patients with suspected bacteremia with appropriate antibiotics, and vigilance for signs of meningitis followed by aggressive treatment, can help minimize morbidity.

Table 57.A1. Anticoagulation Guidelines of ASRA

Drug Class	Drug(s)	Recommendations
Thrombolytics	Urokinase, streptokinase, alteplase, reteplase	Timing of neuraxial blockade at least 10 d after or 10 d before thrombolytic therapy Avoid neuraxial blocks, except for highly unusual situations If thrombolytics are given at or near the time of neuraxial block, continue neurologic monitoring for an appropriate interval If thrombolytics are administered while neuraxial catheter is in place, minimize sensory and motor block to allow for monitoring of neurologic function No recommendation for removal of neuraxial catheters can be made; consider measuring fibrinogen levels, and monitor neurologic function
Unfractionated Heparin	Subcutaneous heparin Intraoperative anticoagulation with IV heparin for vascular surgery Prolonged therapeutic heparinization	No contraindication for neuraxial techniques Time of insertion of needle or removal of catheter: 4 h after last dose, 24 h before next dose Consider platelet count check in patients receiving subcutaneous heparin for >4 d Avoid neuraxial technique in patients with other coagulopathies Delay heparin dose for 1 h after needle placement Remove catheter after evaluation of coagulation status, 1 h before any subsequent dose and 2–4 h after last dose Consider postoperative neurologic monitoring every 2 h and use of weak local anesthetic concentrations Neuraxial technique should be avoided If systemic anticoagulation is begun with catheter in place, delay catheter removal for 2–4 h after discontinuation of heparin. Evaluate coagulation status prior to removal of catheter.
Low Molecular Weight Heparin (LMWH)	<i>High-dose LMWH (therapeutic dosing)</i> Enoxaparin, 1 mg/kg every 12 h or 1.5 mg/kg/d; Dalteparin, 120 U/kg every 12 h; Tinzaparin, 175 U/kg/d <i>Low-dose LMWH (prophylactic dosing)</i>	Start first dose > 24 h after neuraxial block, > 2 h after catheter removal Remove catheter before initiating therapy <i>Twice-daily dosing:</i> Avoid neuraxial technique if LMWH is given within 2 h prior to planned block First dose > 24 h after neuraxial block Remove indwelling catheters > 2 h before first dose <i>Once-daily dosing (European dosing):</i> First dose 68 h postoperatively Second dose no sooner than 24 h after first dose Catheter removal > 10–12 h after last LMWH dose; subsequent LMWH at least 2 h after removal
Oral anticoagulants	Warfarin Antiplatelet agents	Discontinue chronic oral anticoagulation 4–5 d prior to neuraxial block Measure PT/INR prior to performing neuraxial block: only normal PT/INR reflects adequate levels of factors II, VII, IX, X Check PT/INR prior to performing neuraxial block if initial dose was given > 24 h earlier or if second dose of warfarin was given Monitor PT/INR daily for patients on low-dose warfarin (5 mg) receiving epidural analgesia. PT/INR should be < 1.5 before removing catheter. Neurologic testing of sensory and motor function should continue until at least 24 h after catheter removal Withhold or reduce warfarin dose if INR > 3 Consider reducing warfarin dose for patients likely to have enhanced response to the drug NSAIDs alone do not interfere with performance of neuraxial blocks. COX-2 inhibitors should be considered in patients on anticoagulation who require anti-inflammatory therapy. Discontinue ticlopidine 14 d prior to neuraxial block Discontinue clopidogrel 7 d prior to neuraxial block
GP IIb/IIIa receptor inhibitors		Avoid neuraxial blockade until platelet function has recovered: Abciximab: 24–48 h Eptifibatid, tirofiban : 48 h If GP IIb/IIIa receptor inhibitors are administered in the postoperative period, monitor the patient carefully
Herbal therapy Fondaparinux		Herbal medications alone do not interfere with performance of neuraxial blocks The actual risk of spinal/epidural hematoma with fondaparinux is unknown. If neuraxial block is planned, seek alternative method of prophylaxis.

COX, cyclooxygenase; GP, glycoprotein; LMWH, low molecular weight heparin; PT/INR, prothrombin time/international normalized ratio. Adapted from Horlocker TT, et al., Reg Anesth Pain Medicine 2010; **35**:64–101.

Spinal hematoma is a potentially devastating complication that if left untreated, may result in a partial or permanent neurologic deficit. The most common site is the epidural space, however subdural and subarachnoid hematomas are also documented. The actual incidence of spinal hematoma is unknown, however based on the incidence cited in the literature, it is estimated to be 1 in 220,000 for spinal anesthesia and 1 in 150,000 for epidural anesthesia. Known or suspected risk factors include therapeutic anticoagulation or coagulopathy, multiple attempts, and traumatic needle placement. (See the Appendix at the end of this chapter.) The clinical presentation of the spinal hematoma may vary from persistent back pain with or without distinctive motor or sensory deficits to frank paraplegia. Close postoperative neurologic monitoring for signs consistent with hematoma formation is essential for early diagnosis and treatment. An unresolving spinal block in the recovery room should be appropriately investigated. If there is suspicion of a spinal hematoma, an MRI is the gold standard for confirming the diagnosis. Early surgical decompression and evacuation usually are indicated within 6 to 8 hours. If surgery is postponed, recovery is unlikely after 8 to 12 hours.

High spinal or total spinal anesthesia is a serious anesthetic complication caused by depression of cervical spinal cord and brainstem function due to high cephalad spread of local anesthetic. It has a variable presentation and may present with tingling of the fingers, indicating spread of local anesthetic to the C7–T1 level. The patient may complain of nausea, followed by hypotension, bradycardia, difficulty breathing, and respiratory depression. If the anesthetic spreads to C3–5, apnea may occur as a result of blockade of the phrenic nerve (diaphragm). Treatment is supportive, involving IV fluids and pressors to maintain the blood pressure and heart rate, and adequate oxygenation (face mask or tracheal intubation) for respiratory support.

Respiratory effects

Dyspnea is described as an unpleasant sensation of difficulty breathing. This complication has been seen frequently after spinal anesthesia. It results from loss of intercostal muscle proprioception and the inability of patients to sense chest wall movements. Motor blockade of the abdominal and intercostal muscles may have a negative impact on coughing. Patients with preexisting pulmonary problems such as chronic obstructive pulmonary disease are more severely affected. Reassurance and confirmation of adequate ventilation are essential. Apnea may result from a high spinal and direct blockade of C3–5 (phrenic nerve) or severe hypotension. Hypotension may lead to impaired medullary blood flow and hypoxemia of the ventilatory center and may be perceived as chest heaviness.

Other effects

Backache may occur in up to 40% of patients after a lumbar puncture and may last for 1 to 2 weeks. The pain may be related to periosteal trauma from multiple attempts or stretching of the

muscles or ligaments associated with muscle relaxation, TNS, or a spinal hematoma. It is important to remember that the backache may not be related to the spinal injection. Usually, the pain is not severe or debilitating. Application of heat, rest, and massage therapy are usually sufficient.

Urinary retention is common after spinal anesthesia and is caused by blockade of the sacral nerve roots S2–4. The loss of bladder tone may lead to bladder distention. Considering that sacral autonomic fibers are among the last to recover following a spinal anesthetic, bladder distention may be significant, and catheterization may be needed. If a longer spinal anesthetic is planned, it might be prudent to insert a bladder catheter to avoid problems with bladder distention. Bladder distention, if not recognized postoperatively, may be associated with hemodynamic changes such as hypertension and tachycardia or bradycardia. Blockade of higher sympathetic efferent fibers (T5–L1) may result in an increase in sphincter tone, again producing urinary retention.

Nausea and vomiting may occur after a spinal anesthetic as a result of hypotension, administration of opioid in the spinal solution or IV, sympathectomy itself (leading to unopposed vagal tone), or surgical stress. Hypotension should be treated, and antiemetics such as ondansetron may be administered.

Appendix: anticoagulation guidelines of the American Society of Regional Anesthesia

Although preoperative screening is not indicated for healthy patients undergoing neuraxial anesthesia, coagulation studies and platelet count should be checked if the clinical history suggests the possibility of a bleeding diathesis. The decision to perform neuraxial anesthesia in the anticoagulated patient should be made after weighing the risks of bleeding and development of spinal hematoma or other complications versus the benefits of the procedure. [Guidelines](#) for specific anticoagulant medications are given in [Table 57.A1](#).

Epidural anesthesia

Richard S. Field and B. Scott Segal

Introduction

Neuraxial anesthesia is the term used to describe both intrathecal (spinal) and epidural nerve blocks. Drugs delivered into the epidural space do not behave as drugs in the intrathecal space. Understanding the differences allows the anesthesiologist to choose which space to deliver a drug based on the benefits of each (Table 58.1). The epidural space is located within the spinal canal but lies outside the dural sac. Anesthetics delivered into this space may provide regional surgical anesthesia, prolonged postoperative analgesia, or treat chronic pain syndromes. Successful epidural anesthesia depends on proper patient selection, knowledge of the surgery, its location and duration, excellent three-dimensional appreciation of the neuraxial anatomy, and appropriate choice of anesthetic agent. This chapter focuses on these factors and also describes the complications associated with epidural anesthesia.

Anatomy

Appreciation of the bony spinal anatomy, the ligaments connecting these bones, and the contents and borders of the epidural space itself is important for the safe and expeditious performance of epidural blocks. For a detailed description of the spinal bony and ligamentous anatomy, please refer to Chapter 56.

Anatomy of the epidural space

The anatomy of the epidural space is as follows:

- Space inside the vertebral foramen but outside the dural sac
- Enclosed cranially by the foramina magnum and caudally by the sacrococcygeal ligament
- Discontinuous space divided into anterior, posterior, and lateral compartments
 - The lateral compartment is filled with spinal nerves, epidural fat, and blood vessels; communicates with the paravertebral space
 - The anterior compartment is a thin space that also includes the valveless veins of Batson's plexus
 - The posterior epidural compartment is the widest part of the epidural space; it is filled with epidural fat and some minute vessels

Table 58.1. Comparison of spinal and epidural anesthesia

Benefits of spinal anesthesia	Benefits of epidural anesthesia	Benefits of an epidural catheter
Smaller total dose of drug	Less respiratory depression	Ability to titrate a drug to effective level of sensory block
Fewer systemic side effects	Lower incidence of high block	Outlasts a single-shot block
Quicker onset time	Less hemodynamic instability	Can use the catheter for days after surgery
	Use of catheter	Helps reduce chronic pain levels

The dura often touches but does not attach to the periosteum of the spinal canal, unless inflammation has occurred. This results in separate compartments of epidural space, interspersed with areas of potential epidural space. These areas can be opened up, or epidural space created by, injection of a bolus of air or liquid. Epidural fat is abundant in the posterior but also in the lateral compartment. This fat can affect the flow of epidural solutions and act as a sink in sequestering lipid-soluble opioids and local anesthetics.

Performing epidural anesthesia

Increasing evidence supports the use of neuraxial techniques to lower perioperative morbidity and mortality (Table 58.2). Contraindications to epidural anesthesia are the same as for spinal anesthesia (see Chapter 57). The only absolute contraindication

Table 58.2. Beneficial effects of neuraxial anesthesia in the perioperative period

Reduced stress response to surgery
Less intraoperative blood loss (and lower transfusion requirements)
Fewer thromboembolic events (deep vein thrombosis, pulmonary embolism, graft occlusions)
Fewer postoperative pulmonary complications
Increased regional blood flow
Earlier return of gastrointestinal function
Earlier ambulation
Earlier hospital discharge for some surgeries
Less perioperative mortality

to epidural anesthesia is patient refusal. Relative contraindications include bacteremia, coagulopathy, and hypovolemia.

Preparation

Preparation for placement of an epidural block initially includes taking a patient history, examining the patient, reviewing the patient's records and results of relevant laboratory and imaging investigations, and obtaining written informed consent. Once completed, the preparation for the procedure can begin. This includes checking the equipment, placing the monitors on the patient, and correctly positioning the patient. Surface landmarks help identify the vertebral level at which the block will be performed (see [Chapter 57](#) and [Table 57.1](#)), but these are imprecise and studies demonstrate that blocks are often undertaken one to three levels from the intended interspace.

Equipment

The most commonly used epidural needle used in the United States is the 17-gauge 3.5 inch Tuohy needle (with the addition of lateral wings it is known as the Weiss needle). Needles used for epidural blocks are larger gauge than spinal needles to facilitate the loss of resistance technique and to pass a 19- or 20-gauge catheter through the needles. The Weiss needle has a blunt, curved tip (similar to Tuohy) that facilitates threading of the catheter. The blunt tip transmits tactile information to the clinician as the needle is advanced through the “gritty” interspinous and “tough” ligamentum flavum ([Fig. 58.1](#)).

The needles also are supplied with stylets to prevent superficial tissue from becoming embedded within the needle lumen during insertion. Centimeter markings are displayed on the outside of the epidural needle to determine the distance from skin to epidural space. These markings facilitate placement of specific lengths of catheter within the epidural space. The plastic catheters themselves typically have markings every centimeter for the distal 20 cm. By measuring the catheter marking at the skin (after the needle has been removed) and subtracting from this the distance from the skin to the epidural space (measured on the epidural needle), the practitioner can determine the length of catheter left in the epidural space (commonly 3–5 cm). The catheters may be single- or multi-orifice. Some evidence points to fewer patchy and one-sided blocks

with multi-orifice catheters. The tip of the catheter is dark colored to ensure that the entire length of the catheter has been removed from the patient at the conclusion of the anesthetic. Epidural catheters also vary in their stiffness. Less stiff catheters are believed to result in fewer paresthesias on insertion and intravascular placements. Stiffer catheters are easier to thread longer distances into the epidural space.

Syringes for loss of resistance are also present in the epidural kits. Often a glass syringe is used after lubricating the interior walls with saline to reduce friction on the plunger; plastic loss-of-resistance (LOR) syringes are also available and do not require such lubrication but have a distinctly different feel to most operators. In addition to the equipment necessary to perform epidural anesthesia, emergency equipment should be available, including a source of oxygen, suction, bag-valve-mask resuscitator (Ambu bag), equipment to secure an airway, and resuscitation drugs. All patients should have vascular access established, and a “safety pause” should be performed prior to starting the procedure.

Monitoring

The patient's mental status should be continually monitored by verbal communication. Hemoglobin saturation (SpO₂), heart rate and rhythm, and blood pressure should also be monitored throughout the procedure.

Positioning

The sitting, lateral decubitus, or (less commonly) prone position can be used (see [Chapter 57](#) and [Figs. 57.2, 57.3, 57.4](#)). Specialized stands that facilitate proper patient positioning have been developed. A trained attendant who can maintain communication and reassure the patient may optimize establishment and maintenance of appropriate patient position.

Lumbar technique

The spinal cord terminates at L1 in most adults and L3 in most children. Therefore, there is less risk of damage to the spinal cord by placing an epidural block in the lumbar region. After adequate preparation and positioning of the patient, an antiseptic solution is used to clean the back. Sterile drapes are placed, and the surface anatomy is identified. Local anesthetic is used to raise a skin wheal and is then injected deeper to the level of the interspinous ligament. A midline or paramedian approach is then used to introduce the epidural needle and stylet into the subcutaneous tissue. The needle is advanced until the interspinous ligament is identified by its “gritty” texture. A glass or plastic syringe is filled with 2–4 ml of air or saline, or both, and attached to the needle. Several techniques for hand positioning have been described for advancing the epidural needle ([Fig. 58.2](#)). Constant or intermittent pressure on the syringe plunger is applied during advancement. As the ligamentum flavum is reached, increased resistance to pressure on the plunger is felt. As the epidural space is reached, a loss of resistance is felt and the contents of the syringe freely enter the space. At this point,

Figure 58.1. Epidural needle design.

Figure 58.2. Epidural techniques. (A) LOR technique (continuous pressure variant). (B) Hanging drop technique.

pressure on the plunger should be released to prevent injection of all the air or saline in the syringe. A “single shot” of anesthetic may then be administered, or a catheter may be advanced and the needle withdrawn.

An alternate method of identifying needle entry into the epidural space is the hanging drop technique. This technique uses the negative pressure formed in the epidural space (as the advancing needle “tents” the dura) to suck in a drop of liquid that purposely hangs off the hub of the needle. Immediately on noticing this, the clinician stops advancing the needle. This technique has lost favor in the lumbar and thoracic regions, but is still used in cervical epidural anesthesia.

Test dose

Commonly, 3 ml of 1.5% lidocaine with 1:200,000 epinephrine (5 $\mu\text{g}/\text{ml}$) is injected as a *test dose*. Intrathecal (spinal) administration of this dose of local anesthetic (lidocaine 45 mg) will rapidly result in a spinal block with motor weakness. Intravascular administration of 15 μg of epinephrine will typically result in an increase in heart rate of 30 bpm within 45 seconds, in a patient not taking β -blockers.

Thoracic, cervical, and caudal epidural anesthesia

Thoracic epidural anesthesia is most often used, in addition to general anesthesia, for procedures in the thoracic and high abdominal regions. Beneficial effects include less postoperative respiratory compromise from improved postoperative pain control, earlier ambulation, and shortened ileus after intestinal or aortic surgery. More recently, some evidence has suggested better immune function postoperatively with epidural analgesia. Performing the technique in this region is more challenging because of the presence of the spinal cord and a smaller distance from skin to epidural space, in addition to a smaller epidural space. The cervical spine also is used to perform epidural analgesia but mainly in the treatment of chronic pain.

An alternative approach to the epidural space for procedures in the rectal, perineal, genital, inguinal, and lower abdominal region is the caudal approach. A single-shot epidural anesthetic or a catheter to provide continuous infusion may be used. This technique is used more commonly in children, because the sacral hiatus is more often patent in children than in adults. The sacral hiatus is identified by palpating the sacral cornua that lie on either side of the hiatus at the top of the buttock crease or at the most caudal point of an equilateral triangle formed between the hiatus and the posterior superior iliac spines (Fig. 58.3). An epidural needle is advanced through the hiatus at an angle of about 45° . Once the “pop” of the needle passing through the sacrococcygeal ligament is felt, the angle of needle entry is reduced to advance the needle along the sacral canal. The needle is advanced 1–2 cm further. The dural sac ends at about S1 in adults and S3 in infants. Although advancing the epidural needle only 1–2 cm into the caudal canal should ensure epidural rather than intrathecal placement, it is prudent to check for CSF prior to injecting or advancing an epidural catheter.

Combined spinal–epidural anesthesia

Spinal anesthesia offers certain advantages over epidural infusion, including quicker onset, a denser motor and sensory block, and reduced total drug dose. The advantages of epidural anesthesia over an intrathecal delivery include the ability to provide a prolonged, titratable level of anesthesia. Disadvantages of subarachnoid anesthetic include anesthesia wearing off too early, an inadequate level of anesthesia, and adverse cardiovascular effects of a high spinal. The disadvantages associated with an epidural anesthetic that may be avoided by combined spinal–epidural anesthesia include slow onset time, a patchy block with inadequate motor paralysis, and an intravascular injection with subsequent CNS and cardiovascular toxicity. Combining the two techniques offers the advantages of both while minimizing the disadvantages.

The procedure is performed at the lumbar level. A standard 17-gauge 3.5 inch Weiss needle or a specifically designed epidural needle with an additional exit eye near the tip may be used (Fig. 58.4). The spinal needle used is a longer, 4.5–5 inch 24–27 gauge needle. The spinal needle should easily slide through the epidural needle and extend 12–15 mm beyond the curved tip

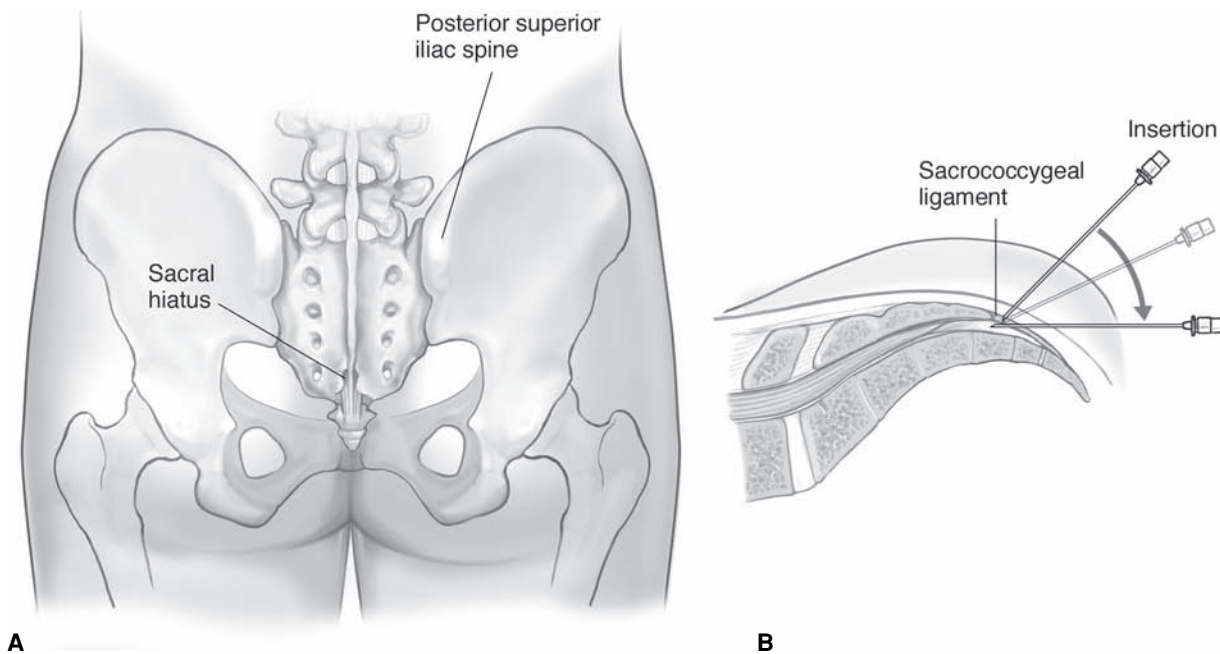

Figure 58.3. Caudal anesthesia landmarks (A) and needle insertion (B).

of the epidural needle. After local anesthetic solution has been injected at the puncture site, the epidural needle is advanced as described for epidural anesthesia. Once in the interspinous ligament, the stylet is removed. An LOR syringe is attached, and the epidural space is identified by the loss of resistance. Once the epidural space has been found, the spinal needle is advanced through the epidural needle. As the spinal needle is advanced, a “pop” indicates puncture of the dura. Removing the stylet from the needle should result in returning CSF that will confirm intrathecal placement. The spinal drug should then be injected through the spinal needle, and this needle is then withdrawn. An epidural catheter may then be inserted, the needle removed, and the catheter secured.

A long spinal needle can be passed through the lumen of a standard epidural needle, although the needle will be slightly

deflected. Specially designed epidural needles with an additional hole for the spinal needle are available, although they may not affect block success significantly.

When surgical anesthesia is obtained by the spinal injection, a test dose or epidural infusion should not be started until the effect of intrathecal anesthesia starts to wear off. Although the catheter is assumed to be in the epidural space, it must be remembered that it can still be intrathecal or intravascular. Administering a bolus of local anesthetic through an epidural catheter that may have migrated into the subarachnoid space, after a full subarachnoid dose of drug has been given, may result in a high or total spinal. Once the level of intrathecal anesthesia has regressed, aspiration of the catheter may be followed by injection of a test dose. Some authorities believe it is safe to begin an epidural infusion immediately if dilute local anesthetic is used, particularly in obstetrics (see Chapter 121).

Figure 58.4. Equipment for combined spinal–epidural anesthesia.

Determinants of epidural spread, onset, and duration of action

To optimize the use of epidural drug delivery, the clinician must have an understanding of what affects spread of the drug in the epidural space, the speed of onset, and the duration of anesthesia and analgesia.

Determinants of epidural spread

The site of injection of local anesthetic is the most important variable in determining segmental anesthetic coverage. Local anesthetic spreads in both cephalad and caudal directions in the epidural space. There is slightly more cephalad than caudal spread. However, it may be that it is simply easier to block the

Table 58.3. Local anesthetic agents for epidural anesthesia: approximate two-segment regression time and dosing intervals for lumbar (L2–4) epidural anesthesia

Local anesthetic	Dose, mg	Peak cephalad block height	Time to two-segment regression (1 SD or range), min ^a	Recommended dose interval, min ^b
Chloroprocaine 2%–3% + 1:200,000 epinephrine	600	T5	80 (15)	45
Lidocaine 1.5%–2% + 1:200,000 epinephrine	300–400	T4	100 (50–60)	60
Mepivacaine 1.5%–2% + 1:200,000 epinephrine	300–400	T4	110–120 (40–50)	60
Bupivacaine 0.5%–0.75% (plain)	100–150	T5	150–190 (60–80)	120
Ropivacaine 1% (plain) age 30 (18–40) ^c	150	T8 ^d	143 (45–298)	120
Ropivacaine 1% (plain) age 51 (41–59) ^c	150	T6 ^d	190 (100–340)	120
Ropivacaine 1% (plain) age 71 (61–82) ^c	150	T4 ^d	203 (105–378)	120

^a Mean (1 SD or range).

^b Dosing intervals are approximate guidelines. In awake and cooperative patients, clinical monitoring for signs and symptoms (increase in blood pressure and heart rate or objective evaluation of dermatomal level of block) of dermatomal regression will indicate the need for a top-up dose.

^c Ages expressed as mean (range).

^d Note for ropivacaine the significant difference in peak block height between the youngest and oldest age groups.

From Wong C. *Spinal and Epidural Anesthesia*. New York: McGraw-Hill; 2007.

smaller, more cranial nerve roots. Local anesthetic uptake may be slower in the more caudal regions because the caudal nerve roots are larger and more length is present in the epidural space.

Dose, volume, and concentration

Whereas the total volume injected determines the spread within the epidural space, the concentration of the drug affects the density of the block. A general guideline for the volume of drug to use is 1–2 ml of local anesthetic per dermatome to be blocked. If motor blockade is desired, the highest available concentration of local anesthetic should be used.

Age

Increasing age has been shown to affect the spread of local anesthetic in the epidural space. Older patients have increased caudal and cephalad spread of local anesthetic within the space. Anatomic changes that may account for this include a more compliant epidural space with reduced epidural fat content and a narrowing of the intervertebral neuroforamen through which the local anesthetic may escape.

Pregnancy

There is conflicting evidence in studies examining longitudinal epidural spread in pregnancy. Studies are limited because there is no practical or reliable quantitative measure of spread of the solution in the epidural space. There is some evidence to support increased local anesthetic sensitivity of nerves in pregnancy that may augment the blocks for a given dose of drug.

Onset of epidural anesthesia

The speed with which epidural anesthesia renders a patient ready for surgical incision is a characteristic of the drug used. Anesthesia is first noticed along the dermatomes nearest the site of injection within a few minutes. Onset of action of local anesthetics is determined by the fraction of the drug in the nonionized forms and the concentration of the local anesthetic solution injected.

Duration

The duration of action of local anesthetics in the epidural space depends on several factors. Time to two-segment regression from a single epidural shot of local anesthetic is summarized in Table 58.3 and include the drug itself, the dose of drug, and the presence of an adrenergic agonist. Local anesthetic duration correlates with the drug's protein-binding ability and its lipid solubility. Sequestration of the local anesthetic into epidural fat can prolong its action by acting as a depot of the drug. The use of adrenergic agonists such as epinephrine (1:200,000) is thought to prolong the block by causing local vessel vasoconstriction. This is believed to prolong the effects of epidural local anesthetics by decreasing clearance of the drug from the epidural space.

Drugs used in the epidural space

Local anesthetics, opioids, and adrenergic agonists have all been used independently and in combinations. Local anesthetics are the most frequently used epidural agents and act at the spinal cord, dorsal and ventral nerve roots, and the exiting spinal nerve itself. The most important sites of action are the lateral dural cuff regions of the dorsal and ventral nerve roots. Here, exposed arachnoid granulations facilitate local anesthetic transport into the CSF.

Opioids also may be used in the epidural space as either a bolus or an infusion. They provide analgesia by binding to pre- and postsynaptic opioid receptors in the substantia gelatinosa of the dorsal horn of the spinal cord as well as to opioid receptors located in the brainstem. Binding of opioids to these pre- and postsynaptic receptors inhibits the transmission of pain signals mediated by neurotransmitters such as substance P. Epidural opioids reach the spinal cord by diffusing across the dura. They reach the brainstem either by vascular uptake in the epidural space or by cephalad spread of hydrophilic opioids within the CSF. Adverse effects of epidural opioids include nausea, vomiting, urinary retention, pruritus, and respiratory depression. Early and late respiratory depression may result. Early

respiratory depression from μ_2 -opioid receptor activation may occur. Late respiratory depression occurs up to 24 hours after administration from slow cephalad CSF diffusion of hydrophilic opioids.

Adrenergic receptor agonists are also delivered into the epidural space. Clonidine is a specific α_2 -adrenergic agonist with an analgesic and sedative effect. Although α_2 -adrenergic receptors are found throughout the body, the analgesic activity of clonidine is believed to result from activation of receptors in the dorsal horn. Activation of these receptors mimics the descending inhibitory pain pathways that use norepinephrine in their signal transmission.

Adverse effects

Major complications from neuraxial anesthesia are uncommon events. In a large multicenter prospective study in France, complications from spinal anesthesia were found to occur significantly more often than from epidural anesthesia. Of 40,640 spinal and 30,413 epidural procedures, cardiac arrest occurred in 26 and three cases, respectively. A more recent study found a similar pattern of uncommon complications. Of 41,079 spinal and 35,293 epidural anesthetics performed at multiple centers in France, 31 serious events were reported in the spinal group and seven in the epidural group. Although serious complications from epidural anesthesia are uncommon, minor complications and adverse effects do occur more frequently. Back pain, urinary retention, pruritus, and nausea and vomiting are often seen as a result. More serious complications discussed here include intravascular injections, complications related to the inadvertent puncture of the dura, infections, and finally, epidural hematomas.

Intravascular injection

Blood vessels are located primarily in the lateral and anterior epidural space. These vessels may become engorged during pregnancy, which increases the risk of intravascular injections. Preventive measures may reduce the risk of this complication and include the use of soft-tipped catheters, restricting the length of catheter inserted to less than 5 cm, aspirating prior to any epidural injection, use of an epinephrine-containing test dose, and fractionation of doses to no more than 3-5 ml at a time. Local anesthetics injected intravascularly in the epidural space may cause CNS toxicity followed by cardiovascular toxicity and collapse.

Dural puncture

Inadvertent puncture of the dura during epidural needle placement may occur and is partly related to the skill of the practitioner. Returning CSF is a definitive sign of a “wet tap.” If this occurs, the practitioner must decide whether to abandon the procedure, try again at a different level, or convert the anesthetic to a continuous spinal. Penetrating the dura either with the large-gauge epidural needle or by a catheter

that has migrated into the subarachnoid space may result in a total spinal or a postdural puncture headache (PDPH). A large epidural dose of local anesthetic unintentionally administered into the subarachnoid compartment can migrate to cervical and even intracranial levels, resulting in bradycardia, hypotension, difficulty swallowing and phonating, dyspnea, and loss of consciousness. It is termed a *high* or *total spinal*. Hypoperfusion of the brainstem may affect the higher respiratory centers and result in apnea. Treatment consists of head-down positioning to improve preload and brainstem perfusion, oxygen, airway management, and circulatory support with vasoconstrictors, inotropes, and chronotropes. Subdural anesthesia is a similar complication from unintentional dural puncture but often is less dramatic. The subdural region is a potential space lying between the closely opposed dura mater and arachnoid mater. Injection into this space by a needle positioned here or from a catheter that may have migrated into the space occurs with an estimated frequency of one in 2000 cases. Signs suggestive of a subdural block include a higher than intended level, a patchy block, Horner’s syndrome (miosis, ptosis, enophthalmus, and anhidrosis), and signs of a total spinal.

Postdural puncture headache

Dural puncture, whether intended or unintended, may result in a severe bilateral fronto-occipital headache that occurs 12 to 48 hours after the procedure. Characteristically, the pain is related to position. Lying flat often relieves the pain, whereas sitting or standing increases the intensity. The pain is thought to occur following CSF leak through the dural puncture that leads to decreased intracranial cushioning effect of the CSF. This may cause increased traction on intracranial structures and result in the sensation of pain in areas innervated by compressed or stretched intracranial nerves. PDPH often resolves within 3 to 7 days but rarely may persist. Conservative management should be started upon presentation and includes reassurance, bed rest, oral or intravenous (IV) hydration, administration of caffeine or theophylline, and analgesics.

If conservative management has failed and the pain is not improving, more invasive measures may be attempted. An epidural blood patch provides rapid and complete improvement in 70%–98% of cases. The procedure involves injecting 15–25 ml of autologous blood, under sterile conditions, into the epidural space at or one interspace below the dural puncture. The procedure is believed to compress and block the defect in the dura while squeezing CSF cephalad and into the intracranial compartment.

Infection

Rarely, bacterial contaminants may cause meningitis, arachnoiditis, or an epidural abscess. Organisms responsible for such infections include skin flora such as *Staphylococcus aureus* and *Staphylococcus epidermidis* but also oral commensals such as *Streptococcus viridans*. A suspected epidural abscess should be confirmed by MRI. Treatment includes IV antibiotics and

surgical incision, drainage, and decompression. Replacing or removing epidural catheters within 5 days of placement may reduce the incidence of this rare complication.

Epidural hematoma

Epidural hematomas may occur spontaneously or secondary to epidural blood vessel trauma from a needle or from insertion or removal of an epidural catheter. The incidence of epidural hematomas has been estimated to be between one in 150,000 cases for epidural anesthesia and one in 220,000 for spinal anesthesia. The increasing frequency of perioperative anticoagulation may be responsible for an increase in the incidence of this complication. Guidelines have been revised by the American Society of Regional Anesthesia and Pain Medicine (see Appendix to Chapter 57). These revised guidelines reflect the changing practice of perioperative anticoagulation. As with epidural abscess formation, early detection of the space-occupying hematoma within the epidural space is critical. Early signs of back pain and lower-extremity numbness or weakness may be masked by epidural anesthesia. However, these signs, in the setting of bowel or bladder incontinence should alert the physician to the possibility of a developing hematoma. An MRI and neurosurgical consult should be obtained immediately, because delays of more than 8 hours

before surgical decompression have been implicated in poorer outcomes.

Principles of ultrasound-guided nerve blocks

Tanja S. Frey and Adam B. Collins

Ultrasound use is rapidly expanding in numerous fields of medicine. This trend is likely to continue as ultrasound image quality improves and equipment becomes less expensive and more portable. High-resolution ultrasound facilitates direct visualization of nerves, adjacent structures, block needle, and local anesthetic distribution. The ability to select an optimal needle path, guide its insertion with great precision, and obtain real-time feedback on the spread of local anesthetic is attracting substantial interest in the regional anesthesia community. A growing body of evidence demonstrates that ultrasound guidance increases the success rate and decreases morbidity compared to traditional nerve stimulator-based techniques for several peripheral nerve blocks.

Ultrasound-related physics

The transducer emits sound waves into the tissue and receives sound that is reflected or scattered back to the receiver. Ultrasound waves are high-frequency sound waves above 20 kHz that are not audible to the human ear (audible range is 20 Hz–20 kHz). Frequencies useful in regional anesthesia are in the 4–17 MHz range. Tissues with different acoustic impedance interact with incident sound waves, causing attenuation, reflection, refraction, and scattering. What is reflected back to the transducer is transformed into an electrical signal that is processed by the ultrasound machine to generate an image on the screen. The greater the echogenicity of a particular tissue, the brighter it is depicted on the sonogram. The time it takes for the sound to be received after emission is used to calculate depth, based on the assumed speed of sound in tissue, which is 1540 m/sec. Anatomic structures can appear hypoechoic, hyperechoic or isoechoic, as summarized below:

- Structures with high water content, such as blood vessels, appear *hypoechoic* (dark or black) because the ultrasound waves are transmitted through these structures easily with little reflection.
- Structures with low water content, such as bone and tendons, appear *hyperechoic* (bright) because the transmission of ultrasound waves is blocked, and the strong signal returned to the transducer gives these structures a white appearance.

- Structures of intermediate density and acoustic impedance appear gray on the screen and are called *isoechoic*.

Transducer selection

In general, linear transducers provide a rectangular image, and sector view transducers produce a pie-shaped image with a small footprint. Because frequency determines the depth of tissue penetration, the depth of the target organ/tissue in an individual patient dictates the frequency range that is most useful. *Deep* structures (>4 cm) require low-frequency transducers in the 3–7 MHz range that penetrate well but at the expense of axial resolution. *Superficial* structures (0.5–4 cm) benefit from high-frequency transducers in the 10–15 MHz range that provide high axial resolution at the expense of penetration. Advanced, high-frequency transducers in particular demonstrate the characteristic fascicular appearance of nerves and the fibrillar appearance of tendons, and differentiate them from surrounding structures. Modern ultrasound equipment offers various enhancements to make high-quality nerve imaging simpler and more consistently achieved.

Imaging plane

Nerves can be viewed in short or long axis. *Short-axis (transverse) imaging* cuts through cylindrical structures in cross-section, producing a circular image on the screen (Fig. 59.1a). This orientation generally provides the most stable and recognizable image of nerves and surrounding structures, even with moderate transducer movement during block performance.

Long-axis imaging shows the same object longitudinally and depicts the course of cylindrical objects as linear (Fig. 59.1b). It is of limited use in ultrasound-guided regional anesthesia but can help confirm catheter placement for continuous nerve block techniques along a selected nerve.

In the *out-of-plane* (OOP) technique, the needle is introduced from outside the plane of imaging and crosses the scan plane so that the needle tip or shaft is shown as an *echogenic dot* (Fig. 59.2). This technique relies on observing tissue displacement caused by the advancing needle, as well as seeking the needle tip by adjusting the transducer position and angle. Aligning the structure of interest in the center of the

A
Figure 59.1. Short- or transverse-axis (A) and long-axis imaging planes (B).

image and then inserting the needle on the centerline of the transducer helps ensure relatively accurate needle placement. A 45° insertion angle from the skin is a good starting point. The needle tip is usually sufficiently hyperechoic that it stands out from muscle and fat, but the shaft may be harder to visualize directly and may be appreciated only by the shadow it casts.

The *in-plane* (IP) technique uses a needle introduced within the plane of imaging and shows the needle as an *echogenic*

line (Fig. 59.3). Only the portion of the needle that lies within this very thin scan plane can be seen, making it possible to advance the needle further than intended when the tip strays from the scan plane. The needle tip has a stepped appearance, whereas the shaft shows reverberation artifact (Fig. 59.4). Special echogenic needles are available that produce a brighter needle image over a broader range of insertion angles. All needles show a decrement in signal intensity when they are inserted at a steeper angle relative to the active face of the transducer.

A
Figure 59.2. Short- or transverse-axis OOP technique (A) and needle tip appearance on ultrasound (B).

Figure 59.3. Short- or transverse-axis IP technique (A) and needle appearance on ultrasound (B).

The IP approach requires a needle that is a few centimeters longer than the width of the transducer, to allow the needle to reach structures imaged on the side opposite the point of needle insertion.

Sonographic appearance of nerves

Nerves in ultrasound images usually have a *fascicular echotexture* that corresponds to the cross-sectional nerve structure seen on light microscopy, but with fewer fascicles resolved. The nerve fascicles appear hypoechoic, surrounded by hyperechoic epineurium and perineurium. Nerves also change shape and echotexture along their course. For example, proximal nerves,

such as the roots and trunks of the brachial plexus, appear hypoechoic and monofascicular but become hyperechoic and polyfascicular as they course into the periphery (Fig. 59.5).

General considerations for ultrasound-guided nerve blocks

As with non-ultrasound-guided techniques, the patient should receive sedation, supplemental oxygen and have standard monitoring. A clean transducer with acoustic coupling gel is covered with a sterile occlusive dressing or special sterile probe cover. Air trapped between the transducer and the sterile cover will result in shadowing because of the poor impedance of air for

Figure 59.4. Appearance of IP needle during brachial plexus block.

Figure 59.5. Proximal (A) and peripheral (B) nerve appearance on ultrasound.

ultrasound waves. Sterile acoustic gel is also required on the outside of the sterile cover and the patient's skin.

Touching one side of the active face confirms the *orientation* of the ultrasound transducer (Fig. 59.6). The orientation of the ultrasound transducer notch is by convention either cranial in longitudinal views or to the patient's right in transverse views. The ultrasound screen has an orientation marker that corresponds to the physical marker on the transducer.

Surface anatomy landmarks used in conventional, non-image-guided techniques can be used to guide the initial placement of the ultrasound transducer. Further adjustments are performed according to the ultrasound image to achieve the best nerve imaging. An optimal needle path is selected, and

the puncture site is infiltrated with a local anesthetic such as lidocaine 1% via a small-gauge needle. The larger block needle is inserted through the skin wheal. It is important to respect the proximity of surrounding structures, especially the lung, arteries, veins, and spinal cord. One should avoid blind needle insertion deeper than expected by the sonogram or if the target structure or needle (tip) is poorly visualized. Nerve stimulation can confirm needle position but does not appear to improve block success rate; moreover, it adds to the complexity of the procedure.

Injection of the local anesthetic for neural blockade is made incrementally, often in multiple sites, with continuous assessment of local anesthetic distribution. Circumferential spread around nerves produces rapid and complete conduction block (Fig. 59.7). If the solution does not appear to surround all components of the target structure, the needle position is adjusted before further injections are made. Injections should be made slowly with frequent aspiration and maintaining low injection pressures (< 20 psi). If local anesthetic distribution cannot be visualized after a test dose of 1 to 2 ml, the injection should be stopped. One should aspirate and reassess needle tip placement to rule out intravascular injection. Air bubbles not removed from the syringe or tubing are highly echogenic and markedly degrade image quality after inadvertent injection (Fig. 59.7). Bicarbonate-containing solutions also may obscure imaging because of their carbon dioxide content.

All blocks can be performed either as a single-shot or continuous technique. The continuous technique is similar to the single shot, but instead of a 20- or 22-gauge short-bevel needle, a 17- or 18-gauge Tuohy needle is used. Once the needle is in optimal position, a small amount of local anesthetic is injected to facilitate passage of the catheter that is then inserted to the desired depth and secured in place. This technique can provide excellent postoperative pain control over several days that may facilitate early rehabilitation.

Upper extremity nerve blocks

Eddy M. Feliz, Tanja S. Frey, Adam B. Collins, and Abdel-Kader Mehio

Introduction

Performing upper extremity nerve blocks requires detailed knowledge of anatomy, understanding of local anesthetic pharmacology, familiarity with the equipment, and preparation for possible complications. Upper extremity blocks are useful for a broad range of surgical procedures, ranging from the shoulder to the distal phalanges. The techniques used for nerve blocks have improved over time. Landmark-based approaches using paresthesias and nerves stimulation have largely been supplanted by ultrasound-guidance. Today ultrasound guidance is considered to be superior to older modalities in terms of maximizing success and minimizing morbidity.

Anatomy

The brachial plexus is formed by the ventral division of the cervical nerve roots of C5 through C8 and T1, with variable contribution from C4 and T2 (Fig. 60.1). These anterior divisions unite, forming trunks, divisions, cords, and terminal nerves. With the exception of the skin over the medial aspect of the arms (innervated by the intercostobrachial branch of T2) and the skin over the anterior portion of the shoulders (innervated by the cervical plexus, C1–4), the brachial plexus supplies all the motor and sensory innervation of the upper extremities.

Trunks

Nerve roots exit the spinal canal through the intervertebral foramina. In the space between the anterior and middle scalene muscles, the anterior divisions of these roots fuse together to form three trunks, the superior, middle, and inferior. The superior trunk receives fibers from C5 and C6, the middle trunk from C7, and the inferior trunk from C8 and T1. At this level, the phrenic nerve (C3–5) lies over the anterior scalene muscle. This explains its vulnerability to blockade during the interscalene approach, causing unilateral diaphragmatic paralysis.

Divisions

At the lateral border of the first rib, just behind the midpoint of the clavicle and posterior to the insertion of the anterior scalene muscle, each trunk forms an anterior and a posterior division to enter the axilla. Eventually, anterior divisions supply flexor muscles and posterior divisions supply extensor muscles.

Cords

The anterior and posterior divisions recombine to create three cords. These are named according to their relationship to the axillary artery. The lateral cord is derived from the anterior division of the superior and middle trunks. The medial cord is a continuation of the anterior division of the inferior trunk and the posterior cord originates from the fusion of the posterior divisions of all three trunks. These cords then divide into terminal branches at the lateral border of the pectoralis minor muscle.

Branches

The lateral cord gives rise to the musculocutaneous nerve and the lateral root of the median nerve. The medial cord contributes to the formation of the median nerve (medial aspect), the ulnar nerve, the medial cutaneous nerve of the forearm, and the medial cutaneous nerve of the arm. The posterior cord divides into the radial nerve and the axillary nerve.

Understanding the anatomic structure of the brachial plexus and the dermatomal innervation of each nerve root will increase the efficacy of the block while minimizing complications (Fig. 60.2). This knowledge allows one to choose the best approach to block the brachial plexus for the intended surgical procedure.

Brachial plexus blockade

Interscalene approach

The interscalene block targets the roots and trunks of the brachial plexus and is useful for surgical anesthesia and post-operative analgesia in the shoulder and arm. The patient is positioned semi-sitting or supine, with the arms adducted and the head turned to the contralateral side. Neck flexion against gravity demonstrates the sternocleidomastoid muscle, which lies just anterior to the interscalene groove. The interscalene groove is formed by the anterior and middle scalene muscles as they course toward their insertion in the first rib.

After patient preparation, a high-frequency linear transducer (10–15 MHz) is applied in the short axis. The carotid artery and internal jugular vein are identified and differentiated

Figure 60.1. Diagram of the brachial plexus.

by compressing with the transducer. The internal jugular vein is collapsible under the pressure, whereas the carotid artery should show distinct pulsations. Sliding the transducer laterally, the roots and trunks of the brachial plexus can be visualized as round, hypoechoic structures coursing between the anterior and middle scalene muscles (Figs. 60.3 and 60.4).

The brachial plexus is usually found 0.5 to 1.5 cm beneath the skin surface. It can be approached with the needle in or out of plane, depending on what appears to be the safest needle trajectory in a given patient. The puncture site is infiltrated with 1% lidocaine via a small-gauge needle. The out-of-plane (OOP) approach uses a 22-gauge short-bevel 1–2 inch needle inserted from outside the plane of imaging either cranial to caudal (Fig. 60.3) or lateral to medial. This may result in unconventional needle approaches that have the potential to cause complications, especially those resulting from the proximity of the lung, carotid, and vertebral arteries, as well as the spinal cord. Hence, it is important to image the needle tip while it is still superficial and to avoid blind passes.

The in-plane (IP) approach (Fig. 60.4) requires a longer needle, depending on the width of the transducer and depth of the target structures. A 22-gauge 2–3 inch needle is advanced slowly into the plane of imaging under real-time visualization. The needle trajectory can be either posterior to anterior, as shown in Fig. 60.4, or anterior to posterior. The IP approach may afford a greater degree of safety as long as the needle is imaged well throughout the procedure. When using the IP approach it is safer to insert the needle lateral to the ultrasound probe. Inserting the needle medial or anterior to the ultrasound probe may result in injury to the phrenic nerve. It is common to see physical separation of the roots of the brachial plexus in the interscalene groove (Fig. 60.4). An injection of 25 to 30 ml of local anesthetic solution is made incrementally, targeting the deeper roots (C8, T1) first so that the mass of local anesthetic does not drive these nerves deeper and make them less accessible later in the procedure. If spread around the more superficial roots is incomplete, the anesthetic should be reserved and the needle repositioned to obtain spread around the entire brachial plexus.

Figure 60.2. Cutaneous innervation of the upper extremity. (A) Arm supinated. (B) Arm prone.

Adverse effects and complications

Neural injury secondary to direct needle trauma can occur, but it is uncommon and self-limited. Ipsilateral phrenic nerve blockade leading to hemiparesis of the diaphragm occurs in almost 100% of patients and can result in up to 30% reduction in pulmonary function. Bilateral interscalene brachial plexus

blockade should be avoided. Frequent aspiration should be done during injection of local anesthetics, even though it does not exclude an intravascular injection. Pneumothorax is a rare complication but is more likely if the needle is directed too caudad ($>45^\circ$). Recurrent laryngeal, vagus, and cervical sympathetic nerve blockade have also been described. Epidural and intrathecal injection can be avoided if the needle orientation is maintained slightly caudad.

Supraclavicular approach

For a supraclavicular block, the patient is positioned in a semi-sitting, upright, or supine position with the arms adducted and the head turned to the opposite side. The clavicle and lateral border of the clavicular head of the sternocleidomastoid muscle provide a reference for where to place the high-frequency linear transducer. After patient preparation, the transducer is applied in the short axis. At this height, the trunks or divisions of the brachial plexus are typically visualized. The ultrasound picture is usually described as hypoechoic clusters of grapes between the anterior and middle scalene muscles, just cephalad to the subclavian artery (Fig. 60.5b). The lung or pleura can be seen deep to the first rib. Careful attention must be paid to the proximity of the lung and subclavian artery when performing a supraclavicular block, because this block carries a higher risk of inadvertent vascular puncture and pneumothorax.

