bone, but mistakes the posterior tubercle for the anterior tubercle. Slight withdrawal of the needle from the posterior tubercle, particularly if in a medial position, can lead to vertebral artery injection. The carotid artery and the spinal radicular artery also lie near the needle path during a stellate ganglion block. Intra-arterial injections can cause seizures or embolic stroke of the brain. Complications of aspiration during a seizure can be minimized by maintaining an NPO status prior to the procedure. The embolic stroke complication can be minimized by not using particulate steroids during a stellate block, given the lack of evidence suggesting added benefit with steroids.

Unintended block of the cervical spinal nerves, recurrent laryngeal nerve, phrenic nerve, and brachial plexus are more commonly seen complications associated with the stellate block. Cervical spinal nerves traversing the intervertebral foramen near the location for a stellate ganglion block results in a selective cervical motor and sensory nerve root block. Recurrent laryngeal and phrenic nerve blocks are frequent side effects of stellate ganglion block. They occur from local anesthetic injection that spreads from the area of the ganglion. Because diffusion of drug is required to obtain a satisfactory block, it can be expected that these nerves will often be temporarily blocked. Symptoms of a recurrent laryngeal nerve block include hoarseness and, occasionally, stridor. Patients often complain of difficulty in catching their breath and the sensation of a lump in their throats. Symptomatic treatment is sufficient along with reassurance that these sensations will resolve when the local anesthetic effect ends. Patients should be cautioned to drink clear liquids initially after a stellate ganglion block to make sure that their upper airway reflexes are not compromised. When they feel comfortable swallowing liquids, they can progress to regular food. Unilateral phrenic nerve block rarely presents as a problem for patients unless they have preexisting severe respiratory compromise. The potential for producing phrenic nerve block is one reason why bilateral stellate ganglion blocks are rarely performed simultaneously. Most practitioners wait several days or a week between injections. Horner's syndrome is often observed following a stellate ganglion block. Horner's syndrome is, theoretically, a side effect, because a stellate ganglion block is most commonly performed for patients with upper extremity pain (to establish the diagnosis of sympathetically mediated pain [SMP] or therapeutically for complex regional pain syndrome [CRPS] type I or II). Horner's syndrome consists of miosis, ptosis, and enophthalmos. In fact, many practitioners look for Horner's syndrome as evidence of sympathetic denervation following stellate ganglion injection of local anesthetic. Brachial plexus block can occur following a stellate ganglion injection and occurs most commonly when the needle has been inserted too deep, bypasses the anterior tubercle, and rests on the posterior tubercle. After retraction from the posterior tubercle, the injection of local anesthetic will commonly block one or more of the roots of the brachial plexus.

Intrathecal injection of local anesthetic at this site typically produces a total spinal block accompanied by loss of airway reflexes and phrenic nerve function. Intubation and assisted

ventilation will be required until the block abates. The duration of the block depends on the drug and the total dose injected. Verbal reassurance of the patient can further calm fears and assure him or her that the effects experienced are temporary.

The pleural dome of the lung extends variably above the first rib. Most commonly, this dome passes laterally to the intended C6 injection site for the stellate ganglion block. Pneumothorax can result despite careful attention to anatomy and technique, and patients should be warned of this potential complication prior to a posterior approach to the sympathetic chain or stellate ganglion. Paratracheal hematoma causing airway obstruction and death has been reported as a complication of stellate ganglion block. Infections are uncommon following stellate ganglion injections, but there are case reports of cervical vertebral osteomyelitis. Other rare complications include transient locked-in syndrome following the stellate ganglion block.

Celiac plexus block and lumbar sympathetic block

Complications that have been reported include intravascular injection, intraspinal injection, infection (including discitis), postdural puncture headache, and hematoma formation.

On the left side of the spine, the aorta lies close to the needle-placement site. The inferior vena cava lies near the placement site for needles on the right side. Large volumes of local anesthetic, particularly bupivacaine, can cause seizures and/or cardiovascular collapse if injected into either vessel. Resuscitation can be prolonged and difficult, especially in cases where bupivacaine is injected. Careful, frequent aspiration and intermittent injection are recommended. If the solution contains epinephrine, changes in heart rate may serve as a warning sign of intravascular injection.

Accidental lumbar nerve root block, epidural, intrathecal, or intraspinal injections occur rarely now that fluoroscopy is more commonly used. The intervertebral disc lies near the path of a lumbar sympathetic block needle. Unintentional injury to the disc usually does not cause any complications. Occasionally it can cause discitis. Postdural puncture headache after a lumbar sympathetic block has been reported, most likely occurring as a result of the needle passing near a nerve root sleeve that contained spinal fluid. Severe bleeding, including both subcutaneous and retroperitoneal hematomas, have been reported. Considerations for performing these blocks in patients taking antiplatelet or anticoagulant medications are similar to those proposed for performing neuraxial blockade.

Complications associated with neurolytic blockades

Chemical neurolytic blockade

Neurolytic blocks are performed in patients with severe pain secondary to advanced cancer or occlusive vascular disease. Their use in nonmalignant chronic pain (e.g., chronic relapsing pancreatitis) remains controversial. The potential

complications of neurolytic blockade can be devastating to the patient and must be carefully weighed against the anticipated benefits.

The different types of neurolytic blocks include local injections, peripheral nerve blocks, lumbar sympathetic blocks, celiac plexus blocks, and epidural and intrathecal blocks. Neurolytic blocks can be done using ethyl alcohol, phenol, or hypertonic saline.

Local complications of neurolytic blocks include skin and subcutaneous tissue necrosis and sloughing secondary to vascular damage and ischemia. Peripheral neurolytic blocks are rarely performed because they can cause motor deficit when mixed nerves are blocked. Neuritis and deafferentation pain are potential consequences, and the block is not predictably permanent. Anesthesia dolorosa is also seen as a complication in neurolytic blocks. Neuraxial blocks can result in prolonged motor and sensory blocks, bladder and bowel dysfunction, and saddle-shaped anesthesia. Systemic complications can result from any of the blocks and include hypotension, central nervous system (CNS) excitation, and cardiovascular collapse.

Neurolytic celiac plexus block (NCPB) has been shown to be an effective analgesic technique for management of pain in patients with intra-abdominal malignancies, particularly pancreatic cancer. Celiac plexus block using a transcrural approach places the local anesthetic or neurolytic solution in direct contact with the celiac ganglion anterolateral to the aorta. In contrast, splanchnic nerve block or retrocrural technique avoids the risk of penetrating the aorta, uses smaller volumes of solution, and is unlikely to be affected by anatomic distortion caused by extensive tumor of the pancreas or metastatic lymphadenopathy. Many of the minor complications of NCPB are the result of effective sympathetic block due to neurolysis of the celiac ganglia. Neurolytic blockade of these sympathetic structures results in the relative increase in parasympathetic tone to the splanchnic region. Subsequent vasodilation of the splanchnic vasculature can result in orthostatic hypotension. Bowel hypermotility causes diarrhea. Major complications – significant neurologic deficits, such as loss of sensation or motor function of the lower extremities, or vascular events, including uncontrolled bleeding, arterial dissection, or injury to the artery of Adamkiewicz – are extremely uncommon. Hematuria and pneumothorax are complications from incorrect needle trajectory or placement. Acetaldehyde dehydrogenase deficiency resulting in sensitivity to ethanol has been reported. Following ethanol injection, individuals with aldehyde dehydrogenase deficiency have increased systemic levels of acetaldehyde causing skin flushing, nausea, headache, tachycardia, hypotension, and drowsiness.

In the event of a major vascular complication, such as significant arterial bleeding or aortic dissection, immediate radiographic imaging coupled with emergent surgical evaluation is recommended. If neurologic deficits occur during the NCPB, emergent consultation with a neurologist is indicated. There are no known remedies for relieving arterial spasm after it has occurred, but at least one case of transient paraplegia following NCPB has been reported and attributed to arterial spasm.

Cryoneurolytic blockade

Cryoneurolysis uses a low temperature to create nerve injury resulting in long-lasting analgesia. The mechanism of nerve injury is unclear. Given the intact nerve sheaths, the nerves tend to slowly regenerate and pain returns to baseline. The complications associated with cryolesioning are secondary to improper insertion of the cryoprobe and thermal injury. Frostbite and ulcerations are the more common complications. When mixed nerves are cryolesioned, reversible paresthesias and motor deficits are not uncommon.

Radiofrequency neurolytic blockade

Radiofrequency (RF) generators use high-frequency waves in the range of 300 to 500 kHz to produce tissue lesions via ionic means. Because high frequencies in this range are also used in radio transmitters, the current was named RF current. Conventional RF treatment uses a constant output of high-frequency electrical current, produces controllable tissue destruction surrounding the tip of the treatment cannula, and, when placed at precise anatomic locations, has demonstrated success in reducing a number of different chronic pain states, including facet arthropathy, whiplash injury, and trigeminal neuralgia. Pulsed RF, in contrast, uses brief pulses of high-voltage, RF range (~300 kHz) electrical current that produce the same voltage fluctuations in the region of treatment that occur during conventional RF treatment, but without heating to a temperature at which tissue coagulates. Conventional wisdom holds that the usefulness of RF stems from the ability to produce a small lesion of precise dimensions in a specific anatomic location.

Despite the widespread use of RF thermoablation for facet-related pain, there are limited data regarding the safety of this technique and its associated complications. As may occur with any technique that requires needle placement, complications may result from direct injury to neural or vascular structures in the vicinity of treatment or from thermal destruction during the RF treatment.

The anatomic configuration of the sensory nerves to the facet joints allows safe destruction without damage to the sensory or motor nerves to the extremities. Precise radiographic guidance allows placement of the RF cannula, and lesions can be produced without affecting the anterior primary ramus, which supplies the sensory and motor innervation to the trunk and extremities (Fig. 149.3). Thermal injury caused by incorrect positioning of the RF cannula has also been reported. Even with proper technique, conventional RF lesions are associated with sensory loss and onset of neuropathic pain in a subset of patients secondary to either direct tissue, periosteal, or spinal nerve injury. The frequency and severity of these neural changes vary with the specific site of treatment, and are common after intracranial RF lesioning of the trigeminal ganglion. Injury to adjacent nerves can also occur; the frequency of these complications is minimized by the proper use of sensory and motor stimulation before lesioning.

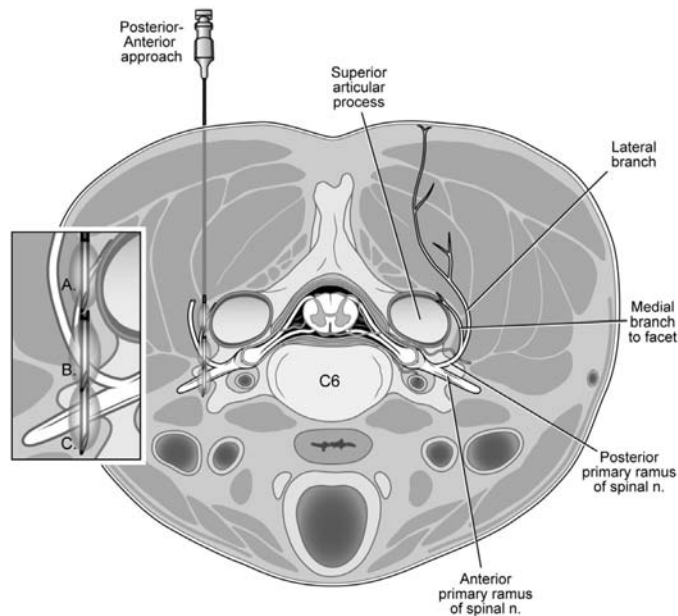

Figure 149.3. Mechanism of complications that arise during lumbar RF medial branch neurotomy. Axial diagram of lumbar RF medial branch neurotomy. A 22-gauge, 10-cm RF cannula with a 5-mm active tip is advanced just anterior to the base of the transverse process where it joins with the superior articular process. **(A)** An RF cannula in correct position for lumbar RF medial branch neurotomy. The point of bifurcation of the posterior primary ramus of the spinal nerve into medial and lateral branches is variable, and conventional RF treatment commonly destroys both nerves. The medial branch supplies sensation to the facet joint, and the lateral branch provides motor innervation to the paraspinal musculature and a small and variable patch of sensory innervation to the skin overlying the spinous processes. **(B)** Neurolysis of the lateral branch does not have any demonstrable effect on strength of the paraspinal muscles; however, cutaneous hyperesthesia and/or hypoesthesia do occur infrequently. **(C)** Placement of the RF lesion directly on the anterior primary ramus of the spinal nerve can cause severe and persistent radicular pain. (Reproduced with permission from: Neal JM, Rathmell JP. *Complications in Regional Anesthesia and Pain Medicine*. Philadelphia: Saunders Elsevier; 2007, Figure 29–3, p. 295.)

The most common complications associated with cervical medial branch neurotomy include postoperative pain (97%); ataxia, unsteadiness, and spatial disorientation (23%); and vasovagal syncope (2%) (Table 149.5). Lord found that brief postoperative pain was the only side effect of lower cervical procedures, but ataxia occurred when the third occipital nerve was treated. Because the third occipital nerve carries a large proportion of fibers involved in cutaneous innervation, numbness routinely accompanies lesioning of this nerve. In patients whose treatment was successful, this numb patch regressed over 1 to 3 weeks and was replaced by dysesthesia and pruritus, followed by the return of normal cutaneous sensation and pain. The incidence of expected treatment-related adverse effects and complications associated with lumbar RF medial branch neurotomy is markedly lower than that observed following treatment at cervical levels.

Major complications have been described mainly in the form of case reports. Serious complications appear to be rare, and the available data prevent meaningful systematic analysis.

Table 149.5. Observed complications of cervical medial branch neurotomy

Complication	Observed frequency, %	95% CI, %
Vasovagal syncope	2	0–6
Postoperative pain	97	94–100
Ataxia, unsteadiness, spatial disorientation	23	14–32
Cutaneous numbness		
TON procedures	88	75–100
C3/4 procedures	80	55–100
Lower levels	19	8–30
Dysesthesias		
TON procedures	56	37–75
C3/4 procedures	30	2–58
Lower levels	17	6–27
Dermoid cyst	1	0–4
Transient neuritis	2	0–6

CI, confidence interval; TON, third occipital nerve.

Lord SM, Bogduk N. Radiofrequency procedures in chronic pain. *Best Pract Res Clin Anaesthesiol* 2002; 16:597–617.

Minor burns due to insulation breaks in electrodes and improper function of grounding pads have been reported. There is no evidence of any significant risk of infection, hemorrhage, or neurologic deficit.

Separate consideration should be given to the emerging use of pulsed RF techniques that do not cause neurodestruction. Complications with this type of neurolysis are limited to direct needle injury and not thermal injury, because the temperature is not high enough to cause nerve damage. Despite the enthusiasm for pulsed RF because it does not appear to be neurodestructive, the nature and extent of lesions made by these methods have not been described, and little evidence has been published to demonstrate their efficacy.

Most sequelae following RF medial branch neurotomy are self-limited and require nothing more than reassurance and time to resolve. Patients should be warned to expect a transient increase in pain for several days to weeks following treatment. Providing a brief course of oral analgesics can obviate unnecessary return visits. If new-onset radicular pain with or without allodynia appears, spinal nerve injury should be suspected, and oral neuropathic pain treatment with a tricyclic antidepressant or anticonvulsant should be started. Localized allodynia described as a sunburn sensation is common, particularly following RF treatment of the high cervical medial branch nerves. Topical 5% lidocaine patches can prove invaluable for symptomatic management in these cases, which also tend to resolve within days to weeks of treatment. Persistent numbness is also common and rarely requires specific treatment.