For the OOP approach, the needle can be advanced in a cranial-to-caudal direction similar to the classical approach, the point of needle insertion being 2–3 cm above the

mid-clavicle, optimally in a 30° angle (Fig. 60.5). Often, there is little working room between the transducer and the neck, and given the potential for pneumothorax, it is preferable to use the lateral-to-medial IP approach. Here, the ultrasound transducer can be placed immediately superior and parallel to the clavicle.

Shadowing artifact may be caused by the bone in this position. The needle is inserted lateral to the transducer and carefully advanced from lateral to medial under real-time visualization (Fig. 60.6). Another approach places the ultrasound transducer at a 90° angle to the clavicle. Here, the needle is inserted near

the clavicular head of the sternocleidomastoid muscle, which resembles the “plumb-bob” approach, and advanced from the anterior-to-posterior direction. The transducer position and angle should be adjusted to image the advancing needle tip. Incremental injections of 25 to 30 ml of local anesthetic solution is made until the brachial plexus shows circumferential spread.

Adverse effects and complications

The most important complication associated with supraclavicular brachial plexus blockade is pneumothorax. Its incidence (0.5%–6%) is reduced with experience and the use of ultrasound to visualize the first rib and the lung while guiding the needle. However, this block should be avoided in patients with poor pulmonary reserve, and it is relatively contraindicated in outpatients if ultrasound is not available. Bilateral supraclavicular brachial plexus blocks should be avoided. Blockade of the phrenic (50%–60%), recurrent laryngeal, and cervical sympathetic plexus have also been described with this approach. Intravascular injection is possible, and frequent aspiration is advised during injection of the local anesthetic. Neural injury is rare and usually transient.

Infraclavicular approach

The patient is positioned supine, with the ipsilateral arm abducted and externally rotated. If this is impossible – for example, secondary to pain with movement – the arm also can be kept in a neutral or adducted position. This, however, may make it slightly more difficult to identify the subclavian/axillary artery. After sterile skin preparation and draping, a linear transducer (5–10 MHz) is placed immediately medial to the coracoid process in the short axis.

The subclavian/axillary artery underneath the pectoralis major and minor muscle is identified (Fig. 60.7b). Often, this is accomplished most easily by keeping the transducer very close to the inferior edge of the clavicle. One should be aware that the

close proximity to bone can cause a shadowing artifact that may reduce image quality. Adding Doppler function to the sonogram may be helpful in distinguishing the subclavian artery and vein, both of which are almost incompressible at this location. The cords may appear hyper- or hypoechoic at this level and take a lateral, medial, and posterior position with respect to the artery.

The puncture site and pectoralis muscles are infiltrated with 1% lidocaine via a small-gauge needle. Using the OOP approach, a 20- or 22-gauge short-bevel 3–4 inch needle is inserted at a 45° angle, or steeper. The needle is slowly advanced under real-time imaging from medial to lateral at this angle toward the subclavian artery and its surrounding cords (Fig. 60.7B). The medial cord may sometimes be difficult to find between the subclavian artery and vein.

For the IP approach, one can choose between the vertical paracoracoid (i.e., lateral; Fig. 60.8) or the classic approach. For the lateral approach, the transducer is placed immediately medial to the coracoid process in a parasagittal plane. If the arm is in the abducted position, the needle entry is approximately 2 cm medial and 2 cm caudal to the most prominent aspect of the coracoid process. A 22-gauge 3–4 inch needle is advanced from cranial to caudal toward the cords that surround the subclavian/axillary artery.

Alternatively, for the classic approach the transducer is applied at the middle of the clavicle in the parasagittal plane. The needle is introduced between the clavicle and the transducer and is advanced in a caudad and lateral direction within the imaging plane.

For a successful block, a total of 30 to 40 ml of local anesthetic should be injected in two locations: lateral (for the lateral and posterior cord) and medial (for the medial cord) from the artery (Fig. 60.7). Overlying muscle attenuates ultrasound waves, and the nerves deep to these muscles are often difficult to resolve well. This block is usually performed in a fairly

Figure 60.7. Infraclavicular block OOP approach. SA, subclavian artery; SV, subclavian vein; M, medial cord; L, lateral cord; P, posterior cord; PMi, pectoralis minor muscle; PMa, pectoralis major muscle.

Figure 60.8. Infraclavicular block IP, lateral approach.

lateral location that makes pneumothorax less common but still possible.

This location also is preferred for a continuous brachial plexus catheter technique to provide postoperative pain control. It has the advantage of an immobile insertion point that limits the risk of dislodgement.

Adverse effects and complications

Hematoma, nerve injury, chylothorax (following left-sided block), and infection are theoretically possible. Again, the risk of intravascular injection is minimized by careful aspiration before injection. If the needle is directed too medially, pneumothorax is also a possibility.

Axillary approach

The axillary block provides safe and effective conduction block of the terminal branches of the brachial plexus for procedures on the elbow, forearm, and hand. The patient is positioned supine, with the arm abducted approximately 90° and externally rotated (Fig. 60.9). Padding under the wrist to reduce extension

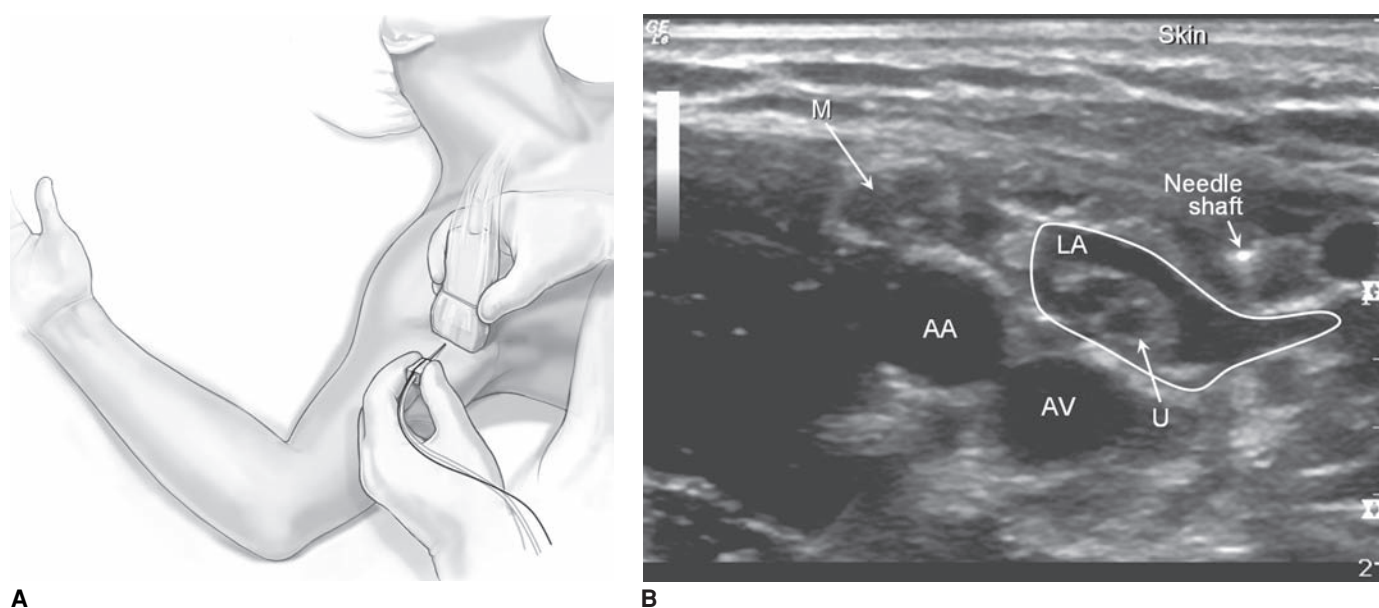

Figure 60.9. Axillary block OOP approach. AA, axillary artery; AV, axillary vein; M, median nerve; U, ulnar nerve; LA, local anesthetic.

and external rotation can make patients more comfortable while not compromising access to the brachial plexus. Surface landmarks include the pulse of the axillary artery, the coracobrachialis, and the pectoralis major muscle.

After patient preparation, a linear high-frequency transducer (10–15 MHz) is placed high in the axilla to image the nerves and vessels in short axis. The axillary artery is visualized easily with one or more nearby veins, and the median, ulnar, and radial nerves lie immediately adjacent to it. These structures usually lie 1 to 2 cm beneath the skin. The musculocutaneous nerve is outside the neurovascular bundle at this level and pierces the coracobrachialis muscle just lateral to the axillary artery.

For the OOP approach, a 22-gauge short-bevel 1–2 inch needle is inserted at a 45° angle to the skin and advanced distally to proximally crossing the plane of imaging. Local anesthetic

solution is deposited incrementally within the axillary sheath and around each accessible nerve, including the musculocutaneous nerve (Fig. 60.9b).

The IP approach requires a 22-gauge 2–4 inch needle that is advanced laterally to medially, starting at the edge of the transducer or going through the distal pectoralis major muscle (Fig. 60.10). The local anesthetic solution injection should surround each identified nerve and also spread in the axillary sheath (see Fig. 60.9b). It is usually best to perform the deep injections (the radial nerve) first so that superficial structures remain superficial and are not pushed deeper by the injected local anesthetic.

About 30 ml of local anesthetic solution is injected around the axillary artery and visible nerves or in at least two locations (anterior for the median and ulnar nerve and posterior to the axillary artery for the radial nerve; Fig. 60.11). About 5 mL of local anesthetic solution is injected around the

Figure 60.10. Axillary block IP approach. AA, axillary artery; M, median nerve; U, ulnar nerve; R, radial nerve; MCN, musculocutaneous nerve.

Figure 60.11. Axillary block postinjection. AA, axillary artery; U, ulnar nerve; R, radial nerve; M, medial nerve; LA, local anesthetic.

musculocutaneous nerve, seeking to fill the fascial plane in which it travels. Another 5-ml subcutaneous injection superficial to these structures blocks the intercostobrachial and medial brachial cutaneous nerves. This provides anesthesia to the medial arm and improves tourniquet tolerance.

Adverse effects and complications

Pneumothorax is not a complication of brachial plexus blockade at the axillary level. Arterial puncture can on rare occasions lead to hematoma is a possibility. Systemic toxicity and neural injury are the most significant complications associated with this approach. The risk of intravascular injection can be decreased by careful aspiration and incremental injection of the local anesthetic solution.

Distal nerve blocks of the upper extremity

Distal nerve blocks of the upper extremity can be useful after an incomplete brachial plexus block and in situations in which contraindications to the brachial plexus block exist. For example, such blocks may be useful when there is infection at the needle insertion site for a brachial plexus block and in patients in whom complications associated with brachial plexus block could be detrimental, such as bleeding diathesis, bilateral procedures and patients with limited pulmonary reserves.

Musculocutaneous nerve block

The musculocutaneous nerve provides the sensory innervation to the lateral aspect of the forearm from the elbow to the radiocarpal joint. This nerve can be blocked by injecting 3 to 5 ml of local anesthetic solution subcutaneously 1 cm proximal to the intercondylar line and 1 to 2 cm lateral to the biceps tendon.

Radial nerve block

The radial nerve provides sensory innervation to the posterior aspect of the forearm, the lateral aspect of the dorsum of the

hand, and the proximal portion of the dorsum of the thumb, index, middle, and radial side of the ring fingers. At the elbow, the radial nerve can be blocked by injecting 3 to 5 ml of local anesthetic solution in a fanlike manner, approximately 2 cm lateral to the biceps tendon on the intercondylar crease. If paresthesia is obtained or periosteum is contacted, the needle should be withdrawn 0.5 to 1 cm before injecting. At the wrist, the radial nerve is blocked by injecting 2 to 3 ml of local anesthetic solution lateral to the radial artery. In addition, a subcutaneous wheal should be raised on the lateral and dorsal aspect of the wrist.

Intravenous regional anesthesia (Bier block)

The upper extremity can be blocked for short procedures by intravenous regional anesthesia, first demonstrated by August Bier in 1908. An intravenous cannula is placed distally in the operative limb, and the limb is elevated and exsanguinated with a tight elastic wrap. A proximal tourniquet is then inflated well above arterial blood pressure (typically two adjacent cuffs are used). Local anesthetic solution is then injected via the intravenous cannula, typically 50 ml of 0.5% lidocaine without epinephrine (Fig. 60.12). Onset of anesthesia distal to the

Figure 60.12. Intravenous regional anesthesia (Bier block).

cuff occurs within 5 to 10 minutes, making this technique suitable for brief procedures below the elbow. If tourniquet pain develops, the distal cuff can be inflated (over anesthetized skin) and the proximal cuff deflated. The block is usually used for no more than 60 to 90 minutes, although reinjection has been described. Most authorities recommend deflation of the cuff no sooner than 20 minutes after injection to minimize the chance of systemic local anesthetic toxicity. Some recommend deflation and rapid reinflation, followed by deflation 1 to 2 minutes later to divide the absorption of drug. The principal risk of the procedure is systemic toxicity that can be minimized by following a careful technique. The simplicity and reliability of the block makes it popular for simple upper extremity procedures.

Lower extremity nerve blocks

Mônica M. Sá Rêgo and Adam B. Collins

This chapter presents an overview of the anatomy and describes the most commonly used techniques for performance of lower extremity nerve blocks.

Lumbar plexus

The lumbar plexus (Fig. 61.1) is formed by the anterior rami of the first four lumbar spinal nerves (L1–4) with occasional contributions from T12 and L5. Lower-extremity nerves originating from the lumbar plexus include the femoral nerve (L2–4), obturator nerve (L2–4), and lateral femoral cutaneous nerve (L2–3).

Femoral nerve block

Anatomy

The femoral nerve originates from L2–4 and is the largest nerve of the lumbar plexus. It emerges from the psoas muscle, descending in the groove between the psoas and the iliacus. On its course to the thigh, it remains deep to the fascia lata and fascia iliaca, where the femoral vessels lie in a plane between these two fascial layers. At the level of the inguinal ligament, it lies anterior to the iliopsoas muscle and lateral to the femoral artery. At the level of the inguinal crease, the femoral nerve is wider and more superficial than at the level of the inguinal ligament. After passing under the inguinal ligament, the femoral nerve divides into anterior and posterior branches. The femoral nerve supplies the sartorius, pectineus, and quadriceps muscles; the knee joint; the skin of the anterior and medial thigh; and the medial aspect of the leg (Fig. 61.2). The surface landmarks for a femoral nerve block are the anterior superior iliac spine, pubic tubercle, inguinal ligament, inguinal crease, and femoral artery pulse (Fig. 61.3).

The femoral nerve is closely associated with the femoral artery and vein but is not located in the same anatomic compartment. These vessels travel in the femoral sheath, but the femoral nerve lies over the iliopsoas muscle and is physically separated from the vessels by the fascia iliaca. This position prevents local anesthetic spread around the nerve if injected on the side of the vascular bundle. The mnemonic *VAN*, which describes the relationship of the femoral vein, artery, and nerve medially to laterally, should be remembered (Fig. 61.4).

Technique

The patient should be supine with the leg to be blocked positioned in slight abduction. After sterile skin preparation and draping, the skin is infiltrated with 1% lidocaine. A 22-gauge short-bevel insulated stimulating needle is inserted at a 45° angle cephalad, 1 cm lateral to the femoral artery pulse just below the inguinal crease. The peripheral nerve stimulator is set at 1.5 to 2.0 mA. The needle is advanced slowly until upward movement of the patella is observed. The current output is decreased and the needle advanced until the patellar movement is seen with a stimulation of 0.3 to 0.5 mA. After negative aspiration, 20 ml of local anesthetic is injected in small increments.

The femoral nerve also may be blocked as part of the fascia iliaca compartment block. A short-bevel needle is introduced below the junction of the medial and lateral thirds of the inguinal ligament and slowly advanced until two losses of resistance are felt (fascia lata and fascia iliaca), then 20 to 30 ml of the local anesthetic is injected.

If using ultrasound technology, a linear high-frequency transducer (10–15 MHz) is applied in the short axis just inferior to the inguinal ligament (that extends from the anterior superior iliac spine to the pubic tubercle; Fig. 61.4). After identifying the femoral vessels, the artery and vein can be distinguished by compression with the transducer. The femoral vein is collapsible under the pressure, whereas the femoral artery has pulsations. At this level, the femoral nerve has a flattened triangular shape, is usually hyperechoic, and may show small fascicles (Fig. 61.5). It lies at an angle at the junction between the hyperechoic subcutaneous tissue and hypoechoic iliopsoas muscle.

Using the out-of plane (OOP) approach, a 22-gauge short-bevel 2–3 inch needle is inserted caudal to the transducer at a 45° cephalad inclination, aiming for the lateral edge of the femoral nerve (Fig. 61.4). Two fascial pops can be appreciated by palpation and sonogram. The first is the needle traversing the fascia lata and the second, the fascia iliaca.

For the IP approach, a longer, 22-gauge 3.5–4 inch needle is advanced laterally to medially under real-time visualization (Fig. 61.5). Efforts should be made to image the tip of the needle, not only the shaft, to avoid vascular puncture that may result from advancing the needle too far. Short-bevel needles tend to deform fascia and then produce significant recoil as they pierce

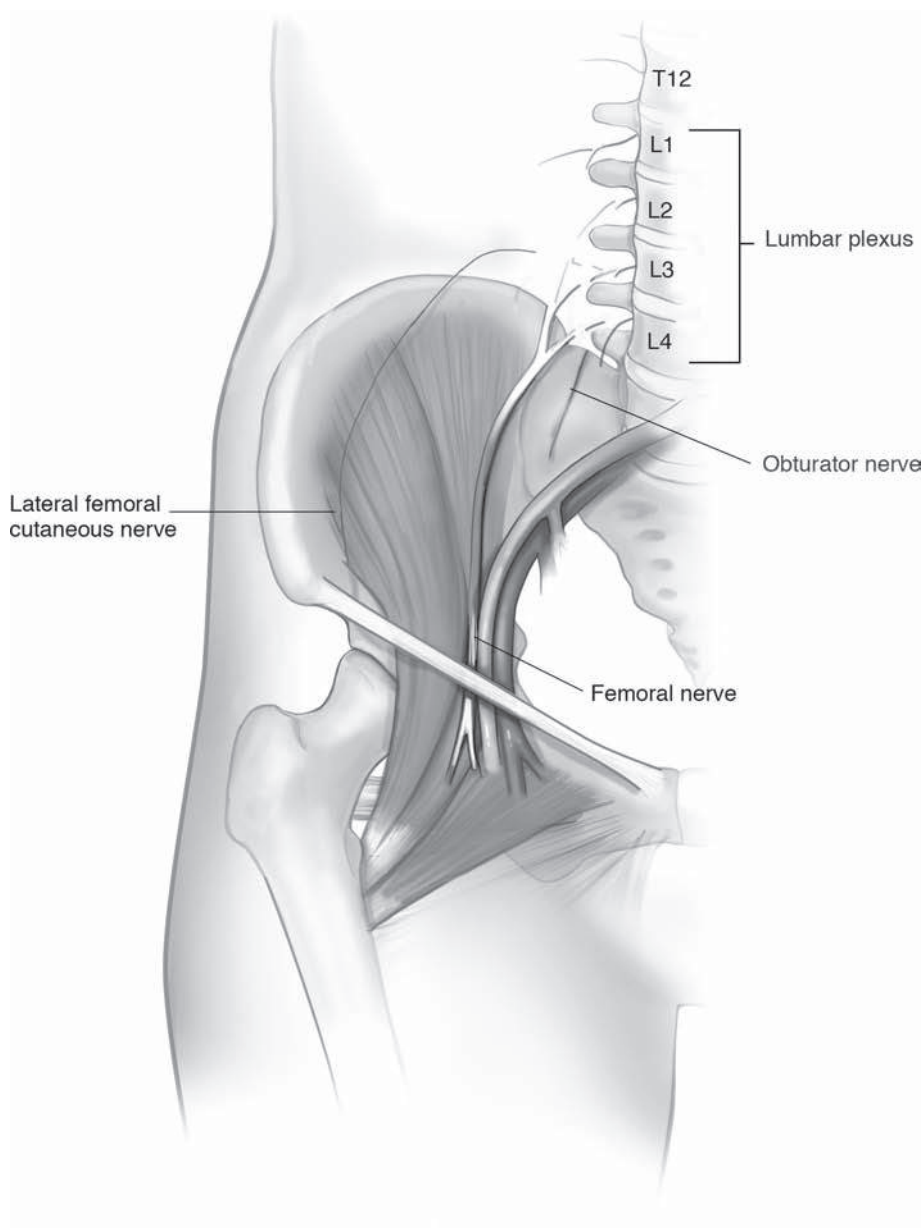

Figure 61.1. The lumbar plexus.

fascial planes, requiring some redirection to achieve optimal needle position.

After negative aspiration, 20 to 30 ml of local anesthetic solution is injected incrementally with real-time monitoring of the distribution of the solution (Fig. 61.6). Needle position may have to be adjusted to produce circumferential spread.

Lateral femoral cutaneous nerve block

Lateral femoral cutaneous nerve block is used for the diagnosis and treatment of meralgia paresthetica, and is combined with femoral and/or sciatic nerve blocks to allow the use of a thigh tourniquet. It also may be done to provide anesthesia on the lateral aspect of the thigh for skin procedures.

Anatomy

The lateral femoral cutaneous (L2–3) nerve emerges along the lateral border of the psoas muscle caudad to the ilioinguinal nerve. It courses deep to the iliac fascia to emerge from the fascia immediately inferior and medial to the anterior superior iliac spine. It divides into anterior and posterior branches below the inguinal ligament.

Technique

A short-bevel 22-gauge needle is inserted 2 cm medial and 2 cm caudal to the anterior superior iliac spine. The needle is advanced until a pop and loss of resistance are felt as the needle passes the fascia lata. About 10 ml of local anesthetic solution is injected in a fanlike fashion above and below the fascia lata.

Figure 61.2. Cutaneous distribution of the femoral nerve.

Obturator nerve block

The obturator nerve block is more often combined with the femoral, sciatic, and lateral femoral cutaneous blocks for surgeries on the lower extremities. It can be used as a single nerve block in urologic surgery to suppress the obturator reflex during transurethral resection of lateral bladder wall, or to relieve adductor muscle spasm.

Anatomy

The obturator nerve (L2–4) emerges medially to the psoas muscle at the pelvic brim. It runs caudad in the retroperitoneum to the obturator canal, where it divides into anterior and posterior branches. These provide sensory innervation of the medial thigh and hip joint and motor supply to the thigh adductors. The landmarks for this block are the anterior and superior iliac spines, pubic tubercle, inguinal ligament, femoral artery, and tendon of the long abductor muscle.

Technique

The block is performed at the inguinal level to facilitate its performance and make it less uncomfortable for patients. The inguinal fold is identified, and a line is drawn from the femoral artery pulse to the tendon of the long adductor muscle (identified during leg abduction). A 22-gauge needle connected to a nerve stimulator is inserted at the midpoint of the line at a 30° angle and directed anteriorly/posteriorly and cephalad. The needle is advanced slowly and slightly laterally until a response at 0.3 to 0.5 mA from the major adductor muscle is obtained. About 10 to 15 ml of local anesthetic solution is then injected after negative aspiration.

Sciatic nerve block

Anatomy

The sciatic nerve, the largest nerve in the body, originates from L4–S3 in the pelvis on the anterior surface of the piriformis muscle (Fig. 61.7). It exits the pelvis through the greater sciatic foramen, then descends between the greater trochanter of the femur and the ischial tuberosity. It runs along the posterior thigh to the lower part of the femur, where it splits into the tibial and common peroneal nerves (usually 5–12 cm proximal to the popliteal fossa crease). In the popliteal fossa, the sciatic nerve runs slightly lateral to the midpoint between the biceps femoris (lateral) and the semitendinosus tendons (medial), where it lies lateral and superficial in relation to the popliteal vessels.

The common peroneal nerve descends along the head and neck of the fibula. Its terminal branches are the superficial and deep peroneal nerves. The tibial nerve is larger and descends vertically through the popliteal fossa. Its terminal branches are the medial and lateral plantar nerves. Because the tibial nerve has a more defined sheath, an injection of a large volume of local anesthetic in its sheath may have a higher success rate compared with injection in the common peroneal sheath. The cutaneous distribution of the sciatic nerve is shown in Fig. 61.8.

Several approaches to block the sciatic nerve have been described since Victor Pauchet first presented the sciatic nerve block in 1920. The sciatic nerve block can be performed via the classic approach (Labat), the subgluteal approach (di Benedetto), the Franco approach, or the popliteal fossa distal approach. The sciatic nerve block is indicated for major procedures below the knee, and it is usually combined with the femoral nerve block.

Technique

Classical approach

The landmarks used for the classical approach are the greater trochanter and the posterior superior iliac spine (Fig. 61.9a). The patient should be in the lateral position, slightly rotated forward, with the dependent leg extended and the leg to be blocked flexed. The landmarks are marked and a line is drawn between them. A perpendicular line is then drawn distal to the midpoint of the above line. The needle insertion site is 4 cm distal to the midpoint (Fig. 61.9b). After sterile skin preparation and draping, the skin is infiltrated with 1% lidocaine. A 4–6 inch needle is inserted perpendicular to all planes. The nerve stimulator is set at 1.5 to 2.0 mA, and the needle is advanced slowly and the current gradually reduced until twitches of the foot are seen at 0.3 to 0.5 mA (Fig. 61.10). The sciatic nerve is usually located at a depth of 5 to 8 cm with this approach. After negative aspiration, 20 to 25 ml of local anesthetic solution is injected slowly. If the aforementioned approach fails to elicit twitches, the needle is redirected in a slightly caudal or cephalad direction.

Figure 61.6. Femoral nerve post injection. FA, femoral artery; FV, femoral vein; FN, femoral nerve; LA, local anesthetic.

Figure 61.7. The sciatic nerve.

Subgluteal approach

The subgluteal approach has the potential to decrease the discomfort usually seen with the classical posterior approach. The patient is placed at the same position as for the classical approach. The landmarks are the greater trochanter of the femur and the ischial tuberosity. A line is drawn between the two, with the midpoint marked. The needle insertion point will be 4 cm caudad to the midpoint marked. The needle should be inserted perpendicular to all planes and foot twitches noticed, as described earlier (Fig. 61.11).

Franco approach

The Franco approach is based on the concept that the relation of the sciatic nerve to the pelvis is similar in all adults and that the posterior projection of the ischial tuberosity is located at approximately the same distance from the midline. The landmark for this approach is the intergluteal sulcus (midline). A point 10 cm lateral to the midline is marked, and the needle is inserted at this point. This approach can be performed with the patient in the lateral or prone position. The rest of the technique is similar to the classical approach.

Popliteal fossa approach (posterior and lateral)

The popliteal fossa block is used primarily for foot and ankle surgery and postoperative pain control. The analgesia provided by popliteal fossa blocks lasts longer than that of ankle blocks. The popliteal fossa block can be performed through a posterior or lateral approach, and it can be done as a single injection or continuous technique. Both approaches are discussed below.

Posterior approach

The patient should be in the prone position, and the foot to be blocked should be either protruding from the end of the bed

Figure 61.8. Cutaneous distribution of the branches of the sciatic nerve.

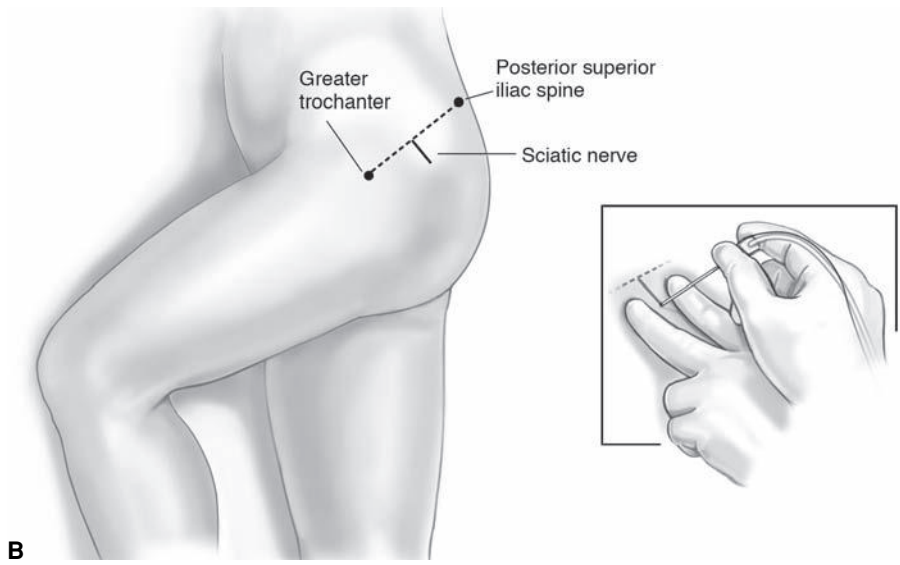

Figure 61.9. Posterior (classical Labat) approach to sciatic nerve block. **(A)** Landmarks. **(B)** Point of needle insertion.

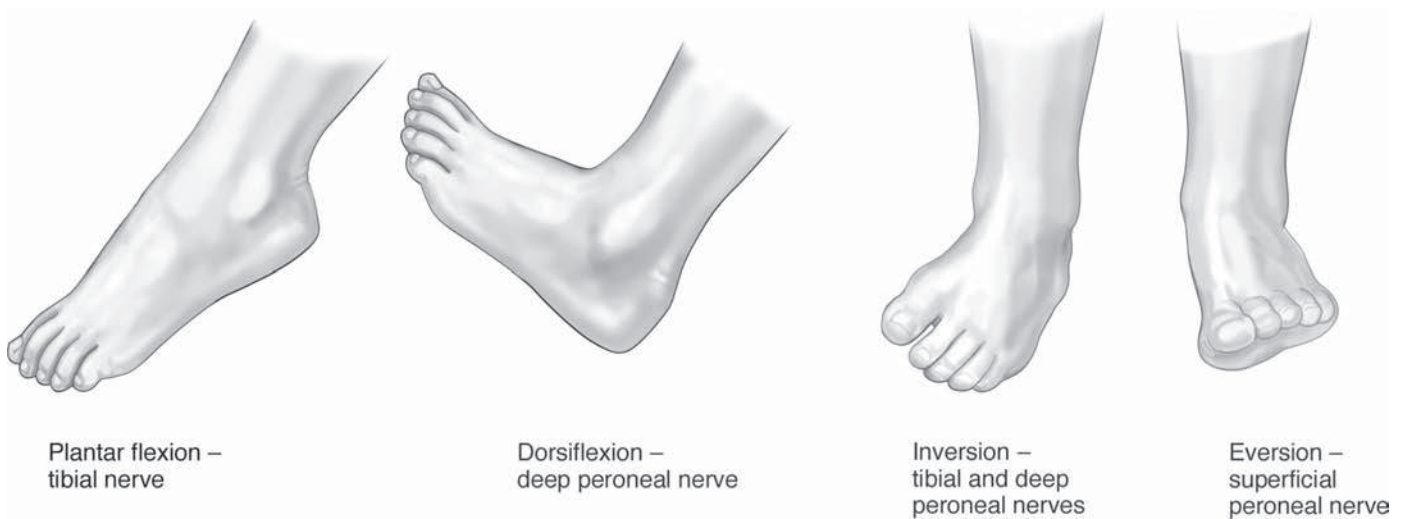

Figure 61.10. Movements observed when stimulating branches of the sciatic nerve.

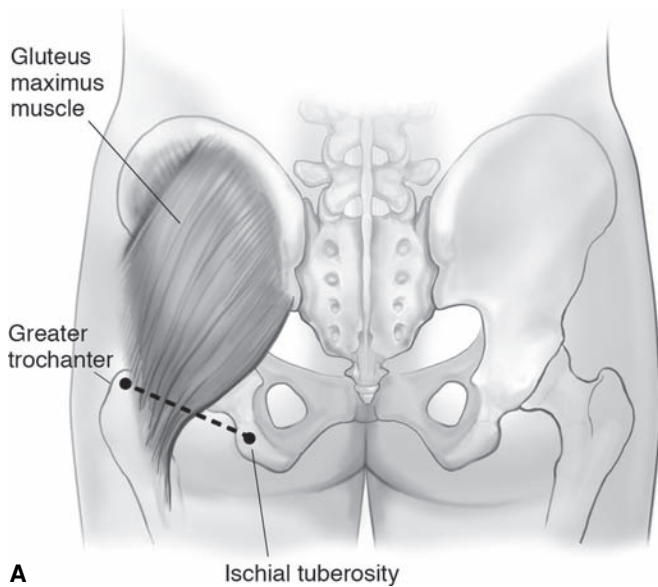

Figure 61.11. Subgluteal approach to sciatic nerve block. **(A)** Landmarks. **(B)** Point of needle insertion.

or slightly elevated, to allow for observation of foot movement. The landmarks are the popliteal fossa crease, the tendon of the biceps femoris laterally, and the tendons of the semitendinosus and semimembranosus medially. The patient is asked to flex the knee to facilitate visualization of the tendons. The point of needle insertion is marked at 7 to 9 cm above the popliteal fossa crease, at the midpoint between the tendons (Fig. 61.12).

Under sterile technique and skin infiltration with 1% lidocaine, a 22-gauge stimulating needle is inserted and directed proximally at a 45° angle. This should not result in local

muscular twitches. The stimulating current is decreased from 1.5 to 2.0 mA until foot twitches are observed at 0.3 to 0.5 mA, usually at 3 to 5 cm from the skin (Fig 61.10b). After negative aspiration, 30 ml of local anesthetic is injected. Injection of local anesthetic after stimulation of the tibial nerve is preferred, because it may result in a higher success rate.

The continuous popliteal block technique is similar to the aforementioned technique, but a 17-gauge Touhy type needle is used to allow insertion of a catheter. The catheter should be inserted 5 to 10 cm beyond the skin. Popliteal catheters

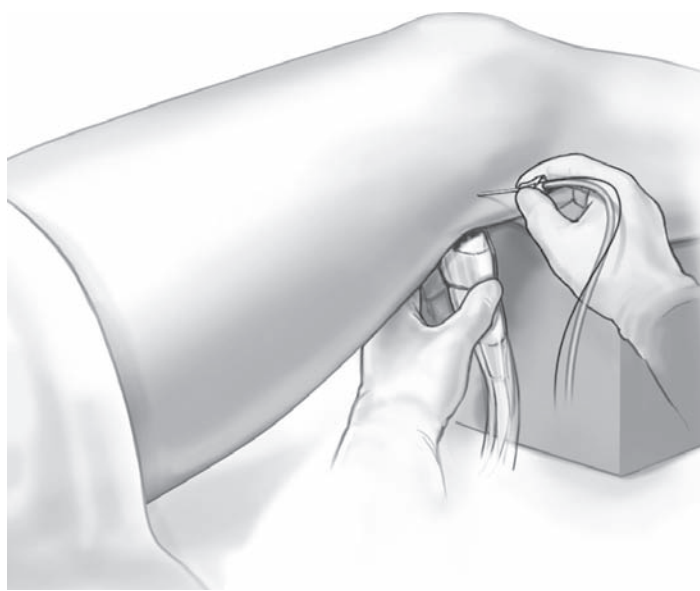

Figure 61.12. Popliteal block OOP approach. X, needle insertion site.

have been used successfully to manage postoperative pain after lower-extremity orthopedic procedures.

When this block is performed with the use of ultrasound imaging, the patient is positioned prone, as described above, for the OOP approach. After patient preparation, a linear high-frequency transducer (10–15 MHz) is applied in short axis slightly above the popliteal crease (Fig. 61.13). Once the popliteal artery is identified, the tibial nerve usually lies just superficial and can be traced retrograde until it joins with the common peroneal nerve, at the point of the bifurcation of the sciatic nerve (Fig. 61.13). Sliding and tilting the transducer tend to make the bifurcation more evident, as the operator can see one structure becoming two. This is usually the best location to perform a successful conduction block, because the proximal sciatic nerve is usually deeper and more encased in muscle, making it harder to image well. A 22-gauge short-bevel 2–3 inch needle is inserted with a 45° cephalad angulation and slowly

advanced as the transducer is manipulated to seek the needle tip position.

Lateral approach

The lateral approach usually is used when the patient cannot be placed in the prone position. The patient should be in the supine position with the foot to be blocked elevated to allow visualization of foot movement. The landmarks for this approach are the popliteal fossa crease, the vastus lateralis muscle, and the biceps femoris muscle. Under sterile technique, the needle is inserted in the groove between the vastus lateralis and biceps femoris muscle, about 10 cm above the popliteal crease. The needle is advanced perpendicular to skin until it contacts the femur, then it is withdrawn and redirected at a 30° angle posteriorly until foot twitches (depth of 5–7 cm) are observed, as with the posterior approach. The IP approach with the use of ultrasound imaging has the advantage of allowing the patient to remain

Figure 61.15. Innervation of the foot. **(A)** Anatomy of the five nerves innervating the foot. **(B)** Cutaneous distribution of the nerves of the foot.

supine. The ipsilateral leg is elevated on a lift or suspended by a sling to allow enough space beneath the thigh for the ultrasound probe. A 20- or 22-gauge 3–4 inch needle is introduced using landmarks as described above (Fig. 61.13). The needle is advanced under real-time visualization, adjusting the angle and position of the transducer to image the needle shaft and tip. Either the entire sciatic nerve or the tibial and common peroneal components should show local anesthetic spreading circumferentially, with approximately 30 ml of solution (Fig. 61.13 and Fig. 61.14).

The popliteal nerve block, in combination with a saphenous nerve block, provides anesthesia and postoperative analgesia for foot and ankle procedures. The saphenous nerve can be blocked

just above or below the anterior and medial aspect of the knee or by performing a femoral nerve block.

Ankle block

The ankle block is indicated for distal foot surgery, the most common being surgery for the diabetic foot and for bunion surgery. It is commonly done with landmarks alone, but ultrasound can help identify many of the nerves and improve success rates.

Anatomy

There are five peripheral nerves that innervate the foot (Fig. 61.15). The saphenous nerve is a branch of the femoral nerve

Figure 61.16. Injection sites for ankle block.

and supplies the medial aspect of the foot and ankle. The other four nerves are branches of the sciatic nerve. The sural nerve originates from the tibial nerve and the communicating superficial peroneal branches, and innervates the lateral aspect of the foot. The deep peroneal and superficial peroneal nerves are branches of the common peroneal nerve and innervate the area between the first and second toes and the dorsal aspect of the foot, respectively. The posterior tibial nerve supplies the lower and posterior surface of the heel and the plantar aspect of the foot.

Technique

The block is most easily performed with the patient supine, with the foot to be blocked elevated on a support (Fig. 61.16). The landmarks are the medial and lateral malleoli, the Achilles tendon, the extensor hallucis longus tendon, and the tibial and dorsalis pedis pulses.

The tibial nerve is blocked posterior to the medial malleolus. A 22-gauge needle is inserted posterior to the posterior tibial artery pulse, and 5 ml of local anesthetic solution is injected. The deep peroneal nerve is blocked with an injection of 5 ml of local anesthetic solution immediately lateral to

the extensor hallucis longus tendon (have the patient extend the great toe) deep to the retinaculum. The saphenous, sural, and superficial peroneal nerves are blocked at the level of the malleoli with a subcutaneous injection of 10 to 15 ml of local anesthetic solution in a circumferential line between the two malleoli.

It is advisable to block all five nerves, as there are variations in the dermatomal nerve supply. Epinephrine should not be used with the local anesthetic for ankle blocks because of the risk of causing ischemia in the foot.

Despite the fact that fluid replacement therapy is one of the most fundamental elements of the anesthetic and critical care of patients, it remains one of the most difficult. Because of a lack of clear data there are no precise rules for the amount, timing, or type (crystalloid vs. colloid or which type of either) of fluid replacement, nor for the hematocrit target for RBC replacement. To further complicate the issue it is not clear on which monitoring parameter the volume given should be based, especially if invasive monitoring is not used.

Fluid compartments

Understanding the general composition of the fluid compartment is the first step in the optimal management of fluids, electrolytes, and acid–base status in the operative and critically ill patient. The multiple fluid compartments are separated by semipermeable membranes through which water can move freely. The total body water (TBW) ranges from 50% (females) to 60% (males) of body mass, is distributed differentially among body tissues (Table 62.1), and is divided into the following compartments:

- Intracellular water is approximately 66% of the TBW (40% of the body mass)
- Extracellular water is approximately 34% of the TBW (20% of the body mass) and can be further divided:
 - Intravascular water is made up of plasma and is approximately 8% of TBW (5% of the body mass)

- Extravascular water is composed of lymph, interstitial fluid, bone fluid, fluids of the various body cavities, and mucosal secretory fluids, and represents approximately 25% of TBW (15% of the body mass)

Movement of water is determined by osmotic and hydrostatic pressure differences. The movement of water directly from tissue into the vasculature and the control of the flux by the relative hydrostatic and osmotic pressures in the two compartments was originally hypothesized by Ernest Starling in 1896 and is referred to as the Starling principle:

$$Q_f = K_f[(P_c - P_i) - \sigma(\pi_c - \pi_i)],$$

where Q_f = fluid flux across the capillary membrane; K_f = a constant; $P_c - P_i$ = the difference between the hydrostatic pressures in the capillary and in the interstitium; $\pi_c - \pi_i$ = the difference between the osmotic pressures in the capillary and in the interstitium; and σ = the reflection coefficient, which describes the permeability of a substance through a specific capillary membrane. Values range from 0 (completely permeable) to 1 (impermeable) in healthy tissue; reflection coefficients typically approximate 0.7.

Oncotic pressure (osmotic pressure in the intravascular compartment) is the result of negatively charged intravascular proteins to which vascular membranes are impermeable or positive ions that are associated with the negatively charged proteins. Albumin is the protein mainly responsible for the oncotic pressure (two-thirds of the total).

Clinical evaluation of fluid status

One goal of the evaluation is to determine the presence of hypovolemia or hypervolemia before the surgical procedure begins. Patients presenting in septic shock, those who may have undergone a bowel preparation preoperatively, or those who are otherwise physiologically deranged may be hypovolemic. Both hypovolemia and hypervolemia are associated with significant risks. Signs of hypo- and hypervolemia are summarized in Tables 62.2 and 62.3.

In addition, certain laboratory values, while very nonspecific, may help in assessment of volume status. For example, a high hematocrit, or plasma $[Na^+]$ may indicate a total body water deficit. A high blood urea nitrogen, a base deficit, a low mixed venous PO_2 , or urine output may indicate an inadequate

Table 62.1. Content of water in various organs of the human body

Organ	Distribution, %
Vessel-rich organs	
Heart	79
Brain	75
Lungs	79
Liver	68
Kidney	83
Vessel intermediate-rich organ/tissue	
Muscle	75
Skin	72
Vessel-poor organ/tissue	
Adipose tissue	10

Table 62.2. Signs and symptoms of hypovolemia

Signs	Fluid loss (percentage of body weight)		
	5%	10%	15%
Mucous membrane	Dry	Very dry	Parched
Sensorium	Normal	Lethargic	Obtunded
Orthostatic changes	None	Present	Marked
Heart rate			> 15 bpm ↑
Blood pressure			> 10 mm Hg ↓
Urinary flow rate	Mildly decreased	Decreased	Markedly decreased
Pulse rate	Normal or increased	Increased > 100 bpm	Markedly increased > 120 bpm
Blood pressure	Normal	Mildly decreased with respiratory variation	Decreased

cardiac output. A low central venous or pulmonary artery pressure, and a high pulse rate suggest inadequate intravascular volume. In addition, indirect signs, such as the response of blood pressure to changes in patient positioning or positive-pressure ventilation, the change in stroke volume to positive-pressure ventilation or the vasodilating or negative inotropic effects of anesthetics, may aid in the assessment of volume status. Although it is true that all the above signs may be helpful in the aggregate and when combined with other findings, it must be remembered that they are nonspecific and are altered by drugs used in the perioperative period and the physiologic effects of surgical stress.

Fluid therapy

Perioperative fluid therapy includes the replacement of:

- Preexisting fluid deficits
- Normal losses (maintenance requirements)
- Surgical wound losses (including blood losses)

Evaluation of preexisting fluid deficit

The constitutive daily losses of water and electrolytes are usually replaced by a maintenance fluid intake, calculated according to the data listed in Tables 62.4 and 62.5. Calculation of estimated hourly fluid needs is shown in Table 62.6. Preoperative fluid deficits should also take into account fluid deficits due to the conditions listed in Table 62.7.

Electrolytes are usually replaced by administration of salt solutions. Although intraoperative glucose replacement is not routinely recommended, the protein-sparing effect of parenteral glucose is one of the goals of basic glucose intravenous

Table 62.3. Signs and symptoms of hypervolemia

Early signs	Late signs
Pitting edema – presacral in the bedridden patient or pretibial in the ambulatory patient	Tachycardia
Increased urinary flow	Pulmonary crackles, wheezing, cyanosis, and pink, frothy pulmonary secretions

Table 62.4. Daily water loss

Insensible water losses
Normal losses by skin and lungs: 600–800 ml/d

Sensible water losses
From kidney and gastrointestinal tract: 1700 ml/d

Table 62.5. Daily requirements of electrolyte and glucose

Electrolyte and glucose	Daily requirement
Na ⁺	1–2 mEq/kg/day
Cl ⁻	1–1.5 mEq/kg/day
K ⁺	1–1.5 mEq/kg/day
Glucose	100–200 mg/kg/h

Table 62.6. Hourly maintenance fluid replacement (based on body weight)

Body weight	Fluid
0–10 kg	4 ml/kg/h
For the next 11–20 kg	Add 2 ml/kg/h
For each kg above 20 kg	Add 1 ml/kg/h for each kg above 20 kg

therapy in critically ill patients. Administration of at least 100 g/d of glucose reduces protein loss by more than one half. As a caloric source supplement, glucose intake should range from 100 to 200 mg/kg/h.

Table 62.7. Fluid losses in various clinical situations

Abnormal fluid losses
Preoperative bleeding
Vomiting
Diuresis

Occult losses
Traumatized tissues
Infected tissues
Ascites

Increased insensible losses due to
Hyperventilation
Fever
Sweating

Table 62.8. Classical procedural classification of redistribution and evaporative surgical fluid

Scale of surgery	Additional fluid requirement
Minimal (herniorrhaphy)	1–2 ml/kg
Moderate (appendectomy)	2–4 ml/kg
Severe (colectomy)	4–8 ml/kg

Maintenance requirements

Patients often present for surgery after an overnight fast without any fluid intake. This does not reduce blood volume. The presumed fluid deficit is proportional to the duration of the fast. This deficit can be estimated by multiplying the normal maintenance rate as shown in Table 62.6 by the length of the fasting period.

For example, for the average 70-kg person fasting for 8 hours, this amounts to $(40 + 20 + 50) \text{ ml/h} \times 8 \text{ hours}$, or 880 ml. (In reality, this deficit will be significantly less as a result of normal renal conservation, though replacement of this amount is routine in practice.) Ideally, all deficits should be replaced preoperatively in all patients. The fluids used should be similar in composition to the fluids lost. With fever, each degree above 98.6°F (37°C) requires one to add 2.5 ml/kg/d for an increase in insensible losses. It should be realized, however, that crystalloids are physiologically distributed over the entire extracellular space. This implies that up to 80% of the fluid administered will leave the intravascular compartment (over a time course on the order of 30 minutes). However, the final distribution of the fluids will depend somewhat on the state of intravascular volume when it was given.

Surgical fluid losses

Evaporative and redistributive losses

Intraoperative fluid losses are mainly the result of evaporation and internal redistribution of body fluids. Evaporative losses classically have been assumed to be directly proportional to the surface area of the exposed surgical wound and the duration of the surgical procedure, leading to gross overestimation of intraoperative fluid requirements and overhydration. Experiments using humidity chambers indicate that evaporative losses

in adults undergoing extensive abdominal procedures merely increase to about 1 ml/kg/h.

Redistribution appears to be related to the extent of surgical trauma (Table 62.8). Internal redistribution of fluids is often called “third spacing” because large amounts of fluid are sequestered into the interstitial space or translocated into anatomic spaces, such as the bowel lumen. This occurs with burns, extensive injuries, surgical dissections, or peritonitis but is also directly proportional to the amount of fluids infused. Lastly, significant losses of lymphatic fluid may occur during extensive retroperitoneal dissections.

Blood loss

Monitoring and estimating blood loss (Table 62.9) is important for guiding fluid therapy and blood product transfusions. Selection of the type of intravenous solution depends on the surgical procedure and the expected blood loss:

- Minimal blood loss and fluid shifts: maintenance solutions
- All other procedures: lactated Ringer’s solution

Fluid replacement therapy

Fluid replacement therapy should optimize cardiac preload and ensure adequate tissue oxygenation. It may consist of infusions of crystalloids, colloids, or a combination of both. The correct choice of fluid replacement therapy depends on the source and type of fluid that has been lost. In practice it is not known where the losses come from or their composition. Therefore, typically half-normal solutions are sometimes preferred for replacement of insensible losses and isotonic fluids (normal saline, lactated Ringer’s or colloids) are preferred for all other deficits.