Complications associated with implantable therapies for pain

Subcutaneous reservoirs or port-a-cath

Complications are similar to those described for tunneled intrathecal or epidural catheters. There is a 1% to 5% reported

risk of infection. As in any external infusion system, late-onset neuraxial infection is a constant risk and appropriate care is required. The presentation of an epidural abscess with the potential of spinal cord compression requires appropriate clinical vigilance. Minor complications can include pocket seromas, hygromas, and spinal headaches from cerebrospinal fluid (CSF) leaks. Inadvertent intrathecal placement may lead to inappropriately high doses of medication. Spinal cord injury and unrecognized catheterization of epidural veins can lead to inadvertent intravascular injection of local anesthetic into the epidural veins. Because of the delayed onset of epidural hydromorphone hydrochloride and morphine, respiratory depression many hours after injection has been reported. Spinal opiates can cause nausea and vomiting, urinary retention, pruritus, sedation, and respiratory depression. These side effects are usually transient and can be symptomatically treated.

Intrathecal infusion pump implantation

Complications are similar to the complications seen with the epidural port-a-cath. Additional complications associated with high-dose opioids are intrathecal granulomas. The incidence of these is not well established, but vigilance is needed to avoid potential devastating spinal cord compression and permanent neurologic changes. Complications involving refilling these pumps include inadvertent side port injections, especially in older pumps that lack safety screens. This mistake may deliver a fatal intrathecal dose of medication initially starting with respiratory and cardiovascular collapse and finally death if left unrecognized and untreated.

Neurostimulation

Specific complications from stimulators depend on the location of the device. Spinal cord injuries from misplaced epidural leads can occur during the procedure or later if dural erosion occurs. Risks from surgical infections are present and are similar in incidence to those from the other implantable devices. Fractured electrodes are the most common complications requiring replacement. Programming errors resulting in painful stimulation are temporary and rarely have long-term consequences. Caution with a turned on stimulator while driving should be discussed with the patient. This problem occurs particularly early after surgery while the stimulation still varies with body position. Lead displacement is also possible and can lead to the need for surgical revision to establish effective stimulation.

Summary

There is a low incidence of serious complications associated with the majority of interventional techniques currently in use for the treatment of chronic pain. Careful history and physical examination will help to identify risk factors such as diabetes, immunosuppression, coagulopathy, and occult infection. Knowledge of the anatomy relevant to each treatment technique and coupling this knowledge with meticulous use of

radiographic guidance can minimize complications. The use of intravenous sedation during these procedures remains controversial. While modest levels of sedation that allow the patient to communicate verbally with the operator throughout the procedure seem reasonable, the use of heavy sedation or general anesthesia that compromises verbal communication with the patient is imprudent. Patients should be informed of the most serious complications as well as common minor complications, such as accidental dural puncture and postdural puncture headache. They should be instructed to report promptly any neurologic changes, new or increasing pain, headache, and fever. There are several complications that arise in the course of pain treatment that, when recognized and treated early in their course, may well result in less catastrophic outcomes; foremost among these are evolving epidural abscess and hematoma. A system of night and weekend coverage should be available, and patients should be instructed how to contact the on-call physician, such that any adverse sequelae of these treatment techniques can be promptly recognized and treated.

Introduction

Painful disorders of the spine are some of the most frequently encountered conditions in the pain clinic. Back pain is also a leading cause of any type of medical visit. In particular, low back pain is one of the most common medical complaints, thereby accounting for millions of primary care physician visits annually, and is a leading factor in disability and lost productivity. This chapter focuses on basic concepts of low back pain, including specific definitions, functional anatomy, epidemiology, and natural history. An overview of diagnosis and treatment is included and will be discussed in more detail in other chapters.

Definitions

The technical term for low back pain is *lumbosacral spinal pain*. The International Association for the Study of Pain (IASP) has defined spinal pain based on the perceived location of pain. Lumbosacral spinal pain can arise from the lumbar or sacral spine (Fig. 150.1). *Lumbar spinal pain* originates in an area of the low back below the T12 spinous process, above the S1 spinous process, and medial to the lateral borders of the erector spinae muscles. *Sacral spinal pain* originates in the sacrum below the S1 spinous process, above the sacrococcygeal joints, and medial to a line between the posterior superior and inferior iliac spines.

Radicular pain is closely associated with lumbosacral spinal pain. Lumbosacral radicular pain is perceived as arising from the lower limbs due to ectopic activation of sensory fibers at a spinal root level. Radicular pain is typically distributed in a bandlike dermatomal pattern corresponding to the affected spinal nerve (Fig. 150.1) and is distinguished from *radiculopathy*, which requires a focal neurologic deficit in the distribution of a spinal nerve. *Neurogenic claudication* is intermittent pain in the buttock, thigh, or leg, exacerbated by prolonged walking or standing. Neurogenic claudication is due to stenosis of the central spinal canal.

Epidemiology and risk factors

Epidemiologic studies of back pain report varying numbers of incidence and prevalence, but studies confirm that lumbosacral

spinal pain is a widespread medical condition. As many as 50% to 80% of adults experience at least one significant episode of low back pain in their lifetime. In a single year, 15% to 20% will have back pain, and 2% to 5% of the entire population will seek medical attention for back pain. One fifth of all physician visits may be prompted by low back pain. Back pain affects children, adolescents, and adults. Among older adults, back pain is more prevalent in women than in men. Back pain has less prevalence with advanced age, decreasing in women older than 85 years and men older than 90 years. Low back pain is the most common cause of disability in persons younger than 45 years and is the third leading cause in other age groups. Up to 1% of the population is disabled at any time due to low back pain. Approximately 25% of workers' compensation costs are due to low back pain. As a leading cause of absenteeism, temporary disability, lost productivity, and workers' compensation claims, back pain has a great cost to society.

Numerous risk factors for low back pain have been described (Table 150.1). Recurrent episodes of back pain and a history of back pain strongly predict recurrence. New-onset back pain is most common in the third decade of life, and incidence rates are highest in the third through sixth decades.

Figure 150.1. Lumbosacral spinal and radicular pain.

Women may be more likely to seek medical care for back pain and develop chronic back pain. Lower socioeconomic status and level of education are associated with markedly increased rates of disability due to back pain. Body mass index greater than 30 is a risk factor for back pain, especially in women. Smoking may be a risk factor for back pain, but studies have not clearly identified it as being independent of other associated factors. Patients with chronic back pain are approximately six times more likely to have depression, and patients with depression are twice as likely to develop back pain. Anatomic risk factors for back pain may include congenital and acquired abnormalities of the spine, but evidence is conflicting, as many subjects have such abnormalities but do not have pain. For example, several studies have demonstrated a high incidence of lumbar disc abnormalities in asymptomatic individuals.

A third or more episodes of low back pain are related to occupational risk factors. Conditions involving heavy lifting; bending or twisting of the back; long-term static positions, such as sitting, prolonged standing, or walking; or low-frequency, whole-body vibration may be risk factors for back pain. Perception of high physical demand may be more of a risk factor than actual demand. Workplace dissatisfaction may be a significant risk factor. A study of a large population of aircraft employees revealed that subjects who had low work satisfaction were

2.5 times more likely to report a back injury than were those who had high job satisfaction.

Natural history

Acute low back pain is usually a self-limited episode that will resolve without intervention. Approximately half of disabling episodes recover in 2 weeks, 70% are recovered by 4 to 6 weeks, and 90% are recovered by 12 weeks. The definition of *chronic* low back pain is typically pain that has persisted for 3 months. Fewer than half of patients who have disabling back pain for 6 months will return to work. Almost none who experience disabling back pain for 2 years ever return to work.

Several age-related and mechanical changes in the spine are important in understanding the development of low back pain. The intervertebral discs lose water content with age, which is associated with loss of disc height. Repeated loading may lead to circumferential tears in the annulus fibrosus, also known as *internal disc disruption*. Such tears may be painful in themselves, as they occur most often in the posterior outer third of the disc, known to have sensory innervation. Internal disc disruption weakens the annulus and may allow herniation of the nucleus pulposus. The lumbar facet joints may develop synovitis, then articular surface degradation, capsular abnormalities, and joint hypertrophy.

Table 150.2. Bogduk's postulates**An anatomic structural cause of back pain must meet these criteria:**

1. The structure must have a nerve supply.
2. The structure should be capable of causing pain similar to what is clinically observed (e.g., when provoked in normal volunteers).
3. The structure should be susceptible to painful disease or injury; such disorders should be detectable by clinical, imaging, biomechanical, or postmortem tests.
4. The structure should be shown to be a source of pain in actual patients, using reliable and valid diagnostic tests.

Anatomy

Anatomic structures of the lumbosacral spine that are responsible for pain are often referred to as *pain generators*. Several conditions are required for a structure to be considered a pain generator, as described in-depth by Nikolai Bogduk (Table 150.2): There must be a nerve supply, because insensate structures are not typically sources of pain. Provocation or irritation of the structure in normal volunteers should produce a distribution of pain that is similar to what is observed in patients. The structure must be naturally susceptible to injury or disease, which may activate or sensitize local nociceptors mechanically or chemically (e.g., via inflammation). Finally, the structure must be demonstrated, using diagnostic techniques of known reliability and validity, as a source of pain in patients.

Specific anatomic causes have been described for lumbosacral spinal pain (Table 150.3). A precise anatomic cause, however, may not be discovered in as many as 90% of individual cases of chronic lumbosacral pain. Well-established pain generators include zygapophyseal (facet) joints, sacroiliac joints, and discs. Incidence of internal disc disruption is estimated to be 39% in chronic lumbosacral pain. Incidences of facet and sacroiliac joint pain are 15% each.

Pain due to facet joints is typically deep aching of gradual onset located near the midline of the lumbar spine, over the location of the actual joints. Lumbosacral facet joint pain may be referred to the buttocks and thighs, but usually not past the knee. Pain may be exacerbated by compression of the joint surfaces or stretching of the joint capsule.

Sacroiliac joint pain is usually deep aching of gradual onset, located in the lower back and upper buttock, over the posterior margin of the joint. Pain may be referred to the thigh, but again,

Table 150.3. Generators of lumbosacral spinal pain

Structure	Example
Vertebral body	Osteoporotic fracture
Muscle, fascia, ligaments	Trigger points
Meninges	Epidural hematoma
Sacroiliac joint	Sacroiliitis
Zygapophyseal joints	Osteoarthritis
Intervertebral disc	Internal disc disruption

usually not past the knee. Numerous physical examination techniques have been described to assess the sacroiliac joint, but the diagnostic block with local anesthetic is the best test.

Pain due to the discs themselves, known as *discogenic pain*, is characterized by deep aching in the lumbosacral midline. As with facet and sacroiliac joint pain, referral can be to the buttock and thigh, but not past the knee. The most distinguishing historic feature of discogenic pain is intolerance to prolonged sitting. Prolonged standing and forward flexion of the lumbosacral spine also exacerbate discogenic pain.

The anatomic cause of radicular pain is most often attributed to herniation of nucleus pulposus of the intervertebral disc. Such ectopic disc material can mechanically irritate the nerve root and can also cause an inflammatory reaction. Radicular pain can also arise from epidural, meningeal, or neurologic disorders, as well as from any cause of foraminal stenosis. Causes of foraminal stenosis other than disc herniations include osteophytes, degenerative changes of ligamentum flavum, cysts, tumors, and infections (Fig. 150.2). *Failed back surgery syndrome* is a nonspecific description of persistent or recurrent pain after lumbar spinal surgery.

Diagnosis and treatment

Initial evaluation of back pain requires screening for potentially dangerous conditions, often referred to as the “red flags” of back pain (Table 150.4). For example, bowel or bladder dysfunction or saddle anesthesia can be associated with *cauda equina*

Table 150.4. The red flags of back pain**History**

Gradual onset of back pain
 Age < 20 y or > 50 y
 Thoracic back pain
 Pain lasting longer than 6 wk
 History of trauma
 Fever/chills/night sweats
 Unintentional weight loss
 Pain worse with recumbency
 Pain worse at night
 Unrelenting pain despite supratherapeutic doses of analgesics
 History of malignancy
 History of immunosuppression
 Recent procedure known to cause bacteremia
 History of intravenous drug use
 Physical examination
 Fever
 Hypotension
 Extreme hypertension
 Pale, ashen appearance
 Pulsatile abdominal mass
 Pulse amplitude differentials
 Spinous process tenderness
 Focal neurologic signs
 Acute urinary retention

Winters ME, Klutz P, Zilberstein J. Back pain emergencies. *Med Clin North Am* 2006; 90(3):505–523.