Crystalloid solutions

Crystalloid solutions are electrolyte solutions of low molecular weight ions (salts) dissolved in water, with or without glucose (Table 62.10). These solutions may be isotonic, hypotonic, or hypertonic. Crystalloid solutions are very inexpensive. They rapidly equilibrate with and distribute in the extracellular fluid space, expanding the interstitial space more than the intravascular volume.

Table 62.9. Methods for estimating blood losses

Empiric measurements

Measurement of blood in the surgical suction container (adjusted to account for the volume of irrigating solutions)

Visual estimation of the blood on surgical sponges and laparotomy pads (“laps”):
 Fully soaked sponge (4 × 4) holds 10 ml of blood
 Soaked “lap” holds 100–150 ml of blood (the size of laparotomy pads may vary considerably among institutions)

More accurate estimates are possible if sponges and laparotomy pads are weighed before and after use. This is especially important when large numbers are used or, for example, in pediatric patients.

Laboratory

Serial hematocrit or hemoglobin may be useful during long procedures or when estimates are difficult (their concentrations reflect the ratio of blood cells to plasma, not necessarily blood loss; rapid fluid shifts and intravenous replacement affect measurements)

Table 62.10. Types and composition of crystalloid solutions

Solution	Na, mEq/L	Cl, mEq/L	K, mEq/L	Ca, mEq/L	Other	Osmolarity
D5W	0	0	0	0	Glucose 5 g/L	253
D5 0.45% NaCl	77	77	0	0	Glucose 5 g/L	432
0.9% NaCl	154	154	0	0		308
7.5% NaCl	1283	1283	0	0		1786
Lactated Ringer's	130	109	4	3	Lactate 28 mEq/L	273
Plasma-lyte	140	98	5	0	Acetate 27 mEq/L Gluconate 23 mEq/L Mg 3 mEq/L	294

D5W, 5% dextrose in water.

Crystalloids are used for maintenance and usually for the initial resuscitation fluid in the operative setting. Because administration of large amounts of saline often leads to a metabolic acidosis due to hyperchloremia, lactated Ringer's is the most common choice. In selecting between lactated Ringer's and saline, the patient's sodium-to-chloride ratio and the acid-base balance should be considered. Lactated Ringer's solution contains potassium and should be used with caution in patients with hyperkalemia or renal failure. Because they contain calcium, Ringer's solutions should not be used to dilute citrated blood products.

Colloid solutions

Colloid solutions contain high molecular weight substances, such as proteins and large glucose polymers dissolved in a solute (Table 62.11). Most colloid solutions are dissolved in isotonic saline but are available also as isotonic glucose and nonglucose solutions, as well as hypertonic saline solutions. For the most part, in healthy patients they remain intravascular and

help maintain the oncotic pressure. Although the intravascular half-life of a crystalloid solution is 30 minutes to 1.5 hours, most colloid solutions have intravascular half-lives of 4 to 6 hours. Colloid solutions should be used cautiously in patients with bleeding disorders, congestive heart failure, or renal disease with oliguria or anuria. The primary difference between Hetastarch and Pentastarch is that the latter has less variability in molecular size in addition to having a smaller average molecular size. The larger molecules contained in Hetastarch, of several million daltons and higher, are taken up by phagocytes in the reticuloendothelial system and are never metabolized or excreted. That is why the limit of units of Hetastarch is a lifetime limit. A reasonable molecular analogy is asbestos. Despite theoretical advantages and some demonstrated physiologic benefits in a few small studies, several large, multicenter randomized and observational cohort trials have failed to demonstrate any outcome advantage from colloid solutions over crystalloids.

Moreover, the substantial cost of colloids (\$44 for 250 ml of 5% albumin and \$21 for 500 ml of 6% hetastarch, versus \$1.10 for 1000 ml of normal saline and lactated Ringer's solution and \$1.75 for 5% dextrose in water and 5% glucose) and occasional complications (rare but severe allergic reactions, alteration in the anticoagulative pattern) associated with colloids tend to limit their use (Table 62.12).

Several types of colloid solutions are available for clinical use, including:

- **Blood-derived colloids:** albumin (5% and 25% solutions) and plasma protein fraction (5%). (Plasma protein fraction

Table 62.11. Types of colloids

Dextrose starches (dextran) – improves blood flow in the microcirculation by decreasing blood viscosity

Dextran 70 (Macrodex; Pharmacia, Piscataway, NJ) – average molecular weight of 70,000

Dextran 40 (Rheomacrodex; Pharmacia) – average molecular weight of 40,000

Dose: shock – 10 ml/kg infused rapidly; 20 ml/kg maximum 1st 24 h; 10 ml/kg maximum beyond 24 h

First-generation HES: hetastarch – 6% solution with an average molecular weight of 450,000 Da, molar substitution 0.7, C₂/C₆ ratio 6:1

Dose: volume expansion – 500–1000 ml (1500 ml/d maximum, 20 ml/kg/h rate)

Second-generation HES: pentastarch – 6% solution with average molecular weight of 264,000 Da, molar substitution 0.45, C₂/C₆ ratio 5:1

Dose: volume expansion: 500–2000 ml (2000 ml/d maximum, 20 ml/kg/h rate)

HES 130/0.4 (Voluven; Fresenius Kabi, Bad Homburg, Germany): 6% solution with mean molecular weight 130,000 Da, molar substitution 0.4, C₂/C₆ ratio 9:1

Dose: volume expansion: 500–2000 ml (3500 ml/d maximum, 20 ml/kg/h rate)

HES, hydroxyethyl starch.

Table 62.12. Adverse effects associated with colloids

Colloid	Adverse effects
Dextran	Antiplatelet effect (decreased aggregation), prolonged bleeding time, interference with blood typing, allergic reactions, renal failure
Hetastarch	High doses (> 1 L) may cause coagulation abnormalities (reduction in factor VIII and vWF, prolonged PTT) Newer formulations – i.e. third-generation HES 130/0.4 (Voluven; Fresenius Kabi, Bad Homburg, Germany) show improved safety profiles due to lower molecular size
Albumin	Expensive; relatively short intravenous half-life

HES, hydroxyethyl starch; PTT, partial thromboplastin time; vWF, von Willebrand factor.

contains α - and β -globulins in addition to albumin and may lead to allergic, hypotensive reactions.)

- Synthetic colloids: dextrose starches and gelatins (Table 62.11). Gelatins are associated with histamine-mediated allergic reactions and are not available in the United States.

Although isotonic saline and colloid-containing solutions both have been used to replace extracellular fluid deficits, controversy exists regarding the use of colloid versus crystalloid fluids for fluid resuscitation. There are two possible theoretical advantages of a colloid-containing solution over fluid repletion with saline:

- More rapid plasma volume expansion, because the colloid solution remains in the vascular space (replacing an intravascular volume deficit with crystalloids generally requires three to four times the volume needed when compared with colloids)
- Less risk of pulmonary edema, because dilutional hypoalbuminemia will not occur

However, as noted earlier, randomized controlled trials and systematic meta-analyses have failed to demonstrate any advantage in terms of pulmonary complications or survival for using colloid-containing solutions. Crystalloid (usually lactated Ringer's if large volumes are given quickly) solutions are therefore generally preferred. The solutions seem to be at least as safe and effective as colloid-containing solutions while costing much less. At the same time, it is important to keep in mind that rapid administration of large amounts of crystalloids (>4–5 L) is associated with significant tissue edema. Marked tissue edema may impair oxygen transport, tissue healing, and return of bowel function following major surgery.

Blood replacement therapy

Blood loss should be replaced with crystalloid or colloid solutions to maintain intravascular volume (normovolemia)

until the danger of anemia outweighs the risks of transfusion. Transfusion therapy is discussed in Chapters 66, 67, and 68.

Acid–base balance in anesthesia and intensive care medicine

George P. Topulos

Despite the fact that they are both common and important in the perioperative period and in intensive care, acid–base disorders are a source of considerable confusion. The imbalance itself is usually only important as a sign that something is wrong. It is the nature of the underlying *cause* of the acid–base imbalance that principally determines the patient’s prognosis and the nature of appropriate therapy. This chapter focuses on the primary causes of acid–base abnormalities, not on the abnormal $[H^+]$ ^a or pH. Imagine two patients, one with an acidemia due to hyperchloremia, another with the same degree of acidemia due to shock-induced lactic acidosis. The first patient is much more likely to do well than the second, and they will need very different therapies. Determining the underlying *cause* of the acid–base imbalance is the key to successful care of the patient. Although it is true that if an acid–base disorder results in a large-enough change in $[H^+]$ or pH (pH < 7.2 or > 7.6) it can cause secondary problems due to protein dysfunction (cardiac arrhythmias, vasoconstriction, or dilation), these secondary problems are uncommon (Adroque 1998a and b).

Respiratory acid–base disturbances are easy to understand and treat. High partial pressure of carbon dioxide (PCO_2) is caused by inadequate alveolar ventilation and results in an acidosis. Low PCO_2 is caused by excessive alveolar ventilation and results in an alkalosis. Short-term therapy is directed at restoring alveolar ventilation toward normal and ensuring adequate oxygenation, often with the use of mechanical ventilation and/or supplemental oxygen. Long-term therapy is directed toward correcting the underlying problem.

It is more difficult to determine the cause and magnitude of nonrespiratory (metabolic) acid–base disturbances. The most important causes of nonrespiratory acid–base disturbances are electrolyte disturbances (Na, Cl), increased organic acids (lactic acid, keto acids), ingested toxins (methanol, ethylene glycol, aspirin), and renal failure (sulfates and phosphates). The most commonly taught methods of acid–base analysis have been the bicarbonate/anion gap (AG) approach, and the base excess/base deficit (BE) approach. More recently, Stewart applied basic physical–chemical principles to acid–base analysis (Stewart 1978, 1981, 1983). Practical clinical applications of Stewart’s findings were developed first by Fencl and colleagues (Fencl

2000, 1993) and later by others (Kellum 2000, 1998, 1995). The Stewart–Fencl method is finding increasing use, especially in anesthesiology, surgery, and critical care. In medicine, considerable debate continues among members of the different schools, but in other scientific fields physical–chemical methods are used without debate (Kleypas 2006). The author believes the Stewart–Fencl method is the most effective, as well as the easiest to understand and implement, and is emphasized here. As the chapter proceeds, we also note how the AG and BE methods could be applied.

We begin by listing the components of normal plasma important in acid–base physiology and their concentrations (Fig. 63.1). This representation is called a *gamblegram*, and it is a useful tool for understanding nonrespiratory acid–base

Figure 63.1. Gamblegram for normal plasma. All concentrations are in milliequivalents per liter. Weak ions are in blue italics, strong ions are in black, and water dissociation products are in bolded blue. The height of individual rectangles is proportional to the concentration of the substances within it. Because all solutions must be electrically neutral, the total height of the right and left columns must be equal.

^a Throughout the chapter, brackets indicate concentrations, that is $[x] =$ the concentration of x, in milliequivalents per liter unless otherwise noted.

balance. Anions are shown on the right and cations on the left. Throughout the chapter, all ion concentrations are in milliequivalents per liter to account for the valence of all ions, and to make the relative concentrations clear. The height of individual rectangles is proportional to the concentration of the substances within them. Because all solutions must be *electrically neutral*, the total height of the right and left columns must be equal (Σ all cations = Σ all anions). Not shown in the diagram is water, which is present in a very high concentration $[\text{H}_2\text{O}] = 5.55 \times 10^4$ mEq/L, more than seven orders of magnitude greater than that of either $[\text{H}^+]$ or $[\text{OH}^-]$.

We then group the components into weak ions, strong ions, and water and its dissociation products.

Weak ions (shown in blue italics in Fig. 63.1) are incompletely dissociated at physiologic pH. They include the dissociation products of the $\text{CO}_2 - \text{H}_2\text{O}$ system $[\text{HCO}_3^-] = 24$ mEq/L and $[\text{CO}_3^{2-}] = 3.7 \times 10^{-2}$ mEq/L, charges on albumin $[\text{Alb}^-] = 12.7$ mEq/L, and inorganic phosphate $[\text{Pi}^-] = 2.2$ mEq/L. The degree of dissociation of each weak ion depends on the net pH of the solution and the dissociation constant for that weak ion. Importantly, the net pH of the solution is determined by other independent factors, discussed later. The Henderson–Hasselbalch equation describes the dissociation of carbonic acid into bicarbonate and a hydrogen ion:

$$pH = pK + \log \frac{[\text{HCO}_3^-]}{S * \text{PCO}_2},$$

where K is the dissociation constant for carbonic acid, and S is the solubility of CO_2 .

The equation's name honors the seminal contributions of Henderson and Hasselbalch. Similar equations describe the dissociation of bicarbonate into carbonate, albumin to $[\text{Alb}^-]$, and inorganic phosphate to $[\text{Pi}^-]$. It is important to note that the Henderson–Hasselbalch equation *describes* the pH-dependent dissociation of carbonic acid into bicarbonate. That is, if we know the values of any two of the three variables (pH, $[\text{HCO}_3^-]$, PCO_2) we can use the equation to calculate the third value. However, the Henderson–Hasselbalch equation alone cannot demonstrate the cause of acid–base imbalance because other factors to be discussed later, which are not present in the dissociation equations, play a key role. We must be careful not to confuse a descriptive equation with one that demonstrates causality.

We might ask ourselves, “What are the dissociation equations for NaCl, or lactic acid or keto acids, equivalent to those just discussed?” We do not need to calculate the degree of dissociation of these and other species in the second group, the *strong ions* (shown in black in Fig. 63.1), because they are completely dissociated (>99.9%) at all physiologic pH levels. The normal concentrations^b of the strong ions $[\text{Na}^+] = 140$, $[\text{K}^+] = 4.3$, $[\text{Ca}^{+2}] = 2.5$, $[\text{Mg}^{+2}] = 2$, and $[\text{Cl}^-] = 103$ (all mEq/L), the electrolytes, are all commonly measured in patients. The concentrations of the strong ions lactic acid, keto acids, and sulfate are each normally less than 1 mEq/L, and their concentrations are often unmeasured; ingested toxins (e.g., methanol, ethylene

glycol, aspirin) also generate strong ions. The organic acids and toxins are often referred to as *unknown anions* (UA), a group that also includes species that are truly unknown.

Because for acid–base calculations all strong ions have the same effect, their concentrations are summarized as the *strong ion difference*, $[\text{SID}] = \Sigma [\text{strong cations}] - \Sigma [\text{strong anions}]$. Note that the concentrations of strong ions may be changed by adding or removing the ion or by adding or removing water. The SID is the same as the “buffer base” of Singer and Hastings. The change in the SID from its normal value of about 39 mEq/L is numerically equivalent to the base excess (normal BE = 0 mEq/L), the amount of strong acid or base in milliequivalents per liter that would be required to titrate the pH of a sample of blood to 7.40 while the PCO_2 is held at 40 mm Hg and the temperature at 37°C. Because base excess is measured with the PCO_2 held at its normal value of 40 mm Hg, it reflects the sum of all nonrespiratory acid–base disturbances.

Water and its dissociation products (shown in bolded blue in Fig. 63.1) are the third group. Water is present in a very high concentration ($[\text{H}_2\text{O}] = 5.55 \times 10^4$ mEq/L) and only very slightly dissociated, $[\text{H}^+] = 4 \times 10^{-5}$ and $[\text{OH}^-] = 1.1 \times 10^{-3}$ mEq/L.^c However, although they are small, the concentrations of water's dissociation products ($[\text{H}^+]$ and $[\text{OH}^-]$) are critically important. Because the $[\text{H}_2\text{O}]$ is more than seven orders of magnitude greater than that of either $[\text{H}^+]$ or $[\text{OH}^-]$, it may be considered a constant, and the dissociation equation may be simplified to $[\text{H}^+][\text{OH}^-] = K'_w$, where K'_w is a temperature-dependent constant. Because at a fixed temperature, $[\text{H}^+][\text{OH}^-] = \text{a constant}$, if the concentration of one increases the other must decrease.

The complete development of Stewart's ideas is beyond the scope of this chapter; detailed reviews are presented elsewhere (Fencel 2000, 1993, Stewart 1981, 1983). Here, we present the principles on which the analysis is based and its major conclusions. We have just described the constituents of plasma important in acid–base physiology. To this system, Stewart applied three rules: (1) Conservation of mass, that is, the total amount of Na, H, albumin, or other entity is fixed unless some is added to or removed from the system. Note that although the total amount of H is fixed, it may exist in the form of H_2O , HCO_3^- , H^+ , and so on. Similarly, the total amount of albumin is fixed, but the amount ionized, Alb^- , will vary. (2) All solutions must be electrically neutral, that is, the sum of all the positively charged ions must equal the sum of all the negatively charged ions. (3) The dissociation equilibria, described earlier, of all weak ions, and water, must be met simultaneously and at all times.

Stewart's analysis (not presented here) showed that three independent variables (i.e., causative factors) determine acid–base balance:

1. PCO_2
2. Total concentration (ionized + nonionized) of weak anions $[\text{A}_{\text{tot}}]$, which in plasma is made up of albumin $[\text{Alb}_{\text{tot}}]$ and inorganic phosphate $[\text{Pi}_{\text{tot}}]$

^c $[\text{H}^+] = 4 \times 10^{-5}$ mEq/L = 4×10^{-8} Eq/L, the $-\log$ of which yields the familiar plasma pH = 7.40.

^b Units and normal values vary according to institution.

3. Strong ion difference ($[SID] = \Sigma [\text{strong cations}] - \Sigma [\text{strong anions}]$)

All the other acid–base variables (pH, $[H^+]$, $[OH^-]$, $[HCO_3^-]$, $[CO_3^{2-}]$, $[Alb^-]$, $[Pi^-]$, etc.) are dependent variables (things that change with but do not cause acid–base disturbances), the values of which depend on the values of the three independent variables.

To summarize all the preceding information: We care about the underlying causes of acid–base abnormalities; abnormal $[H^+]$ or pH is merely a sign that something is wrong. All acid–base abnormalities must be the result of an abnormal value of one or more of the three independent variables: PCO_2 , strong ion difference, and total weak anion (albumin and phosphate) concentration. Abnormalities of dependent variables are signs, not causes, of acid–base disturbances. If we want to change the acid–base status, we must change one or more of the independent variables. Next, we describe how to use the gamblegram as a tool, then examine each of the three independent causes of acid–base abnormalities; we conclude the chapter with a straightforward method for implementing this analysis in practice.

We use the gamblegram (Fig. 63.1) whenever we consider nonrespiratory (metabolic) acid–base balance – that is, the total concentration of weak anions and SID. Because the components of plasma important in acid–base physiology are represented in the diagram, it serves to remind us of all the factors we need to evaluate. In addition, it allows us a straightforward *qualitative* understanding of which dependent variables will change and in what direction after a change in an independent variable. Recall the following to make maximum use of the gamblegram:

1. Electrical neutrality requires that the sum of *all* cations equal the sum of *all* anions. The total height of the left and right columns must be the equal. However, remember that the sum of *strong* cations does *not* equal the sum of *strong* anions. In fact, normally the strong ion difference = $([Na^+] + [K^+] + [Ca^{++}] + [Mg^{++}]) - ([UA^-] + [Cl^-]) \approx 39 \text{ mEq/L}$. The independent variable [SID] is determined by the concentration of strong ions. The [SID] is “filled in by” (but not determined by) the weak ions $[HCO_3^-] + [Alb^-] + [Pi^-]$, which change their ionized fractions to maintain electrical neutrality. That is, the sum of the weak anions $[HCO_3^-] + [Alb^-] + [Pi^-]$ must equal the true SID.^d We use this fact later to estimate the concentration of unknown ions, which cannot be measured directly.
2. Clinically, we measure and control the total $[Pi_{tot}]$ and $[Alb_{tot}]$ (independent variables), but only the charged $[Pi^-]$ and $[Alb^-]$ (dependent variables) appear in the gamblegram. The values of $[Pi^-]$ and $[Alb^-]$ depend strongly on $[Pi_{tot}]$ and $[Alb_{tot}]$ and their dissociation constants, but only weakly on the net pH of the system.

^d For these calculations, the $[CO_3^{2-}]$, $[OH^-]$, and $[H^+]$ are so small they can be ignored.

Therefore, for clinical purposes, the concentrations $[Pi^-]$ and $[Alb^-]$ are taken to be proportional to $[Pi_{tot}]$ and $[Alb_{tot}]$, respectively (Fencel 2000) (see Appendix 1).

3. As the PCO_2 increases, $[H^+]$ and $[HCO_3^-]$ also increase. Surprisingly, as PCO_2 increases, the $[CO_3^{2-}]$ falls.
4. Because at constant temperature, $[H^+][OH^-] = \text{constant}$, if one goes up the other must go down. At concentrations of $[H^+] = 4 \times 10^{-5}$ and $[OH^-] = 1.1 \times 10^{-3} \text{ mEq/L}$, neither can increase or decrease enough to make significant contributions to maintaining electrical neutrality. The same is true of carbonate.

Examples using the gamblegram

Example 1: an isolated increase in $[Na^+]$

The left column has gotten taller and so must the right column (Fig. 63.2a). Neither the concentrations of unidentified strong ions $[UA^-]$ nor those of $[Cl^-]$ can increase, because we have not added them (conservation of mass). So, the only way for the right column to grow to match the increased height of the left is through an increase in dissociation of all the weak anions, especially $[HCO_3^-]$, $[OH^-]$, $[Alb^-]$, and $[Pi^-]$. If $[OH^-]$ increases, then $[H^+]$ must fall. Hence, an increase in $[Na^+]$ causes an alkalosis. The same is true for anything that increases SID, such as a decrease in $[Cl^-]$.

Example 2: an isolated increase in $[Cl^-]$ by 4 mEq/L

If the right column grew taller by 4 mEq/L, then the left column would need to as well (Fig. 63.2b). The concentrations of $[Na^+]$, $[K^+]$, $[Ca^{++}]$, and $[Mg^{++}]$ cannot increase because we have not added them (conservation of mass). The only other way the left column could grow 4 mEq/L would be for the $[H^+]$ to increase by 4 mEq/L (to a pH < 2.4), but $[H^+]$ never exceeds even 10^{-4} mEq/L . When $[Cl^-]$ increases by 4 mEq/L, the $[H^+]$ does increase, but by only a tiny amount. The two columns stay the same height because other parts of the right column shrink to balance the increased $[Cl^-]$. The unidentified strong ions $[UA^-]$ cannot decrease if we do not remove any of them (conservation of mass). Electrical neutrality is maintained through decreased dissociation of all the weak anions, $[OH^-]$, $[CO_3^{2-}]$, $[HCO_3^-]$, $[Alb^-]$, and $[Pi^-]$. $[H^+]$ increases and $[OH^-]$ decreases; an increase in $[Cl^-]$ causes an acidosis. The same is true for anything that decreases SID, such as a decrease in $[Na^+]$ or an increase in $[UA^-]$, as in lactic acidosis or ketoacidosis.

Example 3: an isolated decrease in $[Alb_{tot}]$ by 2 g/dl

If $[Alb_{tot}]$ decreases, then so will the amount ionized, $[Alb^-]$, by about 5 mEq/L (Fig. 63.2c). If the right column gets shorter, then so must the left column. However, the concentrations of the strong cations $[Na^+]$, $[K^+]$, $[Ca^{++}]$, and $[Mg^{++}]$ cannot decrease if we do not remove any of them (conservation of

Figure 63.2A. Gamblegram for isolated increase in $[Na^+]$ by 4 mEq/L. Increase in $[Na^+]$ without change in other strong ions, so $[SID]$ increased to 43 mEq/L. This change in SID , an independent variable, causes a metabolic alkalosis ($pH = 7.43$). No other strong ions were added or removed so their concentrations do not change. In order to maintain electrical neutrality in the face of an increased SID , the degree of ionization of all weak anions – dependent variables (principally $[HCO_3^-]$) – increases to “fill in” the gap.

Figure 63.2C. Gamblegram for isolated decrease in $[Alb_{tot}]$ by 2 g/dL. Decreased $[Alb_{tot}]$ results in decreased $[A_{tot}]$, an independent variable causing a metabolic alkalosis ($pH = 7.45$). No strong ions were added or removed so the SID cannot change. In order for electrical neutrality to be maintained with a decreased $[A_{tot}]$, the degree of ionization of weak anions (principally $[HCO_3^-]$) increases. The $[Alb^-]$ falls as a direct consequence of the decreased $[Alb_{tot}]$ even though the ionized fraction increases somewhat. Note it is the independent variable $[Alb_{tot}]$ that we can control and which decreased by 2 g/dL, but it does not appear in the gamblegram. The dependent variable ionized albumin $[Alb^-]$ is shown.

Figure 63.2B. Gamblegram for isolated increase in $[Cl^-]$ by 4 mEq/L. Increase in $[Cl^-]$ without change in other strong ions, so $[SID]$ decreased to 35 mEq/L. This change in SID , an independent variable, causes a metabolic acidosis ($pH = 7.30$). No other strong ions were added or removed so their concentrations do not change. In order to maintain electrical neutrality with a decreased SID , the degree of ionization of all weak anions (principally $[HCO_3^-]$) decreases.

mass). The $[H^+]$ will fall, but because it is orders of magnitude smaller than $[Alb^-]$, it cannot fall nearly enough to maintain electrical neutrality. Neither the concentrations of unidentified strong anions $[UA^-]$ nor those of $[Cl^-]$ can decrease if we do not remove any of them (conservation of mass). Electrical neutrality must be maintained through increased dissociation of the other weak anions, especially $[HCO_3^-]$ and $[Pi^-]$. $[H^+]$ decreases and $[OH^-]$ increases; a decrease in $[Alb_{tot}]$ causes an alkalosis. Conversely, an increase in $[Alb_{tot}]$ or $[Pi_{tot}]$ causes an acidosis.

Causes of acid–base disturbances

Table 63.1 summarizes all the causes of acid–base disturbances described by Stewart and Fencil. Following, we examine each of the three independent causes of acid–base abnormalities in more detail.

PCO₂ respiratory acid–base disturbances

PCO₂ respiratory acid–base disturbances are easy to understand and treat. High PCO₂ is caused by inadequate alveolar ventilation and results in an acidosis. Low PCO₂ is caused by excessive alveolar ventilation and results in an alkalosis.

Table 63.1. Summary of all causes of acid–base disturbances as described by Stewart and Fencil

	Acidosis	Alkalosis
Respiratory	↑ PCO ₂	↓ PCO ₂
Nonrespiratory (metabolic)	↓ [SID] or ↑ [A _{tot}]	↑ [SID] or ↓ [A _{tot}]
[SID]: [Na ⁺] or [H ₂ O]	↓ [Na ⁺]	↑ [Na ⁺]
[SID]: [Cl ⁻]	↑ [Cl ⁻]	↓ [Cl ⁻]
[SID]: unidentified anions	↑ [UA ⁻] lactic acid, keto acids, toxins	–
Total albumin	↑ [Albumin] rare	↓ [Albumin] common in critical illness
Total Pi	↑ [Pi] renal failure or acute tissue destruction	–

Total concentration of weak anions, albumin [Alb_{tot}], and inorganic phosphate [Pi_{tot}]

Increases in [Alb_{tot}] or [Pi_{tot}] cause acidosis, and decreases cause alkalosis. Because the normal [Pi_{tot}] is so small, low values cannot cause significant acid–base problems. High [Pi_{tot}] is seen in chronic renal failure and, because phosphate is present in high concentrations within most cells, in acute tissue destruction. High [Alb_{tot}] is uncommon but is seen in cases of severe water loss. Low [Alb_{tot}] is very common in critically ill patients. The alkalosis caused by hypoalbuminemia is not in and of itself of great importance. However, unrecognized, the alkalosis of hypoalbuminemia can mask the presence of concurrent acidosis due to increased unmeasured anions such as lactic or keto acids. A patient with an acidosis due to a lactate of 6 mEq/L and an alkalosis due to a [Alb_{tot}] of 2 mg/dl would have a normal pH. It is primarily for this reason that measuring albumin is important in acid–base analysis. Although the [Alb_{tot}] strongly influences acid–base balance, it is regulated for reasons that are unrelated to acid–base homeostasis, mainly to regulate osmotic pressure.

Strong ion difference, [SID] = Σ[strong cations] – Σ[strong anions]

An increase in SID causes an alkalosis, and a decrease in SID causes an acidosis. The concentrations of [K⁺], [Ca⁺²], and [Mg⁺²] each are low and cannot fall individually enough to cause a significant decrease SID. Their concentrations are

Table 63.2. Major causes of decrease in [Cl⁻] relative to [Na⁺] – increase SID alkalosis

Lose Cl in excess of Na	Gain Na in excess of Cl
Renal Diuretics	Na HCO ₃
Gastrointestinal ^a Vomiting Nasogastric tube drainage	Hyperalimentation (when cations are given as acetates rather than chlorides)

^a Gastric fluid has very low SID because of a high [Cl⁻]. Pancreatic, bile, and colonic fluids have very high SID because of a high [Na⁺].

Table 63.3. Major causes of increase in [Cl⁻] relative to [Na⁺] – decrease SID acidosis

Lose Na in excess of Cl	Gain Cl in excess of Na
Renal Renal tubular acidosis Acetazolamide Nephrotoxic drugs	Normal saline Hyperalimentation (when cations are given as chlorides rather than acetates)
Gastrointestinal ^a Biliary (T-tube) drainage Diarrhea	KCl

^a Gastric fluid has very low SID because of a high [Cl⁻]. Pancreatic, bile, and colonic fluids have a very high SID because of a high [Na⁺].

tightly controlled for reasons unrelated to acid–base balance, and if they increase, they cause life-threatening electrophysiologic problems before causing significant acid–base problems. They are not shown in Table 63.1.

Because of their high concentrations, [Na⁺] and [Cl⁻] are the dominant strong ions in plasma. Because it is the strong ion *difference* that controls acid–base balance, it is the relative [Na⁺] and [Cl⁻] that matters, not their individual values. Note that high [Na⁺] may be caused by a sodium excess or a water deficit, and vice versa in the case of a low [Na⁺]. The distinction must be made on clinical grounds. The [Na⁺] is regulated to control total body water, not for acid–base homeostasis. The causes of increased and decreased [Cl⁻], relative to [Na⁺], are shown in Tables 63.2 and 63.3. They are also discussed in chapters on fluids and electrolytes, and on hyperalimentation.

The normal [UA⁻] ≈ 5 mEq/L is the sum of several organic anions, each normally present at a low concentration; they cannot fall enough to significantly increase SID. Strong unknown anions are a problem when their concentrations are high, such as with increased organic acids (lactic acid, keto acids) and ingested toxins (methanol, ethylene glycol, aspirin) and in renal failure, in which sulfates, Cl⁻, and other unknown anions of renal failure are increased (in addition to the weak ion phosphate). Because we cannot measure their values directly, we estimate [UA⁻] as described later.

Proponents of the bicarbonate anion gap approach would describe all nonrespiratory acid–base abnormalities in terms of the changes in the dependent variable [HCO₃⁻], with or without an increased anion gap. The AG = [Na⁺] + [K⁺] – [HCO₃⁻] – [Cl⁻] with a normal value = 16 mEq/L. It is evident from the gamblegram that to maintain electrical neutrality, the “gap” must be filled by anions other than [HCO₃⁻] and [Cl⁻], namely [UA⁻], [Alb⁻], and [Pi⁻]. The idea is that in the presence of a metabolic acidosis caused by increased UA, the anion gap will be elevated.

Proponents of the base excess approach would describe all nonrespiratory acid–base abnormalities in terms of the calculated BE. In the presence of a metabolic acidosis, the BE should be negative (base deficit); in the presence of a metabolic alkalosis, the BE should be positive. Both the AG and BE methods assume a normal [Alb_{tot}] and are inaccurate in its absence.

Methods for correcting the AG and BE for hypoalbuminemia are given in Appendix 1. Fencl and colleagues have shown that without correction, both the AG and BE methods often fail to detect important acid–base disturbances in critically ill patients (Fencl 2000, 1993, Figge 1998).

We conclude the chapter by describing two ways to implement the Stewart approach, both developed by Fencl and colleagues. Both methods quantify the qualitative information described earlier using the gamblegram and in Tables 63.1 and 63.2. The first (Fencl and Leith, personal communications 1982–1985; later a modified version was published by others (Gilfix 1993)) is easy to apply at the bedside; the only calculations necessary are done easily by hand. Initial measurements needed are as follows:

From arterial blood gas	From chemistry
PaCO ₂ , mm Hg	[Na ⁺], mEq/L
pH	[Cl ⁻], mEq/L
BE, mEq/L	Total [albumin], mg/dl

Step 1, determine whether the patient has an acidemia (low pH) or alkalemia (high pH); the net pH of the blood is the sum of all concurrent acidoses and alkaloses.

If there is a single primary disturbance and a secondary compensation, the direction of the primary disturbance will be given by the pH. In simple cases, a primary disturbance in SID will usually result in a respiratory compensation returning the pH toward (but not to) normal. A primary respiratory acid–base disturbance usually results in a nonrespiratory compensation (renal modulation of plasma [Cl⁻]), returning the pH toward (but not to) normal. Respiratory compensation happens quickly, in minutes to hours. Renal compensations are not complete for several days. However, in patients, the normal compensations often are not seen because they are overwhelmed by our clinical interventions, namely intravenous fluid therapy, drugs, and mechanical ventilation. In addition, critically ill patients often have multiple concurrent independent acid–base problems, such as acidosis due to high [Cl⁻], alkalosis due to low [Alb_{tot}], and acidosis due to increased inorganic acids (UA). Using the expected levels of compensation to differentiate the multiple causes of complex acid–base disorders in critically ill patients is ineffective.

Step 2, examine the PaCO₂. If it is high, there is a respiratory acidosis, if low a respiratory alkalosis.

Step 3, use the BE as a measure of the change in SID from its normal value, and determine quantitatively what nonrespiratory factors are responsible for the observed BE. Real changes in SID may be a result of changes in [Na⁺] or [H₂O], [Cl⁻], or increased [UA⁻]. In addition, although albumin is a weak ion, abnormal albumin concentrations cause an error in the measured BE, which must be accounted for. Calculate the magnitude of change in the BE due to [Na⁺] or [H₂O], [Cl⁻], and [Alb_{tot}], as shown in the following table. Any remaining BE must be the result of increased [UA⁻], which we cannot measure directly.

Factors that change BE	Magnitude of change in mEq/L
Abnormal [H ₂ O] or [Na ⁺]	= 0.3 (Na–140)
Abnormal [Cl ⁻]	= 103 – (Cl*(140/Na))
Abnormal [Albtot]	= 3.7 (4.5 – albumin)
Increased [UA]	= Observed BE – sum of 3 terms above

where 140 and 103 are the normal [Na⁺] and [Cl⁻] in milliequivalents per liter, respectively; derivation of the factor 0.3 for abnormal [H₂O] or [Na⁺] is shown in Appendix 1; (140/Na) is a factor to correct the measured [Cl⁻] for abnormal [H₂O] or [Na⁺]; 4.5 is the normal [Alb_{tot}] in grams per deciliter; and 3.7 is an empiric factor to correct the BE for abnormal [Alb_{tot}]. The magnitude of change for each factor is the expected BE (mEq/L) if the abnormality in that row were the sole abnormality. Note the magnitude of change calculated for each variable is zero if its concentration is normal.

Step 4, if “unmeasured anions” are suspected based on the preceding information, then measure phosphate, lactate, ketone bodies, salicylates, and so on, as indicated by the patient’s history. Measuring the [K⁺], [Ca⁺²], and [Mg⁺²] can help identify additional causes of acidosis, as they often are all low, resulting in a decreased SID.

Consider a patient with the following laboratory results:

From arterial blood gas	From chemistry
PaCO ₂ , 29 mm Hg	[Na ⁺], 154 mEq/L
pH, 7.32	[Cl ⁻], 123 mEq/L
BE, –10 mEq/L	[Alb _{tot}], 2.9 mg/dl

Calculate the expected BE for each abnormality. The number in the last column is the expected BE (mEq/L) if the abnormality in that row were the sole abnormality.

Factors that change BE	Magnitude of change	mEq/L
Abnormal [H ₂ O] or [Na ⁺]	0.3 (Na – 140) =	4.2
Abnormal [Cl ⁻]	103 – (Cl*(140/Na)) =	–8.8
Abnormal [Alb _{tot}]	3.7 (4.5 – albumin) =	5.9
Measured BE	From laboratory tests	–10
BE due to UA =	= observed BE – sum of 3 terms above	–10 – (4.2 – 8.8 + 5.9) = –11.3

The patient has:

- An acidemia, a low pH
- A respiratory alkalosis, a low PCO₂, probably in response to the nonrespiratory acidosis
- A high Na, increasing SID, alkalosis
- A high Cl (corrected for the high Na, Cl = 112), decreasing SID, acidosis
- A low albumin, low weak anions, alkalosis
- A measured BE of –10, and so a BE due to UA = (–10) – (4.2 – 8.8 + 5.9) = –11.3

We must now look to the patient's history to determine the likely explanations for the BE due to UA of -11.3 , and which laboratory studies we might order next. The patient presented with hypotension and an acute abdomen, and renal failure (creatinine = 6.5 mg/dl), making high sulfates and phosphates, and the other anions of renal failure, likely in addition to the known high chloride. The blood sugar is normal and the patient has no history of diabetes mellitus, so ketoacidosis is unlikely. The next steps would be to measure phosphate because of the renal failure, lactate because of the history of hypotension and an acute abdomen, and potassium, calcium, and magnesium. In addition, dialysis will help correct much of the problem while causes and therapy for the acute abdomen are pursued.

The second implementation of the Stewart method, detailed in several highly recommended papers by Fencel, Figge, and colleagues (Fencel 2000, 1993, Figge 1991, 1992) is outlined here only briefly. It is more rigorous, but requires a calculator or, even better, a computer. Recall from Fig. 63.1 and the previous discussion that the true $[SID] = ([Na^+] + [K^+] + [Ca^{++}] + [Mg^{++}]) - ([UA^-] + [Cl^-])$ and to maintain electrical neutrality, it must be $[HCO_3^-] + [Alb^-] + [Pi^-]$. If we define a new quantity, the measured or apparent SID $[SIDapp] = ([Na^+] + [K^+] + [Ca^{++}] + [Mg^{++}] - [Cl^-])$, then $[UA^-]$ is estimated as:

$[UA^-] = [SIDapp] - ([HCO_3^-] + [Alb^-] + [Pi^-])$. $[Na^+]$, $[K^+]$, $[Ca^{++}]$, $[Mg^{++}]$, $[Cl^-]$, and $[HCO_3^-]$ are all routinely measured. $[Alb^-]$ and $[Pi^-]$ can be estimated from measured $[Alb_{tot}]$ and $[Pi_{tot}]$, respectively, as described by Figge and Fencel, and in Appendix 1. $[UA^-]$ is then calculated = $[SIDapp] - ([HCO_3^-] + [Alb^-] + [Pi^-])$, and lactate, ketone bodies, salicylates, and so on are measured as indicated by the patient's history. It often is the case that all sources of unknown anions will not be discovered, because, as mentioned earlier, the category contains species that are still truly unknown, as is the case in shock.

Appendix 1:

- I. Calculation of $[Alb^-]$ from $[Alb_{tot}]$ and $[Pi^-]$ from $[Pi_{tot}]$, as described by Fencel et al. (Fencel 2000):

$$[Alb^-] \text{ mEq/L} = [Alb_{tot}] \text{ (g/dL)} * (1.23 * (\text{pH} - 0.631)),$$

which for clinical purposes may be approximated by

$$[Alb^-] \text{ mEq/L} \approx 2.8 * [Alb_{tot}] \text{ (g/dL)}$$

$$[Pi^-] \text{ mEq/L} = [Pi_{tot}] \text{ (mmol/L)} * (0.309 * (\text{pH} - 0.469)),$$

which for clinical purposes may be approximated by

$$[Pi^-] \text{ mEq/L} \approx 1.8 * [Pi_{tot}] \text{ (mmol/L)} \text{ or } [Pi^-] \text{ mEq/L} \approx 0.6 * [Pi_{tot}] \text{ (mg/dl)}$$

- II. Correcting the AG and BE, both mEq/L, for abnormal $[Alb_{tot}]$ g/dL, as described by Figge et al. (Figge 1998) and McAuliffe et al. (McAuliffe 1986):

$$AG_{\text{corr}} = AG_{\text{observed}} + 2.5 * ([\text{normal albumin}] - [\text{observed albumin}])$$

$$BE_{\text{corr}} = BE_{\text{observed}} + 3.7 * ([\text{normal albumin}] - [\text{observed albumin}])$$

- III. Derivation of magnitude of change in BE due to abnormal $[H_2O]$ or $[Na^+] = 0.3(Na - 140)$

For 140 is the normal $[Na^+]$ and 42 is the normal $[SID]$, both in mEq/L

$$\text{Fractional change in Na (or } H_2O) = (Na - 140)/140$$

Change in SID due to Na (or H₂O) = $42^*(Na - 140)/140$

and $42/140 = 0.3$, then

Magnitude of change in BE due to abnormal [H₂O] or [Na⁺] = $0.3(Na - 140)$

Appendix 2: simplified “classical” blood gas analysis

Analysis of blood gases is sometimes presented in a vastly simplified manner, in which one considers only the pH, PCO₂, and HCO₃. As discussed earlier, this approach is incomplete and sometimes misleading in the presence of abnormalities of albumin or in mixed or complex acid–base disorders, which characterize many critically ill patients. Only in patients with a single disorder will this approach give a satisfactory interpretation, so it is presented here for completeness with this caveat.

The simplified approach for patients with one primary acid–base disorder proceeds by following an ordered series of questions. The primary disorder may be metabolic, respiratory, or both and can be determined by assessing PaCO₂ and HCO₃.

1. What is the pH? Is it an acidosis or alkalosis?
2. Is the change in PaCO₂ consistent with a respiratory component?
3. If the change in PaCO₂ does not explain the change in arterial pH, does the change in HCO₃ indicate a metabolic component?

With these questions answered, an initial diagnosis of the underlying primary disorder can be made; then, one can determine whether there is a compensation (see the list at the end of this paragraph). These compensation rules were determined empirically from animal experiments in which a single derangement was induced. If the compensatory response is more or less than expected, a mixed acid–base disorder exists. Measurement of electrolytes provides additional data to determine whether there is an anion gap in the case of metabolic acidosis. In the case of metabolic alkalosis, the urinary chloride concentration is measured. If the urinary Cl[−] < 10 mmol/L, the metabolic alkalosis is chloride sensitive and can be corrected with NaCl. Examples include gastric and intestinal losses and diuretic therapy. If the urinary Cl[−] > 10 mmol/L, the metabolic alkalosis is chloride resistant. Examples include renal artery stenosis, Cushing’s syndrome, primary aldosteronism, and exogenous mineralocorticoids.

Empirically observed compensatory responses to acid–base disturbances:

Metabolic acidosis: $1 \downarrow HCO_3 \geq 1 \downarrow PCO_2$

Metabolic alkalosis: $10 \uparrow HCO_3 \geq 7 \uparrow PCO_2$

Acute respiratory acidosis: $10 \uparrow PCO_2 = 1 \uparrow HCO_3$

Chronic respiratory acidosis: $10 \uparrow PCO_2 = 4 \uparrow HCO_3$

Acute respiratory alkalosis: $10 \downarrow PCO_2 \geq 2 \downarrow HCO_3$

Chronic respiratory alkalosis: $10 \downarrow PCO_2 \geq 5 \downarrow HCO_3$

Following are a few examples of arterial blood gases in which the reader can follow the aforementioned steps to diagnose the disturbance.

Example 1

pH, 7.25

PCO₂, 60

HCO₃, 26

Given the pH of 7.25, there is an acidosis. With a PCO₂ of 60, there is a 20–mm Hg elevation of the PCO₂. Given the 2–mEq/L increase in HCO₃, this example represents an acute respiratory acidosis.

Example 2

pH, 7.35

PCO₂, 60

HCO₃, 32

The pH of 7.35 indicates an acidosis. With the elevated PCO₂ of 60, it is a respiratory acidosis. Given the 8–mEq/L increase in HCO₃, this is a compensated chronic respiratory acidosis.

Example 3

pH, 7.31

PCO₂, 30

HCO₃, 15

Na, 138

Cl, 112

Anion gap, $138 - (112 + 15) = 11$

There is an acidosis. The change in PCO₂ is not consistent with a respiratory component; hence, it is a metabolic acidosis. The HCO₃ decrease is proportionate to the CO₂ decrease. With an anion gap that is normal, this points to a non–anion gap metabolic acidosis.

In this chapter, we discuss sodium, potassium, calcium, magnesium, and phosphorus ion balance. The normal concentrations of each of those electrolytes in the various body compartments are summarized in Table 64.1. Sodium is the most abundant extracellular ion, whereas potassium is the most abundant intracellular ion.

Basic definitions

Basic definitions are as follows:

- The *osmolarity* of a solution is the number of osmotically active particles (osmoles) per liter of solvent.
- The *osmolality* of a solution is the number of osmotically active particles per kilogram of solvent.
- *Tonicity* is the effective osmolality of a solution. It refers to the capacity to exert an osmotic force across a membrane. Hypertonic solutions decrease cell volume, hypotonic solutions increase cell volume, and isotonic solutions have no effect on cell volume.

$$\text{Osmolality (mOsm/kg)} = [\text{Na}^+] \times 2 + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{2.8}$$

(Normal plasma osmolality = 280–290 mOsm/kg)

Sodium

Sodium is critical in regulating extracellular and intravascular fluid volumes. Consequently, total body sodium usually determines clinical volume status, as sodium draws water wherever it is concentrated. Sodium is also essential for generation of action potentials in various tissues of the body. Sodium is regulated mainly by aldosterone, antidiuretic hormone, and atrial natriuretic peptide. The normal range of plasma sodium is 135 to 145 mEq/L, and the adult requirement of daily sodium is 1 to 2 mEq/kg/day.

Hypernatremia (plasma sodium > 145 mEq/L)

Hypernatremia has a relatively high prevalence in the intensive care unit (ICU), usually due to the use of diuretics. About 9% of medical ICU patients have a sodium level > 150 mEq/L

at admission, and an additional 6% develop hypernatremia during the ICU stay. Hypernatremia is always associated with hypertonicity. It can be classified according to the underlying mechanism and the resulting volume status of the patient. Table 64.2 lists common differential diagnoses based on the total body water (TBW) status.

Clinical manifestations

The primary symptoms of hypernatremia are caused by the loss of cell volume. Symptoms include irritability, spasticity, and tremulousness. A decrease in brain volume causes lethargy, weakness, and headache. If sodium levels rise above 158 mEq/L, severe symptoms may emerge, such as seizures, coma, and eventually death. Symptoms are more likely to occur when there are rapid changes in sodium concentration.

Treatment

The aim is to treat the underlying cause (e.g., hypernatremia secondary to drugs, hormonal derangements or central and nephrogenic diabetes insipidus, diabetic ketoacidosis, acute tubular necrosis, chronic renal failure, fever). Treatment may be guided by defining the type of hypernatremia (hypovolemic, euvolemic, or hypervolemic).

- *Hypovolemic hypernatremia*: isotonic saline initially for volume repletion in symptomatic patients with orthostasis, hypotension, or prerenal azotemia, followed by hypotonic crystalloid solutions, such as 0.45% normal saline.
- *Euvolemic hypernatremia*: replacement of free water.

Table 64.1. Fluid electrolyte composition of body compartments

Ions		Plasma, mEq/L	Interstitial, mEq/L	Intracellular, mEq/L
Cations	Sodium	142	145	10
	Potassium	4	4	159
	Calcium	5	5	<1
	Magnesium	2	2	40
Anions	Chloride	104	117	3
	Bicarbonate	24	27	7
	Proteins	16	<0.1	45
	Others	9	9	154

Table 64.2. Causes of hypernatremia

Hypovolemic	TBW loss > sodium loss	Renal loss (urine $[Na^+]$ >20 mmol/L): osmotic or loop diuretic, postobstructive diuresis, recovery phase of acute tubular necrosis Extrarenal loss (urine $[Na^+]$ <20 mmol/L): excessive sweating, diarrhea, burns, fistulae
Euvolemic	TBW loss	Renal losses: diabetes insipidus Hypodipsia, insensible losses
Hypervolemic	TBW increase < total sodium increase	Infusions of hypertonic sodium bicarbonate or hypertonic saline, hypertonic dialysate, overdose of salt tablets, Cushing's syndrome, primary hyperaldosteronism

- **Hypervolemic hypernatremia:** removal of the excess sodium (e.g., thiazide or loop diuretics) while replacing water. Intravenous infusions should be hypotonic compared with the urine.

Free water deficit can be calculated as:

$$\text{Free water deficit} \approx \text{Total body water} \times \{1 - (140/[Na^+])\}.$$

One-half of the calculated water deficit can be administered either enterally or parenterally during the first 24 hours and the rest over the following 1 to 2 days. Sodium can be safely lowered by 10 mEq/L in the first day of therapy, but patients with acute increases in sodium can safely be corrected at 1 mEq/L/h. It is important to remember that if sodium is lowered too quickly, cerebral edema may occur.

Hyponatremia (plasma sodium < 135 mEq/L)

Hyponatremia, the most common electrolyte derangement occurring in hospitalized patients, is usually accompanied by hypo-osmolality but in rare circumstances may be associated with iso-osmolality or hyperosmolality (Table 64.3). Hypo-osmolar hyponatremia may further be classified as hypovolemic, isovolemic, or hypervolemic hyponatremia.

Clinical manifestations

Symptoms seen in hyponatremia are largely neurologic and increase in severity with lower sodium levels. Symptoms are often vague and nonspecific and include malaise, nausea, confusion, and lethargy. Symptoms that are more dangerous follow when $[Na^+]$ falls below 120 mEq/L (e.g., headache, obtundation, seizures, coma, and death).

Treatment

A plasma sodium level < 130 mmol/L should result in initiation of treatment, and the cause of hyponatremia should be identified and addressed. Water restriction should be started if appropriate. Symptomatic patients with plasma sodium levels < 120 to 125 mmol/L generally need more aggressive management. However, rapidly restoring normal osmolality may cause the plasma to be relatively hypertonic to the cells, resulting in

Table 64.3. Causes of hyponatremia

Isotonic hyponatremia (pseudohyponatremia)	Asymptomatic: hypertriglyceridemia, hyperproteinemia (i.e., multiple myeloma) Symptomatic: glycine absorption
Hypertonic hyponatremia	Hyperglycemia, mannitol therapy, radiocontrast
Hypotonic hyponatremia	Hypovolemic hypotonic hyponatremia: renal loss (diuretic therapy or salt-wasting nephropathy), gastrointestinal loss (vomiting, diarrhea, tube drainage), skin loss (sweating, burns, cystic fibrosis), peritonitis Isovolemic hypotonic hyponatremia: antidiuretic hormone excess (SIADH, thiazide diuretics or oral hypoglycemic agents), pain, postoperative status (transurethral prostatic resection syndrome), cortisol deficiency, hypothyroidism, decreased solute intake, psychogenic polydipsia Hypervolemic hypotonic hyponatremia (TBW excess): congestive heart failure, cirrhosis of liver, nephrotic syndrome, renal failure

SIADH, syndrome of inappropriate antidiuretic hormone secretion.

the osmotic movement of water out of the cells. In the central nervous system, this may cause a condition called central pontine myelinolysis or osmotic demyelination syndrome, which results in severe morbidity or death. Therefore, in acute, symptomatic hyponatremia, sodium may be raised more rapidly, initially 1 to 2 mmol/h, but not to exceed 8 to 10 mEq/L in the first 24 hours. Even in patients with seizures and hyponatremia, a correction of 1 to 6 mmol usually leads to a resolution of symptoms. Chronic asymptomatic hyponatremia is well tolerated and should be treated conservatively.

- **Isotonic hyponatremia**, also known as pseudohyponatremia, requires no therapy.
- **Hypertonic hyponatremia** is the result of the increased osmotic pressure (e.g., glucose, mannitol) that moves the water from the intracellular space to the extracellular compartment. Hyperglycemia, for example, decreases plasma sodium concentration by approximately 1.6 mEq/L for each 100 mg/dl of blood glucose. The goals of therapy are to remove the osmotically active substance and to restore euvolemia.
- **Hypotonic hyponatremia**, the most common form of hyponatremia, is subdivided according to the extracellular fluid volume status:
 1. **Hypovolemic hypotonic hyponatremia:** Sodium is lost in greater proportion than water. Therapy should focus on replacement of extracellular volume with isotonic sodium solution.
 2. **Isovolemic hypotonic hyponatremia:** Usually, therapy is focused on water restriction. See Table 64.4.
 3. **Hypervolemic hypotonic hyponatremia:** The goal of therapy depends on the primary cause of hyponatremia. However, fluid and salt restriction and the use of proximal and loop diuretics are usually acceptable.

Table 64.4. Calculation of desired negative TBW balance

Estimated TBW: percentage of body weight in kilograms, 60% in children and men, 50% in women and elderly men, 45% in elderly women

TBW (excess) \approx (actual plasma Na⁺/desired plasma Na⁺) \times (Normal) \times (TBW)

TBW (excess) represents the amount of negative water balance needed to increase plasma Na⁺ to desired level

Potassium

The human body contains 50 mEq/kg of potassium, more than 95% of which is intracellular. Plasma potassium concentration is kept in a narrow range via two main regulating mechanisms: potassium shift between intracellular and extracellular compartments and modulation of renal potassium excretion. In addition, potassium is regulated by aldosterone, insulin, hydrogen ion concentration, and epinephrine. The electrocardiogram (ECG) is useful for the diagnosis of true potassium imbalance, because cardiovascular effects are usually noted early. The level of polarization of an excitable cell and the ability for repolarization are determined by the extracellular and intracellular potassium concentration. Average daily intake of potassium is approximately 1 to 1.5 mEq/kg/d.

Hyperkalemia (plasma potassium > 5.5 mEq/L)

Hyperkalemia usually develops in patients with advanced renal dysfunction (Table 64.5). Succinylcholine may transiently raise the plasma potassium level by 0.5 to 1.0 mEq/L in normal patients. Succinylcholine should not be used in paraplegic or burn patients because it may result in excessive potassium release. Many cases of hyperkalemia are associated with metabolic acidosis. Elective surgery should not be undertaken in the presence of significant hyperkalemia.

Clinical manifestations

Muscle weakness and, rarely, flaccid paralysis, abdominal distention, and diarrhea may occur. With the worsening of hyperkalemia, ECG changes may occur and include atrial and ventricular ectopy, decreased QT interval, peaked T waves, loss

Table 64.5. Causes of hyperkalemia

Decreased renal excretion	Acute and chronic renal failure, drugs (potassium-sparing diuretics, ACE inhibitors, COX inhibitors, decreased mineralocorticoid activity (HIV))
Redistribution	Trauma, burns, rhabdomyolysis, severe infections, acidosis, hyperosmolar states, vigorous exercise
Increased intake	Salt substitutes, blood transfusions, potassium salts of antibiotics
Pseudohyperkalemia	Hemolysis, leukocytosis (WBCs > 50,000/mm ³), thrombocytosis (PLT > 1,000,000/mm ³)

ACE, angiotensin-converting enzyme; PLT, platelets; COX inhibitors, nonsteroidal anti-inflammatory drugs; WBCs, white blood cells.

of P waves, widening of the QRS complex, and merging of the widened QRS complexes with the T wave, leading to ventricular fibrillation and possibly to cardiac arrest.

Treatment

One must first confirm that the elevated level of plasma K⁺ is genuine. Continuous monitoring of the ECG is indicated. Renal dysfunction should be ruled out. The following measures can temporarily reduce the plasma K⁺ level via redistribution to other compartments, or mitigate its effects:

- Calcium chloride (10 ml of 10% solution) intravenously (IV) to stabilize the cellular membrane
- Insulin with glucose (1 U of IV insulin for 2 g of dextrose) is administered to shift the extracellular potassium intracellularly and to stabilize the cellular membrane
- Sodium bicarbonate (50–100 mEq) to shift the potassium intracellularly

The following measures will reduce the plasma K⁺ level by increasing its excretion:

- Loop diuretics (e.g., furosemide) to reduce total body potassium, although patients in renal failure may not respond to diuretics.
- Exchange resins (e.g., sodium polystyrene sulfonate) administered orally may reduce total body potassium in about 1 to 3 hours.
- One or two standard doses of nebulized albuterol can reduce plasma K⁺ within 30 minutes after administration in dialysis patients.
- Hemodialysis, if other measures fail.

Hypokalemia (plasma potassium < 3.5 mEq/L)

Severe hypokalemia may induce dangerous arrhythmias and even rhabdomyolysis (Table 64.6). It is important to remember that the plasma potassium concentration correlates poorly with the total body potassium deficit. Nevertheless, plasma concentration may be used as a rough guide to total body levels, and in the steady state 1-mEq/L change in plasma potassium reflects about a 100- to 200-mEq change in total body

Table 64.6. Causes of hypokalemia

Potassium shift into the cell	Insulin, alkalosis, trauma, barium ingestion, β_2 -adrenergic agonists, hypothermia
Renal potassium loss	Primary and secondary hyperaldosteronism, renovascular hypertension, ACTH and renin-producing tumor, congenital abnormality of steroid metabolism, diuretics, salt-wasting nephropathy, hypomagnesemia
Extrarenal potassium loss	Vomiting, diarrhea, laxatives, NG tube suctioning
Inadequate intake	Usually not a single cause of hypokalemia, because of very effective decrease of renal potassium excretion

ACTH, adrenocorticotropic hormone; NG, nasogastric.

potassium. Usually, mild and asymptomatic hypokalemia ($K^+ > 3.0$ mEq/L) does not warrant cancellation or delay of surgery, especially if it is chronic. Acute hypokalemia is less well tolerated than mild chronic hypokalemia. As a general rule, patients with clinical signs of hypokalemia and/or ECG changes might require correction prior to proceeding with elective surgery. Patients on digoxin are at a higher risk of developing side effects when hypokalemic. Glucose-free infusion solutions should be used in hypokalemic patients, because glucose supports potassium shift into the cell, further reducing the plasma concentration.

Clinical manifestations

Muscular weakness, fatigue, and muscle cramps are frequent in mild to moderate hypokalemia. Flaccid paralysis, hyporeflexia, hypercapnia, tetany, rhabdomyolysis, and arrhythmias may be seen with severe hypokalemia (<2.5 mEq/L). ECG changes that may occur consist of widening of the QRS complex with plasma potassium levels around 3 mEq/L. Furthermore, the ST segments become depressed, and the T waves begin to flatten (inversion). U waves become more prominent. The tendency for ventricular ectopy increases and puts the patient at risk for ventricular fibrillation.

Treatment

Mild to moderate potassium deficiency is safely treated with oral potassium. In the setting of abnormal renal function and mild to moderate diuretic dosage, 20 mEq/d of oral potassium is generally sufficient to prevent hypokalemia, whereas 40 to 100 mEq/d is needed to treat hypokalemia if it occurs. Intravenous potassium replacement is indicated for patients with severe hypokalemia and for those who cannot take oral supplementation. For severe deficiency, potassium may be given through a peripheral IV line in a concentration that should not exceed 40 mEq/L at rates of up to 10 mEq/h because of its local and systemic toxicity. When a central line is present, it should be the route of choice to administer IV potassium. Rates of 10 to 20 mEq/h require continuous ECG monitoring. Daily potassium replacement should not exceed 240 mEq.

Calcium

The normal total plasma (or plasma) calcium concentration is 8.5 to 10.5 mg/dl. Ionized calcium (4.4–5.3 mg/dl; the normal range may vary slightly from laboratory to laboratory) is the physiologically active calcium. Calcium is necessary for almost every function in the human body, including muscle contraction, nerve function, and blood coagulation. Calcium is regulated primarily by parathyroid hormone and vitamin D. Albumin levels do not affect ionized calcium levels, although total calcium increases or decreases with a decrease or an increase in albumin levels, respectively. An albumin level decrease of 1 g/dl increases the calcium level by 0.8 mg/dl. It is also important to remember that metabolic acidosis increases ionized calcium levels.

Table 64.7. Causes of hypercalcemia

Increased intake	Excess vitamin D, vitamin A, or calcium intake
Cancer	Multiple myeloma
Endocrine disorders	Primary hyperparathyroidism, adrenal gland insufficiency
Other	Thiazide diuretics, sarcoidosis, Paget's disease of bone, immobilization

Hypercalcemia (plasma calcium > 10.5 mg/dl)

Tumor production of parathyroid hormone-related protein accounts for most cases of hypercalcemia (Table 64.7). The neoplasm is clinically apparent in nearly all cases when the hypercalcemia is detected, and the prognosis is often poor from the underlying malignancy.

Clinical manifestations

Mild hypercalcemia is often asymptomatic. Symptoms usually occur if the plasma calcium is > 12 mg/dl. Typical symptoms are constipation, polyuria, nausea and vomiting, muscle weakness, ataxia, and confusion. ECG shows a shortened QT interval.

Treatment

Until the primary disease is controlled, renal excretion of calcium with a resultant decrease in plasma calcium concentration should be promoted. Hypercalcemia should be considered a medical emergency, and elective surgeries should not be performed until the calcium level is corrected. Serial measurements of potassium and magnesium should also be done while the calcium is being corrected.

- Saline (250–500 ml/h) with furosemide (20–40 mg every 2 hours) is the treatment of choice.
- Bisphosphonates (pamidronate) or calcitonin is the mainstay of treatment of hypercalcemia of malignancy.

Hypocalcemia (plasma calcium < 8.5 mg/dl)

Development of true hypocalcemia (decreased ionized calcium) implies an insufficient level or impaired action of parathyroid hormone or active vitamin D (Table 64.8).

Table 64.8. Causes of hypocalcemia

Decreased intake or absorption	Malabsorption, small bowel bypass, vitamin D deficit
Increased loss	Alcoholism, chronic renal insufficiency, diuretics, chelation of calcium by citrate ions when large volume of blood is administered
Endocrine disease	Hypoparathyroidism, sepsis, medullary carcinoma of the thyroid
Physiologic	Hyperphosphatemia, aminoglycoside antibiotics

Clinical manifestations

Extensive spasm of skeletal muscle may cause weakness, cramps, tetany, and eventually, laryngospasm with stridor. Seizure, paresthesias of the lips and extremities, and abdominal pain may occur. Carpopedal spasm (Trousseau's sign) or masseter muscle spasm (Chvostek's sign) may be seen. The ECG shows prolongation of the QT interval (due to lengthened ST segment), which predisposes the patient to developing hypotension and ventricular arrhythmias.

Treatment

In the presence of tetany, arrhythmias, or seizures, calcium gluconate 10% (10–20 ml), administered IV over 10 to 15 minutes, is indicated. Its duration of action is short; therefore, an infusion is usually required to maintain the plasma calcium level at 7 to 8.5 mg/dl. ECG monitoring is recommended. Asymptomatic hypocalcemia can be treated with oral calcium and vitamin D.

Magnesium

Normal plasma magnesium ranges between 1.5 and 2.5 mEq/L. Mg^{2+} promotes enzyme reactions within the cell during metabolism, helps in the production of adenosine triphosphate (ATP), participates in protein synthesis, and plays a role in coagulation, platelet aggregation, and neuromuscular activity. Magnesium slows atrioventricular conduction and potentiates the action of both depolarizing and nondepolarizing neuromuscular blocking agents. About two-thirds of magnesium is stored in the bone.

Hypermagnesemia (plasma magnesium > 2.5 mEq/L)

Increased intake, mainly as a result of magnesium-containing antacids and laxatives, may commonly lead to hypermagnesemia (Table 64.9).

Clinical manifestations

Skeletal muscle weakness, hyporeflexia, sedation, vasodilation, bradycardia, hypotension, and impaired breathing may occur.

Treatment

Treatment includes immediate cessation of Mg^{2+} administration/intake, administration of calcium gluconate, increased urinary excretion (diuretic), and dialysis in patients with renal failure.

Table 64.9. Causes of hypermagnesemia

Reduced excretion and/or increased intake	Magnesium-containing antacid or laxative intake, acute and chronic renal failure, clinically induced hypermagnesemia state with preeclampsia treatment
Uncommon causes	Addison's disease, acute diabetic ketoacidosis, hypothyroidism, pituitary dwarfism, lithium therapy, viral hepatitis, milk-alkali syndrome

Table 64.10. Causes of hypomagnesemia

Gastrointestinal	Decreased intake, reduced absorption (chronic diabetes, diarrhea, emesis, steatorrhea, short bowel syndrome, pancreatitis)
Renal excretion	Loop and thiazide diuretics, hypercalcemia, removal of parathyroid tumor, diabetic ketoacidosis, hypersecretion of aldosterone, thyroid hormones or ADH, nephrotoxins, chronic ethanol ingestion
Acute intracellular shift	Refeeding syndromes, glucose infusions, amino acid infusions, insulin, catecholamines, metabolic acidosis

Hypomagnesemia (plasma magnesium < 1.5 mEq/L)

Hypomagnesemia is commonly seen in ICU patients. Common causes of hypomagnesemia are listed in Table 64.10.

Clinical manifestations

Increased neuromuscular irritability, hyperreflexia, confusion, and seizures may occur. Hypomagnesemia is commonly associated with hypocalcemia and hypokalemia and, hence, with their associated manifestations. ECG changes seen with magnesium deficiencies include prolonged PR and QT intervals, widened QRS complexes, depression of ST segments, and inversion of T waves. Atrial fibrillation may be associated with hypomagnesemia.

Treatment

Patients with mild/moderate Mg^{2+} deficiency may require 50 mEq of oral Mg^{2+} per day (i.e., about twice the amount of the estimated deficit in patients with intact renal function, because about 50% of the administered Mg^{2+} is excreted in urine). Serious manifestations of hypomagnesemia (seizures) should be corrected by IV replacement (2- to 4-g infusion over 30–60 min). It is prudent to avoid an IV bolus of magnesium sulfate, as it may cause cardiac arrhythmias.

Phosphorus

In plasma, phosphate is present mainly as a very small inorganic fraction (PO_4 , normal range 2.5–4.5 mg/dl). About 85% of phosphorus is stored in the bone. It is used to form ATP, nucleic acids, 2,3-diphosphoglycerate (off-loading oxygen from hemoglobin), and cyclic adenosine monophosphate.

Hyperphosphatemia (plasma phosphate > 4.5 mg/dl)**Clinical manifestations**

Clinical signs of hyperphosphatemia are related primarily to the development of hypocalcemia and ectopic calcification. Because renal failure is the most common cause of hyperphosphatemia, other signs and symptoms of renal failure may also be associated with it (Table 64.11).

Table 64.11. Causes of hyperphosphatemia

Increased intake	Intravenous infusion, oral supplementation, vitamin D intoxication, phosphate-containing enemas, acute phosphorus poisoning
Increased production	Tumor lysis syndrome, rhabdomyolysis, bowel infarction, malignant hyperthermia, hemolysis, acid–base disorders
Reduced loss	Acute and chronic renal insufficiency, hypoparathyroidism, acromegaly, tumoral calcinosis, magnesium deficiency, multiple myeloma

Treatment

In renal failure, dialysis will reduce plasma phosphate. Absorption of phosphate can be reduced by administration of aluminum hydroxide/carbonate, which binds phosphates. Diuresis can be induced with acetazolamide.

Hypophosphatemia (plasma phosphate < 2.5 mg/dl)

Hypophosphatemia may occur in the presence of normal phosphate stores. Serious depletion of body phosphate stores may exist even with normal or high phosphorus in plasma.

Clinical manifestations

In the presence of severe hypophosphatemia ($\text{PO}_4 < 1 \text{ mg/dl}$), decreased levels of 2-3 DPG will result in an increased affinity of hemoglobin for oxygen, which impairs tissue oxygenation and thus cellular metabolism. Muscle weakness or even rhabdomyolysis, paresthesias, encephalopathy (e.g., irritability, confusion, or seizures), platelet dysfunction, leukocyte dysfunction, respiratory failure, and myocardial dysfunction may occur.

Treatment

The best treatment is prophylaxis, by including phosphate in repletion and maintenance fluids (total parenteral nutrition). When possible, oral replacement of phosphate is preferable, as rapid correction may cause hypocalcemia. For severe, symptomatic hypophosphatemia, an infusion should provide 279 to 310 mg (9–10 mmol)/12 h until the plasma phosphorus exceeds 1 mg/dl; the patient can then be switched to oral therapy.

Total parenteral nutrition

Mallory Williams and Gyorgy Frendl

Total parenteral nutrition (TPN) is intravenous (IV) administration of nutrients for the purposes of metabolic support. TPN can be used in various clinical settings, almost always as an alternate approach to nutrition when nourishment of the patient via the enteral route is not feasible.

The objectives of nutrition therapy are to supply the patients' caloric needs and to provide the appropriate proportions of protein, carbohydrate, and fat to support the metabolic needs of the patient. Enteral nutrition, if possible, should always be the preferred route of nutrient administration. Multiple studies comparing enteral nutrition with TPN in critically ill medical and surgical patients have found that enteral nutrition is safer than TPN, is less expensive, and results in at least similar and sometimes superior clinical outcomes.

Initiation of nutrition therapy

The management of nourishment begins with a nutritional assessment of the patient. It should be acknowledged that nutritional assessments in critically ill patients are often inaccurate. Simple measurements, such as weight, cannot be used because of edema, ascites, and overall fluid overload states that often accompany the postoperative or critical care state. Well-known nutritional parameter levels are affected by underlying disease, inflammatory states, and medications.

Malnutrition in hospitalized patients often goes unrecognized; its prevalence may be 30% to 50%, with 40% of these patients being malnourished at the time of admission. The subjective global assessment (SGA) is a clinical method to evaluate the nutritional status of a patient. The components of this assessment are history taking and physical examination, determination of any effects of malnutrition on end-organ function, and a determination of how the patient's overall disease process affects nutrient requirements. The SGA has been found to be reproducible among blinded observers assessing the same patient, with 80% interrater reliability. It is also a good predictor of complications in general surgery patients. Components of the SGA are described in [Table 65.1](#).

The next step for patients requiring nutritional support is to determine whether they are candidates for enteral nutrition. TPN is not indicated in patients who have a gastrointestinal tract capable of adequate nutrient absorption. For patients who

cannot tolerate enteral nutrition ([Table 65.2](#)), TPN may be an option.

Nutrition as pharmacotherapy

The role of nutrition has progressed from maintaining a positive nitrogen balance to using specific nutrients to modulate organ function.

Branched-chain amino acids

Branched-chain amino acids (BCAAs), including leucine, isoleucine, and valine, undergo very little metabolism by the liver and remain intact until they reach the skeletal muscle. Leucine in skeletal muscle increases protein synthesis by 50% and decreases protein degradation by 25%. This increased protein synthesis reaches physiologic significance during stress or injury states. Increased concentration of BCAAs in TPN may increase prealbumin and retinol-binding protein, leading to lower mortality.

Glutamine

Glutamine is synthesized and stored in skeletal muscle. Catabolism induced by surgery, sepsis, burns, or major injury results in increased release of glutamine from skeletal muscle to the plasma. Patients receiving L-glutamine supplementation have a better nitrogen balance (−1.4 g/d vs. −4.2 g/d) and a lower incidence of infection.

Omega-3 fatty acids

The omega-3 fatty acids are potential immunostimulants. Infections, length of intensive care unit (ICU) stay, and nitrogen balance (−2.2 g/d vs. −6.6 g/d) are better in patients receiving fish oil. Whereas omega-3 fatty acids are present in enteral formulas, the only commercially available IV emulsions in the United States are long-chain triglycerides with omega-6 fatty acids, which are potential immunosuppressants. High intake of omega-6 fatty acids (linoleic acid) is associated with increased synthesis of prostaglandin E₂, which inhibits the immune system.

However, omega-3 fatty acid-rich infusion during parenteral nutrition was recently reported in a prospective open label study and found to reduce both ICU and hospital length of stay and improve mortality in critically ill patients after major abdominal surgery, or who were experiencing peritonitis and abdominal sepsis, non-abdominal sepsis, multi-trauma, and severe head injury (reference listed in recommended readings). This study was not controlled or blinded and variations in dose of omega-3-fatty acids occurred in the trial. These interesting findings need confirmation in randomized controlled trials before they can be considered cost effective.

Route of TPN administration

TPN can be delivered via centrally or peripherally placed venous access catheter port. TPN solutions contain glucose, amino acids, and lipids. Lipid solutions of 10–20% can be given peripherally, whereas lipid concentrations of 30% are

prescribed in the admixture and are administered centrally. Glucose-amino acid solutions of greater than 10% glucose are damaging to peripheral veins and can cause thrombophlebitis. It is very important that the tip of the central venous catheter be evaluated for its presence in the superior vena cava. The tonicity of hypertonic nutrient solutions (>1900 mOsm/L) is so great that thrombophlebitis and venous sclerosis are potential complications of peripheral administration. Superior vena cava placement allows for rapid dilution of this nutrient-rich solution.

The port used for TPN administration should be a dedicated port. Medications, blood draws, or administration of other fluids is not preferred because of an increase in infection risk. In addition, initial placement of a central venous catheter that will be used for TPN should follow the full barrier precautions and nursing checklist protocol. No catheters placed for emergency use should be used to administer TPN. Catheters should never be advanced into patients post placement. Lines need to be secured to patients using a dermal stitch with three-point fixation of the catheter. Clear dressings are used so the line site can be monitored daily.

Occasionally, there are patients in whom percutaneous central venous access is difficult to achieve. These patients are candidates for peripheral IV central catheter (so-called PICC) lines. These lines are placed centrally from peripheral veins using wires (most often by designated IV services). As with central venous catheters, the central venous position of the tip should be confirmed on a regular basis. The administration of TPN through a femoral line is not optimal because of increased risk of infection. If options are confined to femoral line administration, time periods should be limited. However, burn units present unique challenges that at times may call for administration of TPN through a femoral line. Clear documentation as to the risks and benefits of the therapy and the overall lack of IV access in the patient may provide a rationale for administering TPN through a femoral catheter.

The traditional preferred site for TPN infusion is through the subclavian vein due to low infection rates. In general quoted infection rates for subclavian catheters are approximately 3.5–6 per 1000 catheter days versus 6–10 per 1000 catheter days for internal jugular catheters in ICUs. Femoral catheter sites have infection rates that range from 12–16 per 1000 catheter days in ICUs. Peripherally inserted central catheters (PICC) have similar infection rates to centrally venous catheters but sustain a longer duration of treatment before infection. Tunneled catheters can also serve as a long term source for treatment without infection. In general, peripherally placed intravenous catheters and central venous catheters are short-term access sites. PICC are considered midterm access sites, and tunneled catheters are long-term access sites (see Table 65.3).

Nutrient composition of the TPN mixture

The existing body cell mass is the major determinant of total caloric requirement, which is either estimated or measured

Table 65.3. Suggested fluid concentrations, duration of use, and common complications associated with catheters used for TPN administration

Catheter Site	Concentration of IV Fluids (mOsm/L)	Complications
Peripheral IV catheter	<500	Infection Phlebitis
Femoral Vein	>900	Infection Bleeding DVT

directly. There is controversy regarding whether strict calculation and matching of energy expenditure with energy input improve clinical outcomes. Promotion of anabolic functions and avoidance of overfeeding are the goals, meaning that a 25-kcal/kg ideal body weight is usually sufficient. The American College of Chest Physicians consensus statement recommendations are listed in Table 65.4.

In general, 1 ml is required to administer 1 kcal of nutrients. Therefore, a volume of 2 to 2.5 L/d will provide the patient with 2000 to 2500 kcal of energy. This caloric load is sufficient for 90% of surgical patients. The base solution is commonly 500 ml of 10% amino acids and 500 ml of 50% dextrose (Table 65.5). Fluid, electrolytes, vitamins, and trace elements are added to this solution. The final volume is usually 2 to 2.5 L/d. Providing a fat emulsion (500 ml, 20%) 1 d/wk to patients will meet their essential fatty acid requirements.

Modulating the fat content of the mixture is important in specific patient populations. For example, it has been shown that administration of excessive calories to patients on the ventilator elevates CO₂ production due to excessive carbohydrate intake and prolongs efforts at discontinuation of mechanical ventilation. However, in patients with severe COPD, Steiner et al. demonstrated that carbohydrate supplementation improved pulmonary rehabilitation in well-nourished patients.

All three major nutrients may be mixed in a 3-L bag (triple mix or three-in-one). Sodium and potassium are added as chlorides or acetates, with the ratio of acetates to chlorides increasing in patients with hyperchloremia or acidosis. Sodium bicarbonate is incompatible with the nutrient solution; therefore, acetate is used. Phosphate is given as a potassium or sodium salt. Commercially available solutions of vitamins, minerals,

Table 65.4. TPN mixture recommendations

Fat, 15%–30% of total calories
Protein, 5%–20% of total calories
Micronutrient repletion

and trace elements are added to the nutrient mix for daily administration. Vitamin K, proton pump inhibitors or histamine H₂-receptor blockers, and insulin also may be included in the nutrient mix. Iron should be avoided in patients with sepsis. Slightly hypertonic (600–900 mOsm/L) solutions can be made for peripheral administration. These low-caloric density solutions include 5% amino acids, 10% dextrose, and 20% fat emulsion and are administered in a large volume of fluid.

There are studies suggesting that immunomodulation is possible via parenteral and enteral diets. Arginine, glutamine, and omega-3 fatty acids all have been shown to be immunomodulatory when given as a component of the diet. Patients who are septic seem to benefit from the administration of BCAAs.

Metabolic monitoring

All patients receiving parenteral nutritional support should receive accurate daily weights, and data on their fluid balance should be recorded rigorously. Serum glucose should be measured regularly, and euglycemia (serum glucose, 110–150 g/dl) should be maintained. Most alterations of patient weight in the ICU are reflective of excess fluid. However, if the patient's weight decreases and this is persistent, additional calories (500–1000 kcal/d) should be added to maintain lean body mass. The metabolic rate can be calculated and the energy input then

Table 65.5. Various additives/properties of a TPN mixture

Property	Standard solution	Triple mix
Volume, ml		
Amino acids 10%	500	1000
Dextrose 50%	500	1000
Fat emulsion 20%	–	250
Contents, g		
Amino acids	50	100
Dextrose	250	500
Total nitrogen	8.4	16.8
Total calories	1050	2600
Caloric density, kcal/ml	1.0	1.15
Osmolality, mOsm/L	1970	1900

matched to this figure:

$$\text{Metabolic rate (kcal/day)} = \text{VO}_2 \text{ (ml/min)} \times 60 \text{ min/h} \\ \times 1 \text{ L/1000 ml} \times 4.83 \text{ (kcal/L)} \times 24\text{h/d,}$$

where VO_2 is the amount of oxygen consumed per minute.

In patients not on ventilators, metabolic carts offer bedside estimates of oxygen uptake for calculation of metabolic rate. In patients with pulmonary artery catheters, oxygen consumption is calculated using cardiac output data:

$$\text{Vo}_2(\text{ml/min}) = \text{cardiac output (L/min)} \\ \times \text{CaO}_2 \text{ (ml/L)} \\ - \text{CmvO}_2 \text{ (ml/L)} \times 1\text{L}/10 \text{ dl,}$$

where CaO_2 is arterial oxygen content and CmvO_2 is mixed venous oxygen content.

Finally, maintenance of lean body mass should be reflected by a positive nitrogen balance, which can be measured as follows: The urine urea nitrogen (UUN) concentration is multiplied by the total volume of urine in a 24-hour period. This represents only 80% of the total nitrogen excreted. An additional 20% must be added. Also, an additional 2 g is added to account for stool and integumentary losses.

$$\text{Total nitrogen loss (g/d)} \approx 24\text{-hour UUN (g/d)} \\ + 0.2 (24\text{-hour UUN g/day}) + 2\text{g/d.}$$

Complications of TPN

The most common complication of TPN administration is hyperglycemia. Maintaining euglycemia is the standard of care. Insulin protocols with close monitoring of serum glucose have made this practice possible, with a corresponding reduction in mortality and morbidity. There are complications associated with central venous access, which may be mechanical or infectious. Pneumothorax, arterial puncture, and hematomas are all detectable at the time of catheter placement. Infectious complications often occur in a delayed manner. Coagulase-negative staphylococci are the most common pathogens in catheter-related bloodstream infections, followed by enterococcus. Signs of catheter infection, such as fever, leukocytosis, erythema at the puncture site, and positive blood cultures, should prompt catheter removal. A new bag of TPN should be initiated when a new, appropriately positioned central venous catheter is available.

Perioperative and periprocedural management of TPN

Once TPN is initiated, unless otherwise indicated by the procedure, it is recommended that the infusion of TPN should continue during the procedure and in the operating room to maximize the nutritional benefits for critically ill patients.

However, when TPN is discontinued, it is particularly important to be vigilant about the risk of hypoglycemia. This

may happen as TPN runs out and the new supply is not yet available, or when TPN infusion is discontinued (e.g., because of the removal of the central venous catheter or travel of the patient). When TPN is discontinued, it is imperative to regularly measure serum/blood glucose levels (every 30 minutes or every hour, but even more frequently when the measured values are < 60 mg/dl). The administration of 50% dextrose solution is also recommended when blood glucose levels fall below 45 to 60 mg/dl (these levels are determined by institutional guidelines for hypoglycemia). To prevent this scenario, if the TPN needs to be discontinued, the patient should be placed on 10% dextrose infusion at the same rate the TPN was infused, with regular blood glucose measurements.

Refeeding syndrome

Malnourished patients suffer from the depletion of total body phosphorus. In an attempt to maintain homeostasis, phosphorus is redistributed from the intracellular space. Once nutrition is initiated, the delivery of a large amount of glucose causes an insulin surge that initiates cellular glucose uptake, as well as uptake of potassium and phosphate from the extracellular space. The body also begins to retain fluid. Under these conditions, the serum concentration of potassium and phosphorus falls rapidly. The cardiac effects of this are increased cardiac workload, increased stroke work, and increased oxygen consumption with a resultant increase in the respiratory quotient and minute ventilation. Patients may have tachypnea, dysrhythmias, seizures, coma, or respiratory or cardiac failure.

Prevention of refeeding syndrome is best accomplished by a gradual increase in calories per day when nutrition is initiated combined with monitoring and replacement of electrolytes, particularly magnesium, phosphate, and potassium. Refeeding syndrome may occur in any patient who is malnourished or has been subjected to a significant period of starvation prior to the administration of nutrients.

Blood products

Blood component administration carries a significant risk of infectious, toxic, and immunologic complications. All clinicians must be familiar with indications and alternatives to decrease the risks of this therapy (Table 66.1).

Red blood cells

Red blood cells (RBCs) are given to improve oxygen (O₂)-carrying capacity and do not contain viable platelets or significant amounts of coagulation factors or neutrophils. All RBC transfusions must be ABO compatible. RBC units are stored at 1° to 6°C to decrease metabolism and inhibit bacterial growth.

A unit of RBCs (often referred to as “packed” red cells) is prepared from whole blood using a closed sterile system. First, approximately 450 ml of whole blood is collected from a screened volunteer donor into a bag containing 63 ml of a citrate-phosphate-dextrose (CPD) anticoagulant preservative. The donated whole blood unit may then be processed to produce one RBC unit, one platelet concentrate, and one unit of fresh frozen plasma (FFP). To generate a unit of RBCs, a whole-blood unit is centrifuged to separate the RBCs from the plasma. Most of the plasma is then expressed from the unit, leaving about 180 (160–275) ml of RBCs, 30 ml of residual plasma, and 30 ml of CPD solution. Such a CPD RBC unit has a volume of about 250 ml and a hematocrit (Hct) of 70% to 80%, and may be stored for up to 21 days. Typically, an additive solution is added to CPD RBC units to extend the allowable storage time to up to 42 days (below).

The solutions used in manufacturing RBC units are:

- CPD is the basic anticoagulant preservative solution used to collect whole blood. Citrate acts as an anticoagulant by binding calcium, and dextrose serves as an energy source for the RBCs. CPD units may be stored for up to 21 days at 1° to 6°C.
- CPDA-1 is identical in composition to CPD, except for the addition of 17.3 mg of adenine. Adenine provides a substrate for the production of adenosine triphosphate. CPDA-1 RBC units may be stored for up to 35 days at 1° to 6°C.
- Additive solutions are crystalloid solutions that include dextrose, adenine, and other components in varying concentrations. Currently licensed additive solutions are

AS-1 (Adsol; Baxter, Round Lake, IL), AS-3 (Nutricel; Miles Inc, Elkhart, IN), and AS-5 (Optisol; Oxonica, Bucks, UK). Typically, 100 ml of an additive solution is added to a CPD RBC unit, resulting in a final product of about 310 ml with an Hct of 55% to 65%. Additive solutions contain monobasic sodium phosphate (AS-3) or mannitol (AS-1 and AS-5) to limit cell lysis. The additive solutions serve to extend RBC survival, increasing the unit’s shelf-life to 42 days. Also, by lowering the product’s viscosity, additive solutions yield excellent flow characteristics.

Recently, there has been some discussion regarding a possible link between “older” blood (still within the 42-day shelf life) and increased morbidity and mortality in transfused patients. At this point, currently available evidence does not indicate a clear linkage, although some large randomized trials (e.g., Red Cell Storage Duration study, Age of Blood Evaluation trial) are currently investigating this question.

Leucocyte-reduced red blood cells

Patients who have a history of febrile nonhemolytic transfusion reactions, require cytomegalovirus-negative blood, are at risk for HLA alloimmunization, or are receiving an exchange transfusion should receive leukocyte-depleted RBCs. These RBC units are prepared with special filters that remove $\geq 99.99\%$ of white blood cells (WBCs) prior to storage. Leukoreduction is usually effective in preventing febrile nonhemolytic transfusion reactions and also has been shown to be effective in decreasing platelet alloimmunization and cytomegalovirus transmission. The filtration system used will remove some portion of the other cellular components present but the RBC unit should still have a therapeutic efficacy equal to at least 85% of the original component. Leukoreduction does not prevent graft-versus-host disease (GVHD). Cryoprecipitate and FFP do not contain significant numbers of viable leukocytes, so leukoreduction is unnecessary.

Washed red blood cells

Patients who have a history of severe reaction to transfusion, such as anaphylactoid reactions, should receive washed RBCs. RBCs are washed using 0.9% sodium chloride to remove almost all IgA (99%) and other plasma proteins and WBCs. This may

not be sufficient to prevent hypersensitivity reactions, so blood collected from an IgA-deficient donor may be needed to support an IgA-immunized patient. Because units are typically washed using an open system, washed products must be transfused within 4 hours of preparation. The wash process reduces RBC content by approximately 20%.

Frozen red blood cells

RBC units with rare antigen combinations and other requirements for extended storage can be frozen with the addition of glycerol as a cytoprotective agent. Expired units that are rare can be “rejuvenated” by washing in a biochemical solution, and can then be glycerolized and frozen. These units are stored at $\leq -65^{\circ}\text{C}$ for up to 10 years. They must be washed with successively lower concentrations of sodium chloride to remove the glycerol prior to transfusion. These units contain at least 80% of the RBCs present in the original unit and have the same expected posttransfusion survival.

Platelets

Platelet transfusions are indicated to prevent or treat bleeding in patients with qualitative or quantitative platelet deficiencies. Platelet concentrates (“random donor platelets”) are derived from donated whole blood. First, a whole blood unit is gently centrifuged (“soft spin”) to produce a bag of platelet-rich plasma (PRP) plus one unit of RBCs (see earlier). The PRP is centrifuged a second time (“hard spin”) to produce a platelet concentrate plus one unit of plasma. The platelet concentrate is resuspended in 40 to 70 ml of plasma and should contain a minimum of 5.5×10^{11} platelets. Platelet concentrates are stored at room temperature (20° – 24°C) with continuous gentle agitation for up to 5 days. Platelet metabolic activity continues during storage; agitation of platelet units facilitates gas exchange and helps preserve the pH of the unit. Because platelets are stored at room temperature, bacterial growth may occur during storage. Rarely, septic transfusion reactions are observed, particularly in immunocompromised recipients.

A single platelet concentrate is expected to increase the platelet count of a 70-kg adult by 5 to 10,000/ μl . Platelet concentrates are usually pooled into packs of four to six units of platelets for transfusion in adults. Pooling requires entry into the sterile units, so platelet concentrates are required to be transfused within 4 hours of pooling. Low numbers of RBCs are present in platelet concentrates. Rarely, Rh sensitization may be induced if an Rh-positive platelet unit is transfused to an Rh-negative recipient, but sensitization can be prevented by administering Rh immune globulin.

Most platelet units used in the United States are actually obtained via plateletpheresis, in which a therapeutic adult dose can be harvested from a single donor (hence, “single-donor platelets”). In plateletpheresis, whole blood is withdrawn and centrifuged by an automated device, and the red cells, leukocytes, and most plasma are returned to the donor. Apheresis platelet units contain the equivalent of four to eight

whole-blood-derived platelet concentrates (at least 3×10^{11} platelets per unit in a volume of about 300 ml). Most apheresis platelets contain $<1 \times 10^6$ leukocytes and can be labeled *leukocyte reduced*. Apheresis platelet units contain very low numbers of contaminating RBCs, typically <0.1 ml.

Blood banks strive to provide ABO-compatible platelet units; however, transfusing ABO-compatible platelets is not required. In rare cases, hemolytic transfusion reactions have been seen as a result of high-titer isoagglutinins (e.g., anti-A antibody) present in the donor plasma in the platelet unit.

Lower-than-expected posttransfusion platelet count increments may represent a refractory state. Nonimmune factors that can cause refractoriness to platelets include fever, sepsis, medications, disseminated intravascular coagulation (DIC), bleeding, splenomegaly, hepatic veno-occlusive disease, and GVHD. In a subset of cases, refractoriness to platelets is immune mediated, which is generally the result of class I anti-HLA antibodies in the recipient. These patients may respond to HLA-matched platelets or crossmatched platelet units. Although platelets express class I HLA antigens, transfusion recipients are usually stimulated to make anti-HLA antibody not by the platelets themselves, but rather by HLA-expressing leukocytes present in the unit. Providing leukoreduced blood products has been demonstrated to be highly effective in preventing HLA alloimmunization.

Fresh frozen plasma

FFP is prepared by centrifuging a unit of whole blood. One unit of FFP has a volume of approximately 225 ml (200–250 ml) and contains all clotting factors in normal concentrations (1 IU/ml), as well as fibrinogen. FFP is frozen within 8 hours of collection to avoid degradation of coagulation factors (particularly the labile factors V and VIII). ABO-compatible FFP is generally used, but transfusing ABO-compatible FFP is not required. FFP is the primary source of replacement coagulation factors for patients with multiple factor deficiencies, and is the component most prone to inappropriate use.

Indications for the use of FFP include correction of bleeding due to factor deficiencies (when specific factor concentrates are not available) and states in which multiple factor deficiencies must be corrected (e.g., massive hemorrhage and transfusion, DIC, hepatic failure, acute reversal of warfarin therapy). These deficiencies should be demonstrated by abnormal coagulation studies (prothrombin time [PT] or activated partial thromboplastin time. Minor prolongations of the PT and aPTT ($<1.5 \times$ the mean of normal range), volume expansion, and nutritional support are not indications for FFP transfusion. Reversal of warfarin should be treated with vitamin K rather than FFP, unless more urgent correction is required (e.g., for ongoing hemorrhage). There are advantages and disadvantages to using Vitamin K versus FFP. The latter has the associated transfusion risks, but its action is essentially instantaneous and it permits the easy reestablishment of anticoagulation with warfarin. With Vitamin K, there is no transfusion risk; however, its action

Table 66.1. Summary of blood components

Blood component	Contents	Expected increment	Time to receive product, min	Volume, ml	Shelf life
RBCs	RBCs with ~25 ml of plasma; 100 ml of saline; additive solution (adenine, mannitol); Hct 60%	Hct, 3%	10 (if T&S complete)	340	42 d at 4°C
Pooled platelet concentrates	Platelets; includes some WBCs; 50 ml of plasma, a few RBCs	5000–10,000 plt/ μ l/unit (30,000–60,000 for 6-pack)	30	50 ml/concentrate; 300 ml/pool	5 d at 20°C
Apheresis platelets	Platelets; includes some WBCs; 300 ml of plasma; a few RBCs	30,000–60,000 plt/ μ l	15	300	5 d at 20°C
FFP	Plasma proteins; all coagulation factors; complement	Factor levels 3%/unit FFP	30	225	1 y at –18°C
Cryoprecipitate	200 mg of fibrinogen, at least 80 units of factor VIII, von Willebrand factor, factor XIII, fibronectin	Fibrinogen: 70 mg/dl (pool of 10 units)	45	15 ml	1 y at –18°C

requires hours to be manifest. In addition, a patient given Vitamin K becomes temporarily very resistant to warfarin, and this resistance decreases gradually over a period of weeks. Therefore, it becomes very difficult to establish a constant anticoagulant effect with warfarin for weeks following a dose of Vitamin K.

One milliliter of FFP per kilogram of patient weight will raise most clotting factors by approximately 1%, so one unit of FFP will raise factor levels in a 70-kg adult by about 3%. In clinically significant coagulopathy, one to two units of FFP likely is inadequate. The amount of FFP needed depends on the patient's clotting factor levels, levels needed to achieve a therapeutic effect, whether or not the patient is bleeding, and the patient's blood volume. FFP should be used as soon as possible after (and always within 24 hours of) thawing.

Cryoprecipitate

Cryoprecipitate is a concentrate prepared by thawing FFP at 1° to 6°C and isolating and refreezing the cold-insoluble precipitate that forms. Each unit of cryoprecipitate contains about 80 units each of factor VIII and von Willebrand factor and about 200 mg of fibrinogen, as well as lesser quantities of fibronectin and factor XIII. When needed, the unit is thawed, suspended in normal saline, and often pooled for administration. It must be used within 6 hours of thawing or, if pooled, within 4 hours. Compatibility testing is not needed, nor is ABO or Rh type specificity, although in infants, specificity is often observed if trace amounts of A or B isoagglutinins are present (because of their small blood volume).

Historically, cryoprecipitate was used for hemophilia and von Willebrand's disease, although now virus-inactivated factor concentrates are preferred. It is primarily used for control of bleeding with hypofibrinogenemia, such as acute DIC with bleeding. Each unit should raise the fibrinogen level in an adult by 0.1 mg/kg/dl. It is often pooled so that 10 units provide approximately enough fibrinogen to raise the fibrinogen 60 to 70 mg/dl in a 70-kg adult. Cryoprecipitate also is used for the treatment of uremic bleeding, obstetric emergencies such as abruptio placentae, and HELLP (*hemolysis, elevated liver enzymes, and low platelet count*) syndrome, and rare factor

XIII deficiency. In general, it should not be used for other indications.

Irradiated blood products

Viable transfused lymphocytes present in RBC or platelet units can potentially respond to host antigens and cause transfusion-associated GVHD (TA-GVHD). Most cases have been observed in immunocompromised recipients, as infused lymphocytes are normally eradicated by a recipient's immune system. TA-GVHD is usually fatal. No effective therapy exists, but TA-GVHD can be prevented by blood product irradiation. Irradiated products must receive a minimum of 25 Gy of gamma radiation at the center of the unit. Cryoprecipitate and FFP have not been associated with TA-GVHD and do not require irradiation. RBC units that have been irradiated have a shortened shelf-life of 28 days.

Absolute indications for irradiated components include bone marrow transplant recipients (allogeneic, autologous), T-cell immunodeficiency, intrauterine transfusions, transfusions from any family member, or HLA-matched platelet transfusions. Hematologic malignancies, lymphomas, and some solid tumors (neuroblastoma and glioblastoma) are also indications for irradiated products. Patients with solid tumors of most types, those receiving chemotherapy, and those on other routine immunosuppressive (chronic steroids or solid organ transplant recipients) drugs do not typically require irradiated products. However, TA-GVHD has occurred in patients on fludarabine; therefore, patients on this agent should also receive irradiated products. Because there is no effective treatment for TA-GVHD, and because the list of indications for irradiation has expanded over time, some institutions are moving toward "universal" irradiation of blood products.

Pretransfusion testing and time to receipt of blood components

The time required to receive blood when it is ordered depends on the amount of pretransfusion testing required and laboratory processing requirements. Pretransfusion testing can

reduce or eliminate the risk of hemolytic reactions and other types of transfusion reactions. Standards for testing are established by the American Association of Blood Banks, as well as local and national regulations.

ABO/Rh type

Once an adequate specimen arrives in the blood bank, pre-transfusion testing begins with determination of blood type. This phase takes about 10 minutes and involves determining what ABO antigens are present on the patient's RBCs (forward typing) by mixing the RBCs with commercial antibody preparations of anti-A and anti-B antibodies. RhD antigen determination is also performed. The blood bank also tests for the presence of expected ABO antibodies in the patient's sera (reverse typing).

Antibody screen

The patient's serum is tested for the presence of unexpected RBC antibodies to clinically significant red cell antigens. The patient's serum or plasma is mixed with commercially available reagent type O RBCs that express the 20 or so antigens most commonly associated with hemolytic transfusion reactions. The various stages of incubation conditions designed to elicit agglutination or hemolysis require about 45 minutes. If unexpected antibodies are discovered, the identification and location of appropriate antigen-negative units may require several hours or, in rare cases, days.

Crossmatch

Compatibility between a unit of RBCs and the patient's serum is assured via the crossmatch. If no antibodies are detected on the antibody screen, the unit may be crossmatched by the "immediate spin" method. Donor RBCs are mixed with recipient plasma at room temperature, and the presence or absence of agglutination is noted. This test is done simply as a final check to rule out ABO incompatibility. If a validated information system is in use in the blood bank, an electronic crossmatch can replace the immediate spin crossmatch procedure. If unexpected RBC antibodies are identified on the screen, serologic crossmatching must be performed.

If a patient has a current type and screen without unexpected antibodies, RBCs can be made available in about 10 minutes. If antibodies are present and unknown, finding crossmatch-compatible units may take considerable time. If the antibodies have been characterized, a serologic crossmatch requiring 30 minutes must be performed.