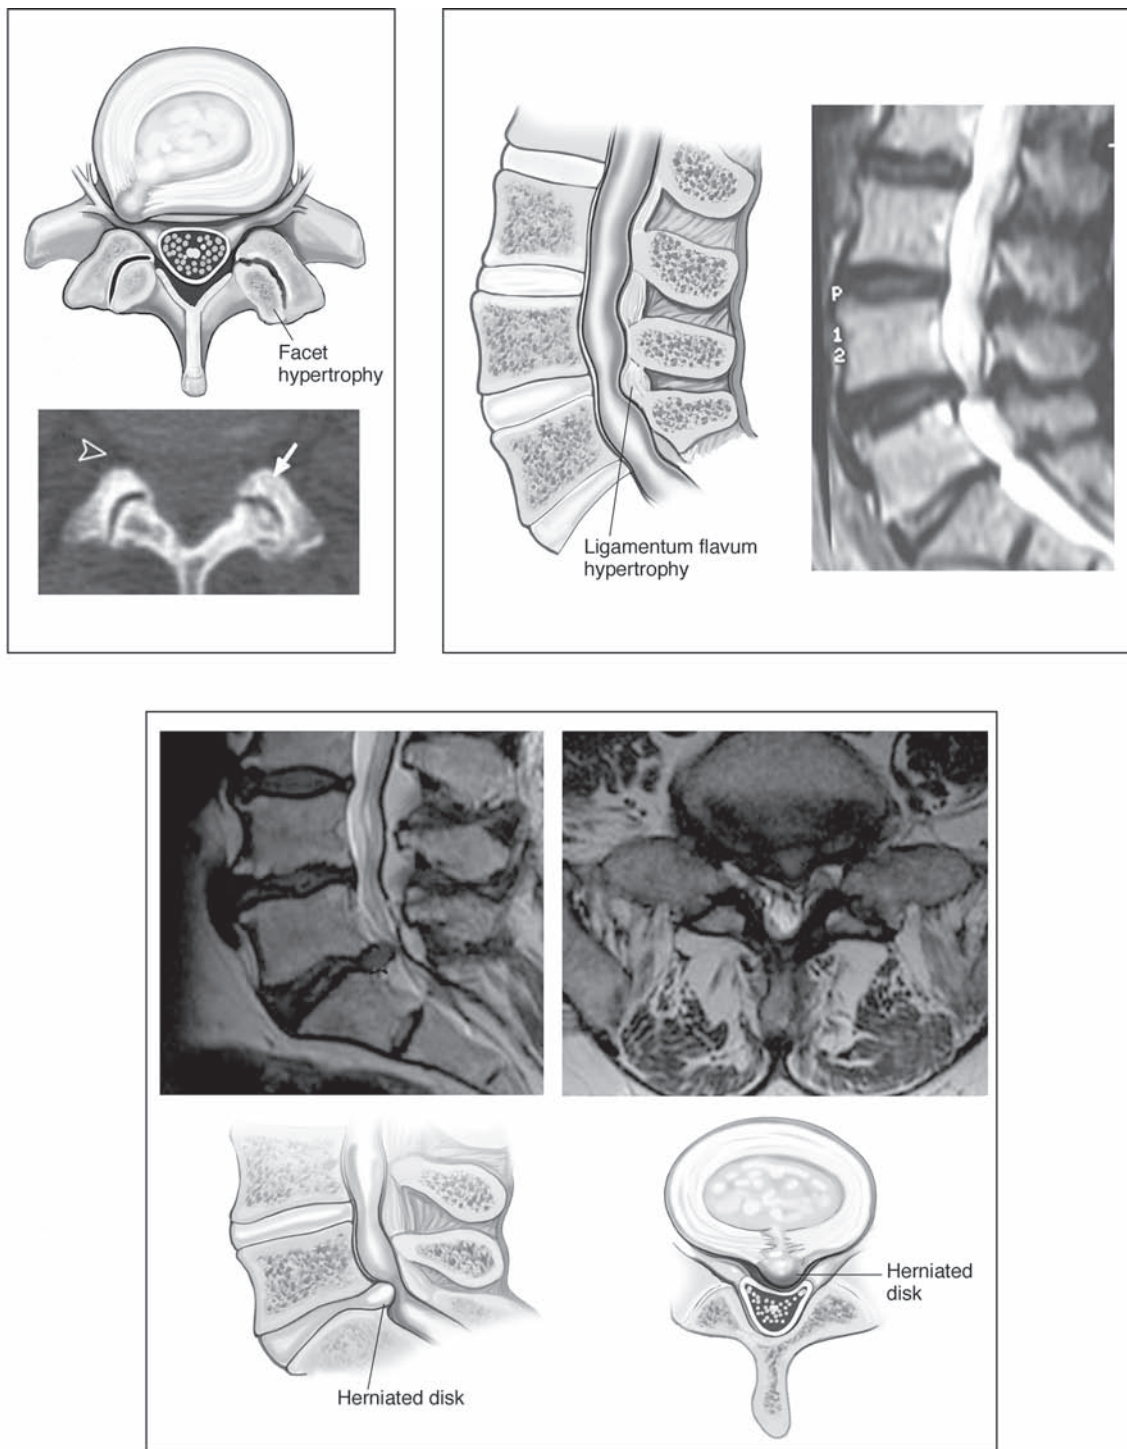

Figure 150.2. Anatomic sources of back pain.

syndrome, which may require emergency surgical decompression to prevent permanent neurologic injury. Urinary retention and overflow incontinence are pathognomonic of cauda equina syndrome (90% sensitivity, 95% specificity), and absence of a postvoid residual urine has a 99.99% negative predictive value. History or examination suggesting compression of the spinal cord is critical, as 20% of patients with spinal metastases

will present with these features as the first evidence of their malignancy. MRI is the gold standard diagnostic test in such cases. Unexplained weight loss or fever can also be suggestive of infection or malignancy. Pain that is unrelenting when recumbent has also been associated with spinal tumors. Red flags can indicate serious conditions that need immediate imaging or surgical consultation.

After exclusion of red flags, the general algorithmic approach to back pain begins with determining if the predominant pattern of pain is lumbosacral or radicular, then deciding if the episode is acute or chronic. Physical examination is beyond the intended scope of this chapter (the reader is referred to several existing sources in the “Suggested readings” section), but a few common tests should be mentioned here. The straight leg raise, also known as Lasègue’s test, consists of passive hip flexion with knee extended, with passive ankle dorsiflexion. This sensitive maneuver causes traction of L4, L5, and S1 nerve roots, and provokes radicular pain extending past the knee in the elevated leg. The crossed straight leg is a more specific test that provokes radicular pain in the symptomatic leg when lifting the asymptomatic leg. Facet loading tests are usually positive in facet arthropathy. The flexion, abduction and external rotation (FABER) test and Gaenslen’s test are characteristic signs in diagnosis of sacroiliitis.

Acute lumbosacral or radicular pain may initially respond to a brief course of nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen, with a centrally acting muscle relaxant. Acute lumbosacral pain that persists may respond to physical therapy and patient education. Lumbar epidural steroid injections may speed resolution of acute radicular pain in the 2- to 6-week timeframe (level 2 evidence). Bed rest is no longer advised for back pain.

Diagnostic imaging is not generally used in the first 6 weeks of an episode of lumbosacral spinal pain. If there is evidence of acute nerve root compression, it is reasonable to obtain a lumbosacral MRI in preparation for performing an epidural steroid injection. In cases of prior back surgery or failed back surgery syndrome, the MRI should be ordered with gadolinium. Flexion and extension radiographs can identify mobile segments due to pseudoarthrosis in patients who have had spinal fusion. CT and CT myelogram can be used when MRI is not possible, but CT cannot distinguish causes of compression as is possible with MRI.

Patients with chronic radicular pain may benefit from neuropathic pain medications, such as tricyclic antidepressants, selective norepinephrine reuptake inhibitors, or antiepileptic medications as described in [Chapter 145](#). Interventional options including epidural injections, transforaminal injections, selective nerve root blocks, and pulsed radiofrequency lesioning of the dorsal root ganglion, will be considered as a part of multidisciplinary care for worsening pain. In cases of chronic radicular pain refractory to more conservative treatments, implantable spinal cord stimulation may be an option.

Facet joint treatment can be considered for chronic lumbar spinal pain. Diagnostic blocks of the medial branch nerves (or posterior primary ramus at L5) that innervate the facet joints can determine if these joints are pain generators. If a series of blocks significantly relieves pain for the duration of injected local anesthetic, it suggests that facet joints mediate the pain. Following this, radiofrequency lesioning of the same nerves can be performed, potentially providing 3 to 6 months of relief.

A similar approach can be used for the chronic sacral spinal pain. For facet and sacroiliac joints, diagnostic injections are the gold standard for determination of the pain source. If such blocks do not determine the source of chronic lumbosacral spinal pain, provocative discography can be used to determine if a disc is the source of pain, in cases where treatment options would include intradiscal electrothermal therapy (IDET) or surgical fusion. Multidisciplinary pain programs that incorporate physical therapy and cognitive behavioral therapy are also indicated for chronic lumbosacral spinal pain.

Use of long-term opiate therapy for back pain remains controversial. Evidence does exist for efficacy and improved function in chronic noncancer pain; however, there is also evidence of difficulties with chronic opiate therapy, including addiction, hyperalgesia, and hormonal imbalance.

Surgery is sometimes indicated for painful disorders of the lumbosacral spine. The patient must be healthy enough otherwise to undergo surgery. Surgical indications include cauda equina syndrome, progressive or severe motor deficit, or persistent motor deficit that does not improve after 6 weeks of conservative treatment. Reflex or sensory abnormalities are not indications for surgery. Severe, intractable radicular pain may also be an indication for surgery.

Conclusion

Lumbosacral spinal pain is one of the most common and costly medical problems in the world. Most episodes, however, will resolve without treatment within 6 weeks. A specific anatomic source of pain is often not found in individual cases. For chronic painful disorders of the lumbar spine, good evidence exists for multidisciplinary comprehensive treatment, including activity and physical therapy, psychological treatments, medications, and interventional techniques.

Complex regional pain syndrome

Omid Ghalambor

Complex regional pain syndrome (CRPS) refers to a group of pain conditions that are characterized by continuous, intense neuropathic pain out of proportion to the severity of the injury. Typical features include burning pain and dramatic changes in the color and temperature of the skin over the affected limb or body part, accompanied by hyperesthesia, hyperhidrosis, edema, and, rarely, ulceration (see Fig. 151.1). Early in the course of the syndrome, the skin may be warm and erythematous. As the process becomes chronic, the involved extremity is usually cool and pale or cyanotic. Dystrophic changes manifest as bone demineralization, and skin in the affected area becomes smooth and glossy. Joints in the affected extremity become stiff and painful. The exact etiology of CRPS is yet to be determined. In some cases, the sympathetic nervous system seems to play an important role in sustaining the pain. Several pathophysiologic concepts have been proposed to explain the complex symptoms of CRPS: (1) facilitated neurogenic inflammation; (2) pathologic sympatho-afferent coupling; and (3) neuroplastic changes within the central nervous system (CNS). Furthermore, there is accumulating evidence that genetic factors may predispose for CRPS. Another theory postulates that CRPS is caused by a triggering of the immune response, which leads to the characteristic inflammatory symptoms of redness, warmth, and swelling in the affected area.