In an emergency, un-crossmatched type O or type-specific blood may be given. The risk of hemolytic reaction is low in young patients (0.1% in patients < 30 years old) but rises with a history of transfusion, age, and female sex. In patients who have received prior transfusions, the risk rises to 2% to 5% because of the presence of abnormal antibodies to RBC antigens other than A or B. A negative antibody screen decreases the risk of a hemolytic transfusion reaction to 0.06%.

Fresh frozen plasma

FFP requires 20 to 30 minutes to thaw in a 37°C water bath. No compatibility testing is required.

Platelets

Apheresis platelets are ready immediately; pooling whole-blood-derived platelet concentrates takes about 30 minutes. No compatibility testing is required.

Cryoprecipitate

Cryoprecipitate requires 45 minutes to thaw and pool. No compatibility testing is required.

Blood substitutes

Blood substitutes using hemoglobin-based O₂ carriers or inert chemicals to deliver O₂ to tissues are currently under investigation. Perfluorocarbon solutions, which are chemically inert but carry O₂ in solution, are undergoing phase II and III clinical trials in the United States and Europe. Hemoglobin-based O₂ carrier solutions (chemically modified human or bovine hemoglobin that carries O₂ in solution) are undergoing or have completed phase III clinical trials in the United States. Polyheme (Northfield Labs, Evanston, IL), a hemoglobin-based carrier, is the only blood substitute to complete phase III clinical trials, but was not approved for use by the FDA and is no longer manufactured. Both perfluorocarbons and hemoglobin-based O₂ carriers have short plasma half-lives, and none currently is licensed for use in North America.

Blood transfusion

Jonathan E. Charnin

Introduction

Perioperative blood transfusions comprise about two-thirds of all transfusions in the United States. All anesthesiologists must have expertise with transfusion and maintain open lines of communication with their colleagues in transfusion medicine.

Current practices in blood transfusion utilize blood component therapy. Whole blood is separated by centrifugation into red blood cell (RBC) units, platelet concentrates, and plasma. Plasma derivatives such as cryoprecipitate, albumin, pooled clotting factors, and immunoglobulins may later be generated from the separated plasma. Component therapy allows the targeted treatment of anemia, thrombocytopenia, and coagulopathy with the appropriate fraction of whole blood: RBCs, platelets, or plasma, respectively. Component therapy also facilitates storage of blood components, screening for transmissible pathogens, and management of the blood supply. The most commonly transfused blood components are RBC units (sometimes called *packed RBCs* or *PRBCs*) and fresh frozen plasma (FFP).

Blood product transfusion is a medical intervention. Whenever possible, informed consent must be obtained from the patient before transfusion. It is mandatory to discuss preoperatively the likelihood of blood transfusion and its attendant risks with patients undergoing surgery. Patients who refuse to receive blood products may present additional anesthetic challenges.

Blood compatibility testing

RBCs express a variety of surface antigens that limit the compatibility of blood for transfusion between individuals. A collection of RBC antigens produced by a single genetic locus is called a *blood group*. The ABO system is the most important blood group (Table 67.1). The ABO gene on chromosome 9 encodes a glycosyltransferase enzyme. An individual's ABO type – A, B, AB, or O – is dictated by which allelic forms of the ABO gene are inherited. The gene product of the A allele adds a terminal N-acetylgalactosamine (GalNAc) residue to specific RBC surface carbohydrates, forming the A carbohydrate antigen. The gene product of the B allele instead adds a galactose residue to the exact same substrates. The O allele encodes a truncated, non-functional protein – neither A nor B antigen is generated on the RBC surface.

An ABO-incompatible RBC transfusion may cause an immediate, life-threatening hemolytic transfusion reaction. Continuous exposure to ubiquitous environmental antigens that are structurally similar to the ABO antigens ensures that all recipients have circulating preformed antibodies against the ABO antigens their own RBCs lack. For instance, individuals who are type B always form potent, complement-fixing anti-A antibody – without ever having been exposed to type A RBCs through transfusion or pregnancy. Patterns of compatibility between recipients of a known blood type and donor blood products are worth committing to memory (Table 67.2). When transfusing RBCs, the preformed anti-ABO antibodies in the recipient are the limiting factor for transfusion. Because type O blood lacks A and B antigen, it is the “universal donor” RBC type. When transfusing plasma products (FFP and platelets), preformed anti-ABO antibodies in the donor plasma are the limiting factor for transfusion, so type AB plasma is the “universal donor” plasma type.

To determine a patient's blood type, the patient's RBCs are mixed with anti-A and anti-B reagent antibodies to provoke visible agglutination (antibody-mediated clumping). RBCs expressing A or B antigens will agglutinate when mixed with the appropriate antibody. This process is called “forward” blood typing. To confirm the forward typing results, the blood bank also tests for the expected presence of the appropriate anti-ABO antibodies in the recipient's plasma. This is called “back typing.” Both forward typing and back typing are used to determine a patient's blood type.

There are many blood group antigens outside the ABO system. In most cases, these antigens represent immunogenic

Table 67.1. Blood type frequencies by percentage and skin color

ABO	Whites	Blacks
O	45	49
A	40	27
B	11	20
AB	4	4

Table 67.2. ABO compatibilities for transfusion of PRBCs and FFP

Recipient blood type	ABO-compatible PRBC donor blood types	ABO-compatible FFP donor blood types
O	O	AB, A, B, O
A	A, O	A, AB
B	B, O	B, AB
AB	AB, A, B, O	AB
Rh ⁺	Rh ⁺ , Rh ⁻	Rh ⁺
Rh ⁻	Rh ⁻	Rh ⁺ , Rh ⁻

epitopes present on the extracellular portions of RBC membrane proteins. Most of these antigens are created by single nucleotide polymorphisms in the genome. Unlike the case with ABO antigens, prior exposure through blood transfusion or pregnancy is usually necessary for a patient to form antibodies to these antigens. Five blood group systems account for most of the clinically significant transfusion reactions that occur: the Rh blood group system, the Kell system, the Duffy system, the Kidd system, and the MNS system. After ABO, the Rh system is the most important blood group. Rh antigens are expressed on proteins encoded by two closely linked genes on chromosome 1. The *RhD* gene encodes the D antigen; the *RhCE* gene encodes the C, c, E and e antigens. The D antigen is extraordinarily immunogenic: approximately 80% of D-negative individuals will form anti-D antibody following a single D-positive RBC transfusion. For this reason, transfusion recipients are routinely matched for RhD in addition to ABO. Individuals whose RBCs express the D antigen are referred to as “Rh positive”; those lacking the D antigen are called “Rh negative.” Other clinically important RBC antigens include the K antigen (Kell system), Fy^a and Fy^b (Duffy system), Jk^a and Jk^b (Kidd system), and S (MNS system).

When a patient is exposed to a foreign RBC antigen through transfusion or pregnancy, the patient may form an alloantibody to that antigen – for example, anti-K or anti-E. This primary sensitization is almost never associated with any clinical consequences. However, upon reexposure to the same antigen, a vigorous secondary immune response may occur. If reexposure to the antigen is via blood transfusion, the transfused, antigen-positive units may be cleared rapidly from the circulation of the recipient, resulting in an acute or delayed hemolytic reaction (see later). If reexposure to antigen occurs via fetomaternal hemorrhage during pregnancy, hemolytic disease of the newborn may be caused by these antigens when the mother transfers to the fetus maternal antibodies that recognize and cause hemolysis of the fetal red cells that carry other blood group antigens inherited from the father.

Prior to transfusion, a patient in need of a blood transfusion should have a sample of his or her blood sent to the blood bank. The blood bank first determines the patient’s ABO type as described earlier. The patient’s RhD status (positive or negative) is determined simultaneously. Next, an antibody screen is performed to test the patient’s plasma for “unexpected”

anti-RBC antibodies (antibodies against non-ABO RBC antigens). The antibody screen is an example of an indirect antiglobulin test (i.e., indirect Coomb’s test). In the antibody screen, patient plasma is incubated with two or three different type O reagent RBCs that have been phenotyped for the 20 or so RBC antigens that cause the vast majority of non-ABO-related hemolytic reactions. The reagent RBCs are chosen so that at least one example of each of the most important RBC antigens from the Rh, Kell, Duffy, Kidd, and other blood group systems is present. During the incubation step, anti-RBC antibodies in the patient’s plasma will bind to the cognate antigens on the reagent RBCs. These antibodies, if present, are usually IgG, so they will not agglutinate the reagent RBCs directly. Therefore, to detect the antibodies, antihuman globulin (AHG, or Coomb’s reagent) must be added. AHG is antibody directed against human IgG. AHG will crosslink the reagent RBCs if they have been coated with recipient antibody, causing visible agglutination. If no agglutination is observed with AHG, the antibody screen is reported as negative. If agglutination is seen, however, the blood bank must perform further testing to determine the specificity of the patient’s RBC antibody (or antibodies). It is important to be aware that this testing may take several hours to days, depending on the antibodies present. If it is determined the patient has clinically significant RBC antibodies (capable of causing decreased RBC survival), RBC units lacking the appropriate antigens are selected for transfusion. The final step in pretransfusion compatibility testing is the crossmatch. If the patient’s antibody screen is negative, an “immediate spin” crossmatch is done: recipient plasma is mixed with an aliquot of the RBCs intended for transfusion, and the sample is checked for agglutination. This test will detect only IgM antibody, so it essentially just serves as a last-minute confirmation that the patient’s plasma and donor RBCs are ABO compatible (i.e., no ABO error has been made). At many institutions, the “immediate spin” crossmatch is actually omitted. An “electronic crossmatch” is performed instead – a validated computer system ensures that ABO-compatible units are being issued. If a patient does have a positive antibody screen, a more sensitive AHG crossmatch (“Coomb’s crossmatch” or “full crossmatch”) must be performed to ensure RBC compatibility.

Life-threatening hemorrhage will occasionally not wait for blood typing and crossmatching. In the most emergent circumstances in which no delay is appropriate, type O negative PRBCs can be used as universal donor blood without waiting for blood typing or crossmatching. Only for male patients is it permissible to transfuse O positive PRBCs for emergency use. In urgent situations in which transfusion can be delayed by 5 to 15 minutes, it is preferable to have the patient’s blood sample sent to the blood bank for blood typing. Once the patient’s blood type is known, un-crossmatched PRBCs of the same type with an appropriate Rh status, or type-specific blood, can be used to meet the needs of emergency transfusion. When the need for transfusion is not immediate, fully crossmatched PRBCs should be used. In emergency situations, universal donor FFP, which comes from type AB donors, can be used. Because it takes 30

to 45 minutes to thaw FFP, and blood typing can be performed rapidly, it is unusual to require universal donor FFP.

Platelets express ABO antigens, but they may be given without an ABO match. ABO-incompatible platelet transfusions have a reduced survival time in comparison with ABO-matched platelets, but this may not be of clinical importance in some settings.

Reactions and complications of blood transfusion

Blood component transfusions may be lifesaving, but they may also produce life-threatening complications. Anesthesiologists should focus on preventing complications of blood transfusion by transfusing blood components only when indicated and scrupulously attending to good transfusion techniques. Some immediate complications of transfusion can be recognized before the transfusion is complete, and it may be possible to limit the morbidity of a transfusion reaction by interrupting the transfusion. Transfusion reactions may be difficult to identify in patients who are anesthetized. Therefore, it is important to be mindful of adverse events and complications during transfusions, especially when transfusing emergency-released blood products when the donor blood has not been fully crossmatched with the recipient's blood.

Acute hemolytic transfusion reaction

ABO-incompatible red cell or FFP transfusions cause an immediate hemolytic transfusion reaction. Hemolytic transfusion reactions also may occur with some of the other blood group antigens, when red cells with particular antigens are transfused to a patient who has already been sensitized to those antigens. During a hemolytic transfusion reaction, a recipient may report pain at the infusion site, chest pain, dyspnea, and flank pain. He or she also may experience fever, rigors, and hypotension. Red urine, colored by free hemoglobin, and coagulopathy manifesting as diffuse bleeding at the surgical site may be observed. Acute hemolytic transfusion reactions produce red cell lysis by anti-red cell antibodies provoking both intravascular agglutination of red cells and fixing the complement system to the red cell. These reactions are life threatening and require discontinuation of the transfusion and prompt measures to support the patient. (See Table 67.3 on management of hemolytic transfusion reaction.)

Delayed hemolytic transfusion reactions

Delayed hemolytic transfusion reactions usually happen 3 or more days after PRBC transfusion. In these reactions, the recipient has an undetected antibody that coats the donor red cells and leads to hemolysis, usually in the reticuloendothelial system. These reactions may be asymptomatic or may produce anemia and jaundice a few days after a blood transfusion. Investigating delayed (and acute) hemolytic reactions by the blood bank is done by (1) rechecking identification of the patient

Table 67.3. Management of a suspected acute hemolytic transfusion reaction

Stop the transfusion, save the remaining blood product for testing
Check for an obvious error in patient identity or blood product match
Support the patient's circulation, treat hypovolemia and hypotension
If immediate transfusion is needed, give type O negative blood and AB + FFP if needed
Send a new blood sample for crossmatch to the blood bank, along with the remainder of the suspect unit for testing
Support the patient's renal function with fluids and diuretics, starting with furosemide and then mannitol if needed
Monitor the coagulation system for signs or laboratory values suggestive of disseminated intravascular coagulation, and treat if needed
Send the patient's blood for a direct antiglobulin test, free hemoglobin, and haptoglobin; send urine for free hemoglobin

Modified from Table 34–2 in *Clinical Anesthesia Procedures of the Massachusetts General Hospital*, 7th ed., 2007, p. 612.

and transfused units, (2) checking for visual hemolysis (pink or red discoloration) of the recipient plasma, and (3) performing a direct antiglobulin test (DAT, or “direct Coomb's test”). AHG is added to the recipient's sample; if recipient IgG antibody has coated the transfused RBCs, the DAT will be positive. The absence of visual hemolysis and a negative DAT essentially exclude a hemolytic transfusion reaction.

Allergic reaction

Allergic reactions may occur when a recipient has a reaction to an allergen in transfused blood products. Urticarial reactions may complicate up to 3% of transfusions. Anaphylactic, anaphylactoid, or delayed allergic rashes are possible but rare. A potential allergen is donor IgA antibodies when a recipient has a congenital IgA deficiency. Allergic transfusion reactions are not typically accompanied by fever. If an allergic reaction to transfusion is suspected, the transfusion should be stopped. If the reaction is limited to a rash, the transfusion may be restarted after an antihistamine is given. Supportive care and treatment of anaphylaxis should be given promptly if anaphylaxis is suspected. In some cases, it may be difficult to distinguish an anaphylactic reaction to transfusion from an ABO-incompatible transfusion or transfusion-related acute lung injury (TRALI). Patients with a history of IgA deficiency or allergic reactions to blood transfusion may benefit from having RBCs washed by the blood bank in saline before administration.

Febrile nonhemolytic transfusion reaction

Fever is associated with several serious transfusion reactions, including acute hemolytic transfusion reactions and transfusion of blood products infected with bacteria and is noted in about one in 300 red cell transfusions. When fever is associated with transfusion, prompt attention and evaluation are indicated. If there is no evidence of a serious complication, the reaction is called a *febrile nonhemolytic transfusion reaction*

(FNHTR). Fevers associated with transfusion are defined as a rise of $> 1^{\circ}\text{C}$ without any other explanation. FNHTR may complicate 0.5% to 6% of transfusions of non-leukocyte-reduced red cells. Recipients with prior exposures either through transfusions or gestations are at greater risk for having FNHTRs. Treatment with acetaminophen is indicated. Meperidine injection may help with rigors. For patients with a history of FNHTR, use of leukocyte-reduced blood products may prevent future reactions.

Transfusion-related acute lung injury

TRALI is a syndrome of dyspnea, hypoxia, and bilateral chest radiograph abnormalities within 6 hours of blood product transfusion. Multiple mechanisms appear to contribute to TRALI, and it is one of the leading causes of transfusion-related mortality. Most cases of TRALI appear to be caused by donor antileukocyte or anti-HLA antibodies that recognize recipient leukocytes or recipient HLA cell surface markers and then activate an inflammatory response. The occurrence of TRALI usually involves donor antibodies and therefore is related to donor plasma. Although the small amount of donor plasma transfused with PRBCs or cryoprecipitate may cause TRALI, it is about 12 times more common with FFP and eight times more common with platelet transfusions than with PRBCs. Blood product donors who have been exposed to foreign HLA through prior transfusion or prior pregnancy are more likely to have the antibodies that cause TRALI. For this reason, there is interest in using only male donor plasma for FFP transfusion.

Transfusion-associated circulatory overload

Blood product transfusion expands the intravascular space. Transfusion of blood products in sufficient quantity may induce congestive heart failure, especially in patients prone to it. This condition is referred to as *transfusion-associated circulatory overload* (TACO). When congestive heart failure manifests as respiratory distress, it may be difficult to differentiate TRALI from TACO without an assessment of the cardiac filling pressures.

Hypotensive response to transfusion with angiotensin-converting enzyme inhibitor use

Patients who take angiotensin-converting enzyme inhibitors (ACE-Is) are at risk for hypotensive reactions during PRBC transfusions. ACE-Is block the metabolism of bradykinin in addition to blocking the conversion of angiotensin. Bradykinin is a vasodilatory nonapeptide. Leukocytes in cellular blood products elaborate bradykinin that is infused with the blood product. The use of bedside leukocyte reduction filters increases bradykinin production and incidence of hypotensive reactions. Because these patients cannot metabolize bradykinin because

of the actions of ACE-Is, they experience hypotension that may be profound.

Stopping the transfusion and supporting the blood pressure are the first priorities if this reaction is observed. ACE-I cessation prevents recurrence of the reaction.

Hyperkalemia

PRBCs in storage experience a leak of intracellular potassium to plasma and the storage solution packaged with the red cells. Because the volume of plasma and storage solution packaged with the red cells is small, the potassium concentration in the fluid may be very high, ≥ 30 mEq/L, and its magnitude relates to the duration of red cell storage. Because the volume of the plasma is low, the total potassium given with a transfusion of red cells does not usually produce clinical hyperkalemia. Hyperkalemia is more worrisome when transfusions are given quickly or when the recipient is an infant or small child. During blood transfusion, the acute widening of the QRS complex on electrocardiography is concerning for hyperkalemia. Prompt administration of calcium chloride may be necessary while other measures to control the hyperkalemia are undertaken.

Patients who are at risk of experiencing hyperkalemia with transfusion may benefit from having RBCs washed in saline by the blood bank before administration.

Citrate toxicity

Citrate is used as an anticoagulant to prevent clotting during the storage of blood products. Citrate's anticoagulant action is mediated by chelation of the extracellular calcium required for coagulation. Typically, the citrate contained in blood products is quickly metabolized by the liver and, to a lesser degree, by many other organs. Calcium stores in the body also may be mobilized to restore blood calcium levels. During rapid transfusion, massive transfusion, liver transplantation, or hypothermia, or in patients already experiencing hypocalcemia, an accumulation of citrate may cause a profound decrease in ionized calcium that may produce muscle spasms, arrhythmias, or cardiac dysfunction. Intravenous injection of calcium chloride and correction of volume status and body temperature are recommended to treat the symptomatic decrease in ionized calcium due to citrate intoxication. Calcium gluconate requires the metabolism of the gluconate before the calcium is available and therefore may not be effective in treating citrate toxicity.

Air embolus

Rapid administration of blood product, especially when using positive pressure devices, has been associated with a life-threatening iatrogenic venous air embolism. This should be considered when hypotension complicates blood transfusions infused with positive pressure. Care should be taken when spiking blood product bags to minimize the volume of air in the plastic bags.

Table 67.4. Current risks of infection from test-negative blood

Components	Risk
HIV-1	1 in 1,525,000–2,135,000
Hepatitis C virus	1 in 1,935 000
Hepatitis B virus	1 in 205,000–488,000
West Nile virus	Approaching zero

Adapted from Stramer SL. Infectious risk from blood transfusion. *Arch Pathol Lab Med* 2007; 131:703.

Infectious complications

Blood product transfusions may transmit life-threatening infections. Transmission of viral and bacterial infections is of particular concern to physicians and patients. Transmission of blood-borne parasitic diseases such as malaria or prions such as those that cause Creutzfeldt-Jakob disease has been reported but is exceedingly rare. Testing for viral illnesses has substantially reduced the risk of transfusion-related viral transmission, especially since the introduction of nucleic acid amplification testing in 1999.

Bacterial contamination of blood products is not common, but it may produce an immediate septic reaction during transfusion. Platelets stored at room temperature are more commonly infected than other blood products, in which the rate of septic transfusion is one in 33,000 units transfused.

Screening blood donors and testing donated blood for viral contamination reduce but do not eliminate the transmission of viral illness. Some viruses, such as cytomegalovirus, may be transmitted less frequently through leukoreduced blood products. See [Table 67.4](#) for rates of transmission.

Transfusion-associated graft-versus-host disease

Transfusion-associated graft-versus-host disease (TA-GVHD) is caused by donor lymphocytes engrafting in the recipient and attacking his or her tissues. This is a very rare but often fatal complication that is seen more commonly in immunosuppressed recipients. Leukocyte reduction filters do not eliminate the risk of TA-GVHD, but pretreatment of blood products with radiation is preventive.

Transfusion-related immunomodulation

Red cell transfusions modulate the immune response, particularly the innate immunity. The mechanisms of immunosuppression are still unclear. The deleterious effects of this immunosuppression may contribute to increased rates of hospital-acquired infections in trauma patients, as well as increased rates of cancer recurrence after surgical resection. The work by Carson and his colleagues suggests that there is a dose-response relationship between perioperative transfusion and postoperative infectious complications in patients undergoing hip fracture repair.

Transfusion triggers

Morbidity and mortality are associated both with unnecessary transfusion and uncorrected critical anemia. The desire is to transfuse when the benefits are thought to outweigh the risks. Debate continues about what degrees of anemia, coagulopathy, and thrombocytopenia should prompt a transfusion. It appears there is no one laboratory value, or transfusion trigger, that is an appropriate guide to transfuse for all patients. Few data from randomized prospective trials are available to guide the transfusion decision. Often, a clinician must consider the comorbid illnesses of the patient, the patient's vital signs, the potential for hemorrhage, and data from physiologic studies when deciding when to transfuse.

RBCs and their hemoglobin are the vehicles for oxygen transport in the body. During anemia, blood viscosity decreases and the ability of blood to transport oxygen may increase. Optimization of oxygen-carrying capacity with respect to hemoglobin concentration and viscosity appears to occur in healthy subjects when the hemoglobin is 10 g/dl. Outdated transfusion dogma suggested treating anemia with blood transfusion to keep the hemoglobin > 10 g/dl. Most patients tolerate hemoglobin levels between 7 and 9 g/dl without additional morbidity or mortality. Observational studies and small prospective trials have not demonstrated benefit for using transfusion triggers above 9 g/dl, with the exception of patients who are experiencing an ST elevation myocardial infarction. Transfusions of PRBCs are rarely indicated when the hemoglobin is >10 g/dl.

Healthy volunteers can survive profound normovolemic anemia without lasting harm, but their cognition is impaired when the hemoglobin reaches 5 g/dl. Observations of patients who experienced perioperative anemia and refused blood transfusion suggests that postoperative mortality increases when hemoglobin concentrations are <6 g/dl. To prevent this anemia-related mortality, transfusion of PRBCs is indicated when a patient's hemoglobin is below 7 g/dl. During active hemorrhage, it may be difficult to achieve a hemoglobin target. A transfusion trigger of 8 g/dl during active hemorrhage is a reasonable target to provide red cell margin during ongoing hemorrhage.

Hebert and his colleagues published the largest prospective trial evaluating red cell transfusion triggers. They randomly assigned 838 euvolemic intensive care unit patients with hemoglobin levels < 9 g/dl to a restrictive or a liberal transfusion strategy. The restrictive group had hemoglobin levels maintained by transfusion in a range of 7 to 9 g/dl, whereas the liberal group had their hemoglobin maintained in a range of 10 to 12 g/dl. The primary end point of 30-day mortality showed no statistical difference in mortality between the groups. The patients in the restrictive strategy group received 53% fewer red cell transfusions than patients in the liberal strategy group. Subgroup analyses suggest there may be additional survival benefit from restrictive transfusion in patients with less severe illness. However, because of possible selection bias, the results

Table 67.5. Cryoprecipitate dosing formula

Milligrams of fibrinogen needed = [weight (kg) × 70 ml of blood/kg × (1 – hematocrit) × (desired fibrinogen in mg/dl – starting fibrinogen in mg/dl)/100 ml/dl]

Bags of cryoprecipitate needed = milligrams of fibrinogen needed/250 mg of fibrinogen per bag of cryoprecipitate

Modified from American Association of Blood Banks. (2005). *Technical Manual* (15th ed.). Bethesda, MD: American Association of Blood Banks, p. 501.

of this trial may not be applicable to patients with active coronary ischemia.

Acute coagulopathy may require both administration of clotting factors and platelet transfusion to correct thrombocytopenia. Clotting factor deficiencies and reversal of warfarin anticoagulation are commonly treated with transfusion of FFP; 10 to 15 ml of FFP per kilogram of body weight can be transfused to rapidly correct anticoagulation with warfarin. Hemostasis is usually normal when coagulation factors remain above 30% of their normal level. The clotting factor fibrinogen requires about 50% of its normal 200 to 400 mg/dl level to produce normal clot formation. Intraoperatively, transfusion of FFP likely will produce no benefit until the prothrombin time or activated partial thromboplastin time is prolonged to >1.5 times reference values, or when blood loss exceeds one blood volume. During active hemorrhage, many anesthesiologists begin to transfuse FFP when 4 or 6 U of PRBCs have been transfused. When clotting factors are depleted and massive transfusion is ongoing, FFP is often transfused in a 2:1 ratio of PRBCs to FFP. Some authors advocate earlier transfusion of FFP and PRBCs-to-FFP ratios of 3:2 or 1:1 during the resuscitation of hemorrhage from major trauma.

Cryoprecipitate contains the concentrated clotting factors VIII, XIII, von Willebrand, and fibrinogen that precipitate out when FFP is thawed at a temperature of 4°C. Currently, cryoprecipitate is commonly used for the treatment of hypofibrinogenemia, and the dose required to correct the fibrinogen can be estimated using a formula (Table 67.5). Cryoprecipitate may also be used to treat hemorrhage due to hemophilia A or von Willebrand disease, but commercially available factor concentrates are better therapies for these coagulopathies.

Sufficient platelet number and adequate platelet function are both important in forming an effective clot. Platelet transfusion can be undertaken to treat thrombocytopenia. The effectiveness of treating platelet dysfunction with transfusion depends on the cause of the platelet dysfunction, but it is often more effective to

treat the cause of the platelet dysfunction. In the surgical setting, thrombocytopenia without platelet dysfunction should affect hemostasis only when the platelet count is < 50,000/mm³. Perioperative platelet transfusion is indicated to keep the platelet count > 50,000/mm³. Neurosurgical or ophthalmologic operations, in which small bleeding may create a poor outcome, may merit a platelet transfusion threshold of 80,000 or 100,000 platelets/mm³.

Massive transfusion

Amy J. Ortman and Susan Vassallo

Massive transfusion is a relatively infrequent event, although the precise incidence is unknown, perhaps in part because of the variable definitions for *massive blood loss* and *transfusion*. Some authors arbitrarily define *massive transfusion* as the administration of at least 8 to 10 units (U) of blood transfused within a 12-hour period. Other definitions are the replacement of one blood volume within 24 hours, or the replacement of half of a patient's blood volume in 3 hours. Yet another, more dynamic, definition is the transfusion of ≥ 4 U of packed red cells within 1 hour when there is a high likelihood of ongoing need for further transfusion.

Regardless of the definition used, massive hemorrhage and the requisite massive transfusion comprise a clinical situation that presents a unique challenge to anesthesiologists. Although there is no substitute for prompt and appropriate surgical management to limit blood loss, anesthesiologists must be prepared to direct a large-volume resuscitation and have a ready, working knowledge of the issues involved.

Epidemiology and clinical context

Elective surgeries

Within hospitals, the most common cause of massive blood loss and transfusion are surgical procedures. Populations particularly at risk include those undergoing cardiopulmonary or vascular procedures, liver transplantation or resection, major orthopedic procedures, or emergency obstetric surgery. In the elective setting, resuscitation frequently begins with crystalloids, and then quickly shifts to blood products as the blood loss increases. Despite the volume of literature on the subject of transfusion, there are no precise guidelines outlining the appropriate time to transition from crystalloid resuscitation to blood product transfusion. Clinicians determine the timing by incorporating factors such as the patient's comorbidities, clinical evidence of perfusion, oxygenation and clotting ability, and anticipation of ongoing surgical losses.

Trauma

Trauma patients comprise a significant portion of patients who receive massive transfusions. Hemorrhage is the second leading cause of death following severe injury, and mortality among patients who have acute massive blood loss and transfusion

within the first 24 hours of presentation may be as high as 70%. Although the percentage of trauma patients who require a massive transfusion is relatively small, this population accounts for most blood products transfused at a trauma center. In one retrospective study linking blood bank use to trauma admissions, only 9% of all trauma admissions received blood products and of those, about 30% had a massive transfusion. Despite representing a small fraction of the total trauma admissions, the patients who received massive transfusions accounted for more than 72% of all the red blood cells (RBCs) used in the trauma center.

In the setting of trauma, massive transfusion within the first 24 hours is correlated with increased severity of injury, failure to control hemorrhage, and lower Glasgow coma scores, all of which contribute to the ongoing blood requirement and a greater mortality. Further complicating the clinical picture are the comorbidities that are frequently present when trauma patients arrive: hypothermia, hemorrhagic shock, acidosis, and coagulopathy.

Table 68.1 outlines some of the differences in massive transfusion between elective surgery and trauma situations.

Coagulopathy

Coagulation is a complex process of clot formation following vascular injury involving platelets and clotting factors, and results in hemostasis. Abnormal coagulation may occur because

Table 68.1. Differences in massive transfusion between elective surgery and trauma situations

	Elective surgery	Trauma
Tissue trauma	Controlled	Extensive and uncontrolled
Volume status	Normovolemic	Hypovolemic shock common
Temperature	Normothermic	Hypothermia common
Laboratory studies	Drawn regularly and frequently	Drawn late
Initiation of massive transfusion	Little or no delay in initiation of transfusion following hemorrhage	Transfusion may be significantly delayed following hemorrhage
Coagulopathy	Usually dilutional	Disseminated intravascular coagulopathy, dilutional, or coagulopathy of trauma

of inherited or acquired factor deficiencies, medications, hypothermia, acidosis, dilution and consumption of clotting factors, the use of fractionated blood products, or disseminated intravascular coagulation (DIC). When patients receive a massive transfusion, anticipation, recognition, and prompt intervention are essential to prevent development of a coagulopathy, further blood loss, and the resultant complications.

Hemodilution

Both trauma patients and patients undergoing elective surgery are at risk for the development of a dilutional coagulopathy. Although there is tremendous reserve and clotting factors may be decreased to approximately 30% of normal without clinical consequence, initial and ongoing resuscitation with crystalloids, colloids, or RBCs may lead to a deficiency of factors necessary for normal coagulation. Additionally, some synthetic colloid solutions may also act via platelet inhibition to further compromise coagulation.

Another important consideration is the role RBCs play in hemostasis. Erythrocytes help activate platelets by release of adenosine diphosphate and activation of platelet cyclooxygenase. RBCs also contribute to the margination of platelets against the vessel wall and thus affect their ability to act at the site of a vascular lesion. Experimental evidence suggests that in patients receiving massive transfusions, relatively high hematocrits – as high as 35% – may be required to sustain hemostasis.

Administration of fractionated blood products

Historically, administration of whole blood or modified whole blood was common and dilutional coagulopathies were rarely reported. Since then, whole blood therapy has been replaced by component therapy, largely because of storage impediments to the former and more efficient use of the components. Although component therapy is effective, massive resuscitation with fractionated blood products predisposes patients to hemodilution and development of a dilutional coagulopathy. When packed RBCs (PRBCs), fresh frozen plasma (FFP), and leukoreduced platelets are separated from whole blood, half of the platelets are lost, and the cells and clotting factors are diluted by anticoagulant and RBC nutrient solutions. Mixing the components at the classic 1:1 ratio essentially makes a reconstituted whole blood with a hematocrit of 29%, a platelet count of 88,000, and clotting factor activity of 62%.

Hypothermia

The coagulation cascade is largely a series of enzymatic reactions. Hypothermia slows the activity of the enzymatic process, reduces the synthesis of coagulation factors, increases fibrinolysis, and affects platelet function. The contribution of hypothermia to coagulopathy may be underestimated in routine testing because the laboratory studies are usually performed at a temperature of 37°C. Hypothermia, which is typically defined as a core temperature of <35°C, is a significant problem in the trauma population; Ferrara et al. reported that

hypothermia occurred in 80% of nonsurvivors and 36% of survivors in a series of 45 trauma patients. Further, hypothermia combined with trauma is associated with a worse prognosis than either insult alone.

Acidosis

Massive blood loss and resuscitation occur in patients who may also be in hemorrhagic shock. Hemorrhagic shock predisposes patients to hypoxia, anaerobic metabolism, and acidosis. Although the mechanism is not clear, the evidence is that a pH < 7.10 is associated with significant coagulopathy.

Disseminated intravascular coagulation and coagulopathy of trauma

By definition, DIC is an acquired, inappropriate, systemic activation of thrombin and deposition of fibrin with consumption of platelets and coagulation factors. In the setting of elective surgery, DIC accompanying massive transfusion is relatively uncommon. However, trauma patients are at risk for the development of a consumptive coagulopathy for three reasons. The first relates to tissue trauma such as central nervous system injuries or bone fractures with embolization of tissue; these microembolic events lead to consumption of tissue factor and inappropriate initiation of the coagulation cascade. Traumatic brain injuries also cause release of tissue thromboplastin into the circulation, rapidly resulting in activation of the extrinsic coagulation pathway. Last, significant soft tissue trauma also leads to consumption of platelets and thrombocytopenia. In each case, intravascular consumption of coagulation factors results in the development of a coagulopathy, and more specifically DIC.

Within the trauma literature, a second form of coagulopathy is described. The coagulopathy of trauma is a syndrome of non-surgical bleeding associated with serious injury, hypothermia, acidosis, hemodilution, and occasionally DIC. Coagulopathy of trauma may occur in the setting of depleted coagulation factors, or in the setting of normal levels but dysfunctional coagulation factors. In a recent series review of 58 trauma patients without major brain injury or preexisting coagulopathy who required massive transfusion, four risk factors for the development of coagulopathy were identified using multiple logistic regression analysis. They are, in order of importance, pH < 7.10 (relative risk [RR], 12.3), core temperature <34°C (RR, 8.7), mean injury severity score >25 (RR, 7.7) and a systolic blood pressure <70 mm Hg (RR, 5.8). Patients without any risk factors had a 1% risk of coagulopathy, a single risk factor was associated with a 10% to 40% risk, and a combination of all four was associated with a 98% risk of coagulopathy.

Prevention of coagulopathy

The basic tenets of a massive transfusion and resuscitation require that one pay attention to the factors that contribute to or exacerbate a coagulopathy. Anesthesiologists should strive

for normovolemic resuscitation, and regularly send studies to evaluate oxygen delivery, hemoglobin, acid–base status, and coagulation status. Failure to normalize these parameters may result in inappropriate activation of the clotting cascade and subsequent hemorrhage. It is also important to remember that even when these parameters are controlled, activation of the clotting cascade may still occur from tissue trauma alone.

Management

The basic goals of the management of massive transfusion are maintenance of tissue perfusion and oxygenation by preservation of blood volume and hemoglobin; judicious use of blood component therapy; avoidance of acidosis, hypothermia, and coagulopathy; and surgical control of the bleeding.

The essential equipment and components necessary for massive transfusion will vary depending on the clinical situation, patient comorbidities, and practice style, but should include the following:

1. Adequate intravenous (IV) access (large-bore peripheral IV line, rapid-infusion catheter, and/or central venous introducer)
2. Standard American Society of Anesthesiologists (ASA) monitors and arterial line (for invasive hemodynamic monitoring and lab draws), with or without a central line (for invasive hemodynamic monitoring, infusions, and/or medication administration)
3. Warming blankets
4. Fluid warmers and/or a rapid-infusion device
5. Adequate blood products (PRBCs, FFP, cryoprecipitate, platelets)
6. Ready access to laboratory results

Resuscitation for elective surgery

The ASA has published guidelines on perioperative blood transfusions. Although these recommendations do not specifically address massive transfusions, they are useful to review, particularly those regarding blood loss and transfusion in the setting of elective surgery. The members of the guideline committee agreed that RBCs should usually be given when the hemoglobin is <6 g/dl and are usually not necessary when the hemoglobin is >10 g/dl, and that between the two values, clinical judgment should be applied to determine the need for a transfusion. The guidelines suggest that platelets be administered when the platelet count is $<50,000$ /dl. The committee recommends checking coagulation studies, if possible, prior to the transfusion of FFP. FFP transfusion is indicated for a prothrombin time (PT) > 1.5 times normal or for an activated partial thromboplastin time (aPTT) > 2 times normal and should be given in doses calculated to achieve a minimum of 30% of plasma factor concentrations. Last, the ASA's recommendations regarding cryoprecipitate are to administer it when the fibrinogen level is <80 to 100 mg/dl.

In the setting of elective surgery, tissue trauma is controlled and thus less extensive; blood loss is usually more predictable,

and patients are kept normothermic and normovolemic. Resuscitation is initially started with crystalloids and colloids to maintain normovolemia. As the blood loss becomes more significant, PRBCs are administered, followed by FFP and platelets – typically as guided by laboratory studies. Thus, coagulopathy is less common, and if it occurs, it is usually dilutional in origin. In a study of elective surgical patients, when normovolemia and a normal hemoglobin were maintained, abnormalities of the PT and the aPTT were found to occur after the transfusion of 12 U of PRBCs, and thrombocytopenia did not occur until after transfusion of 20 U. Similarly, in a study of ASA I and ASA II patients undergoing elective surgical procedures and resuscitated with plasma-poor RBC concentrates, critical hemostatic levels of fibrinogen and platelets were calculated to occur at losses of 1.42 and > 2 calculated blood volumes, respectively.

Resuscitation for trauma

As noted previously, massive blood loss and transfusion in a trauma patient is different from that in a patient undergoing an elective surgical procedure, for the following reasons: The initial resuscitation may be significantly delayed and is frequently complicated by hypothermia, acidosis, hypovolemic shock, and a predisposition to DIC. Prior to arrival at the hospital, patients typically receive only crystalloids, and even after arrival, the administration of RBCs may be delayed while blood typing is performed. The delay will be even greater for FFP and platelets because of the length of time required to thaw, prepare, and issue type-compatible products.

Traditionally, trauma transfusion protocols have called for 4 to 6 U of RBCs prior to administration of FFP. These empiric guidelines are based on washout equations and models that assume a stable circulating volume, which is almost never present in severely injured trauma patients who receive massive transfusions. Additionally, many of the initial studies and protocols were developed when whole blood or modified whole blood products were the standard of care. More recently, the medical literature on massive transfusion in trauma suggests that coagulopathy is common and, once present, is difficult to correct. Early and intensive therapy with plasma and platelets appears to be associated with better patient outcomes. A reasonable goal is to keep the international normalized ratio (INR) < 1.7 , recognizing that in the setting of massive transfusion, the INR is unlikely to be normal.

Hirshberg et al. developed a mathematical model that captures the interactions among bleeding, hemodynamics, hemodilution, and replacement as they happen during massive hemorrhage. They investigated the time interval to the subhemostatic values of coagulation studies for a range of replacement strategies. Their model demonstrates that the sentinel event for the development of coagulopathy is the prolongation of the PT (to >1.8 times normal) and it occurs early in the resuscitation. To prevent coagulopathy, the optimal replacement ratios are 2 U of FFP for every 3 U of PRBCs, or concurrent transfusion of FFP and PRBCs. In a retrospective review of

trauma patients who received a massive transfusion within the first 24 hours of admission to the intensive care unit (ICU) of a single hospital, transfusion with a traditional protocol (6 U of RBCs prior to FFP administration) before ICU admission was associated with coagulopathy and the severity of the coagulopathy was correlated with mortality. Following ICU admission and initiation of resuscitation using a 1:1 ratio of FFP to RBCs, the coagulopathy improved. The authors concluded that more aggressive early intervention to correct coagulopathy might be effective in decreasing blood requirements and improving outcomes. Similarly, Malone et al. suggested that the prevention of coagulopathy is superior to its treatment, and in trauma patients at risk for massive transfusion, a ratio of 1:1:1 (RBCs to FFP to platelets) appears to be associated with improved outcome. While provocative, these and similar studies are limited by their retrospective nature. Currently, it remains unclear whether patients survived because they received more plasma, or whether the patients who were less ill after trauma simply lived long enough for plasma to be thawed, and thus happened to receive a higher ratio of FFP to RBCs. Prospective studies in this area are badly needed.

Medical therapy

Recombinant activated factor VII

Recombinant activated factor VII (rFVIIa) was licensed for the treatment of bleeding associated with hemophilia in patients who have antibodies inactivating factor VIII and IX. It is believed to act by binding to tissue factor at the site of injury, generating thrombin, and activating platelets. Use of rFVIIa has been expanded in an attempt to minimize bleeding complications and transfusion requirements associated with major surgery and trauma. Trials investigating these indications for rFVIIa have had variable results. In a small randomized trial of rFVIIa versus placebo in patients undergoing transabdominal prostatectomy, administration of rFVIIa was associated with a 50% reduction in blood loss and elimination of transfusion of blood products, whereas 60% of patients randomly assigned to the placebo arm required transfusion. Conversely, studies in patients undergoing liver transplantation or liver resection, showed little benefit in patients who received rFVIIa versus placebo. Moreover, in two separate randomized controlled studies of patients undergoing cardiopulmonary bypass, administration of rFVIIa reduced the need for blood products, although in one of the trials, rFVIIa was associated with an increased incidence of acute renal failure. In a multicenter, randomized, controlled trial of rFVIIa in patients with blunt or penetrating trauma, administration of rFVIIa resulted in a reduction of blood transfusions in those with severe blunt trauma. In patients with penetrating trauma, there was a trend toward a reduced transfusion requirement, but the difference failed to reach clinical significance. A statistically significant difference in survival was not demonstrated. In summary, use of rFVIIa in trauma patients is controversial, and rFVIIa is not approved for this patient population.

There are trials under way investigating these issues, but until further data are available, use of rFVIIa in trauma patients should be individualized and this agent should be used with caution.

Complications

Citrate toxicity

Citrate, which binds calcium, is used as an anticoagulant in stored blood products, and FFP and platelets are the major sources of citrate. Following transfusion, citrate is rapidly metabolized by the liver and, as such, usually has little effect on plasma ionized calcium levels. However, in patients with hypothermia, massive transfusion, diminished liver perfusion, or hepatic dysfunction, and in those undergoing liver transplantation (i.e., during the anhepatic phase), citrate toxicity and the resultant decrease in ionized calcium with associated hypotension and decreased myocardial contractility may become clinically important.

In the setting of massive transfusion, ionized calcium levels should be followed at regular intervals. Ionized calcium levels are preferred because the total plasma calcium level will include the portion bound by citrate and thus may not accurately reflect the free plasma calcium. Hypocalcemia should be treated with calcium chloride rather than calcium gluconate because with the latter, liver metabolism of gluconate is required for the release of calcium.

Hyperkalemia

Over time, potassium leaks out of stored RBCs into the extracellular storage fluid because of impaired membrane integrity and diminished Na^+/K^+ adenosine triphosphatase function. With transfusion, this abnormality is rapidly reversed; consequently, hyperkalemia from massive transfusion is very uncommon. More common causes of hyperkalemia in this patient population include significant soft tissue damage from trauma or renal impairment. Regardless of the etiology, treatment includes calcium chloride administration, glucose and insulin, and bicarbonate as appropriate.

Acid–base disturbances

The pH of stored blood products is significantly acidotic owing to two factors: the acidity of the storage media and the accumulation of cell metabolites over time. Following transfusion, the metabolites (CO_2 and lactic acid) are rapidly cleared and the RBCs' buffering capacity is restored. Anecdotally, some have observed a transient metabolic alkalosis following transfusion, which some have attributed to citrate metabolism by the liver into bicarbonate. Thus, even in the setting of massive transfusion, acidosis from transfusion itself is uncommon. Persistent acidosis in the setting of transfusion should prompt a careful evaluation for more likely causes, particularly inadequate tissue perfusion and hypovolemia, rather than empiric treatment with bicarbonate.

Normovolemic hemodilution, perioperative blood salvage, and autologous blood donation

Thomas J. Graetz

Normovolemic hemodilution, preoperative autologous blood donation, and perioperative blood salvage are techniques that may limit the need for allogeneic blood transfusions. These are all forms of autologous transfusion, and some may even be acceptable to Jehovah's Witnesses because the blood is able to stay in continuity with the body. By limiting allogeneic blood transfusions, these techniques can conserve blood resources and limit the complications associated with them. Allogeneic transfusions should be used judiciously because they may cause alloimmunization, immunomodulation, bacterial and/or viral infection, transfusion reactions (e.g., febrile, hemolytic), and transfusion-related acute lung injury (TRALI). These techniques may all be used as part of an integrated approach to reduce the use of allogeneic blood. They may play an even larger role in patients who refuse allogeneic blood transfusions (Jehovah's Witnesses) or have rare blood phenotypes (Bombay), antibodies to common red cell antigens (anti-Kp^b, anti-Js^b), or multiple alloantibodies (anti-c, -Fya, -S), making crossmatch difficult.

Acute normovolemic hemodilution (intraoperative autologous donation)

Acute normovolemic hemodilution (ANH) is a technique described in the 1950s. Relative anemia is iatrogenically induced by harvesting a patient's whole blood and returning an acellular substitute (e.g., crystalloid) to maintain normovolemia. A large portion of the patient's red cell mass is harvested and stored in anticoagulant-filled blood storage bags prior to major blood loss occurring in the surgical field. When surgical bleeding occurs, the patient loses lower-hematocrit (Hct) blood, thus reducing actual red cell loss. The harvested blood is reinfused after the major blood loss has occurred, or sooner if necessary to maintain the target hemoglobin level. Appropriate patient selection for preoperative hemodilution is an important issue. Some criteria have been developed by Kreimeier (Table 69.1). These are guidelines and are not a universally accepted standard. Each patient's comorbidities and clinical picture must be addressed individually by the clinician. The benefits of normovolemic hemodilution are greatest when the starting hemoglobin is high, the target hemoglobin is low, and the blood loss is high. Kreimeier proposed using an estimated blood loss of 30% of the total blood volume; however, a more recent analysis suggests the

estimated blood loss may need to be closer to 70% of the average patient blood volume to save 1 U of red cells.

One essential component of normovolemic hemodilution is calculation of the amount of blood to be removed. A commonly used integrative equation was described by Bourke et al. as $\text{blood loss} = \text{estimated blood volume (EBV)} \times \text{natural log of the ratio of initial to final Hct}$. This logarithmic equation may be approximated by $\text{blood loss} = \text{EBV} \times (\text{change in Hct}) \times (3 - \text{average Hct})$. A more recent iterative model has been described by Meier and accounts for some factors potentially leading to an overestimation of blood loss by 15% to 20% (homogeneous distribution of red cells in large and small vessels, continuous and simultaneous substitution of the blood, and constancy of blood volume during dilution process). Crystalloid, colloid, or both are used to replace the intravascular volume. The blood volume is frequently replaced 3:1 with crystalloid or 1:1 with colloid. The replacement ratio at steady state using crystalloid may actually be closer to 5:1. The blood is harvested from an arterial catheter or large-bore venous cannula draining to gravity. The harvesting may start before the induction of anesthesia or after, but harvest should be complete prior to major blood loss. Blood is collected in standard blood collection bags, which can be kept at room temperature for up to 8 hours or refrigerated at 1° to 6°C for up to 24 hours. Blood is reinfused in the reverse order of its harvest. The blood may contain drugs circulating from when it was harvested (e.g., opioids and muscle relaxants).

ANH decreases the blood's oxygen-carrying capacity as hemoglobin is removed. The body maintains adequate oxygen delivery to the tissues by compensatory mechanisms, including an increase in cardiac output and oxygen extraction, as shown in Fig. 69.1. The decrease in blood viscosity allows venous

Table 69.1. Selection criteria for acute normovolemic hemodilution

Estimated blood loss is 1500 ml (30% of blood volume)
Preoperative hemoglobin concentration above 12 mg/dl after correction of normovolemia
Normal electrocardiogram and myocardial function
Absence of restrictive or obstructive lung disease
Absence of renal disease
Absence of liver cirrhosis
Absence of untreated hypertension
Absence of coagulation abnormalities
Absence of infection

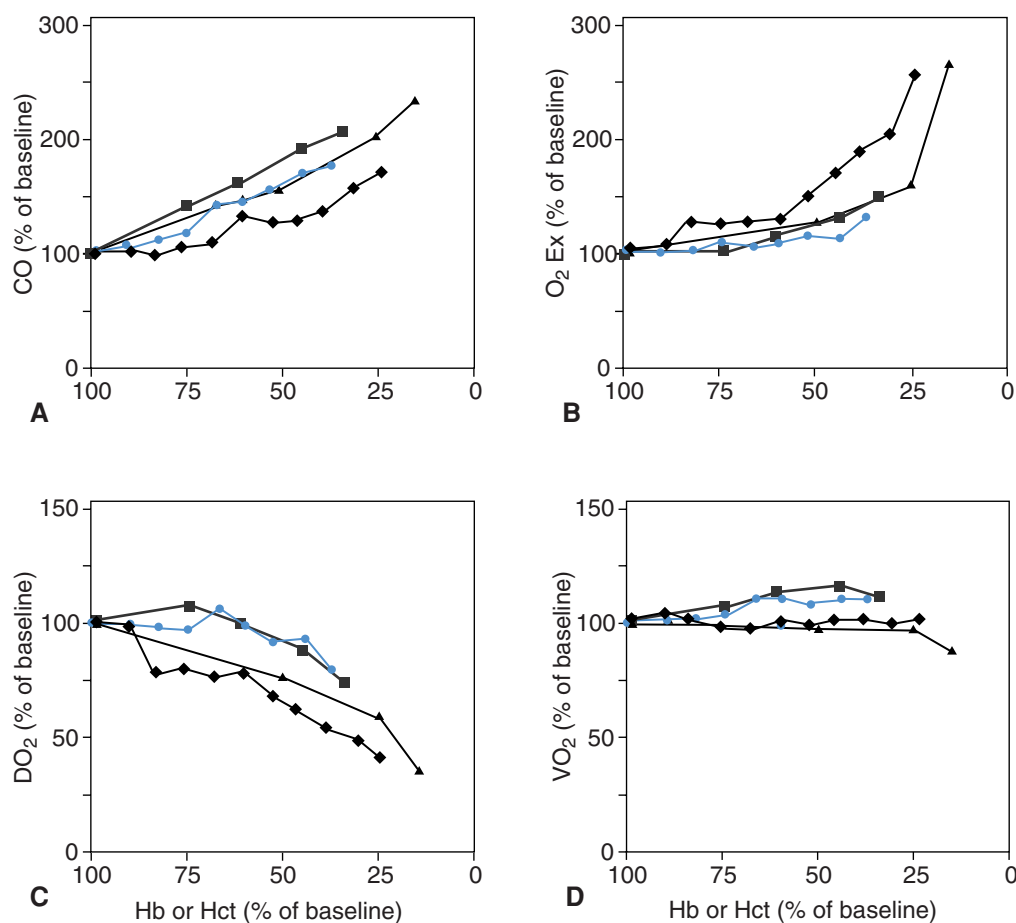

Figure 69.1. Relative changes in (A) cardiac output (CO, % of baseline), (B) O₂ extraction (O₂-Ex, % of baseline), (C) O₂ delivery (DO₂, % of baseline), and (D) O₂ consumption (VO₂, % of baseline) during progressive ANH in pigs (■), dogs (■), baboons (▲), and humans (●). Note that the combined increases of CO and O₂ extraction allow maintenance of VO₂, even at very low hemoglobin levels. Reprinted with permission from Jamnicki M, Kocian R, van der Linden P, Zaugg M, Spahn D. Acute normovolemic hemodilution: physiology, limitations, and clinical use. *J Cardiothor Vasc Anesth* 2003; 17(6):747–754.

return to increase, increasing cardiac output as well as central venous pressure. The increased cardiac output occurs through an increase in stroke volume and myocardial contractility with little change in heart rate. The increase in oxygen extraction coupled with the increase in cardiac output allows the oxygen delivery to decrease, whereas the tissue oxygen consumption does not change until a critical hemoglobin level is reached. The critical level of hemoglobin in humans is not known.

ANH is a “point-of-care” technique that eliminates blood wastage, because all collected blood is given back to the patient; it is convenient for patients and has decreased administrative costs associated with testing and collecting of allogeneic blood. Problems with the technique include the additional time and mental energy directed from other aspects of patient care. Additional assays are ordered to monitor the current hemoglobin concentration during dilution and during the operation to guide management. The literature regarding the clinical benefits of the technique is mixed with poor reporting of complications from trials. A recent meta-analysis of all trials was inconclusive; it showed a reduced likelihood of allogeneic transfusion, but there was a substantial amount of heterogeneity among trials,

many of which did not have a well-defined transfusion protocol. The ones with a protocol did not show a benefit with ANH. A recent trial with well-defined triggers showed sparing of allogeneic transfusion in patients undergoing liver resection randomly assigned to undergo hemodilution. ANH is a technique that is not part of routine practice but is supported by transfusion guidelines for specific procedures. Some, although not all, Jehovah’s Witness patients will accept ANH, as long as the harvested blood bags are continuously connected with the patient.

Intraoperative blood salvage (cell saver) and postoperative blood salvage

Perioperative blood salvage includes both intra- and postoperative blood salvage as techniques used to recover and transfuse blood lost during an operation. Intraoperative blood salvage (IOBS) had its origins in the 1960s with the first attempts to salvage and re-infuse shed blood by Klebanoff using the Bentley device. In the 1970s the first acceptable surgical blood salvage system was introduced as Cell Saver (Haemonetics, Braintree, MA). The term *cell saver* is now frequently used to describe the

strategy of IOBS. During IOBS, an aspiration wand draws blood from the operative field to a reservoir for the aspirated blood. The wand contains dual-chamber tubing that mixes anticoagulant with the aspirated blood. Blood is then taken from the reservoir and added to the centrifuge bowl, where it is spun and washed with normal saline. At least three times the bowl volume is used before the cell washing is considered finished; larger wash volumes lead to removal of more contaminants. The liquid wash is discarded. The washed packed cells are transferred to a bag for transfusion back to the patient. The blood should be filtered through a standard 170- μ m filter prior to transfusion. The bowl fill rate and size determine the hematocrit and volume of the washed blood, but a bowl of 250 ml is commonly employed and requires 500 to 750 ml of salvaged blood to properly wash the cells. It delivers cells at a hematocrit of approximately 50% to 70%. Postoperative blood salvage is a technique whereby the contents of wound drains are either infused directly or washed prior to transfusion. The use of unwashed wound blood is falling out of favor for many because of the cell mediators, debris, and other substances that may be present and the ability to wash shed drain blood prior to transfusion. Others continue to practice the transfusion of unwashed wound blood. Those who advocate unwashed wound blood frequently limit the volumes to 500 to 1000 ml because of concerns regarding the non-red cell constituents of the wound blood.

IOBS is applied to a variety of operative domains, including trauma, vascular, cardiac, orthopedic, transplantation, urologic, and gynecologic surgery. Cell saver also has been used in surgical oncology, obstetrics, and bowel operations, but these are areas of some controversy and disagreement. If IOBS is used in these settings, two suction wands are used, one for contaminants and the other for salvaged blood. Previously, contraindications had included obstetric procedures because of the risk of amniotic fluid contamination potentially leading to amniotic fluid embolus. A small but growing body of literature describes the use of IOBS after removal of the placenta, although none of the reports has been large enough to document complete safety from this uncommon albeit potentially fatal event. Similarly, oncologic and bowel procedures (potentially including trauma) have been considered contraindications, although clinical data show its use in these circumstances. Although these data exist, it would not be considered standard practice to use IOBS for oncologic procedures or open bowel.

Autologous blood donation

Autologous donation of blood (preoperative blood donation) is a technique originally described in 1921, but the practice did not spread until subsequent publications in the 1970s. The technique is available to patients undergoing elective procedures that have a high likelihood of transfusion (e.g., redo total joints, multilevel spine cases, or major vascular procedures). Parturients who are at increased risk of peripartum hemorrhage (as in placenta previa) or who have multiple antibodies or rare blood types may also be candidates for this technique. Preoperative

Table 69.2. Contraindications to autologous blood donation

Active bacterial infection or evidence of infection
Significant aortic stenosis
Unstable angina
High-grade left main coronary artery disease
Myocardial infarction or stroke within 6 mo prior to donation
Cyanotic heart disease
Uncontrolled hypertension
Prolonged fainting episode during prior blood donation or history of epilepsy
Impaired placental blood flow (e.g., preeclampsia, diabetes, intrauterine growth retardation)
Other significant disease that has not yet been optimized preoperatively

blood should not be collected if the likelihood of transfusion is low because of the small but real risks of blood donation and the increased risk of blood transfusion if autologous blood is collected, thereby predisposing to perioperative anemia. An additional problem is the wastage of a collected but untransfused unit, thus increasing the overall expense of autologous blood.

Autologous donation requires an order from a physician. This is a decision the anesthesiologist and surgeon make based on a variety of factors that affect the eligibility of the patient for preoperative blood donation. Factors that have an impact on this decision include the likelihood of transfusion for a particular procedure, the surgeon's operative experience, the patient's medical comorbidities, and the patient's motivation to donate preoperatively. Additionally, the patient should meet certain criteria at the time of donation: Hemoglobin must be ≥ 11 g/dl, all donations are to occur more than 72 hours prior to the anticipated surgery, and a donation may not be made if the patient is at risk for bacteremia. Some contraindications to autologous donation are shown in Table 69.2, but others may disagree with some of these, having shown safe donation can occur in patients undergoing various cardiac procedures. Additional consideration should be given to patients with congestive heart failure and cerebrovascular disease. The ultimate decisions rest with the responsible clinicians and patient, weighing the risks, benefits, and alternatives for each patient with special emphasis on whether the risks of allogeneic blood transfusion outweigh the risks of donation.

Oral iron supplementation should be started prior to initial unit donation and continue afterward to mitigate iron-limited erythropoiesis; care should also be taken to limit the side effects of oral iron supplementation. Erythropoietin may be used in autologous donation programs to increase red cell production during autologous donation, although this currently is an off-label use in the United States. The effectiveness of this technique varies based on the dose used in the treatment regimen, the route of administration (intravenous vs. subcutaneous), and the degree and underlying cause of the anemia. Autologous units are generally donated at 1-week intervals, and the last unit is generally donated at least 1 week prior to the scheduled procedure. The total number of collected units is at the discretion

of the ordering physician and the director of the transfusion service. An essential part of this technique is the ability of the patient to produce enough new red blood cells to replace the harvested cells, thereby reaching the goal number of units. The factors limiting harvest of additional units are frequently an inadequate hemoglobin level and the limited time frame available to collect blood units because of expiration dates of previously collected units. One possible approach, infrequently used, is freezing previously donated units of blood. This can prolong blood's shelf life, but also leads to some cell lysis during the freeze/thaw process; it also is time-consuming and expensive. The blood units are collected in standard collection bags and preservative solutions. If a unit is collected and stored as whole blood, it can be refrigerated for 35 days. The blood can be separated into its constituent components (with red cell shelf life possibly being extended to 42 days using AS-1 or another additive solution) but is frequently kept as whole blood. Autologous blood is not allowed to enter the general pool of allogeneic blood under most circumstances.

As outlined in [Table 69.3](#), transfusion of autologous blood is not without risk. One risk is the potential for volume overloading the patient, a risk that is smaller if whole blood is used rather than packed cells. The same criteria or “trigger” (a topic outside the scope of this chapter) should be used for both allogeneic and autologous blood when deciding whether to transfuse blood, because the greatest risk to the patient is administrative in nature. If a patient who has autologous blood available is going to be transfused, great care should be taken to transfuse the autologous unit prior to the allogeneic blood. The oldest unit of blood should generally be transfused first to prolong the fixed shelf life of each collected autologous unit.

Perioperative collection of blood components including platelets is an area some have found beneficial, but it is not a routine practice and is currently not recommended for blood conservation for cardiac procedures involving cardiac bypass. Blood component collection can be performed with a standard cell salvage machine by altering the specifics of the centrifugation to optimize the collection of the components being

collected. Blood is aspirated into the centrifuge bowl through a large venous access site (e.g., an introducer side port) and then separated into its components in the centrifuge bowl. The various components can then be given back to the patient as indicated during the procedure. All components are returned at the end of the procedure.

Normovolemic hemodilution, preoperative autologous blood donation, and perioperative blood salvage can all reduce the use of allogeneic blood. Nevertheless, how to best use these techniques remains controversial and merits further investigation.

Table 69.3. Autologous blood donation

Advantages	Disadvantages
Prevents transfusion-transmitted disease	Does not eliminate risk of bacterial contamination
Prevents red cell alloimmunization	Does not eliminate risk of ABO incompatibility error
Supplements the blood supply	Is more costly than allogeneic blood
Provides compatible blood for patients with alloantibodies	Results in wastage of blood that is not transfused
Prevents some adverse transfusion reactions	Subjects patients to perioperative anemia and increased likelihood of transfusion
Provides reassurance to patients concerned about blood risks

Cardiac Anesthesia

Stanton K. Shernan, editor

Cardiac physiology

Nelson L. Thaemert and Rena Beckerly

Introduction

A thorough understanding of cardiovascular physiology is essential for the practice of anesthesia. Heart rate (HR), blood pressure, cardiac rhythm, systemic tone, electrolytic balance, and myocardial oxygen consumption are all examples of variables to be considered part of an anesthetic, and understanding their role in cardiac physiology is important to the cerebral, scientific aspects of anesthesia and to its safe and practical delivery to patients.

The heart and circulatory blood vessels comprise the cardiovascular system, and function to provide oxygen and nutrients to the body and remove carbon dioxide and byproducts of metabolism. The heart can be considered two pumps that exist in series, separated by both the pulmonary and systemic circulatory vascular beds. As blood is perfused through the pulmonary circulation, oxygen is taken up and carbon dioxide is eliminated across the alveolar–capillary membrane. In the systemic circulation, oxygen and nutrients are delivered to perfused tissues, and carbon dioxide and metabolic wastes are removed.

Anatomy of the heart

Chambers

Anatomically, the heart is composed of four chambers, two atria and two ventricles; functionally, it is divided into two separate circulatory pumps. One pump delivers deoxygenated blood from the venous system to the pulmonary circulation, and the other delivers oxygenated blood from the lungs to the systemic circulation. Each pump consists of an atrium, which serves as a filling chamber and priming pump, and a ventricle, which serves as a pulsatile pumping chamber. Four valves exist to ensure forward flow of blood as the heart contracts. Myocardial contraction and pulsatile ejection of blood occur through a series of complex electrical and mechanical events. Understanding these concepts is essential to developing an appreciation of cardiac physiology.

Coronary blood supply

Blood is supplied to myocardium through the coronary arteries. The right and left coronary arteries arise from the aortic root and run on the surface of the heart, giving branches that

supply the myocardium. Blood flows from the epicardium to the endocardial vessels to meet the metabolic demands of the heart. Thereafter, blood drains into the coronary sinus and the small anterior cardiac veins, where it empties into the right atrium. In addition, a small amount of blood drains directly into the right ventricle via the thebesian veins. Approximately 85% of coronary venous blood is returned to the right atrium through the coronary sinus.

The coronary anatomy of the heart is depicted in [Fig. 70.1](#). The right coronary artery (RCA) exits from the aortic root and travels in the atrioventricular (AV) groove between the right atrium and ventricle. It supplies blood to the right atrium and right ventricle, and in 70% of people becomes the posterior descending artery (PDA). This anatomic configuration is known as a “right dominant” circulation. In 10% of people, the PDA arises as a branch of the left circumflex artery and is referred to as “left dominant.” Finally, in about 20% of people, the PDA is supplied by both the RCA and circumflex artery and is classified as “codominant.” The PDA travels in the posterior interventricular groove on the back wall of the heart between the right and left ventricles, and supplies blood to the inferior wall of the left ventricle.

The left main coronary artery exits from the aortic root and shortly divides into the left anterior descending (LAD) artery and the circumflex artery. The LAD artery travels in the anterior interventricular groove between the right and left ventricles, giving rise to the diagonal branches (D1 and D2). It supplies blood to the anterior wall of the left ventricle and the interventricular septum. The circumflex artery wraps around the left side of the heart in the AV groove between the left atrium and ventricle, giving rise to the obtuse marginal arteries (OM1 and OM2). It supplies blood to the lateral wall of the left ventricle. In some patients, a third branch called the ramus originates between the LAD and circumflex arteries. Blood supply to a large portion of the left ventricle is dependent on blood supply from the left main coronary artery. In hearts with left dominant circulation, in which the PDA circulation arises from the circumflex, all the left ventricular (LV) blood supply is dependent on a patent left main coronary artery. [Fig. 70.2](#) depicts the typical blood supply to the different walls of the left ventricle.

Blood supply to the conduction system is variable. The sinoatrial (SA) node is perfused by the RCA in 60% of people,

Figure 70.1. Coronary anatomy of the heart.

and the LAD in the remaining 40%. The arterial supply to the AV node is generally determined by the dominance of the circulation. The AV nodal artery arises from the RCA in right dominant hearts, from the left circulation in left dominant hearts, and from the RCA in 75% of codominant hearts. The bundle of His has a dual blood supply from the PDA and LAD.

Blood supply to the papillary muscles tends to correlate with their anatomic location within the ventricles. The anterolateral papillary muscle, which attaches to both the anterior and lateral walls of the left ventricle, has a dual blood supply from both the LAD and circumflex arteries. The posteromedial papillary muscle is attached to the inferior wall of the left ventricle and receives its blood supply exclusively from the PDA. This solitary blood supply makes the posteromedial papillary muscle more susceptible to ischemic dysfunction and postinfarct rupture.

Figure 70.2. Transesophageal echocardiographic view of ventricular walls and coronary blood supply in a right dominant heart.

Cellular anatomy and electrical physiology

The heart consists of a specialized striated muscle that exists around a skeleton of connective tissue. Cardiac muscle can be divided into several different types of tissue, including atrial, ventricular, and specialized pacemaker cells. Pacemaker cells exist in various parts of the conduction system, including the SA node, AV node, bundle of His, and Purkinje network, and contain self-excitatory properties that can independently stimulate electrical activity. Low-resistance connections between individual myocardial cells allow the efficient propagation of electrical activity to adjacent cells within the atria or ventricles. Normally, no direct electrical communication exists between the atrial cells and the ventricles. Instead, specialized conductive pathways allow for the rapid and organized propagation of electrical activity from the atria to the ventricles, leading to an efficient filling of the ventricles, followed by a synchronized, pulsatile ejection of blood to the circulation.

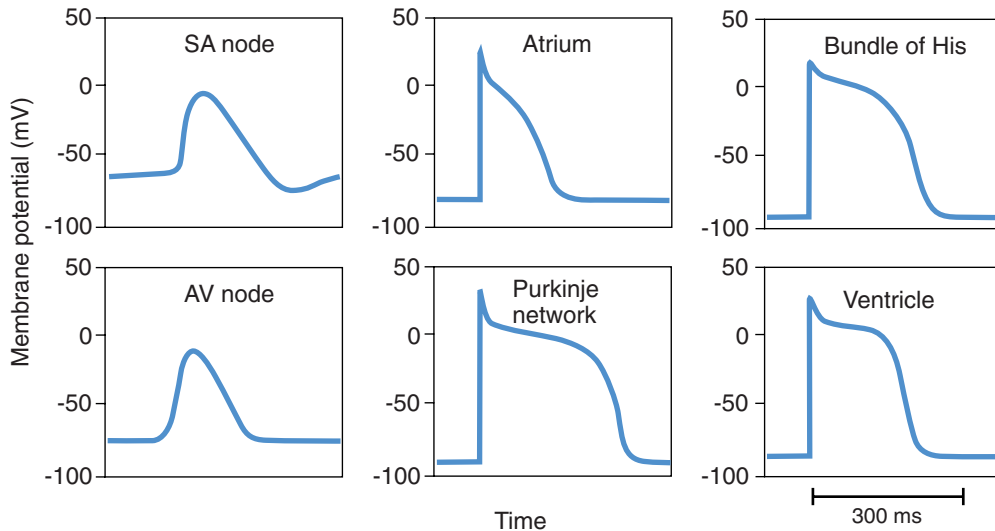

Figure 70.3. Cardiac action potential in various fibers of the heart.

Action potentials

Like other conductive cells, myocardial cell membranes are relatively impermeable to ions and maintain a membrane resting potential through the activity of Na^+/K^+ -adenosine triphosphatase (ATPase). This ionic exchange serves to keep a normal voltage gradient of -80 to -90 mV. When the cell membrane becomes less negative and reaches a threshold value, a characteristic action potential is generated, which raises the membrane potential of the myocardial cell to $+20$ mV. This depolarizing change in voltage is a result of the opening of both fast-acting sodium channels and slower-acting calcium channels, and results in a rapid spike in action potential followed by a prolonged plateau phase of 0.2 to 0.3 seconds. Electrical balance is then restored through the action of potassium channels, which are responsible for repolarizing the myocardial cell. Following depolarization, the cells are refractory to subsequent depolarizing stimuli for a period of time.

Action potentials may be triggered by electrical impulses or occur spontaneously. Because of differences in the composition of atrial, ventricular, pacemaker, and conductive myocardial cells, the characteristics of action potentials vary with different excitatory tissues throughout the heart (Fig. 70.3). Note the prolonged plateau phases in the ventricle, bundle of His, and Purkinje network, in contrast to the rapid repolarization in the SA and AV nodes. In addition, note the unstable resting membrane potential and spontaneous depolarization in the cells of the SA node.

Cardiac impulse initiation and electrical propagation

Each cardiac cycle is initiated by generation of an action potential in the SA node, located at the posterior junction of the right atrium and the superior vena cava. Pacemaker cells of the SA node differ from other typical myocardial cells because of

their relatively leaky cell membrane, permitting a slow influx of sodium and regular spontaneous depolarization, which occurs at a rate of 70 to 80 per minute, thus setting the resting HR.

The electrical impulse generated at the SA node is propagated locally through atrial myocardial cells, culminates in simultaneous atrial contraction, and is ultimately transmitted to the AV node. The AV node, located on the septal wall of the right atrium between the ostium of the coronary sinus and the septal leaflet of the tricuspid valve, serves as a gatekeeper for the fast conduction system to the ventricles. It has an intrinsic spontaneous depolarization rate of 40 to 60 per minute, allowing the faster SA node to set the HR under normal circumstances. Impulses reaching the AV node are delayed by 100 ms, allowing ventricular filling, and are then conducted to the bundle of His. This specialized group of fibers passes into the interventricular septum and divides into the right and left branches to form the Purkinje network that serves to rapidly depolarize both ventricles. The His–Purkinje fibers have the most rapid conduction velocities of any cells in the heart, allowing nearly simultaneous depolarization of the myocardium of both ventricles. The total amount of time for a depolarization to travel from the SA node to the entire ventricle is approximately 200 ms.

Electrocardiogram correlation

The appearance of electrical activity on an electrocardiogram correlates well with the electrical signal propagation described earlier. Once an electrical impulse leaves the SA node to travel across the atria, it becomes visible as a P wave. The time to conduct across the atria is reflected in the duration of the P wave, and the normal delay within the AV node can be appreciated in the length of the P-R interval. The rapid depolarization of the ventricles is evident in the QRS complex. Any conduction delays within either the right or left Purkinje bundles can be appreciated with proper analysis. Ventricular repolarization is represented by the T wave. The relationship

Figure 70.4. Ventricular action potential in relation to other cardiac parameters.

between the ventricular action potential, ventricular ejection, and the electrocardiogram is depicted in Fig. 70.4. Junctional rhythms, atrial and ventricular arrhythmias, varying degrees of AV block, detection of bundle branch blocks, and significance of ventricular escape beats are discussed elsewhere, but can all be appreciated when considering the conduction system and electrocardiograms.

Mechanism of contraction

Myocardial cells contract as a result of the interaction of actin and myosin, two overlapping contractile proteins. Actin is attached to the cell membrane, or sarcolemma, via dystrophin and when allowed to interact with myosin, produces cell shortening. Normally, this interaction is prevented by two regulatory proteins, troponin and tropomyosin, which serve to cover the active binding site on actin. During depolarization, an influx of calcium from the sarcoplasmic reticulum within the cell interacts with troponin, producing a conformational change in these regulatory molecules and exposing the actin-active site to myosin. Through interactions that require ATP, a series of attachments and reengagements between actin and myosin occur, shortening the protein structure within the cell. Returning calcium to the sarcoplasmic reticulum during repolarization allows the troponin–tropomyosin complex to revert to its original confirmation, covering the actin-active site and preventing further interaction between the actin and myosin proteins.

The intracellular calcium change that occurs during the plateau phase of depolarization is insufficient to produce cellular contraction by itself. Instead, the action potential depolarizes the T tubules via dihydropyridine Ca^{2+} channels, which produce an even greater inflow of calcium from the sarcoplasmic reticulum into the cell. Upon the initiation of repolariza-

tion, calcium is pumped back into the sarcoplasmic reticulum and is also extruded extracellularly.

The force of the contraction is directly dependent on the magnitude of the calcium influx from the sarcoplasmic reticulum. The amount of calcium delivered, its rate of delivery, and its rate of removal all directly determine the amount of muscular tension developed, the rate of contraction, and the rate of relaxation. The intracellular second-messenger cyclic adenosine monophosphate (cAMP) directly affects the number of open calcium channels from the sarcoplasmic reticulum. β_1 -Adrenergic stimulation results in increased cAMP via stimulatory G proteins, leading to larger intracellular calcium concentrations and more vigorous muscle contractions. Likewise, inhibited breakdown of cAMP from phosphodiesterase inhibitors such as milrinone and theophylline augment the action of calcium. Conversely, acetylcholine produces increased concentrations of cyclic guanosine monophosphate via inhibitory G proteins, leading to inhibition of the generation of cAMP. Other agents affecting strength of contraction include digoxin, which leads to larger Ca^{2+} influx after altering Na^+/K^+ -ATPase; glucagon, which increases cAMP via a nonadrenergic receptor; volatile anesthetics, which depress contractility by decreasing entry of Ca^{2+} into cells during depolarization and altering kinetics of its release from sarcoplasmic reticulum; and acidosis, which affects the slow calcium channels of the plateau phase, unfavorably altering intracellular calcium action.

Innervation

Although the nervous system does not directly initiate myocardial beats, it does regulate rhythm and contractility. Central control of the heart originates in the medulla and consists of the cardio-acceleratory and cardio-inhibitory centers. The cardio-acceleratory center sends signals via the sympathetic nerve fibers via T1–4 to the SA and AV nodes, in addition to widely innervating the myocardium. The sympathetic activation from norepinephrine leads to increased chronotropy (faster rate), dromotropy (faster AV conduction), and inotropy (stronger contraction) through increased β_1 -adrenergic stimulation and elevations in intracellular cAMP. Additional adrenergic stimulation from circulating epinephrine produces similar effects on the myocardium. Both have additional systemic effects on the vasculature.

The cardio-inhibitory center signals the heart via the vagus nerve to the SA and AV nodes, conduction system, and selected areas of the atrium. Acetylcholine works through muscarinic receptors to produce negative chronotropic, dromotropic, and inotropic effects. Muscarinic effects of acetylcholine include increased conductance for potassium, suppressing the pacemaker current and hyperpolarizing the SA node in phase 4, increasing the time until threshold voltage is reached to initiate a new action potential. Vagal effects tend to have a fast onset and offset, whereas sympathetic influences are more gradual and take longer to reverse.

Cardiac cycle

The rhythmic nature of the heart can be characterized by two energy-requiring phases: systole, during which ventricular contraction occurs, and diastole, when ventricular relaxation occurs. Understanding the relationship of these phases to filling, ejecting, and heart valve mechanics is paramount to understanding cardiac physiology.

The entire systolic and diastolic cardiac cycle can be divided into four distinct phases: isovolumetric contraction, systolic ejection, isovolumetric relaxation, and diastolic filling. At the end of diastole, the ventricle has finished filling and the pressure in the left ventricle and left atrium have equilibrated. At the onset of systole, the ventricle depolarizes, generating a QRS complex; myocardial contraction begins; and the pressure in the left ventricle exceeds the atrial pressure, closing the mitral valve. Isovolumetric contraction continues until the pressure in the ventricle exceeds the diastolic aortic blood pressure, driving open the aortic valve. During systolic ejection of blood, the stroke volume (SV) is pumped from the left ventricle, and the peak pressure generated at this time is the systolic blood pressure. As the ventricle concludes contracting, the pressure in the aorta exceeds the pressure in the left ventricle, closing the aortic valve. The small vascular rebound that occurs here is visible as the dicrotic notch, marking the end of systole and the onset of diastole.

Isovolumetric relaxation is marked by a period of myocyte repolarization and T-wave formation. The ventricle undergoes isovolumetric relaxation until its pressure is less than the left atrial pressure, at which time the mitral valve opens and blood passively starts filling the ventricle. Diastolic filling continues in a passive manner, rapidly at first, then more slowly as the pressures equilibrate, until an atrial contraction is generated, thus actively filling the ventricle. Atrial contraction contributes up to 30% of the filled volume of the ventricle. These events are logically followed in Fig. 70.5.

The cardiac cycle can be represented in different ways – for example, as pressure and volume versus time, as shown in Fig. 70.5, or as pressure versus volume, as indicated in Fig. 70.6.

Several physiologic variables can be appreciated by studying Fig. 70.6. The volume of the left ventricle at the end of diastole is the *end-diastolic volume* (EDV), which has a corresponding *end-diastolic pressure* (EDP). The difference between the end-diastolic volume and the end-systolic volume (ESV) is the SV:

$$SV = EDV - ESV$$

Likewise, the ejection fraction (EF) is the percentage of the EDV ejected with each systolic beat:

$$EF = (EDV - ESV)/EDV = SV/EDV$$

Other variables, including aortic systolic and diastolic pressures, can also be appreciated on a pressure-versus-volume loop.

Figure 70.5. Normal cardiac cycle depicted as pressure versus time and volume versus time.

Atrial filling and emptying

Atrial filling occurs in two phases, systole and diastole; atrial emptying also occurs in two phases, passive and active. During systolic ventricular contraction, the atria fill from the venous system. Systole concludes, diastole begins, and once isovolumetric relaxation has allowed the ventricular pressure to decrease sufficiently, the mitral and tricuspid valves open and blood flows passively into the ventricles. However, even as the atria empty into the ventricles, they continue to fill to replace some of the volume passively lost. With the initiation of atrial contraction, the atria empty into the ventricle and no further atrial filling occurs from the veins. Upon initiation of systole, the mitral and tricuspid valves close, ventricular systolic ejection occurs, and atrial filling resumes.

Figure 70.6. Normal cardiac cycle depicted as pressure versus volume.

These elements can be seen on central venous pressure (CVP) tracing (Fig. 70.7). The “a” wave represents atrial contraction with active ventricular filling. Diastole ends and systole begins at the “c” wave, marked by tricuspid valve closure. As the ventricle contracts, the tricuspid annulus is slightly pulled into the ventricle, decreasing the pressure in the atrium, marked by the “x” descent. As the ventricle continues to contract, atrial filling is reflected in the “v” wave. Finally, as the tricuspid valve opens, passive emptying of the atrium into the ventricle occurs, as shown by the “y” descent. This is immediately followed by another a wave as the cycle repeats.

When studied by Doppler echocardiography, this cycle is seen in a slightly different form (Fig. 70.8). Here, the Doppler beam is measuring flow in the pulmonary vein either toward or away from the left atrium. During systole, the prominent up-spike and the much smaller phase represent two phases of systole, S1 and S2, when the atrium is filling from the pulmonary veins toward the Doppler probe near the left atrium. The second prominent hump, the D wave, indicates further forward filling of the atrium during early diastole, when the ventricle is passively being filled through the mitral valve. The down-spike is the A wave, representing a brief reversal in pulmonary venous blood during atrial contraction, when the ventricle is undergoing active filling from a contracted atrium.

Figure 70.7. Central venous pressure waveform.

Figure 70.8. Doppler echocardiography of the pulmonary veins.

Several pathologic conditions can be detected on assessment of a CVP waveform. Large a waves occur during diastole when a pressure gradient exists during atrial contraction. This can be seen when the atrium is contracting against a closed tricuspid valve, such as during premature ventricular systole, or when tricuspid valvular stenosis is present. Prominent v waves may occur during systole when part of the ventricular ejection pressure is communicated through the tricuspid valve, such as during tricuspid regurgitation. Other pathognomonic conditions exist as well, such as a “steep x and y descent,” in which the atrial pressure is very elevated and the ventricle is dangerously underfilled, such as in pericardial tamponade.

Ventricular performance

The cardiac cycle represents a unique coordination of both electrical and mechanical events, culminating in ventricular systole (contraction) and diastole (relaxation). The synchronized function of both ventricles is crucial, and factors affecting one side will invariably affect the other.

Systolic function involves ventricular ejection and primarily focuses on the left ventricle. It is often measured by the cardiac output (CO), which is the SV multiplied by HR:

$$CO = SV \times HR.$$

Average SV and HR are approximately 70 ml and 75 bpm, with a cardiac output of 4 to 6 L/min. Thus, the body’s entire blood volume circulates through the heart every minute. Because changes in body size require different cardiac outputs to meet basal requirements, the cardiac index is used to account for these differences. The cardiac index is expressed as the cardiac output divided by the body surface area, with a normal range of 2.5 to 4 L/min/m².

In addition to cardiac output, other measures of adequacy of function include assessing for appropriate change in cardiac output with exercise and measurement of mixed venous oxygen saturation. A large amount of variability exists in baseline

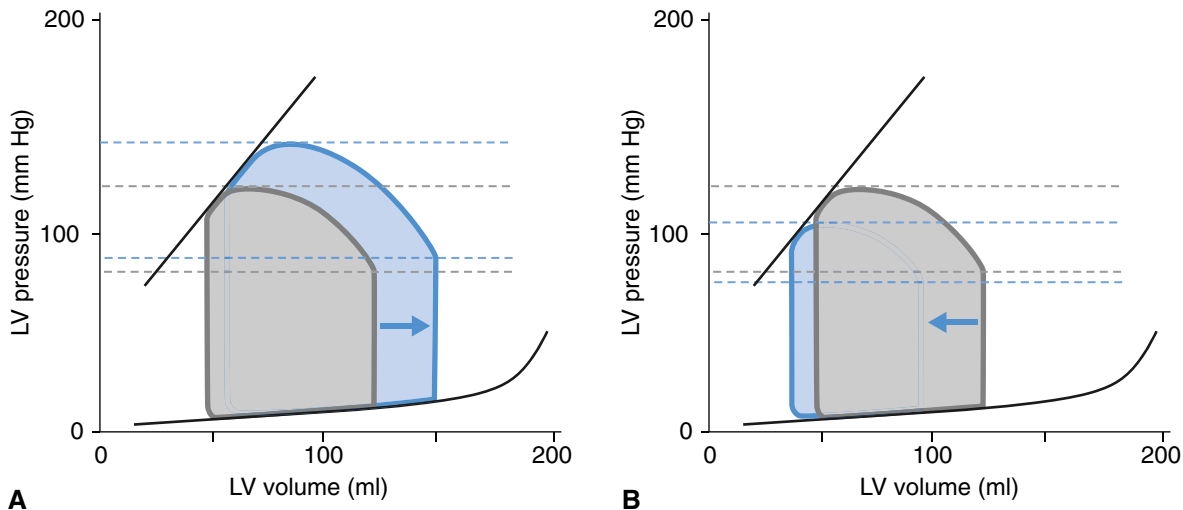

Figure 70.9. Increasing and decreasing preload.

cardiac output, and an abnormal cardiac output is not seen until gross abnormalities exist. However, failure to keep up with higher metabolic demands with exercise can be seen by a lack of an increase in cardiac output when stressed. Similarly, a falling mixed venous oxygen saturation, in which greater proportions of oxygen are extracted from the systemic blood to make up for a lack in rise of cardiac output, is indicative of inadequate ventricular performance.

Heart rate

HR is a major determinant of ventricular function and is affected by autonomic, humoral, and local factors. The intrinsic rate of the SA node is normally set at 70 to 80 bpm. It is influenced by sympathetic and parasympathetic tone, circulating inflammatory mediators, drugs, hormones, and conduction abnormalities. At normal HRs, systolic time occupies approximately one third of the entire cardiac cycle, with diastolic time occupying the remaining two thirds. However, as HR increases, this ratio changes and a lower percentage of time is spent in diastole.

Stroke volume

There are three main determinants of SV: preload, afterload, and contractility. All three variables are subject to a variety of influences, including circulating volume, ventricular compliance, systemic circulatory tone, and autonomic influences, in addition to geometric alterations in the chambers and the presence of valvular dysfunction.

Preload

Preload represents the EDV of the left ventricle and depends on ventricular filling. Starling's law describes the direct proportional relationship between cardiac output and the final volume in the ventricle prior to contraction, LV EDV. As LV EDV increases and the HR is held constant, SV increases until the

muscle fibers become maximally distended. Any further stretch compromises the heart's ability to eject that volume, and no further increase in SV is achieved. In fact, overdistention may lead to a decrease in cardiac output. Clinically, in addition to diminishing cardiac myocyte stretch, this can produce cardiac valvular incompetence.

Preload for both the left and right ventricles depends on ventricular filling, which is most heavily influenced by venous return. Circulating volume, changes in blood volume (position, intrathoracic pressure, pericardial pressure, venous tone), cardiac rhythm, and HR all influence venous return. Although the presence of other pathologic factors, such as severe mitral stenosis or aortic regurgitation, may also play a role in ventricular filling, venous tone and circulating intravascular volume have the greatest role in normal circumstances. For example, increases in venous tone from ephedrine administration or decreases in venous tone from a regional anesthetic can alter LV EDV. Likewise, hypovolemia or fluid resuscitation can also alter LV EDV.

The pressure–volume relationship of the ventricle during diastole is a nonlinear curve that depends on ventricular compliance and is not affected simply by altering the preload. Instead, this diastolic relationship holds true over a variety of filling conditions and describes the corresponding filling pressure required at any given filling volume (Fig. 70.9). Until the point at which maximum stretch is reached, a larger LV EDV produces an increased SV and increased cardiac output at a higher systemic blood pressure.

Ventricular preload is also sensitive to changes in rhythm and HR. As HR increases, diastolic time is reduced and ventricular filling is slightly impaired. Likewise, deviation from a normal sinus rhythm can adversely affect ventricular filling. Perturbation in sinus activity becomes especially crucial in patients with impaired ventricular compliance, which is discussed later.

Clinical assessment of preload may present several challenges. The most important determinant of right ventricular

Figure 70.10. Compliance changes altering the EDP–EDV relationship.

filling is venous return, and in the absence of significant pulmonary hypertension, right heart dysfunction, or mitral valvular disease, venous return is also the most important determinant of LV filling. Trends in central venous filling pressure can be used to approximate LV filling volume. Pulmonary capillary wedge pressure (PCWP) can be used to estimate LV EDP, which with normal ventricular compliance, serves as a good surrogate measurement of LV EDV. However, this requires several assumptions, including insignificant intrathoracic positive end-expiratory pressure and absence of mitral stenosis. Other methods to try to assess the adequacy of ventricular filling include echocardiography, radionuclide imaging, and ventriculography.

Diastolic compliance determines what sort of ventricular filling pressure is generated at any given filling volume. The nonlinear curve describing the diastolic pressure–volume relationship is influenced by factors such as presence of ventricular hypertrophy, ischemia, or pericardial compression (Fig. 70.10).

“Diastolic dysfunction,” a concept poorly understood by many, can be explained by examining an EDP–EDV relationship curve. The presence of factors impairing the heart’s ability to relax and fill during diastole will shift this curve up and left from normal. The clinical implication is that significantly higher filling pressures may be required to achieve an adequate LV EDV. This may leave patients closer to being in pulmonary edema at what appears to be normal heart sizes. Conversely, in the event the heart deviates from a sinus rhythm, LV EDV may be significantly impaired from the loss of a higher-pressure “atrial kick.”

Hearts with pathologically increased compliance are generally those that have been dilated for a long period, allowing for adaptation. Patients with dilated cardiomyopathy or chronic severe aortic insufficiency may have dramatically increased LV EDV with normal filling pressures.

Ventricular EDP–EDV relationships may be difficult to measure, but the presence of impaired relaxation and restricted filling can be assessed with echocardiography by examining inflows across the mitral valve and pulmonary veins, although

that discussion is beyond the scope of this text. However, it is important to note that conditions such as LV hypertrophy and aortic stenosis exist that shift the compliance curve up and to the left, thus requiring active atrial filling. In these situations, assessing CVP, PCWP, or LV EDP may not provide an accurate surrogate for the LV EDV.

Afterload

Afterload represents the tension the ventricle must generate during systole that is sufficient to produce contraction. In normal circumstances, this is influenced by the arterial impedance, but in the presence of aortic stenosis, it is also affected by the additional gradient across the valve. The wall tension the ventricle generates is the force required to reduce its chamber size against a given pressure. For a spherical object, the wall tension is determined by the law of Laplace:

$$\text{Wall tension} = P \times R/2h,$$

where P is the pressure in the chamber, R is the radius of the chamber, and h is the wall thickness. Therefore, hearts ejecting against higher pressures, with larger chambers, generate a higher wall tension. Having a larger wall thickness decreases wall tension but comes at a price of higher oxygen consumption and impaired oxygen delivery, which is discussed later.

In normal circumstances, the pressure the heart must develop wall tension against is determined by the arterial tone, or systemic vascular resistance (SVR). Drawing from Ohm’s law, remember that voltage (V) = I (current) \times R (resistance), or put another way, the pressure change across a bed of resistance is determined by the current, or flow, multiplied by the resistance:

$$\Delta P = Q \times R \text{ or } R = \Delta P/Q,$$

where ΔP is the pressure change, Q is flow, and R is resistance. Therefore:

$$\text{SVR} = 80 \times (\text{MAP} - \text{CVP})/\text{CO},$$

where MAP is the mean arterial pressure and CVP is the central venous pressure. ΔP , or $(\text{MAP} - \text{CVP})$, is simply the pressure change across the vascular bed in question, in this case the systemic circulation, and 80 is a conversion factor to leave the answer in appropriate units. Normal SVR is 900 to 1500 dyne $\text{sec}/\text{cm}^{-5}$.

Similarly, the pulmonary vascular resistance (PVR) can be calculated applying the same concepts to the pulmonary vascular bed:

$$\text{PVR} = 80 \times (\text{PA mean} - \text{LAP})/\text{CO},$$

where PA mean is the mean pulmonary arterial pressure and LAP is the left atrial pressure. In normal circumstances, PCWP is substituted for LAP. Normal PVR is 50 to 150 dyne $\text{sec}/\text{cm}^{-5}$.

Increases in afterload can decrease the cardiac output but may be difficult to conceptualize until analyzing a pressure–volume loop (Fig. 70.11). Increases in afterload do not alter

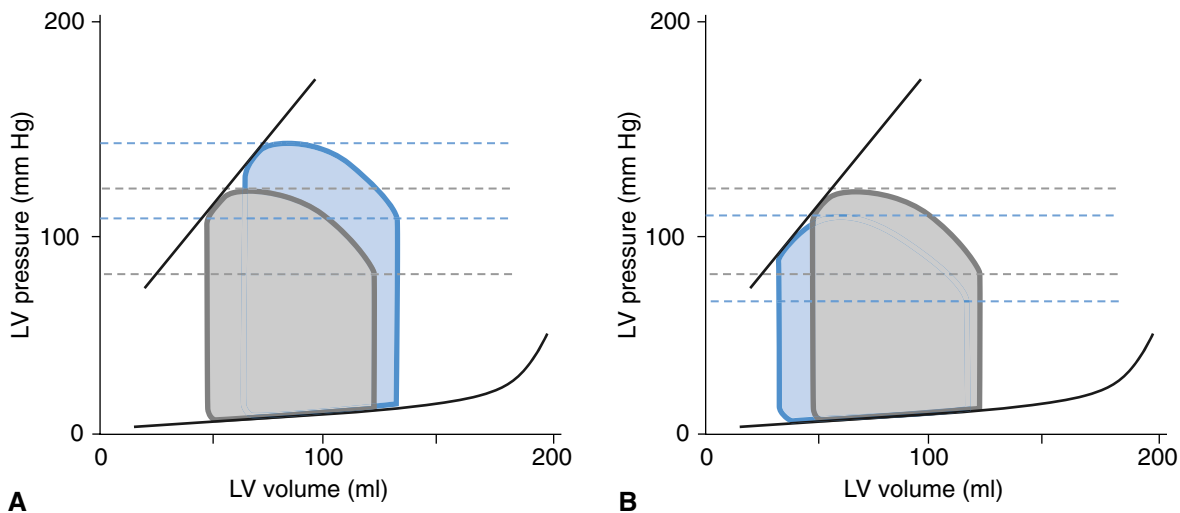

Figure 70.11. Increasing and decreasing afterload.

either the nonlinear EDP–EDV curve, which was previously discussed, or the linear end systolic pressure volume (ESP–ESV) curve, which represents the pressure–volume relationship at which the aortic valve closes at the end of systole. Instead, changes in afterload influence how SV falls between these two curves.

An increase in afterload leads to a higher systemic blood pressure but an earlier closure of the aortic valve, and thus a smaller SV for any given preload. A small amount of physiologic compensation is indicated by a subtle change in preload. The net effect is a higher systemic blood pressure, but with a lower cardiac output. Conversely, a decrease in afterload leads to a lower systemic blood pressure and a larger SV. Clinical examples of extremes of this spectrum include aortic stenosis, in which the ventricular preload must remain very high to have an adequate SV against a very high afterload, and septic shock, in which dilated systemic vascular tone leads to a high cardiac output state despite a low systemic blood pressure.

Contractility

Contractility represents the strength of ventricular contraction and is related to the rate of myocardial muscle shortening during systole. It is an intrinsic property of the muscle and is independent of preload and afterload. Myocardial contractility is influenced by neural, humoral, and pharmacologic factors. In addition, adequate intracellular calcium concentrations can improve myocardial contractility (Table 70.1).

On a pressure–volume loop, contractility is represented by the slope of the linear ESP–ESV relationship. Greater contractility shifts this curve up and to the left, whereas depressed contractility shifts it down and to the right (Fig. 70.12).

Agents that increase contractility lead to a higher systemic blood pressure, a larger SV, and a greater ejection fraction. Agents that decrease contractility lead to a lower systemic blood pressure, a smaller SV, and a decreased ejection fraction.

Changes during exercise

Several changes occur as a normal physiologic response to exercise, including increased HR, SV, and contractility, all to achieve an increase in cardiac output. Hearts that are not capable of mounting a response to this increase in physiologic demand leave the patient with an inability to tolerate the increase in exertion (Fig. 70.13). Changes in preload are still reflected as Starling curves, but the course and shape of the curves are determined by the contractile state of the heart.

Wall motion abnormalities

Regional wall motion abnormalities may lead to a decrease in SV generated under otherwise normal preload and afterload conditions. These abnormalities may be the result of ischemia, old infarction, or intraventricular conduction delays leading to asynchronous contraction. All serve to impair the ability of the ventricle to produce an SV. Normal or enhanced contractility in other regions of the ventricle may be insufficient to compensate

Table 70.1. Factors affecting myocardial contractility

Increase contractility	Decrease contractility
Sympathetic (innervate atria, ventricle, nodes)	Parasympathetic stimulation – minimal
Epinephrine and norepinephrine	Hypoxia, acidosis, hypercapnia
Hypercalcemia	Depletion of catecholamine stores in the heart (as seen in congestive heart failure, chronic hypertension, and elderly patients)
Digitalis	Loss of functioning muscle mass with ischemia/infarction
Glucagon	Anesthetics, especially potent inhalational agents, propofol, and thiopental
	Electrolytes: hyperkalemia, hypocalcemia
	Antiarrhythmic agents, including β -blockers and calcium blockers

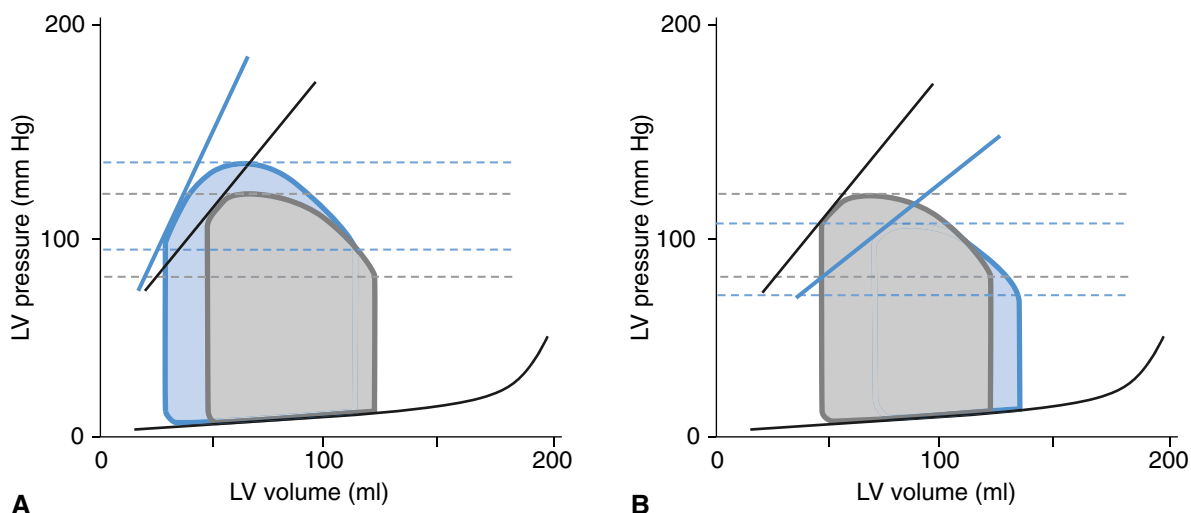

Figure 70.12. Increasing and decreasing contractility.

for hypokinetic or akinetic regional wall segments. It is through this process that patients with ischemic heart disease develop a decrease in SV and ejection fraction.