CRPS is classified into two types: CRPS type I (formerly referred to as reflex sympathetic dystrophy [RSD]) includes cases in which the nerve injury cannot be immediately identified, and CRPS type II (formerly referred to as causalgia) in which a distinct major nerve injury has occurred. Generally, CRPS type II provides more objective evidence of disease due to neurologic changes (numbness and weakness). Because there is no single laboratory test to diagnose CRPS, an arbitrary set of criteria has been suggested to establish the diagnosis.

Criteria for diagnosing CRPS

1. The presence of an initiating noxious event, or a cause of immobilization in CRPS type I or signs of major nerve damage in CRPS type II
2. Continuing pain, allodynia, or hyperalgesia with which the pain is disproportionate to any inciting event
3. Evidence at some time of edema, changes in skin blood flow (skin color changes, skin temperature changes more

- than 1.1°C different from the homologous body part), or abnormal sudomotor activity in the region of the pain
4. Change in tissue growth; atrophy or dystrophy

The diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

Patients do not need to meet all of these criteria for the diagnosis. Also, one should remember that many of these symptoms, especially the temperature differences, are not static. The involved body region may be hotter or colder than the contralateral region. Moreover, in any one patient, the same region may fluctuate from hot to cold. The skin temperature can undergo dynamic changes in a relatively short period of time (within minutes), depending critically on room temperature, local temperature of the skin, and emotional stress. In some cases, the

Figure 151.1. Hand exhibiting features of CRPS, including significant focal skin changes and contractures from disuse.

differences in temperatures may fluctuate spontaneously even without any apparent provocation.

Historically, CRPS type I had been described to have three phases. The staging system is now abandoned because many patients do not follow the described phases. In fact, only a minority of patients have symptoms and signs of trophic changes corresponding to the described stage III of the disease.

There is a natural tendency to rush to the diagnosis of CRPS with minimal objective findings, although early diagnosis is critical. If undiagnosed and untreated, CRPS can spread to all extremities, making the rehabilitation process a much more difficult one. It seems that the speed with which therapy is commenced after the precipitating event or onset of symptoms determines the outcome of the disease. If untreated, CRPS can lead to permanent deformities and chronic pain.

Treatment

As with all pain conditions, an interdisciplinary approach has the most chance for success. The key disciplines needed for the management of CRPS include pharmacotherapy, psychotherapy, interventions, and physiotherapy. The cornerstone in the treatment of CRPS is normal use of the affected part as much as possible. Therefore, all other modalities of therapy are employed to facilitate movement of the affected region of the body.

Medications

Pulse doses of corticosteroids for 2 weeks have been reported to be beneficial in CRPS type I patients. For constant pain associated with inflammation, nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, may prove beneficial. For constant pain not caused by inflammation, centrally acting medications by an atypical mechanism, such as tramadol, could be used. Tricyclic antidepressants, such as amitriptyline and nortriptyline, have been tried with some success. Anticonvulsants (in particular, gabapentin) have been shown to provide good results for controlling the pain symptoms of CRPS patients and are becoming more and more popular given excellent safety and side-effect profile. Intranasal or intramuscular calcitonin, intravenous (IV) bisphosphonates, as well as free-radical scavengers (dimethyl sulfoxide or acetylcysteine) have been reported to successfully reduce symptoms. In patients determined to have sympathetically maintained pain (SMP), clonidine patches have shown some benefit. Oral lidocaine (mexiletine) has proven to be beneficial in patients in whom IV lidocaine infusions have helped. For muscle cramps (spasms and dystonia) in the involved extremity, muscle relaxants, such as clonazepam and baclofen, are useful. Recently, promising results have been described using ketamine and midazolam in anesthetic doses in severe spreading and refractory CRPS cases.

Psychotherapy

The psychiatrist's role is to identify comorbid psychiatric conditions, such as depression, posttraumatic stress disorder, and

anxiety disorder, and to treat them if needed. Moreover, psychological treatment approaches include cognitive behavioral techniques and supportive psychotherapy, with the goal of teaching the patient chronic pain coping skills, biofeedback, and relaxation techniques.

Interventions

For patients who are significantly impaired in their ability to mobilize their extremity, it is important to offer the patient the opportunity to determine the contribution of their sympathetic nervous system to their pain. This determination can be made by a sympathetic nerve block to the affected extremity. Future therapeutic options for the patient will depend on whether the pain is determined to be SMP or sympathetically independent pain (SIP). A patient with CRPS who reports pain relief after a sympathetic block is defined to have SMP. Published reports suggest that the best response to sympathetic blocks will occur if the blocks are given as soon as possible during the course of the disease. Blockade of the sympathetic nervous system is performed at the level of the stellate ganglion for upper extremity involvement or at the level of lumbar sympathetic chain for lower extremity involvement. The pain relief following sympathetic nerve block (SNB) generally outlasts the effects of the local anesthetics and, in the case of the SMP group, may be long lasting.

IV regional anesthetic (IVRA) blocks in the affected extremity have been performed using guanethidine, lidocaine, clonidine, droperidol, bretylium, and reserpine, with the first two being more extensively studied.

Neurostimulation

Spinal cord stimulation (SCS) has been shown to be effective in reducing pain and improving the function and quality of life in patients with CRPS in the upper extremities. This option should be considered when alternative therapies have failed.

Physiotherapy

The primary goal of physiotherapy is the restoration of function through activity. Interventions include passive and active assisted range-of-motion work and strengthening exercises aiming to improve motor control as well as to build functional tolerance to activities such as standing, sitting, walking (in cases of lower extremity involvement), and weight-bearing (for upper extremities).

Introduction

According to the American Society of Anesthesiologists (ASA) Task Force, cancer pain is defined as “pain that is attributable to cancer or its therapy.” Cancer is the cause of approximately 10% of deaths globally and 20% of deaths nationally. Each year several thousands of patients suffer from cancer pain, including 25% of patients in active treatment and 90% of those with advanced disease. Although cancer pain can be relieved, surveys have shown that pain is often undertreated in as many as 50% of patients. Barriers to adequate treatment of cancer pain include underreporting by patients and family members, lack of provider knowledge regarding current treatment standards, inadequate assessment of the patient by health care providers, fear of prosecution by federal and state agencies for the prescription of opioids, lack of accountability regarding failure to control pain, and inadequate reimbursement or excessive paperwork required by payers for the treatment of pain by health care providers. The World Health Organization (WHO) and other governmental agencies have recognized the importance of pain management as part of routine cancer care.

Etiology and pathophysiology

Cancer pain may occur in different parts of the body. There are three types of pain, depending on where in the body the pain is felt:

1. *Somatic pain* is caused by the activation of pain receptors in either the cutaneous (body surface) or deep tissues (musculoskeletal tissues) and could be caused by metastasis in the bone (an example of deep somatic pain) or involve postsurgical pain from a surgical incision (an example of surface pain). It is usually sharp and well localized.
2. *Visceral pain* is caused by activation of pain receptors from infiltration, compression, extension, or stretching of the thoracic (chest), abdominal, or pelvic viscera. Visceral pain is not well localized and is usually described as pressure-like, deep, squeezing.
3. *Neuropathic pain* is caused by injury to the nervous system as a result of either a tumor compressing nerves or the spinal cord or cancer actually infiltrating the nerves or spinal cord. It also results from chemical damage to the nervous system that may be caused by cancer treatment

(chemotherapy, radiation, surgery). This type of pain is severe and usually described as burning or tingling. Tumors that lie close to neural structures are believed to cause the most severe pain that cancer patients feel.