Valvular abnormalities

The presence of valvular abnormalities may further compromise the ability of the heart to fill and empty in a forward fashion. Any of the four valves may be stenotic or regurgitant. Although valvular disease is discussed in detail elsewhere, it is useful to point out some brief key concepts here and correlate them with pressure–volume loops of the heart.

Aortic stenosis produces a pressure gradient that exists between the left ventricle and aorta. Although *afterload* normally refers to SVR, here it also applies to the additional resistance the ventricle must work against by ejecting against a stenotic valve. Once the stenosis becomes critical, the afterload is dramatically increased. The only way to achieve an adequate SV is to ensure that the ventricle, which has developed worsening compliance, is adequately full. These patients are thus very sensitive to hypovolemia and arrhythmias, and can quickly decompensate or even die with loss of a sinus rhythm. The

very high wall tension generated also leads to greatly increased myocardial oxygen consumption.

Aortic regurgitation leads to diastolic retrograde filling of the left ventricle from the aorta. With time, the ventricle becomes grossly dilated and has an increase in its compliance. Forward flow to the body becomes a function of the difference between the total stroke volume and the diastolic regurgitant fraction. Physiologic conditions that worsen the regurgitation, such as higher aortic pressures and longer diastolic times, will impair forward flow. In addition, if severe, the aortic regurgitation may interfere with ventricular filling from the atrium by prematurely forcing the mitral valve shut once the pressure in the ventricle exceeds that in the atrium.

Mitral stenosis produces a pressure gradient between the left atrium and ventricle. These patients have normal systolic and diastolic pressure–volume relationships, but the ventricle is chronically underfilled. Patients may appear systemically hypovolemic with small SVs and low blood pressures even though they may present with symptoms of heart failure. Maximizing diastolic filling time and maintaining a sinus rhythm allow for optimum ventricular filling. Temporizing patients with inotropes may be an alternative if the ventricle remains grossly underfilled.

Mitral regurgitation leads to retrograde filling of the atrium during systole. Functional forward flow is the difference between the total SV and the systolic regurgitant volume. Higher atrial pressures may predispose patients to pulmonary edema, and higher ventricular systolic pressures will worsen the regurgitant fraction.

Figure 70.13. Changes in SV and LVEDP with exercise.

Myocardial oxygen supply and demand

Consideration of cardiac physiology, with its variables – including HR, wall tension, and contractility – requires an understanding of myocardial oxygen supply and demand. Myocardial oxygen is delivered via the coronary arteries branching off the aortic root. In contrast to other organs, perfusion to the

Figure 70.14. LV coronary blood flow during the cardiac cycle Note: a, isovolumetric contraction; b, systolic ejection; and c, diastole.

myocardium occurs intermittently and is timed to the cardiac cycle. Within the LV wall, the pressure generated is similar to the aortic systolic pressure, which can transiently occlude the myocardial perforating arteries. Not until diastole, when the intramyocardial pressure is low, does coronary pressure to the left ventricle occur (Fig. 70.14). The coronary perfusion pressure (CPP) to the left heart is the difference between the aortic diastolic blood pressure (AoDBP) and the LV end diastolic pressure (LVEDP):

$$\text{CPP} = \text{AoDBP} - \text{LVEDP}$$

LVEDP is generally between 10 and 20 mm Hg, so the magnitude of the coronary perfusion gradient to the left ventricle depends greatly on changes in systemic diastolic blood pressure. Conditions that decrease systemic diastolic blood pressure or increase LV end diastolic pressure may lead to decreased coronary perfusion. LV hypertrophy, which decreases overall ventricular wall tension due to increased wall thickness, impairs coronary perfusion by changing compliance and increasing LV end diastolic pressure. In addition, higher intramural pressures and compression of perforating arteries make the ventricle susceptible to subendocardial ischemia.

Perfusion to the right ventricle differs somewhat from that to the left ventricle. Because the intramyocardial pressures within the right ventricle are significantly less than those of the left ventricle, right ventricular myocardial perfusion can occur during both systole and diastole. For this reason, the coronary perfusion gradient to the right ventricle depends more on the systemic mean arterial pressure than the systemic diastolic blood pressure.

Autoregulation of coronary blood flow

In the absence of a blockage in the coronary arteries, coronary blood flow matches myocardial oxygen demand.

Autoregulation of blood flow between perfusion pressures of 50 and 120 mm Hg ensures optimum matching under most normal physiologic conditions. Changes in myocardial oxygen demand produce several effects through autonomic, humoral, and local mechanisms. Sympathetic stimulation produces both α_1 - and β_2 -adrenergic effects – α_1 -induced vasoconstriction affects large-bore arteries, but β_2 -induced vasodilation occurs in smaller intramyocardial vessels. The overall effect is for increased myocardial blood flow with sympathetic stimulation, mostly through β_2 stimulation. Likewise, local tissue hypoxia releases adenosine, leading to coronary vasodilation. All these effects help match myocardial oxygen supply to demand.

Myocardial oxygen demand

Myocardial oxygen consumption is influenced by several factors, including basal tissue oxygen consumption, generation of electrical activity, generation of wall tension under varying loading volumes and against varying pressures, and rate of systolic ejections. Hearts that beat faster, have higher filling volumes, and eject against higher pressures consume more oxygen. In addition, hearts that beat faster have less time in diastole. Therefore, increases in HR and diastolic pressure increase consumption and decrease delivery.

Myocardial tissue very efficiently extracts oxygen from arterial blood – typical blood in the coronary sinus has saturations near 30%, compared with 75% for the rest of the body. Any increase in oxygen consumption must be matched by an increase in oxygen delivery through increased coronary blood flow. For patients with a coronary blockage who cannot deliver an increase in coronary blood flow, strategies to minimize increases in myocardial oxygen demand and maximize delivery of oxygen until the blockage can be corrected are a mainstay of treatment.

Conclusion

Understanding cardiac physiology is essential to the perioperative care of patients who present for a variety of procedures. Core concepts of cardiac electrical physiology, systolic and diastolic function, ventricular filling and ejection, and myocardial oxygen supply and demand apply to almost all patients presenting for surgery, regardless of the status of their health. Developing a solid foundation of principles is essential when studying normal cardiac physiology before applying those same principles to patients with a variety of pathologic cardiovascular disorders. Conditions ranging from coronary disease to valvular disorders and hemodynamic changes from interventions such as fluid and drug administration can be explained by building on a strong understanding of cardiac physiology. The reader is advised to revisit these principles as these conditions are elaborated upon in the following chapters.

Cardiovascular pharmacology

Arti Ori and Douglas C. Shook

Introduction

Cardiovascular drugs are used to alter cardiac performance and end-organ blood flow, with the goal of maintaining adequate tissue perfusion and oxygen delivery. The choice of drug depends on the complex interrelationship among preload, contractility, afterload, and the rate and rhythm of the heart. If the patient's hemoglobin level and oxygen saturation are adequate, the cardiac output (CO) becomes an important determinant in oxygen delivery and systemic vascular resistance (SVR) for permitting optimal tissue perfusion. An understanding of these important concepts is integral to choosing among the variety of cardiovascular drugs available.

The central role of calcium

Intracellular calcium levels have a dominant effect on myocardial contractility and smooth muscle vascular tone. During the cardiac action potential, extracellular calcium enters the cell via L-type (slow) calcium channels. Calcium entry triggers calcium release from the sarcoplasmic reticulum (calcium-induced calcium release). The increased free intracellular calcium binds to the cardiac myofilament protein troponin C, which then allows actin to form cross-bridges with myosin and for contraction to occur. For myocardial relaxation, calcium must be removed from troponin C. This is accomplished by decreasing intracellular calcium levels, primarily by reuptake of calcium into the sarcoplasmic reticulum by an energy-dependent process. Calcium is also removed from the cell by ion transport channels in the cell membrane to keep the overall intracellular calcium unchanged with each contraction–relaxation cycle.

This transient increase and decrease of intracellular calcium is central to myocardial contractility. In normal hearts, only about 25% of the cardiac myofilaments are saturated with calcium. This reserve may be activated by drugs that either increase the amount of calcium in the myocyte or sensitize the myofilaments to the calcium already present. Several conditions change the sensitivity of calcium to cardiac myofilaments, and thus the effectiveness of inotropic and vasoactive drugs (Table 71.1).

Calmodulin in vascular smooth muscle modulates the interaction of actin and myosin, leading to vasoconstriction in the presence of intracellular calcium. Thus, in both vascular smooth muscle cells and cardiac myocytes, an increase in intracellular

calcium promotes greater contraction, leading to increased vasoconstriction and increased contractility, respectively. All the drugs used to manage myocardial contractility and smooth muscle tone act by altering intracellular calcium.

The most common inotropic drugs augment intracellular calcium by either cyclic adenosine monophosphate (cAMP)-dependent or cAMP-independent mechanisms. β -Adrenergic agonists act via G_s proteins that activate adenylate cyclase, increasing the synthesis of cAMP. Acting as a second messenger, cAMP activates protein kinase A, which phosphorylates a variety of intracellular targets, increasing intracellular calcium for contraction (inotropy) and enhancing its reuptake, promoting relaxation (lusitropy). α -Adrenergic agonists may also increase intracellular calcium, but by a different mechanism. The clinical significance of this mechanism for myocardial contractility is uncertain, but its clinical significance in promoting vasoconstriction in vascular smooth muscle is well known. Phosphodiesterase inhibitors act by inhibiting the breakdown of cAMP, thereby increasing intracellular calcium and contractility (Fig. 71.1).

α -Adrenergic stimulation (catecholamines) and phosphodiesterase III inhibition increase cAMP, which acts via protein kinase A to phosphorylate calcium channel protein, phospholamban, and troponin I. Phosphorylation of calcium channel protein enhances sarcolemmal inward movement of Ca^{2+} , which subsequently increases Ca^{2+} movement from the sarcoplasmic reticulum (SR) through the calcium release channel (ryanodine receptor type 2) to the cytosol (calcium-induced Ca^{2+} release). Digoxin increases cytosolic Ca^{2+} by

Figure 71.1. Effect of inotropic drugs on intracellular calcium.

inhibition of sarcolemmal Na–K–adenosine triphosphatase and Na–Ca²⁺ exchange. Cytosolic Ca²⁺ binds to troponin C (TnC) and initiates contraction (inotropic effect). Phosphorylation of phospholamban enhances relaxation by increased reuptake of Ca²⁺ back into the SR by the SR Ca²⁺ adenosine triphosphatase isoform 2 (SERCA2; lusitropic effect). Phosphorylation of troponin I enhances the rate of relaxation by decreasing the sensitivity of myofilaments to Ca²⁺. Levosimendan binds to troponin C during systole and thereby increases the sensitivity of myofilaments to Ca²⁺ without alteration of Ca²⁺ levels.

In the vascular smooth muscle, cAMP and cyclic guanosine monophosphate (cGMP) have the opposite effect on intracellular calcium by promoting its reuptake into the SR, thereby decreasing its availability for contraction. Thus, drugs that increase cAMP, such as β -agonists or phosphodiesterase inhibitors, will promote vasodilation. Nitroglycerin and nitroprusside act by producing nitric oxide, which stimulates the production of intracellular cGMP, promoting vasodilation.

Inotropic drugs

In most patients with depressed CO, taking advantage of Starling's curve by increasing preload will increase stroke volume and CO. If the patient does not respond to preload management, then adding drugs that increase contractility may improve CO and tissue perfusion. Positive inotropic drugs increase cardiac contractility, stroke volume, heart rate, and CO.

The most commonly used inotropic drugs increase CO by increasing the amount of cAMP produced in the cardiac myocyte or inhibiting its breakdown. More cAMP in the cardiac myocyte promotes greater calcium interaction with troponin C, increasing contractility.

The difference among the cAMP-dependent agents is in their effect on the peripheral vasculature. Some are inoconstrictors (increase contractility and increase vasoconstriction), some are inodilators (increase contractility and promote vasodilation), and some have mixed effects on the peripheral vasculature. The choice of inotropic agent depends on the desired

“side effect” on the vasculature to promote better tissue perfusion. cAMP-independent inotropes also have effects on the peripheral vasculature that must be anticipated to determine their effect on blood pressure and tissue perfusion. The most commonly used inotropic agents are listed in the following text and summarized in Table 71.2.

Epinephrine (mixed inotrope) is a naturally occurring catecholamine that directly binds to β_1 -, β_2 -, α_1 -, and α_2 -receptors, with β effects predominating at lower doses and α effects predominating at higher doses. Therefore, it is an inodilator at lower doses, in which β_1 - and β_2 -receptors dominate, and an inoconstrictor at higher doses, in which α -receptor stimulation becomes stronger. At higher doses, stroke volume and CO may decrease because of the intense α -receptor stimulation.

Dopamine (mixed inotrope) is another naturally occurring catecholamine, whose effects are dose dependent. Dopamine acts by directly stimulating dopaminergic receptors, as well as β_1 -, β_2 -, and α_1 -receptors, and inducing the release of stored norepinephrine. As with epinephrine, lower doses produce increased contractility and vasodilation, which transitions to α -receptor-mediated vasoconstriction at higher doses. At higher doses, stroke volume and CO may decrease because of the intense α -receptor stimulation.

Dobutamine (inodilator) is a synthetic catecholamine with a strong affinity for β_1 -receptors and weaker affinity for β_2 -receptors. Its overall effect is to increase contractility and heart rate with mild vasodilation (β_2 effects).

Milrinone (inodilator) is a phosphodiesterase III inhibitor that increases myocyte and vascular smooth muscle cell cAMP by inhibiting its breakdown. Milrinone produces positive inotropy and improved diastolic relaxation (lusitropy). It may induce less tachycardia compared with catecholamine inotropes. It is a potent vasodilator affecting both venous and arterial vascular beds. Loading milrinone may cause hypotension in patients who do not have adequate preload, because of the arterial and venous dilation caused by the drug. It has a longer half-life than a catecholamine drug, which may make it harder to titrate. Milrinone is usually chosen when catecholamine drugs do not produce the desired increase in CO or the clinician wants to take advantage of its vascular dilating properties. It may also have advantages in patients with reduced available β -receptors due to chronic sympathetic stimulation (i.e., congestive heart failure) or blocked by β -receptor antagonists, and may have synergistic inotropic effects when combined with inotropes that act directly through β -receptor activation.

Glucagon (inodilator) binds to the glucagon receptor and causes an increase in intracellular cAMP. This increase in cAMP in cardiac myocytes enhances cardiac contractility. It is rarely used, however, because of its multiple side effects (nausea, vomiting, hyperglycemia, hypokalemia, and anaphylaxis).

Calcium chloride (inoconstrictor) provides a source of free calcium ions and acts as an inotrope if free ionized calcium concentrations are low within the patient. If free ionized calcium concentrations are normal, fewer inotropic effects will be noticed. Calcium chloride is also a potent vasoconstrictor and

likely will have negative effects on cardiac diastolic function. The administration of calcium *immediately* after reperfusion of the myocardium after cardiopulmonary bypass should be performed cautiously, because it may be associated with exacerbating reperfusion injury and worsening diastolic function of the heart.

Vasoconstrictors

Vasoconstrictors induce contraction of vascular smooth muscle. Arterial vasoconstriction results in increased SVR, leading to increased mean arterial pressure ($MAP = CO \times SVR$). Constriction of venous capacitance vessels results in increased preload and increased CO. When using vasoconstrictors, end-organ perfusion must be monitored closely. Vasoconstrictors may be used to temporize hypotension due to decreased preload, but should not replace adequate volume resuscitation. Table 71.3 describes the different vasoconstrictors or vasopressors commonly used in the operating room.

Phenylephrine is a direct-acting α_1 -agonist that causes primarily peripheral arterial vasoconstriction, with minimal venous effects. It has a short duration of action (minutes). Phenylephrine is commonly used to treat hypotension due to decreased vascular resistance by increasing afterload. It usually does not affect heart rate or contractility, but may cause a reflex bradycardia.

Ephedrine is a sympathomimetic drug that acts by indirectly releasing norepinephrine from stores in the nerve terminal. It also has mild direct α , β_1 , and β_2 effects. The mild β effects will increase heart rate and contractility. Repeat dosing may lead to tachyphylaxis, with less norepinephrine being released from the nerve terminal than with the initial dose.

Norepinephrine is a direct-acting α_1 -, α_2 -, and β_1 -agonist. The α effects dominate, causing intense α -receptor vasoconstriction throughout the dosing range. It is useful in hypotension refractory to phenylephrine (α_1 only) and has the added effect of increasing cardiac contractility.

Vasopressin is an antidiuretic hormone that at higher doses stimulates smooth muscle vasopressin receptors to cause vasoconstriction. Vasopressin does not affect α - or β -receptors. It is used in a variety of low SVR states and as a second-line agent when norepinephrine fails to adequately increase SVR (persistent vasoplegia). Vasopressin may be effective for treating angiotensin-converting enzyme inhibitor- or angiotensin receptor blocker-mediated hypotension during general anesthesia.

Methylene blue has a complex mechanism of action, and there are only a limited number of clinical trials available. It inhibits the nitric oxide/cGMP pathway by inhibiting nitric oxide synthase. Methylene blue has been used effectively in nitric oxide-mediated vasoplegic syndrome, in which patients with profound vasodilation do not respond to conventional vasopressors.

Vasodilators produce vascular smooth muscle relaxation, resulting in decreased SVR. Their primary indications are

for elevated SVR and myocardial ischemia and failure. Table 71.4 lists the most commonly used vasodilators in anesthesia.

Nitroglycerin is a direct smooth muscle vasodilator metabolized in the body to nitric oxide. This results in increased vascular smooth muscle cell cGMP, which causes vascular smooth muscle relaxation. Nitroglycerin primarily causes venous dilatation, decreasing cardiac preload, with some arterial dilation at higher doses. Coronary arterial blood vessels are dilated throughout the dosing range. Nitroglycerin may be used to control hypertensive episodes, but other agents are more effective. Nitroglycerin is also effective in treating myocardial ischemia by decreasing preload and myocardial wall tension and improving coronary blood flow to ischemic areas of myocardium, as long as perfusion pressure is maintained. Tolerance to infusions may occur after 24 hours. It is less toxic than nitroprusside, although methemoglobinemia is possible after prolonged infusions at high doses.

Nitroprusside is a direct vasodilator that acts by producing nitric oxide. It causes profound vasodilation of both arteries and veins, with arterial dilation predominating at lower doses. It is used to control systemic hypertension. Nitroprusside needs to be protected from light. Continuous blood pressure monitoring via an arterial line is recommended because of its potency. Nitroprusside may cause both cyanide and thiocyanate toxicity. Cyanide production results from nitroprusside metabolism. Cyanide inhibits oxidative phosphorylation, drastically reducing adenosine triphosphate (ATP) production in cells. Signs of toxicity include tachypnea, elevated mixed venous oxygenation (cells unable to use oxygen), and metabolic acidosis. In patients receiving prolonged (>24 hours) or high-dose (>8 µg/kg/min) infusions or in those with end-organ dysfunction (liver or kidney), it is advisable to check cyanide levels. The kidneys eliminate thiocyanate, a product of cyanide metabolism by the body. Toxic levels of thiocyanate may exist in patients with renal dysfunction or after prolonged infusions, resulting in central nervous system dysfunction.

Fenoldopam is a selective peripheral dopamine receptor (DA1) agonist, rapidly lowering blood pressure by causing dilation of arteries. It also induces diuresis. It does not have toxic metabolites.

Hydralazine, a direct vasodilator, acts via the cGMP pathway. It causes more arterial than venous dilation, with little effect on preload. Its onset of action is the slowest of the drugs on this list, taking up to 20 minutes to achieve peak effect. Hydralazine is not an effective drug for acute hypertensive crisis because of its slow onset. However, it can be used to reduce doses of other, faster-acting drugs (e.g., nitroprusside).

Nicardipine is a dihydropyridine calcium channel blocker that has an intravenous formulation used to treat hypertension. It primarily causes arterial dilation with minimal venous (preload) and cardiac (contractility, heart rate) effects. It has a longer half-life than vasodilator infusions so bolusing is needed to achieve therapeutic levels.

β-Blocking drugs

β-Blocking drugs bind to β-receptors, antagonizing their effects. β-Blockers decrease heart rate and contractility and affect cardiac conduction (atrioventricular [AV] nodal conduction, refractory period). Each β-blocker has different receptor affinities (β₁, β₂, α), although selectivity for a particular receptor likely decreases as dosages of the medication are increased. Metabolism and half-life are different for each β-blocker. In patients with chronic obstructive lung disease or asthma, a selective β₁-blocker is less likely to exacerbate symptoms. Table 71.5 lists examples of selective and nonselective β-blockers commonly used in the operating room. The following bulleted list includes β-blocker indications, complications, and treatment of toxicity.

Indications:

- Hypertension
- Arrhythmias (especially supraventricular)
- Myocardial ischemia and infarction
- Dynamic ventricular outflow tract obstruction
- Perioperative cardiac morbidity and mortality

Monitor for:

- Severe bradyarrhythmias
- Heart block
- Bronchospasm (use a selective β₁-blocker in susceptible patients)
- Congestive heart failure (especially in patients with low ejection fractions)
- Withdrawal syndrome with abrupt discontinuation of β-blockers (hypertension and tachycardia)

Treatment of toxicity:

- β-Agonists (may need large doses to overcome blockade)
- Cardiac pacing
- Calcium, milrinone, glucagon, thyroid hormone (the mechanism of action of these agents does not involve β-receptors)

Hemodynamic effects:

- Decreased heart rate
- Decreased contractility
- Decreased blood pressure
- Decreased CO
- Decreased AV node conduction
- Increased refractory period

Calcium channel blockers

Calcium channel blockers interact with L-type calcium channels, blocking calcium entry into the cell. Calcium entry into the myocardial cell not only is part of the cardiac action potential but also induces calcium release from the SR, dramatically increasing calcium in the cytoplasm, thereby increasing contractility of the myocardium and increasing smooth muscle

Table 71.4. Vasodilators

Drug	Action	HR	Contractility	Preload	SVR/PVR	BP	CO	Indication	Use
Nitroglycerin	Direct vasodilator ↑cGMP production Venous > arterial Excellent coronary effects	↑ (reflex)	-	↓↓	↓	↓	↑/↓	Myocardial ischemia Increased coronary perfusion Relief of coronary spasm HTN Pulmonary HTN CHF	40–80 µg IV bolus Infusion: 10–200 µg/min At infusions higher than 200 µg/min, switch to SNP or another agent Tolerance if infused for long periods Infusion 0.1–2.0 µg/kg/min Max. infusion 10 µg/kg/min (short periods only) Avoid prolonged doses > 2.0 µg/kg/min (toxicity) Protect from light Continuous BP monitoring (A-line)
Nitroprusside	Direct vasodilator ↑cGMP production Arterial = venous	↑ (reflex)	-	↓	↓↓	↓	↑/↓	HTN, ↑SVR Controlled hypotension	Use with caution in liver or kidney dysfunction 2.5–5 mg IV bolus every 15 min (max. 20–40 mg) 20 min to peak effect IV infusion 0.01–1.6 mcg/kg/min Readjust dose every 15–20 min for effect
Hydralazine	Direct vasodilator Arterial >>> venous	↑ (reflex)	-	-	↓↓	↓	-/↑	HTN, ↑SVR	
Fenoldopam	Synthetic dopamine receptor agonist Rapid-acting arterial dilator Maintains renal perfusion	↑ (reflex)	-	-	↓↓	↓	↑	Severe hypertension in patients with impaired renal function	
Nicardipine	Dihydropyridine calcium channel blocker Arterial >>> venous	↑ (reflex)	-	-	↓↓	↓	-/↑	HTN To improve lusitropy in cardiac ischemia Coronary vasospasm	Infusion 1–4 µg/kg/min Titrate to BP May cause phlebitis in peripheral IV (if infused for > 12 h)

HR, heart rate; SVR, systemic vascular resistance; PVR, pulmonary vascular resistance; BP, blood pressure; CO, cardiac output; HTN, hypertension; CHF, congestive heart failure; IV, intravenous; SNP, sodium nitroprusside.

Table 71.5. β -Blockers

Drug	Action	Onset	β Half-life, h	Elimination	IV dose
Propranolol	β_1 -, β_2 -antagonist	2–5 min	3.5–4.0	Hepatic	0.5–1.0 mg prn
Labetalol	β_1 -, β_2 -, α_1 -antagonist Ratio of α -to- β blockade is 1:7	2–5 min	3–5	Hepatic	10–40 mg prn (max. 300 mg)
Metoprolol	Selective β_1 -antagonist	5 min (peak 20 min)	3–4	Hepatic	1–5 mg prn (max, 15 mg)
Esmolol	Selective β_1 -antagonist	Rapid	9 min	Red blood cell and plasma esterases	0.25–0.5 mg/kg prn Infusion: 50–300 μ g/kg/min

IV, intravenous; prn, as needed.

tone in arterial vessels. By blocking the L-type calcium channel, contractility and heart rate are decreased. Calcium channel blockers are arterial vasodilators with minimal venous dilation. Verapamil and diltiazem affect the myocardium and produce arterial vasodilation. Nicardipine only produces arterial vasodilation. [Table 71.6](#) gives examples of calcium channel blockers commonly used in the operating room. Following are the hemodynamic effects, indications, and treatment of calcium channel blocker overdose.

Hemodynamic effects:

- Prolong AV nodal refractory period (verapamil > diltiazem)
- Decrease heart rate by affecting the sinoatrial node (verapamil > diltiazem, possible reflex increase with nicardipine)
- Cause no change in preload
- Decrease SVR
- Decrease blood pressure
- Decrease CO (verapamil, diltiazem, possible increase with nicardipine)
- Depress myocardial contractility (verapamil > diltiazem, not nicardipine)

Indications:

- Hypertension
- Supraventricular arrhythmias (verapamil, diltiazem)
- Arterial and coronary vasospasm
- Myocardial ischemia (not as well established as β -blockers)

Monitor for:

- Hypotension (negative inotropic effects and vasodilation)
- Severe bradyarrhythmias
- Heart block
- Congestive heart failure (especially in patients with low ejection fractions)
- Beware of additive effects in patients on β -blockers

Toxicity: Give calcium chloride, β -agonists, α -agonists, or milrinone, or consider cardiac pacing.

Choice of inotrope or vasoactive drug

The most commonly used inotropes and vasoconstrictors are adrenergic receptor agonists (epinephrine, norepinephrine, dopamine, dobutamine, phenylephrine). They have been around for a long time, with well-documented effects on the cardiac myocyte and peripheral vasculature. Other inotropes and vasoconstrictors work via other mechanisms noted in

Table 71.6. Calcium channel blockers

Drug	Action	Onset	β Half-life	IV Dose	Comments
Verapamil	Strong myocardial effects Arterial dilation	3–5 min	3–10 h Hepatic	1–2 mg prn (low dose, especially during anesthesia)	Myocardial depression > peripheral arterial vasodilation Use low doses in GA, unstable patients, or patients with reduced EF Rx: SVT, HTN, vasospasm, ischemia
Diltiazem	Weaker myocardial effects Arterial dilation	2–5 min	3–5 h Hepatic and renal	20 mg bolus, then 5–15 mg/h infusion Lower doses with hemodynamic instability	Less myocardial depression compared with verapamil Causes selective coronary artery vasodilation Rx: SVT, HTN, vasospasm, angina
Nicardipine (see vasodilators)	No myocardial effects Arterial dilation	Minutes	14 min Hepatic	1–4 μ g/kg/min	Titrate to blood pressure May cause phlebitis in peripheral IV if infused for > 12 h

IV, intravenous; prn, as needed; GA, general anesthesia; EF, ejection fraction; SVT, supraventricular tachycardia; HTN, hypertension.

the previous lists (milrinone, levosimendan, vasopressin, methylene blue). Each inotrope and vasoactive drug has different advantages, disadvantages, and side effect profiles. The nonadrenergic drugs often are used when adrenergic receptor agonists either cause unwanted side effects (dysrhythmias, tachycardia, changes in vascular tone) or fail to treat the cardiovascular problem (persistent vasoplegia, continued myocardial depression). In addition, the combination of an adrenergic receptor agonist (epinephrine) with a nonadrenergic inotrope (milrinone) may result in an increased, synergistic response (contractility), because both agents work to increase cAMP via different mechanisms.

Understanding the complexity of calcium modulation in cardiac myocytes and vascular smooth muscle cells is an important factor in deciding the appropriate inotrope and/or vasoactive drug needed to maintain adequate tissue perfusion and oxygen delivery. There is no gold standard for choosing an inotrope, vasoconstrictor, or vasodilator. The ideal drug would have a singular effect, such as increasing contractility, and have no effect on heart rate, rhythm, or vascular tone. Such drugs do not exist, as each has different effects or side effects. Catecholamines affect not only inotropy and chronotropy, but also vascular smooth muscle tone. Milrinone increases contractility in the cardiac myocyte by increasing cAMP, but increased cAMP also causes vasodilation. The choice of inotrope or vasoactive drug has as much to do with its intended effect as its side effects.

Adjunct cardiovascular drugs

Alexander C. Gerhart and Balachundhar Subramaniam

Although cardiovascular drugs that have a direct impact on cardiac performance are important, it is also essential to understand the mechanism, side effects, and utility of adjunct drugs that are used for controlled anticoagulation and its reversal and to minimize perioperative bleeding.

Heparin

Heparin is a naturally occurring, negatively charged mucopolysaccharide with a molecular weight that varies from 10,000 to 30,000 Da. It is derived from either bovine lung or porcine intestine. The anticoagulant effect of heparin occurs via binding of a specific pentasaccharide sequence within the heparin molecule to antithrombin, also known as antithrombin III. Antithrombin functions in the normal coagulation cascade to limit the effect of thrombin. Binding of the heparin molecule increases the activity of antithrombin by 1000- to 4000-fold. Antithrombin also regulates the activity of factors Xa, IXa, XIa, and XIIa.

Heparin has been used in clinical medicine for decades to treat acute thrombotic events, to prevent deep vein thrombosis (DVT), and for anticoagulation to facilitate cardiopulmonary bypass. The anticoagulant effect of heparin is most often measured by activated partial thromboplastin time (aPTT) or activated clotting time (ACT). Serial monitoring of anticoagulation and titrated heparin dosing is essential because of the variable and unpredictable effect of heparin *in vivo*. The anticoagulant effect of heparin depends on multiple factors. The size of the heparin molecule delivered is highly variable, with smaller molecules having a greater anticoagulant effect. The underlying health of the patient, the amount of circulating antithrombin, and preexisting liver disease or coagulopathy all affect heparin dosing.

Adverse effects of heparin, in addition to bleeding complications, are well described. The most important is that the drug has a narrow therapeutic window. The goal is to provide adequate anticoagulation without inducing bleeding. Given the variable response to heparin dosing, this requires frequent measurement of aPTT or ACT. As a derivative of either bovine or porcine tissues, heparin may cause allergic reaction. Additionally, heparin is known to induce osteoclast activity and therefore may lead to bone demineralization. Finally, heparin may induce thrombocytopenia.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) may be the most frequent cause of drug-induced thrombocytopenia, with an estimated incidence between 10% and 20% of patients exposed to heparin. HIT describes two distinct clinical scenarios. HIT type 1 is the result of direct antiplatelet effects of heparin and produces a mild transient thrombocytopenia that is usually asymptomatic and rarely requires treatment. HIT type 2 is the result of naturally occurring IgG antibody-binding complexes within the plasma formed by heparin and platelet factor IV (PF4). HIT type 2 is much more serious and carries a significant mortality risk if not identified and promptly treated. The remainder of this discussion focuses on HIT type 2.

HIT is a clinical syndrome that may occur in any patient exposed to heparin. Risk factors include the use of unfractionated heparin, long-term exposure, a large dose, the postsurgical setting, and repeat exposure. Common findings include thrombocytopenia (platelet count decrease of 50%), occurring approximately 4 to 10 days after exposure; signs of thrombosis; and skin lesions at the site of heparin injection. In patients exposed to heparin within the preceding 90 days, HIT may develop as soon as 10 hours because of the presence of residual HIT antibodies.

Thrombotic events more commonly are venous, but may be arterial and present as venous outflow obstruction, myocardial infarction, mesenteric ischemia, cerebral vascular accident, pulmonary embolism, or upper- or lower-extremity DVT. HIT most commonly occurs in the setting of DVT prophylaxis or in patients receiving long-term therapeutic anticoagulation; however, cases have been reported after catheter flushes with doses as small as 250 IU, and in patients whose only exposure is heparin-coated central venous catheters.

HIT occurs when naturally occurring IgG antibodies bind the heparin/PF4 complex. This heparin/PF4/antibody complex binds other platelets, causing increased release of PF4 and prothrombotic particles. PF4 released from platelets binds additional heparin and IgG heparin-dependant antibodies, forming more complexes in a positive-feedback manner. Additionally, this heparin-platelet complexes and prothrombotic particles form aggregations at sites of endothelial injury. These aggregations are responsible for the two most common

clinical findings in HIT, thrombocytopenia due to consumption of platelets, and thrombus formation.

A presumptive diagnosis of HIT is based on an otherwise unexplained thrombocytopenia in a patient exposed to heparin. The gold standard for diagnostic evaluation is the serotonin release assay. This test is cumbersome, time consuming, expensive, and unavailable in many laboratories. However, its sensitivity and specificity both are very high. It is performed by radiolabeling normal donor platelets with C^{14} -serotonin. These labeled platelets are then washed and exposed to patient serum with low-dose heparin (0.1 U/ml). A positive test occurs when the patient's heparin/PF4/antibody complexes bind donor platelets and cause release of the labeled serotonin.

More commonly, an enzyme-linked immunosorbent assay (ELISA) is performed to identify heparin-dependant IgG antibodies in a patient's plasma. The sensitivity of this assay is 97%, suggesting that a negative test makes the diagnosis of HIT very unlikely; however, the specificity is only 74% to 87%, making a positive test result less useful in the clinical setting. Because many patients with heparin-dependant antibodies by ELISA do not develop HIT, the clinician must carefully consider pretest probability and interpret results accordingly. In many institutions, ELISA is used as a screening test; in the case of positive results and a high pretest probability, the serotonin release assay is used to confirm the diagnosis. Treatment of HIT is focused on the removal of all heparin, including heparin-coated central lines and, in the setting of thrombosis, initiating anticoagulation.

Anticoagulation in the setting of HIT

Anticoagulation may be required for the treatment of thrombosis associated with HIT or in the event of an emergent vascular or cardiac event. Common clinical scenarios involve a patient with either acute HIT or a recent history of HIT who develops myocardial infarction or pulmonary embolism or requires anticoagulation for cardiac or vascular surgery. Therapeutic anticoagulation may be accomplished with any of the direct thrombin inhibitors, including lepirudin, bivalirudin, argatroban, and danaparoid. It should be noted that danaparoid is not available in the United States, and that ideal dosing strategies and monitoring systems have not been fully developed for any of the aforementioned agents. Low molecular weight heparin, although it is less likely to trigger heparin-dependant antibody formation, has nearly 100% cross-reactivity with heparin-dependant antibodies; therefore, it cannot be used in the treatment of HIT.

Direct thrombin inhibitors

Lepirudin was the first direct thrombin inhibitor approved for the treatment of HIT in the United States. It is a recombinant form of hirudin, a naturally occurring protein found in the saliva of the medicinal leech *Hirudo medicinalis*. Metabolized and excreted by the kidney, massive overdose is possible in the setting of undiagnosed renal failure.

Bivalirudin is a synthetic drug designed from lepirudin. It also is approved for the treatment of HIT and has been approved for use in percutaneous coronary intervention (PCI). Metabolism occurs in the circulation by the action of plasma proteases; however, there is a renal component to metabolism and its effective half-life is prolonged in the setting of renal failure.

Argatroban is another direct thrombin inhibitor that has been approved for treatment of HIT and for PCI. It is metabolized primarily by the liver and may be a safer agent in the setting of renal failure.

Danaparoid has been approved for the treatment of HIT in many countries, including the European Union, Canada, and Australia. It is currently unavailable in the United States. It has approximately 17% cross-reactivity with heparin-dependant antibodies and therefore may trigger HIT.

Unlike the anticoagulant effect of heparin, which can be reversed with protamine and monitored with aPTT and ACT, the effects of direct thrombin inhibitors are irreversible and difficult to monitor. Bleeding time, aPTT, international normalized ratio, and ACT all show increased values with the direct thrombin inhibitors, but none has proven to be an ideal measure of adequate coagulation. When using direct thrombin inhibitors, the clinician must work with available laboratory resources to find the most suitable measure of anticoagulation.

Anticoagulation in a patient with HIT

None of the direct thrombin inhibitors has been approved for use in coronary bypass procedures; therefore, the following description describes off-label uses. The use of heparin for prophylaxis of DVT or treatment of acute thrombotic events continues to increase. The incidence of HIT is reportedly 0.3% to 2% of patients exposed to heparin. Therefore, the clinician is likely to encounter a patient needing anticoagulation in the setting of HIT. The choice of direct thrombin inhibitor must be based on the patient's medical history, with a focus on renal and hepatic function, and the familiarity of the anesthesiologist, surgeon, and perfusionist with the available drugs. Additionally, adequate laboratory services and monitoring equipment must be confirmed.

The American College of Chest Physicians (ACCP) published guidelines describing the approach to anticoagulation in a patient with HIT. The guidelines separate patients into three categories (Table 72.1). Those with a history of HIT and with negative heparin-dependant antibodies, those with acute HIT and positive antibodies, and those with subacute HIT whose platelet counts have normalized but who have positive heparin-dependant antibodies.

A starting reference for appropriate dosing regimens is listed in Table 72.2. These doses are not meant to be absolute recommendations. Actual dosing will depend on the type of monitoring device used, the need for bypass, and the specific underlying medical condition.

Table 72.1. Approach to anticoagulation in a patient with HIT

History of HIT, negative antibodies	Use unfractionated heparin Can use familiar drug and monitoring Avoid any heparin exposure before or after coronary bypass Safety is provided by the fact that heparin-dependant antibodies require 4–5 d to appear
Acute HIT, positive antibodies	Consider waiting until antibody negative Consider all available agents Review patient's medical history Lepirudin: renal metabolism Bivalirudin: metabolized by plasma proteases Some renal metabolism Argatroban: hepatic metabolism Consider familiarity of team with available agents and monitoring equipment
Subacute HIT, positive antibodies	Consider waiting until antibody negative If unable to wait, proceed as in the situation of acute HIT

Protamine

Protamine is the only widely available agent for the reversal of heparin. Protamine is a polycationic compound derived from salmon milt. The mechanism of action involves the formation of ionic bonds with free circulating heparin, which prevents the binding of antithrombin. It is unclear what if any effect protamine has on heparin that has already bound to thrombin. Protamine is usually dosed at 1 mg/100 U of heparin to be reversed. Caution must be used in the administration of protamine. If rapidly infused (>50 mg/10 min), hypotension may result from histamine released from mast cells. Additionally, protamine has been implicated in both allergic and anaphylactoid reactions.

IgE-mediated allergic reactions may occur in any patient who previously received protamine. IgG-mediated anaphylactoid reactions may be life threatening, leading to vasoconstriction, pulmonary hypertension, and possible right heart failure. If typical clinical manifestations of protamine reaction occur, including hypotension, urticaria, flushing, bronchospasm, pulmonary edema, or right heart failure, the initial treatment is to immediately stop the protamine infusion and institute supportive therapy.

Hypotension may be treated with volume expansion and an α -agonist such as phenylephrine or norepinephrine. Epinephrine may be required to support right ventricular function, and nitrates may be used in the setting of pulmonary hypertension. After hypotension related to histamine release is treated with fluids and pressor agents, protamine can usually be restarted and slowly infused. However, in the case of allergic or anaphylactoid reaction, protamine may be contraindicated. This has led to increasing research into agents that may be used to reverse heparin. Presently researched alternatives to protamine include heparinase, recombinant PF4, hexadimethrine, and dialysis-like heparin removal devices.

Antifibrinolytics

There are several drugs commonly in use that inhibit fibrinolysis. Aprotinin, a nonspecific protease inhibitor, and the lysine analogues tranexamic acid and aminocaproic acid are discussed in this chapter.

Aprotinin is a serine protease inhibitor that has intrinsic procoagulant effects as well as antifibrinolytic and anti-inflammatory effects mediated via its actions on thrombin, kallikrein, plasmin, and other chemical mediators. It is derived from bovine lung tissue and has been implicated in anaphylaxis and anaphylactoid reactions that have led to mortality. Exposure may lead to formation of IgG antibodies, and repeat exposure within 12 months is relatively contraindicated. It is administered most often for cardiac surgery in patients with increased risk of bleeding. Facilities should always be in place to treat precipitous hypotension, anaphylaxis, and circulatory collapse prior to administering aprotinin. It is recommended that a 1-ml test dose be given 10 minutes before additional dosing. Standard dosing varies between 1,000,000 to 2,000,000 kallikrein-inhibiting units (KIU) over 20 to 30 minutes, followed by an infusion of 250,000 to 500,000 KIU/h for the duration of surgery. Aprotinin has been associated with an increased incidence of perioperative renal failure and mortality; consequently, its current availability is exceptionally limited.

The two commonly used lysine analogues are aminocaproic acid (5-g loading dose over an hour, then 1 g/h up to 8 hours) and tranexamic acid, which share a common mechanism of

Table 72.2. Dosing regimens of alternate drugs

Drug	Half-life	Elimination	Dose	Notes
Argatroban	39–51 min	Hepatic	PCI 2–3 μ g/kg/min CPB 5–10 μ g/kg/min	Unavailable in US Ab cross-reactivity
Danaparoid	~25 h	Renal	Not clearly defined	
Lepirudin	~80 min	Renal	Bolus, 0.25 mg/kg Infusion, 0.5 mg/min	
Bivalirudin	25 min	Plasma proteases	Bolus, 1.5 mg/kg Infusion, 2.5 mg/kg/h	

Ab, antibody; CPB, cardio pulmonary bypass; PCI, percutaneous intervention.

action. Most often given in the setting of cardiac surgery, or in the treatment of bleeding following oral or urologic surgery, lysine analogues are competitive inhibitors of lysine binding sites located on plasminogen and fibrinogen. They inhibit the formation of plasmin and inhibit fibrinolysis. Caution should be used in the setting of renal disease; dose reduction may be considered. Lysine analogues have been known to cause transient hypotension with rapid intravenous administration.

Coronary artery bypass grafting utilizing cardiopulmonary bypass

Theresa S. Chang and John A. Fox

Introduction

The introduction of cardiopulmonary bypass (CPB) techniques in the 1950s helped facilitate surgical treatment of congenital and valvular heart disease. Surgical treatment of coronary artery disease using the heart–lung machine was pioneered in the 1960s when surgeons bypassed obstructive coronary artery lesions using saphenous veins or left internal mammary arteries as conduits. In the recent decade, technologic advances in surgical instrumentation have paved the way for surgeons to employ novel techniques to graft obstructed coronary lesions, ranging from robotic and port access surgery, in which small incisions are placed in the chest, to avoiding use of the heart–lung machine entirely in so-called off-pump coronary artery bypass graft (CABG) surgery or by transmyocardial laser revascularization. However, because surgical treatment of coronary artery disease in most patients still requires use of the heart–lung machine, this chapter focuses on the anesthetic management of CABG while on CPB. In addition to CABG procedures, CPB has been used for surgical procedures such as cardiac valve repair or replacement; repair of congenital heart defects, aneurysms, septal defects; and heart transplantation.

The American College of Cardiology and the American Heart Association reviewed the literature on studies related to CABG and put together guidelines outlining the indications for the procedure. These include (1) significant left main coronary artery disease; (2) left main equivalent, defined as 70% stenosis of both the proximal left anterior descending artery (LAD) and proximal left circumflex artery (LCA); and (3) multivessel disease (with a greater survival benefit in those with normal left ventricular function, defined as a measured left ventricular ejection fraction > 50%). For those with stable angina, indications for surgery are broadened to include (1) two-vessel disease with significant proximal LAD obstruction, (2) one- to two-vessel coronary artery disease without proximal LAD stenosis but with a large area of viable myocardium at risk; and (3) severe, incapacitating angina despite maximal medical therapy.

Coronary artery anatomy

To understand coronary revascularization, one must first understand coronary artery anatomy (Fig. 73.1). The left main coronary artery (LMCA) and the right coronary artery (RCA)

originate from the aortic root. The LMCA divides into the left anterior descending coronary artery (LAD) and left circumflex coronary artery (LCA). The LAD divides further to the diagonal and septal branches, providing blood to the anterolateral portion of the heart, the interventricular groove, and the His–Purkinje system. The obtuse marginal branches coming off of the LCA, supply blood to the lateral free wall of the left ventricle. The RCA splits off into the acute marginal branches, which perfuse the anterior wall of the right ventricle. In most patients, the RCA gives rise to the posterior descending artery (PDA), providing blood to the posterior portion of the left ventricle. These patients are considered to have a right dominant system. In the remaining patients, the PDA comes off the LCA and therefore is classified as having a left dominant system. Rarely, the PDA can arise from both the LCA and RCA and be classified as a codominant system.

Myocardial oxygen supply and demand

Cardiac function depends on maintaining a balance between oxygen supply and demand. Increasing myocardial contractility, heart rate, or myocardial wall tension increases the oxygen demand of the heart, whereas myocardial oxygen supply is decreased by decreasing coronary artery blood flow, arterial oxygen content, or oxygen extraction. Heart rate and end-diastolic pressure are on both sides of the supply–demand equation. Thus, any increase in heart rate and end-diastolic pressure (volume) decreases myocardial oxygen supply while increasing myocardial oxygen demand.

Monitoring

In addition to the standard American Society of Anesthesiologists monitors, specialized monitors are used in CABG patients to help guide perioperative management. A Foley catheter measures urine output throughout the procedure. Five-lead electrocardiographic (ECG) monitoring allows for the discernment of arrhythmias, as well as the detection of more than 90% of all ischemic events if leads II and V5 are used. Arterial blood pressure monitoring permits assessment of beat-to-beat perfusion and provides a port for frequent arterial blood gas (ABG) and other laboratory measurements. Central line placement provides available ports for vasoactive medication

Figure 73.1. Coronary artery anatomy

administration; the transduction of a central venous pressure waveform can provide an assessment of volume status. In more complex patients with cardiac failure or pulmonary hypertension, a pulmonary artery catheter may be placed to evaluate ventricular filling pressures, pulmonary vascular resistance, cardiac output, core temperature, and mixed venous oxygen saturation. It may also be used for transvenous pacing. Although a transesophageal echocardiogram (TEE) is not essential in all patients undergoing a CABG, in those with baseline ventricular dysfunction (left ventricular ejection fraction $<40\%$) or valvular disease, it may be a useful tool to detect new wall motion abnormalities, areas of ischemia, or changes in valve function. The electroencephalogram or cerebral saturation may be used to monitor the well-being of the brain, and both have been used in situations in which deep hypothermic circulatory arrest is warranted to place a graft on a diseased aorta.

Perioperative management

Induction of anesthesia

Debate on the proper type of anesthetic agent to induce a patient undergoing CPB surgery has steadily evolved throughout the years. Early in the advent of cardiac surgery, barbiturates and inhalational agents were commonly used, in the first cardiac surgical patients of Gibbon and Lillihei in the 1950s. As monitoring techniques became more advanced, the need for achieving hemodynamic stability and preventing myocardial depression became recognized.

As time passed, observations were made that sedating post-cardiac surgical patients in the intensive care unit on a morphine regimen of 0.5 to 3 mg/kg provided little derangement in hemodynamic measurements. In 1969, Lowenstein et al. published hemodynamic observations based on patients undergoing cardiac surgery who were induced with 1 mg/kg of morphine, which validated the relative safety of its use, ushering in the era of a high-dose narcotic technique for these patients. This type of anesthetic was not optimal, however, because patients still had inadequate anesthesia and hypotension, likely related to the histamine effects of morphine, and required large volumes of fluid and blood perioperatively.

In the late 1970s, a fentanyl-based anesthetic was used by Stanley and Webster for inducing cardiac surgical patients and gradually supplanted the use of morphine for an opioid-based induction agent. When first used as a total anesthetic with a relaxant and a benzodiazepine, doses of up to 100 to 150 $\mu\text{g}/\text{kg}$ of fentanyl comprised the total anesthetic. This technique produced hemodynamic stability and allowed a prolonged recovery time so that the heart could recuperate from the effects of CPB and achieve homeostasis. Rarely were these patients extubated the day of surgery. In the past decades, however, studies have suggested that heavy postoperative sedation does not change outcomes. It was soon appreciated that patients in the younger age range with normal ventricles who underwent an uncomplicated operation could be extubated sooner (with a potential increase in patient satisfaction and decrease in resource utilization). Thus, “fast-track” anesthesia was synonymous with the goal of having patients extubated and recuperated early,

Table 73.1. Effects of anesthetics on hemodynamics

	Contractility	Rate	Afterload (SVR)	Blood pressure	Comments
Intravenous induction agents					
Propofol	↓	↑	↓	↓	Dose-dependent BP decrease, mostly secondary to decrease in contractility and SVR
Thiopental	↓	↑	↓	↓	Decreased SVR leads to venous pooling and preload with reflex tachycardia
Etomidate	–	–	↓	↓	Decline in MAP and SVR minimal compared with other agents
Ketamine	↑	↑	↑	↑	Not typically used unless tamponade is an issue
Benzodiazepines	–	↑	↓	↓	Hypotensive effect is dose-dependent, slow onset time
Fentanyl	↓/-	↓	–	↓	Previously used in large doses to achieve hemodynamic stability
Volatile agents					
Desflurane	↓/-	↑	↓	↓	Potential myocardial protection with desflurane use
Isoflurane	↓/-	↑	↓	↓	Theories of coronary steal unproven
Sevoflurane	↓/-	↑	↓	↓	Useful for inhalation induction

BP, blood pressure; MAP, mean arterial pressure.

which was advocated for CABG patients without complications. In some institutions, all patients are administered a fast-track cardiac anesthetic protocol and the decision to ventilate a patient overnight is based on the surgery or the postoperative course. An anesthetic technique using 10 to 15 $\mu\text{g}/\text{kg}$ of fentanyl combined with etomidate or thiopental for induction and an inhalational agent for maintenance is used in many institutions. Recently, anesthetics such as propofol, remifentanyl, sufentanyl, dexmedetomidine, and desflurane have been used to allow extubation within the first few hours post cardiac surgery. Multimodal approaches with intrathecal opioids or thoracic epidural analgesia also may be used in the CABG patient, but only after discussion with the surgical and intensive care unit teams.

Any technique can (and has) been used safely and successfully in caring for cardiac surgical patients; therefore, whatever anesthetic is chosen, one must first understand the pathophysiology of the disease process for which the patient requires surgery and must treat the hemodynamic consequences accordingly. The hemodynamic effects of intravenous agents and selected inhalational agents are summarized in Table 73.1.

Effects of anesthetics on hemodynamics

A thorough understanding of the effects of anesthetic agents is crucial, because the anesthesiologist must anticipate the physiologic consequences of the medications administered to prevent imbalances in the myocardial oxygen supply–demand ratio.

Anesthetic management prior to CPB

After the induction of anesthesia, the anesthesiologist must be aware of the sequence of events leading up to a patient being safely placed on CPB. After prophylactic antibiotics are administered, antifibrinolytics are administered to prevent the onset of primary fibrinolysis triggered by CPB. Aminocaproic acid is given at a bolus of 5 to 10 g followed by an infusion at

1 g/h. If tranexamic acid is used, then a bolus of 10 mg/kg is given, followed by an infusion at 1 mg/kg/h. Aprotinin is an antifibrinolytic that previously was popular for its effectiveness in decreasing perioperative blood loss and transfusion requirements (especially for those at high risk for perioperative bleeding). In the past few years, however, its use has fallen out of favor because of the potential increased risk of renal failure, myocardial infarction, and stroke, as well as the increased mortality rates compared with the other lysine analogues.

During the maintenance of anesthesia, one must be able to anticipate the times high levels of stimulation are about to take place versus the times low levels of stimulation will occur. Periods of high sympathetic stimulation (incision, sternal split/spread, aortic cannulation) must be foreseen and managed so that tachycardia, dysrhythmias, hypertension, and heart failure can be prevented, because these alterations ultimately increase the myocardial oxygen demand and decrease the myocardial oxygen supply. In particular, during aortic cannulation, most surgeons prefer that the systolic blood pressure be dropped to below 100 mm Hg to prevent an aortic dissection or excessive bleeding during cannulation. At this time, a sufficient level of anesthetic must be achieved. If this is not enough to blunt the sympathetic response, then the administration of β -blocking agents or other blood pressure-lowering agents (venodilators such as nitroglycerin or nitroprusside) may be warranted. Doses of at least 20 $\mu\text{g}/\text{kg}$ of fentanyl are commonly given preemptively to blunt the response. The patient's hemodynamic status should be thoroughly monitored with arterial pressures, central venous pressures, pulmonary artery pressures, mixed venous oxygen saturations (if applicable), and TEE. During times of low-level stimulation (saphenous vein graft/internal mammary harvesting), the pressure may decrease, and perfusion to the coronaries might be compromised, with resultant signs of ischemia. In this situation, one may add back sympathetic tone with phenylephrine

or ephedrine or simply increase intravascular volume to bring the blood pressure to the desired level. Should ischemia occur persistently despite optimal anesthetic and hemodynamic management at any time before bypass, the surgical team should be informed and a discussion should take place regarding whether to initiate bypass or place an intra-aortic balloon pump. Should this need arise, it is essential that communication regarding the level of heparinization take place prior to cannulation. If a retrograde cardioplegia cannula is placed in the coronary sinus, the blood pressure should be watched vigilantly for sudden declines due to manipulation of the heart. If sudden hypotension occurs after securing the cannula, the differential diagnosis includes blood loss, compression of the heart, dysrhythmias, systemic embolization of clot/air, and aortic dissection. After the retrograde catheter is placed, the waveform should be transduced to assure proper placement and for pressure monitoring during bypass. Oftentimes, if a TEE is placed, the retrograde cannula placement can be confirmed by echoing the coronary sinus.

For repeat CABG operations, blood should be immediately available in case there is inadvertent damage to the right ventricle or grafts adherent to the sternum. In many of these patients, cannulation of the femoral vessels might be performed prior to the sternotomy, so that the patient can be placed on partial CPB. Oftentimes, this will allow the empty heart to fall away from the sternum, facilitating a safer sternotomy. Again, a proper level of heparinization should be confirmed with an intraoperative coagulation measurement.

Heparin is administered for anticoagulation prior to CPB to prevent clot formation in the CPB circuit and is monitored by checking either the activated clotting time (ACT) or heparin levels (depending on the bedside device used at each institution). An ACT level of at least 300 seconds is required before initiating CPB if the circuits are coated with a heparin/anticoagulation surface or from 400 to 480 seconds if no anticoagulation coating is used. Different institutions have different target levels. Cannulation and institution of CPB must not be performed unless adequate anticoagulation is confirmed. Anticoagulation is checked at regular intervals during CPB, and additional heparin is administered if necessary. If resistance to heparin becomes an issue, then the patient most likely has an antithrombin III deficiency. If antithrombin III is low, there is not enough of this serine protease, which irreversibly inactivates thrombin and other factors, to bind to heparin and cause adequate anticoagulation. Patients with this deficiency must then be administered fresh frozen plasma, antithrombin III concentrate, synthetic antithrombin III, or a recombinant form of the molecule. However, if the patient has a history of heparin-induced thrombocytopenia, then alternate anticoagulants such as hirudin, bivalirudin, or argatroban can be administered, because exposure to heparin might cause thrombocytopenia, with a potential for thromboembolism.

After adequate anticoagulation is achieved and the patient is cannulated, one may review the pre-CPB checklist to ensure that a patient is ready to go on CPB (Table 73.2).

Table 73.2. Pre-CPB checklist

A	Anticoagulation: Is it adequate (ACT > 300 s); anesthetic depth: Is it appropriate? (Need for hypnotic, neuromuscular blocker? Good MAC of volatile anesthetic?)
B	Blood: What was the most recent Hct? Should packed RBCs be included in the pump prime?
C	Cannulas: Are they working appropriately? Catheters: Are the monitors in place, functioning well? Pulmonary artery catheter should be pulled back a couple of centimeters to prevent a pulmonary artery rupture? Are transducers zeroed?
D	Drips: are they off?
E	Eyes: Note baseline pupil size for comparison, rule out neurologic complications, edema
F	Foley: Is the bag emptied (to ensure good urine volume while on CPB)?
G	Glucose: What is the most recent level? Should insulin be started?

Hct, hematocrit; MAC, minimum alveolar concentration; RBCs, red blood cells

CPB

The CPB circuit and heart–lung machine are complex tools used in cardiac surgery to give the surgeon a quiet (nonbeating) bloodless heart so that an efficient and effective operation may be performed. The heart–lung machine mechanically maintains systemic circulation, oxygenates the blood, and allows for carbon dioxide elimination. In addition, it provides for the rapid cooling and rewarming of blood.

The CPB machine has the following components (Fig. 73.2):

1. **Venous reservoir:** Venous blood is drained either by gravity or by suction from the right heart. Venous blood enters the CPB circuit via a cannula placed in the right atrium, superior vena cava (SVC), inferior vena cava (IVC), or femoral vein, and travels to the reservoir, where other fluids and medications can be mixed. *Total CPB* occurs when all the venous return goes to the venous reservoir. This occurs only when tourniquets are placed around the SVC and IVC. *Partial CPB* occurs when only a portion of blood bypasses the heart, but the rest is allowed to enter the pulmonary circulation.
2. **Oxygenator:** Blood is pumped from the venous reservoir to an artificial membrane that allows the diffusion of oxygen and anesthetic agents to the blood, and elimination of carbon dioxide.
3. **Heat exchanger:** A heat exchanger allows cooling and warming of the blood.
4. **Arterial filter:** It is used to prevent air and unwanted debris from being returned to the patient, and is the last device placed in the circuit before blood returns to the patient.
5. **Venous blood pump (arterial pump head):** This pump forces venous blood through the membrane oxygenator and then to the patient's aortic root or arterial system. The venous blood pump is the "heart" of the heart–lung machine.

Figure 73.2. Essential components of a cardiopulmonary bypass circuit.

6. **Cardiotomy pump:** This separate device in the pump allows blood to be returned to the heart–lung machine instead of being placed in the disposal reservoir. There are usually two cardioplegia or “waste” pumps in a heart–lung machine.
7. **Cardioplegia:** This separate pump head is used to deliver solutions (usually high potassium) to arrest the heart during aortic cross-clamping.
8. **Monitors:** The perfusionist is trained to set up several pressure monitors within the circuit, level detectors on the venous reservoir that provide a feedback loop to lower the flow if the reservoir decreases and to calibrate saturation or blood gas monitors within the circuit.

9. **Tubing:** The tubing and connectors through which blood flows may be coated with a heparin-like material or they may be plain polyvinyl chloride.

An understanding of the physiologic effects of CPB allows for optimal perioperative management of patients undergoing cardiac surgery. The physiologic effects of CPB are shown in Fig. 70.3.

1. **Change in blood flow:** Systemic blood flow is dialed by the machine. Generally, blood flow is maintained at 2.5 L/min/m² to meet the metabolic needs of an anesthetized patient. Maximal flow is limited by the venous return, which is a function of the patient’s venous capacity, or in

Figure 73.3. Physiologic effects of CPB.

institutions where gravity drains the right heart, can be determined by the difference in height between the operating room table and the bypass reservoir. Resistance of the venous and arterial cannulas, extracorporeal circuit, and vasculature also plays a role.

2. Change in pulsatility: When transitioning from the systemic circulation to the CPB machine, pulsatile flow stops. Potential advantages of persistent pulsatility include enhanced lymphatic flow and tissue perfusion, as well as a decreased neuroendocrine response. Although theoretically it would be better to maintain flow in the extracorporeal circulation nearly physiologic, there is still controversy over whether the proposed benefits really make a difference in outcomes. For this reason, and because methods of producing pulsatile flow are complex

and expensive, focus has turned away from achieving pulsatile flow during bypass in many centers.

3. Interaction between blood and nonphysiologic surfaces compounded by shear stresses: Initiation of CPB triggers many potential causes of adverse hematologic and inflammatory responses. An increase in shear stress causes red blood cells to become stiffer and more vulnerable to hemolysis. Neutrophil concentrations initially decrease while a patient is on the heart–lung machine, but then may rebound during rewarming. Complement is activated, and the production of anaphylatoxins from ischemia reperfusion injury causes a systemic inflammatory response. As a result, there is a decrease in systemic vascular resistance and increased capillary permeability.

Platelets are activated, degranulated, and basically rendered nonfunctional by the heart–lung machine.

4. Exaggerated stress response: Because CPB is not a natural phenomenon for the body, high concentrations of catecholamines such as epinephrine, norepinephrine, and adrenocorticotropic hormone are secreted into the circulation. Not only does this affect end-organ blood flow patterns, it also causes increased metabolic requirements and potential tissue breakdown. Hyperglycemia is common in both diabetics and nondiabetics. Thus, strict glucose monitoring and control become necessary.
5. Temperature change: Hypothermia (both systemic and myocardial) decreases myocardial oxygen consumption. Myocardial hypothermia is achieved by the administration of cold cardioplegia in the aortic root (i.e., antegrade cardioplegia) while the aorta is clamped, or in the coronary sinus (known as retrograde cardioplegia). Placing chilled saline or ice directly on the heart may allow topical cooling. Systemic cooling can be achieved with the blood heater/cooler device in the machine. Lower oxygen consumption from hypothermia should result in a lower mixed venous O₂ saturation on CPB.
6. Hyperkalemia: Cardioplegia high in potassium concentrations is used to achieve cardiac arrest. Although such high levels are anticipated during CPB, if high potassium levels persist after the patient is taken off CPB, treatment with calcium chloride or glucose and insulin may be helpful. Potassium also may be shifted into cells by hyperventilation or bicarbonate administration.
7. Hypotension: This results from several factors at the initiation of CPB that cause a decrease in systemic vascular resistance:
 - The administration of priming fluid (usually 800–1500 ml of crystalloid) decreases blood viscosity by hemodilution. Normally, the hematocrit during CPB is between 20% and 25%.
 - Dilution of systemic catecholamines
 - Temporary hypoxemia from asanguinous fluid
 - Fluid that has a low pH, and low levels of calcium and magnesium

Management of patients on CPB

Once CPB has been initiated, the cardiac output is determined by the pump flow rate, which is controlled by the perfusionist. Because all respiratory functions are also controlled by the machine, ventilation of the lungs is stopped, allowing a quiet operating field for the surgeon.

ACT is frequently monitored to ensure adequate anticoagulation while on CPB. Arterial blood gases should be checked every 30 to 60 minutes to monitor for appropriate oxygen and CO₂ levels. Electrolytes, hemoglobin, and blood glucose levels should also be monitored and treated accordingly. Although

a degree of hyperkalemia is typical secondary to cardioplegia administration, potassium levels should be normalized by the time a patient is ready to be weaned from CPB.

Inhalational agents may be administered via the bypass circuit, and intravenous anesthetics may be given via an infusion. Monitoring of neurologic function may be helpful in assessing anesthetic depth.

Urine output should be monitored, and if oliguria occurs, increasing the flow rate or administration of an osmotic (mannitol) or loop diuretic (furosemide) may be considered. Temperature should be checked regularly from different sites. The core temperature monitors organs that are well perfused (bladder, nasopharyngeal probes); rectal and skeletal muscle sensors measure the shell temperatures, which may lag behind core temperature changes secondary to hypothermia-induced vasoconstriction. The pulmonary artery catheter temperature cannot be used while on CPB because of lack of blood flow through the heart. The esophageal temperature readings also may not be accurate because of the addition of ice or cold saline to the thoracic cavity during CPB.

Circulatory arrest

Circulatory arrest is used during surgery that may involve the cerebral vessels originating from the aorta, or when a severely diseased aorta cannot be cross-clamped. During circulatory arrest, the patient's systemic temperature is decreased to 15°C to 18°C. This degree of hypothermia is crucial for decreasing the cerebral metabolic rate while flow to the body is stopped. Some clinicians advocate topical hypothermia by wrapping a towel around the head and then icing the head. Additionally, some clinicians administer medications such as sodium thiopental to achieve electroencephalographic suppression), steroids (methylprednisolone, 30 mg/kg) for cerebral protection, and mannitol (25g/kg) for end-organ and renal preservation. However, few data support the benefits of these aforementioned medications, whereas the consensus is that only profound hypothermia and the shortest possible time while in circulatory arrest are actually known to prevent ischemic organ damage. During ascending and aortic arch surgery, some surgeons give antegrade cerebral perfusion to provide intermittent cerebral flow and oxygenation, thus prolonging the allowable time for repair. Other surgeons may prefer the use of retrograde cerebral perfusion through the SVC.

ABG monitoring

When monitoring ABGs, clinicians must understand the basic principles of temperature correction. Because there usually is a difference in temperature between the ABG machine and the patient, the results may vary. This is based on the idea that as the temperature of blood decreases, oxygen and carbon dioxide become more soluble. As a result, the partial pressure of the two gases decreases. Another consequence is that less water is dissociated into OH⁻ and H⁺, causing an elevation in the pH. During analysis of the blood sample, however, the temperature of the ABG machine is higher compared with that of blood. This

Table 73.3. Arterial blood gas interpretation: pH-stat vs Alpha-stat

Parameter	pH-stat viewed by alpha-stat	Alpha-stat viewed by pH-stat
CO ₂	↑	↓
pH	↓	↑
Condition	Respiratory acidosis	Respiratory alkalosis

elevated temperature decreases the solubility of gas in the blood, causing the sample to have falsely elevated partial pressures of CO₂ and O₂. The pH also is falsely lowered, because more H⁺ dissociation occurs with the higher temperature. Temperature correction takes the machine's values and corrects them to what the patient is actually experiencing in vivo. Two methods have been executed to manage patients undergoing CPB. In the pH-stat approach, CO₂ is added to the inspired gases to keep the *corrected* CO₂ level at 40 mm Hg. This in turn normalizes the pH. In the alpha-stat approach, nothing is added. It is thought that at the low in vivo temperature, although there is less dissociation of H⁺, there is an equally decreased amount of OH⁻ dissociation. Electrochemical neutrality is thus maintained. In this method, the constant charge (of the amino acids in proteins) is preserved and homeostasis is kept. This allows the patient's *uncorrected* PaCO₂ and pH to be kept at normal levels. Table 73.3 shows the perspective of each method when viewed by the alternative approach.

It has been theorized that alpha-stat management might be preferential in patients undergoing CPB. This is based on the suspicion that cerebral blood flow, and therefore the risk of embolization, would increase with the addition of CO₂ in pH-stat management, because CO₂ causes cerebral vasodilation. With alpha-stat management, however, cerebral autoregulation is preserved. Because infants with congenital heart disease undergoing CPB with deep hypothermic circulatory arrest do not have atherosclerosis, the risk of embolization is extremely low. pH-stat is commonly used in this population because increased cerebral perfusion becomes the primary concern. However, studies have not shown improved long-term neurologic outcomes with either strategy.

Rewarming

Adequate time for rewarming is necessary when preparing for weaning from CPB. If the rewarming process is too fast, there is a risk of creating temperature gradients between the well-perfused organs and those that are vasoconstricted. The administration of vasodilators (e.g., nitroglycerin) can circumvent this and helps speed up the rewarming process. Rapid rewarming also may cause the formation of gas bubbles, as gas solubility decreases with increasing temperatures. During this time, because the patient's metabolic activities also escalate, intravenous medication (opioids, benzodiazepines, or muscle relaxants) is administered to provide additional anesthesia, because

the risk for recall is greatest then, unless an intravenous anesthetic was instituted at the start of CPB. As the patient's temperature rises and the aortic cross-clamp is removed, the heart's electrical activity resumes as the heart is filled with blood. A TEE may be used to evaluate for air, new valvular disease, or change in myocardial function. The ECG is assessed for ST-segment abnormalities, especially the right coronary artery – leads II, III, aVF – because it is positioned at the superior aspect of the heart and is thus vulnerable to air entrainment. If ventricular tachycardia or fibrillation is seen, the heart should immediately be defibrillated with internal paddles. A pacemaker may be used to assist with cardiac output if the heart rate is low or if the rhythm is irregular. Communication with the perfusionist about vasopressor requirements on CPB may indicate the need for intravenous support while coming off bypass. Ventilation is resumed once blood flow is permitted through the respiratory circulation.

Management of patients during the post-CPB period

Weaning from CPB is a gradual process in which 100% of the mechanical work is transitioned from the CPB machine to the patient's own heart. Assessment of whether the patient can tolerate weaning from CPB is crucial. The patient's physiologic variables must be analyzed and optimized quickly. Core temperatures should be at least 36°C. A vasodilator should also be available in case hypertension develops or new ECG changes ensue. Laboratory values should be adequate (without anemia, acid–base, or electrolyte abnormalities), and a stable rhythm should be present. A heart rate of 80 to 100 bpm is usually necessary to ensure adequate cardiac output (paced or otherwise), because otherwise there is a decreased ability to increase stroke volume post CPB. Coronary arteries that are grafted have a more favorable oxygen supply/demand ratio, so ischemia should not be an issue at higher rates. If the heart rate is > 120 bpm, however, the etiology should be identified and treated quickly, because too high a heart rate may prevent left ventricular filling. If ST changes occur, nitroglycerin should be initiated and the surgeon informed. If hemodynamic compromise is anticipated because of either poor ventricular function preoperatively or an inability to obtain complete revascularization, inotropic or vasopressor support may be started. Central filling pressure monitoring and TEE assessment can determine the need for volume or pharmacologic support. TEE monitoring is especially useful in evaluating for new regional wall motion abnormalities indicative of ischemia. If the cardiac function is insufficient despite the infusion of inotropes, the surgeon may reexamine the grafts either on or off CPB. If the grafts are patent but the patient is still showing signs of ventricular failure, then a discussion of initiating intra-aortic balloon pump (IABP) or other mechanical devices should be considered.

If, however, all the aforementioned criteria have been met, the following sequence of events will occur:

1. Prevention of venous flow back to the pump
 - The venous line is partially occluded by the surgeon or perfusionist.
 - Blood flow from the right atrium to the right ventricle increases.
 - Partial bypass is attained because some of the blood goes to the CPB machine and some goes to the heart.
 - Assessment is made about optimal preload (either by TEE or by central venous and pulmonary capillary wedge pressures).
2. Decrease of pump flow into the aorta
 - The perfusionist gradually reduces the pump flow rate as the patient's own heart is able to maintain its own cardiac output.
3. Termination of bypass
 - The CPB pump is stopped when the heart can maintain adequate systolic pressures at acceptable preloads.

After the termination of CPB, blood from the pump is usually administered in 50- to 100-ml increments to increase preload. The blood pressure and filling pressures need to be monitored closely. Volume is given slowly to avoid overdilation of the heart and to prevent inadvertent emptying of the venous reservoir. Slow volume administration should increase the cardiac output in the best circumstances. If this is not the case, one should consider investigating for the following: (1) ongoing blood loss, (2) vasodilatory effects from rewarming or systemic inflammatory response, or (3) a change in ventricular compliance. To assess that the cardiac performance is adequate, a cardiac output should be obtained and/or the TEE reviewed. Review of the physiologic variables helps determine which adjustments need to be made in the inotrope/vasopressor infusions and/or volume administration. Once it is safe to proceed, the venous and aortic cannulas can be removed. The aortic cannula can be removed when approximately half the protamine dose has been given.

Protamine administration

Protamine is given to reverse anticoagulation. Post-CPB ACT and heparin levels are evaluated to verify adequate reversal. Protamine is a large negatively charged protein from salmon known as a histone binding the DNA in the salmon sperm. It gets its negative charge from high numbers of the amino acid arginine, and hence will bind the positively charged heparin molecule. Once the heparin-protamine complex is formed, it is thought that the reticuloendothelial system removes this complex.

The protamine dosage varies from practice to practice, with a standard dose of 1 mg/100 U of heparin given for initial heparinization. Some practices use an automated heparin-protamine titration system (used to calculate heparin dosage to specific ACT by applying patient volume algorithms). This helps determine the amount of circulating heparin present at the end of bypass and hence the amount of protamine needed to bring

the heparin levels back to zero. Use of this system usually results in less protamine being administered.

Adverse reactions to protamine are usually divided into three groups as a result of several different mechanisms. The first is defined as a nonimmunologic reaction known as an anaphylactoid reaction. Because the protamine molecule is a large heterogenous protein, its rapid infusion may cause a decrease in blood pressure by either vasodilation or a direct decrease in myocardial contractility and is the reason some practices advocate that protamine be given slowly over a 5- to 10-minute period. This reaction can mimic a true anaphylactic reaction.

Anaphylactic reactions to protamine imply that they are IgE mediated and therefore require the patient to have seen the molecule previously. True anaphylactic reactions to protamine in the patient after weaning from the heart-lung machine are characterized by arterial hypotension, low central venous pressure, and low left atrial pressure. Histamine levels in these patients are noted to be elevated. Patients considered at risk for a protamine reaction have included diabetics on NPH insulin (which contains protamine) and patients who have had prior catheterizations, fish allergies, or vasectomies. The evidence that patients with these risk factors will have a protamine reaction is very poor, but most clinicians believe the group at highest risk is diabetic patients. For this rare event, it has been advocated that a small test dose be given prior to administering the full dose.

The last adverse protamine reaction is a catastrophic pulmonary vasoconstriction. In this group of patients, it was noted after protamine administration that the arterial blood pressures and left atrial pressures were low and the central venous pressures were elevated. Unlike the patients who experienced anaphylactic reactions, the histamine levels drawn from these select patients were low. An animal model of this reaction noted that the large heparin-protamine complexes activated complement. This in turn induced pulmonary macrophages to produce thromboxane, ultimately causing pulmonary artery vasoconstriction and right ventricular failure.

Treatment of protamine reactions immediately post bypass depends on the severity. Protamine administration needs to be stopped, supportive therapy (epinephrine with histamine blockers) instituted, and a return to cardiopulmonary bypass (after reheparinization) considered. If bypass is reinstated, an attempt to reverse the heparin with another protamine dose can be done after treatment with histamine H₁ and H₂ blockers and steroids. If another protamine reaction occurs, heparin reversal should be avoided and the bleeding patient should be supported with factors until the heparin is metabolized.

Fortunately, protamine reactions are rare, and because they are rare, pretreatment is not advocated in all patients who undergo cardiopulmonary bypass.

Laboratory assessment post CPB

ABGs should be monitored to ensure adequate ventilation/oxygenation and to be aware of any acid-base or electrolyte abnormalities. A hemoglobin level is also checked to estimate

the need for cell saver or red blood cell administration. A complete blood count, chemistry panel, and coagulation studies are sent for analysis. If nonsurgical bleeding occurs even if thrombocytopenia is not evident, platelets may be administered because platelet dysfunction is the most prevalent cause of hemostatic abnormalities after CPB. If the coagulation panels are abnormal and there is clinical evidence of a significant coagulopathy, fresh frozen plasma and/or cryoprecipitate may be given to treat factor deficiencies or low fibrinogen.

Failure to wean off CPB

A need for inotropic support during separation from CPB may be anticipated if a patient presents with the following risk factors: a combined CABG/MV repair or MV replacement, a left ventricular ejection fraction <35%, a reoperation, moderate to severe mitral regurgitation, and a long aortic cross-clamp time. If after the administration of fluids/blood and pharmacologic support the patient still has left or right ventricular failure, then a differential diagnosis must quickly be reviewed and managed appropriately. Common causes of failure to wean off CPB are listed below.

Contractility Left or right ventricle	<ul style="list-style-type: none"> • Insufficient cardioplegia/ischemic injury leading to myocardial stunning/diastolic dysfunction • Embolic (air/atheroma) • Thrombotic (early graft occlusion) • Graft kinking • Prolonged aortic cross-clamp • Reperfusion injury
Rate	<ul style="list-style-type: none"> • Bradycardia, causing decreased cardiac output • Tachycardia, preventing adequate filling, perfusion
Rhythm	<ul style="list-style-type: none"> • Bradyarrhythmias • Tachydysrhythmias
Afterload	<ul style="list-style-type: none"> • Vasodilatory shock secondary to systemic inflammatory response, drug reaction (protamine) • Anaphylaxis
Preload	<ul style="list-style-type: none"> • Intraoperative, perioperative blood loss secondary to coagulopathy, surgical bleeding • Inadequate fluid administration • Excess preload, leading to overdistention of the heart
Valve failure	<ul style="list-style-type: none"> • During valve procedures, the prosthesis can have a leak, mechanical obstruction • Acute ischemic mitral regurgitation (papillary muscle rupture)

After evaluation of the patient's blood pressure, filling pressures, and TEE, if any of the above are thought to occur, the etiology of hypotension should be treated accordingly with more aggressive pharmacologic support (inotropes, pressors, or vasodilatory agents if ischemia is suspected) or fluids if necessary. If a surgical cause of the cardiovascular derangement is thought to occur or if no etiology can be determined after 3 to 5 minutes after coming off bypass, then a discussion about returning to CPB should be made. This decision should not be made lightly, considering the risk of inadequate heparinization after protamine administration and hemolysis. If the decision is made to proceed back onto CPB, then a full dose of heparin should be given based on the last ACT measurement. If the issue is nonsurgical and the patient is refractory to

medical management even after the aggressive administration of inotropes and/or pressors, one may also consider the placement of an IABP. Occasionally, the placement of a ventricular assist device may be necessary to help the myocardium recover after the period of "stunning" or to serve as a bridge to heart transplantation.

Off-pump coronary artery bypass

Theresa S. Chang and John A. Fox

Experimentation with off-pump coronary artery bypass (OPCAB) surgery began in the 1960s. Since then, its practice evolved from grafting single-vessel disease to multivessel disease with the technologic development of mechanical coronary artery stabilizers (Fig. 74.1). Although the technique is more technically demanding for the surgeon, it theoretically avoids the side effects and potential complications associated with cardiopulmonary bypass (CPB), including the development of a systemic inflammatory response, which is thought to be responsible for multiple organ dysfunction. Nonpulsatile flow achieved during CPB potentially affects the microcirculation, which also may cause end-organ damage. Avoiding aortic manipulation by avoiding aortic cannulation and cross-clamping should decrease atheroma embolization and potentially decrease stroke rate and neurocognitive impairment. With these theoretic advantages to avoiding use of the heart–lung machine, it is anticipated that the recovery time, hospital stay, and costs are reduced.

Patient characteristics

Since the advent of myocardial positioning and stabilizing devices, OPCAB surgery has been performed in patients needing myocardial revascularization on multiple coronary lesions and not just in a single area on the left anterior descending artery. As OPCAB techniques have developed, indications for this operation have expanded, from patients who initially were young and without many comorbidities to those with more

critical conditions, who theoretically would benefit most. Contraindications to the procedure are shown in Table 74.1.

Surgical principles

To optimize surgical conditions for OPCAB, several goals must be met:

1. The heart must be positioned appropriately to allow good surgical exposure. Many of these devices use suction to pull the heart up by its anatomic attachments (apical and nonapical).
2. The tissues surrounding the area of focus during coronary arteriotomy must be stabilized to allow the surgeon to place vascular sutures. This also is done with suction devices or by direct local compression so that certain areas of the heart can be immobilized.

The mechanical manipulation required during OPCAB surgery makes the heart vulnerable to cardiac arrhythmias.

In addition to hemodynamic changes from mechanical cardiac stabilization, temporary target vascular occlusion may contribute to regional myocardial ischemia during the anastomosis. To allow for myocardial protection, occasionally intraluminal shunts are placed to allow perfusion of the distal vessel during graft placement. Passive coronary perfusion also may be performed, allowing blood to flow from the aorta or femoral artery to the distal coronary target vessels. Another likely superior option is active coronary perfusion, in which an inline pump increases flow to the distal vessel.

Implications for anesthetic management

The placement of monitors is similar to that in coronary artery bypass graft surgery using the heart–lung machine. Standard American Society of Anesthesiologists monitors are placed prior to induction. Large-bore peripheral intravenous access is essential to allow for the rapid infusion of volume and blood products if needed. An arterial catheter helps guide intraoperative hemodynamic challenges, provides for beat-to-beat monitoring, and allows for frequent arterial blood gas/laboratory measurements. A central line facilitates the administration of pressors and inotropes in case of hemodynamic compromise, whereas a pulmonary artery catheter enables the measurement

Table 74.1. Contraindications to OPCAB

Absolute contraindications	Relative contraindications
Hemodynamic instability	Cardiomegaly/congestive heart failure
Poor-quality target vessels including:	Critical left main disease
Intramyocardial vessels	Small distal targets
Diffusely diseased vessels	Recent or current acute MI
Calcified coronary vessels	Cardiogenic shock
	Poor left ventricular function (LVEF <35%)

MI, myocardial infarction; LVEF, left ventricular ejection fraction.

Figure 74.1. OPCAB technology in use. (A) The Medtronic (Minneapolis, MN) Octopus4 tissue stabilizer with Starfish2 heart positioner isolates and exposes the left anterior descending (LAD) coronary artery. (B) An intraluminal shunt is shown inserted and positioned across the LAD arteriotomy. The Medtronic Starfish2 heart positioner lifts the heart and exposes the posterior vessels, whereas the Octopus4 tissue stabilizer immobilizes a segment of the posterior descending artery.

of mixed venous oxygen saturation and monitoring for changes in oxygen consumption during heart manipulation, along with changes in central pressures. Transesophageal echocardiography can provide the earliest detailed information regarding myocardial ischemia, as long as images are well visualized (i.e., the heart is not malpositioned during grafting). Temperature monitoring and techniques to avoid hypothermia in the operating room must be employed.

Induction techniques are the same for those undergoing myocardial revascularization using CPB. A thorough understanding of the hemodynamic consequences of anesthetic agents as they relate to myocardial oxygen supply–demand balance is essential. “Fast-track” cardiac anesthesia is administered using a limited dose of short-acting narcotics to aid in early (1–4 hours) extubation postoperatively. Some small studies have shown that anesthetic regimens including thoracic epidural analgesia provide good results, with improved hemodynamic stability and postoperative pain control. The risk for potential epidural hematoma is still unknown, especially because some level of anticoagulation is still required in OPCAB surgery. Heparin is administered and the ACT is checked regularly to ensure adequate anticoagulation, which may vary depending on the institution, because some institutions require full heparinization as if preparing to initiate CPB, whereas other institutions use smaller doses. Toward the end of the procedure, protamine is not given, or may be given in smaller incremental doses, because acute reversal is not required. Because the heart–lung machine, with its triggering fibrinolytic processes, is not used, antifibrinolytic agents generally are not administered.

Anesthesiologists must be prepared to manage the patient promptly when surgical consequences cause sudden physiologic changes. Ensuring adequate anesthetic depth is important at the time of incision and sternotomy, when sympathetic stress is greatest. After that period, however, anesthesiologists need to prepare for immediate hypotension, preemptively giving fluids to prevent the deleterious effects from lifting and rotating the heart, reacting with inotropic support as necessary. Defibrillation pads must be on the patient, and paddles must be ready

in case arrhythmias become problematic. The surgeon must be notified immediately to stop manipulating the heart. If myocardial ischemia occurs, the patient should be managed medically until the surgical anastomosis is completed. At all times, everyone in the OPCAB room should be ready to institute CPB if the patient becomes refractory to hemodynamic manipulations. This implies that a dose of heparin to institute CPB is available and that a member of the perfusion team is present and ready to operate the heart–lung machine.

After uncomplicated OPCAB procedures, patients may be extubated immediately in the operating room if they are normothermic, are hemodynamically stable, and have no evidence of significant bleeding. Otherwise, the anesthetic technique should allow for extubation within 1 to 2 hours in the intensive care unit if extubation is not performed in the operating room.

Outcomes

Theoretic benefits of OPCAB surgery sparked a resurgence of its use in recent years. Initial studies supported a benefit of OPCAB techniques, citing decreased blood transfusion requirements, less evidence of myocardial ischemia (detected by myocardial enzyme release), diminished acute but not long-term neurocognitive dysfunction, and decreased renal insufficiency. Some studies, however, have shown a lower patency of grafts, potentially necessitating subsequent revascularization with conventional CPB techniques. It is clear that experience and comfort with the OPCAB technique among surgeons, anesthesiologists, and other essential members of the operating team are important for a successful OPCAB program. Nonetheless, due to the absence of large-scale studies that consistently show definitive improvement in perioperative morbidity and mortality associated with OPCAB versus myocardial revascularization with CPB, anesthesiologists must be familiar with managing patients undergoing either procedure.

Transesophageal echocardiography

Karinne Jervis and Balachundhar Subramaniam

Introduction

Transesophageal echocardiography (TEE) is an important tool for perioperative patient assessment, decision making, and clinical care. The goal of perioperative TEE is to allow assessment of ventricular function and volume status, regional wall motion, structure and function of valvular structures, and evaluation of the great vessels.

American Society of Echocardiography/ Society of Cardiovascular Anesthesiologists standard TEE examination

The American Society of Echocardiography (ASE)/Society of Cardiovascular Anesthesiologists (SCA) published guidelines for performing a comprehensive intraoperative multiplane TEE examination of the heart and great vessels. These guidelines emphasize 20 cross-sectional, two-dimensional views for the recommended comprehensive TEE examination (Fig. 75.1). Each view is based on the transducer location, multiplane angle, and main anatomic structures in the image.

Nomenclature

It is assumed that the imaging plane is directed anteriorly from the esophagus through the heart. Nomenclature exists as follows: A superior indication connotes that the object is in a cephalad position. An inferior position indicates the object is in a caudad direction. Posterior is toward the spine, and anterior is toward the sternum. *Left* and *right* denote the patient's left and right. Advancing the probe refers to moving the tip of the probe distally (Fig. 75.2). Turning to the patient's right refers to the movement of the probe in the clockwise rotation. Turning the probe tip to the patient's left refers to the movement of the probe in the counterclockwise rotation. Anteflexion of the probe allows for the flexing of the probe tip anteriorly with the large control wheel; whereas *retroflexing* is the movement of the tip posteriorly. Axial flexion of the probe tip can be accomplished by means of another control wheel on the probe handle and multiplane rotation from 0° to 180°. Images are displayed in the same manner as radiographic images; in addition, images are shown with transducer angle and near field of the image sector at the top of the display screen and the far field at the base of the screen.

Physics of TEE

The TEE probe is an ultrasound machine mounted to the tip of a gastroscope. The generation of ultrasound is based on the principle of piezoelectricity. Most commonly, materials such as quartz or titanate ceramic are used. Piezoelectric crystals are materials with a distinct property that respond to an applied current with an alignment of polarized particles perpendicular to the face of a crystal, resulting in the expansion of the crystal size. When alternating electric currents are applied, the crystals are compressed and expanded, thereby generating an ultrasound wave. When an ultrasound wave is received by a crystal, an electric current is generated. Crystals in a TEE probe function as a generator and a receiver. In a cycle, transmission duration is 1% of the cycle, whereas reception is 90%. In essence, the ultrasound transducers transmit a burst of ultrasound activity and then switch to receive reflected ultrasound signals. The cycle is repeated temporarily and based on ultrasound transmission and return of the reflected signal.

Guidelines and indications

The American Society of Anesthesiologists (ASA) released practice guidelines for the use of perioperative TEE in 1996. Improved imaging has enabled echocardiographers to use TEE intraoperatively to diagnose myocardial ischemia, confirm the efficacy of valvular reconstruction, determine the etiology of hemodynamic instability, and obtain diagnostic information that could not be obtained preoperatively. Recommendations of the taskforce address indications for the use of TEE, the clinical settings in which TEE should be considered, and the proficiency of the operator performing TEE.

Guidelines delegate the three levels of evidence-based indications for TEE implementation and use. Category I indications are supported by the strongest evidence or expert opinion. TEE frequently is useful for category I indications in improving clinical outcomes, and often is indicated. Category II indications are supported by weaker evidence and expert opinion; TEE may be useful in improving clinical outcomes, but appropriate indications are less certain. Category III indications are based on little current scientific or expert support; TEE is infrequently useful in improving clinical outcomes, and appropriate settings for use are uncertain (Table 75.1).

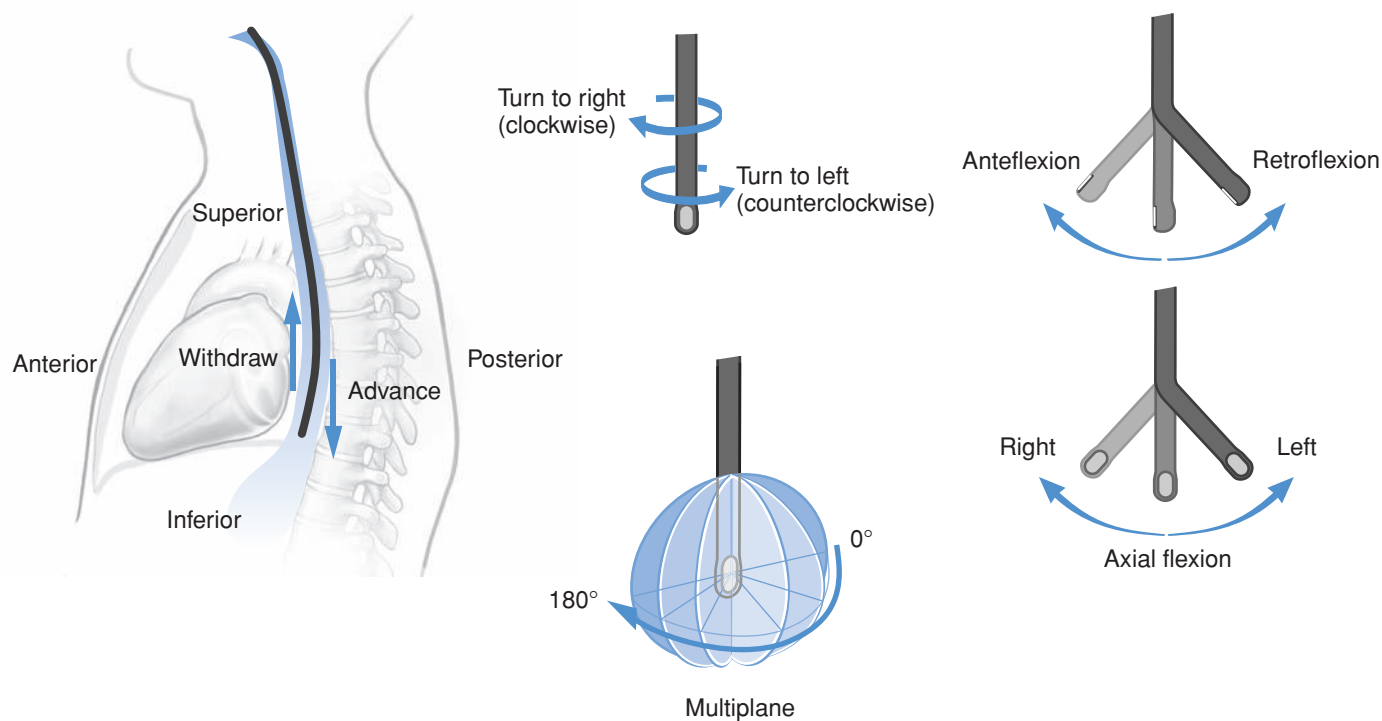

Figure 75.2. Nomenclature of probe positioning.

Table 75.1. Indications for perioperative TEE

Category I	Category II	Category III
Intraoperative evaluation of acute, persistent, and life-threatening hemodynamic disturbances	Perioperative use in patients with increased risk of myocardial ischemia or infarction	Intraoperative evaluation of myocardial perfusion, coronary artery anatomy, or graft patency
Intraoperative use in valve repair	Perioperative use in patients with increased risk of hemodynamic disturbances	Intraoperative use during repair of cardiomyopathies other than HOCM
Intraoperative use in congenital heart surgery requiring CPB	Intraoperative assessment of valve replacements	Intraoperative use for uncomplicated endocarditis during noncardiac surgery
Intraoperative repair of HOCM	Intraoperative assessment of repair of cardiac aneurysms	Intraoperative monitoring for emboli during orthopedic procedures
Intraoperative use for endocarditis when preoperative testing was inadequate or extension of infection is suspected	Intraoperative evaluation of removal of cardiac tumors	Intraoperative assessment of repair of thoracic aortic injuries
Preoperative use in the unstable patient with suspected thoracic aortic aneurysm, dissection, or disruption	Intraoperative detection of foreign bodies	Intraoperative use for uncomplicated pericarditis
Intraoperative assessment of aortic valve function in repair of aortic dissections with possible aortic valve involvement	Intraoperative detection of air emboli during cardiotomy, heart transplants, and upright neurosurgical procedures	Intraoperative evaluation of pleuropulmonary disease
Intraoperative evaluation of pericardial window procedures	Intraoperative use during intracardiac thrombectomy	Monitoring placement of intra-aortic balloon pumps, AICD, or PA catheters
Use in ICU for unstable patients with unexplained hemodynamic disturbances, suspected valvular disease, thromboembolic disease	Intraoperative use during pulmonary embolectomy	Intraoperative monitoring of cardioplegia administration
	Intraoperative use for suspected cardiac trauma	
	Preoperative assessment of patients with suspected acute thoracic aortic dissections, aneurysms, or disruption	
	Intraoperative use during repair of thoracic aortic dissections without suspected aortic valve involvement	
	Intraoperative detection of aortic atheromatous disease or other sources of aortic emboli	
	Intraoperative evaluation of pericardiectomy, pericardial effusions, or evaluation of pericardial surgery	
	Intraoperative evaluation of anastomotic sites during heart and/or lung transplantation	
	Monitoring placement and function of assistive devices	

AICD, automatic implantable cardioverter–defibrillator; CPB, cardiopulmonary bypass; HOCM, hypertrophic obstructive cardiomyopathy; ICU, intensive care unit. American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography. Practice guidelines for perioperative transesophageal echocardiography. *Anesthesiology* 1996; 84:986–1006.

Common uses of TEE

Evaluation of cardiac function

The midpapillary short-axis view permits the estimation of the global left ventricular function based on the amount of ventricular wall thickening and the difference between end-diastolic volume and end-systolic volume (Fig. 75.3). This view enables the anesthesiologist to assess regional wall abnormalities and determine the presence of myocardial ischemia, and permits the practitioner to postulate the location of coronary artery disease, if present (Fig. 75.3). The ASA guidelines have determined that there is good evidence that the development of regional wall motion abnormalities increases the risk of the development of perioperative myocardial infarction (Fig. 75.4). The ASA

taskforce believes that TEE provides a “more meaningful reference standard for ECG.”

As noted in Table 75.1 under category II indications for the use of perioperative TEE, a patient at increased risk for myocardial ischemia is a noted indication for TEE. An increased risk may occur in a patient with an increased risk of myocardial disease, a higher-risk procedure/surgery, or the clinical setting.

The midesophageal four-chamber views give useful information regarding biventricular function, tricuspid and mitral valve visualization, and the major cardiac chambers (Fig. 75.5). In this view, all chamber sizes may be evaluated and may give the practitioner vital information regarding ventricular function.

Figure 75.3. Transgastric short-axis view of the left ventricle (LV) and right ventricle (RV).

Assessment of valves

For patients requiring valve surgery, TEE is critical in the evaluation of the diagnosis of valve abnormalities intraoperatively. Surgeons rely on the anesthesiologist to accurately evaluate and confirm preoperative studies, if available, or to initially evaluate valvular anatomy to diagnose abnormal pathology. The ASA taskforce expert opinion confirms that there is indirect evidence that postulates the beneficial use of intraoperative TEE for valve surgery. TEE evaluation appears to have decreased the need for replacement of valves.

Midesophageal aortic valve (AV) short-axis (Fig. 75.6) and AV long-axis (Fig. 75.7) views, along with the transgastric AV long-axis views, are used to evaluate AV lesions such as stenosis and regurgitation.

AV stenosis is commonly seen, and the AV area is calculated using a continuity equation. The flow at the left ventricular outflow tract is a product of its area and the flow at that point. The former is obtained with the midesophageal AV long-axis view (Fig. 75.7). The latter is obtained from the transgastric AV long-axis view (Fig. 75.8).

$$\begin{aligned} \text{Left ventricular outflow tract (LVOT) stroke volume} \\ = \text{LVOT area} \times \text{LVOT velocity time interval (VTI)} \end{aligned}$$

$$\text{Cardiac output} = \text{LVOT stroke volume} \times \text{heart rate.}$$

The pulse wave Doppler cursor is placed at the LVOT, and the velocity time integral is obtained (Fig. 75.9). This product should be equal to that obtained at the AV level. However, the unknown is AV surface area. The flow velocities are higher across a stenotic AV around 4 to 6 m/sec and are obtained with continuous-wave Doppler across the AV (Fig. 75.8).

$$\text{AV area} \times \text{AV VTI} = \text{LVOT area} \times \text{LVOT VTI.}$$

The mitral valve is evaluated by the midesophageal four-chamber, commissural, two-chamber, and long-axis views. The transgastric basal short axis view yields plenty of information about the anatomy and location of a lesion such as a regurgitant lesion. A color flow Doppler along with flow Doppler calculations quantifies the mitral valve stenosis and regurgitant lesions. Figure 75.10 shows a transgastric basal short-axis view, and both the anterolateral and inferomedial commissures are seen. The anterior and posterior leaflets are easily recognized. The scallops closer to the anterolateral commissure are A1 and P1 and those closer to the posteromedial commissure are A3 and P3. The mid-scallops are A2 and P2.