Somatic, visceral, and neuropathic pain can occur separately or together and can be felt at the same time or at different times. Somatic and visceral pains are easier to manage than neuropathic pain.

Cancer pain can be acute or chronic. Acute cancer pain is caused by nociceptor stimulation from actual damage to tissues. It is arbitrarily defined as lasting from the time of insult to the tissues to about 3 months. It can occur intermittently (episodic or intermittent pain) or constantly. Chronic cancer pain is defined as pain lasting for more than 3 months. It is much more subjective and not as easily described as acute pain. According to the American Cancer Society, chronic cancer pain may involve persistent (constant and sustained) pain or breakthrough pain. Breakthrough pain is a brief superimposed episode of severe pain that occurs while the patient is regularly taking pain medication. It usually comes on quickly and lasts from a few minutes to an hour. Many patients experience a number of episodes of breakthrough pain each day.

Cancer pain can be also categorized into three basic subtypes:

1. Pain associated with the tumor: bone lesions, metastases, local infiltration, hollow viscera obstruction, organ capsule distension, mono- and polyneuropathies, leptomeningeal metastases, cauda equina syndrome, and paraneoplastic syndrome;
2. Pain associated with the therapy: postradiation enteritis, radiation fibrosis, osteoradionecrosis, cystitis; chemotherapy and posthormonal related arthralgia, myalgia, avascular necrosis, chronic abdominal pain, mucositis, neuropathy; postsurgical phantom limb pain, postthoracotomy pain; and
3. Pain not specifically related to the malignancy: preexisting chronic pain problem; headaches, muscles strains, other aches and pains associated with arthritis, kidney stones (these conditions can normally be treated along with cancer pain).

Figure 152.1. Universal pain assessment tool. Reproduced with permission, Mosby press.

Assessment and evaluation

The following items are essential to the initial assessment: detailed history of the pain, physical examination, including a complete neurologic examination, diagnostic testing, and development of a management plan.

The patient history should include information about the premorbid chronic pain, drug or alcohol use, medications, cancer diagnosis, staging of the tumor, progression of malignancy, and specific characteristics of treatments. Evaluation of cancer pain involves many features: duration of the pain (acute vs. chronic), intensity of the pain (mild, moderate, or severe), quality of the pain (neuropathic, nociceptive, or mixed), and temporal pattern (continuous, breakthrough, or both); initiating factors (pain related to posture, position, or activity); radiation; previous therapy; and associated psychological and emotional components. If there is more than one pain complaint, each source of pain should be considered independently. The intensity of the pain should be determined. Common forms of measurement include facial expression scale (Fig. 152.1) or linear analog scale from 0 to 10 in which 0 is no pain and 10 is the worst pain level imaginable. Scales may be verbal or written (which can be colors, numbers, or lines).

Patients who identify themselves as having pain should thereafter be evaluated with a more thorough assessment, such as the Brief Pain Inventory. A psychosocial evaluation is necessary, including the patient's as well as the family's objectives in treatment of pain as well as cancer.

Comprehensive physical examination should include weight, vital signs, determination of nutritional status, thorough examination of the site of pain and referring sites, complete musculoskeletal and neurologic examination, and auscultation of heart and lungs. Provocative bedside maneuvers reproducing pain help to better identify the pain-sensitive structure and should be a routine part of the comprehensive assessment of cancer pain patients. Patients should also be evaluated for associated physical symptoms, such as fatigue, constipation, and changes in mood.

The data obtained from the history and physical examination may prompt further diagnostic workup to exclude the presence of medical emergencies requiring rapid specialist con-

sultation and intervention. Diagnostic testing should be used only when it will contribute to the treatment of the patient or confirm a suspected diagnosis. Plain films and CT should be used to determine fracture or visceral pathology. Radionuclide studies will reveal changes in bone growth or destruction of bone. MRI should be used for the evaluation of soft tissue changes. The amount of the diagnostic testing should be decreased or eliminated with progression of disease, especially in terminally ill patients.

Formulating a plan of care is essential, including a substitute plan in case of resistant pain. Discussion with the patient is essential, and the patient may need assurance that the first plan is not the only option available.

Management

Treatment goals for cancer pain patients should be geared toward cure or prolonging life, maintaining function, and providing comfort. They should include inhibition of the transmission of pain as well as modulation of the patient's perception of pain. Although it has been suggested that more than 85% to 95% of cancer patients can be treated by the use of appropriate pharmacologic and anticancer therapy, some patients require invasive interventions to relieve their pain or to assist in the management of their pain when the secondary effects of the opioids are so significant as to compromise the cancer patient's quality of life. Frequent reevaluation of the patient is required.

Pharmacologic management

There are a number of suggested algorithms for pharmacologic treatment of cancer pain. The best known of these is the WHO's three-step analgesic ladder and the four-step modified analgesic ladder. The WHO's analgesic ladder provides adequate analgesia in the majority of cases.

1. Step one – mild pain: nonopioid analgesics including nonsteroidal anti-inflammatory drugs (NSAIDs) +/- adjuvant therapy, such as anticonvulsants and acetaminophen

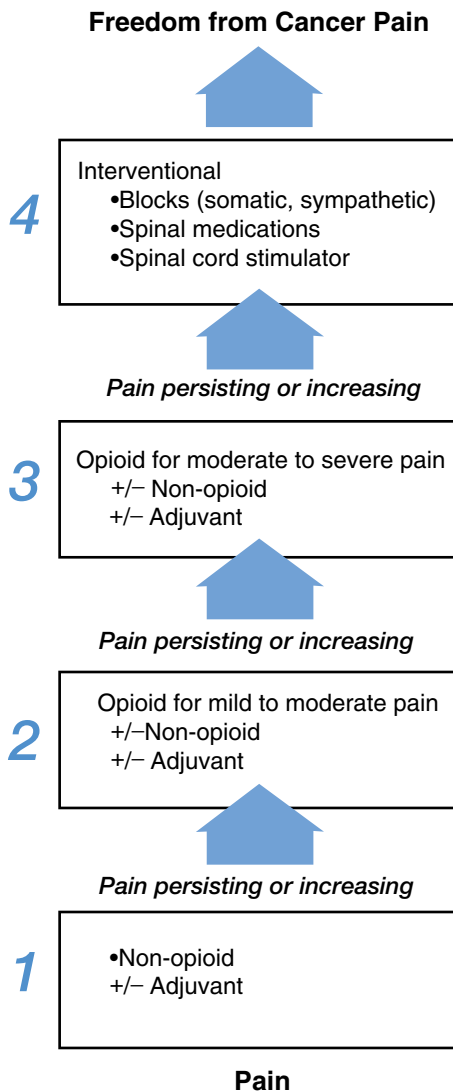

Figure 152.2. Modified analgesic ladder for cancer pain, including interventional management. Adapted from World Health Organization. *World Health Organ Tech Rep Ser* 1990; 804:1–73; Miguel R. *Cancer Control* 2000; 7:149–156; and Krames E. *Med Clin North Am* 1999; 83:787–808.

2. Step two – mild to moderate pain: opioids +/- nonopioid analgesics and adjuvant therapy
3. Step three – moderate to severe pain: strong opioids, such as long acting opioids, in addition to short-acting opioids +/- adjuvant therapy
4. Severe to intractable pain/failure-to-treat persistent pain with increasing doses of opioids warrants interventional therapies as mentioned in the modified analgesic ladder (Fig. 152.2).

Medication management in cancer pain uses all the drug classes including nonopioid, opioid, and adjuvant medications. The doses required are much higher, and the side-effects profile seen is more severe. Breakthrough medications should be fast acting.

Adverse effects management

Side-effect management is an integral part of any cancer pain treatment regimen and requires a proactive approach. Patient education should be implemented to decrease apprehension about the use of opioids and clear concerns regarding issues of addiction, dependence, tolerance, and pseudoaddiction. Reassurance should be used to decrease underreporting of pain. Goals should include reduction of pain to tolerable levels, titration of dose to effect, and use of the minimum amount of medication required to achieve analgesic goals without significant side effects.

Nausea is the most common side effect, affecting approximately one third of patients. In most cases, nausea is mild or resolves spontaneously, but in a small number of patients it may become unremitting, and failure to manage it may limit the patient's use of the most effective form of treatment. Evaluation of nausea in the cancer patient on opioids should begin with review of the bowel function. Many factors can be considered as a cause of nausea including opioid therapy, bowel obstruction from disease progression or increase in the intracranial pressure from tumor growth. Chemotherapy and radiotherapy frequently lead to nausea. Treatment of nausea should be based on the associated symptom reported by the patient. Alternatives include phenothiazines, serotonin antagonists, or atypical antipsychotics. Other options include intestinal motility agents, antivertiginous agents, and oral dexamethasone. In patients who develop anorexia secondary to opioids, one should consider hormonal therapy, such as dronabinol, megestrol acetate, corticosteroids, or anabolic steroids. Patients should also be evaluated for mood disorders.

Opioid-induced constipation is the second most common side effect of opioid therapy. Treatment of constipation should be started prophylactically with the initiation of opioid therapy. Stool softeners, strong laxatives, and dietary adjustments should be implemented to ensure regular bowel habits. Orally administered naloxone, a pure opioid antagonist, improves idiopathic constipation. Opioid agonist-antagonists exhibit a lower frequency of constipation than do the pure agonists.

Opioid therapy can cause a wide range of effects on the central nervous system (CNS). Patients may exhibit drowsiness, confusion, dysphoria, or euphoria. Sedation could be minimized by decreasing the dosage, changing the medication, slow dose titration, and using psychostimulants such as methylphenidate and methylphenidate modafinil.

The excitatory effects on the CNS may present with hyperalgesia, myoclonus, or seizures. Opioid-induced hyperalgesia was recognized as an emerging side effect of opioid therapy. Patients experiencing hyperalgesia complain of pain out of proportion to physical findings, which is a common cause for loss of efficacy of these medications over time. As it can be difficult to distinguish from tolerance, opioid-induced hyperalgesia is often compensated for by escalating the dose of opioid, potentially worsening the problem by further increasing sensitivity to pain.

It may develop in response to both chronic and acute exposure to opioids. This side effect can be severe enough to warrant discontinuation of opioid treatment.

Chronic opioid use may lead to the development of tolerance to the analgesic effect. The patient becomes less susceptible to the effect of the opioid as a consequence of its prior administration. Tolerance to one opioid, however, does not lead to tolerance to an equianalgesic dose of another opioid. Due to this concept of “incomplete cross tolerance,” it is necessary to decrease the equianalgesic dose of a drug in a naïve patient by 30% to 50%.

Physical dependence is the term used to describe the phenomenon of withdrawal when an opioid is abruptly discontinued or an opioid antagonist is administered. Both tolerance and physical dependence are predictable pharmacologic effects seen in response to repeated administration of an opioid and can be easily managed after being identified. These effects are distinct from psychological dependence or addiction. Psychological dependence describes a pattern of drug use characterized by a continued craving for an opioid, manifested as compulsive, drug-seeking behavior and overwhelming involvement in drug procurement and use.

Pseudoaddiction is a term describing behavior that appears to be drug-seeking in a patient who has been undertreated or in whom the disease has progressed. Such behavior should prompt review of the therapeutic plan or further investigation of the disease.

Less common side effects of opioid therapy include urinary retention, respiratory depression, pruritus, and miosis. Whereas tolerance to nausea, vomiting, sedation, euphoria, and respiratory depression occur rapidly, there is minimal development of tolerance to constipation and miosis.

Palliative therapy

The use of external beam radiation therapy in the treatment of painful metastasis is particularly important. Radiation for bone pain, pain secondary to apical lung mass, and so forth, can lead to a quick and lasting pain relief. Therapeutic radionuclides, such as strontium-89 chloride and samarium-153-ethylenediaminetetramethylene phosphonic acid (EDTMP), are useful in patients with multiple bony metastases, such as those in breast cancer. The agents are picked and concentrated within the bone. They exhibit little toxicity except mild sedation. The expected effects occur within a week and can be used to supplement external beam radiation. They also might prevent formation of new metastases.

Chemotherapy reduces the size of the targeted tumors and can be helpful with pain due to compression, stretching, or ischemia. Bisphosphonates are helpful as analgesics. These drugs bind to the hydroxyapatite crystals within bone and inhibit osteoclastic activity. Prospective randomized studies in patients with myeloma and metastatic breast cancer show that bisphosphonates improve pain and reduce morbidity secondary to bony pathology.

Interventional therapies

If pharmacotherapy for pain associated with malignancy is inadequate or is found to cause intolerable secondary effects, interventional techniques should be considered. These modalities include antitumor therapy, neural blockade with or without neurolytic drugs, CNS opioid therapy, electrical stimulation, or surgery.

Local anesthetic blocks can be used for diagnostic, prognostic, or therapeutic purposes. A diagnostic nerve block can help to determine which anatomic structure is responsible for generation and transmission of the pain and to distinguish between somatic, visceral, sympathetic, and central pain. The effects from the block should be carefully analyzed, and the results used to determine the potential for more permanent ablative procedure. A diagnostic block should always precede an ablative block. Such a trial block will enable the patient to be aware of the effect and possible side effects of the block and also will identify any neurologic deficits that may be intolerable to the patient.

Therapeutic blocks are often administered to treat pain caused by tumor compression of nerve structures; neuropathies and neuralgias from direct nerve damage such as postthoracotomy pain or post-herpetic neuralgias; and trigger points from muscle spasm.

Neurolytic blocks involve injection of a destructive substance close to a spinal or peripheral somatic nerve and the sympathetic nervous system. It may be beneficial for targeted areas of pain, such as head and neck cancer, pancreatic cancer, pelvic malignancies, and pain related to the perineum.

The most common neurolytic agents used are alcohol and phenol. They both produce equal effects. Alcohol causes severe pain on injection that may be alleviated by pretreatment with local anesthetic. A phenol injection is better tolerated and causes almost immediate sensation of numbness and pain relief.

Specific applications

Neurolytic sympathetic blocks can be helpful in controlling pain that is either visceral or dysesthetic (causalgic) in origin. Visceral pain occurs when sympathetic nerves or visceral structures are stretched, traumatized, or invaded by the cancer. The patient complains of dull, burning pain that is poorly localized. Referred pain can occur (e.g., shoulder pain from tumor invasion of the diaphragm). In some cases, the causalgia can respond to a blockade alone, but in others ablation of involved ganglia or surgical rhizotomy may be necessary.

The various other ganglion blocks include the stellate ganglion block, celiac plexus block, hypogastric plexus block, and ganglion impar block. These blocks are described in detail in other chapters.

Chest and abdominal wall pain can be treated with neurolytic intercostal nerve block. The intercostal nerves provide sensory innervation to the skin of the chest and abdomen anterolaterally. They travel in the inferior part of the ribs posterior to the intercostal artery. Subcostal nerve comes from the

ventral ramus of T12 and is equivalent to the intercostal nerve at the above levels. For diagnostic block, 1 to 2 ml of bupivacaine 0.25% to 0.5% is injected. For neurolytic block, 4 to 5 ml of phenol 10% can be injected. Alcohol should be avoided because of the risk of intercostal neuritis after the block. Most clinicians now favor the use of radiofrequency lesion of the intercostal nerves instead of injecting neurolytic medications. Common complications include pneumothorax and potential local anesthetic toxicity. Postprocedural intercostal neuropathy may occur, which can be treated with a transcutaneous electrical nerve stimulation (TENS) unit, transdermal lidocaine patch, or neuropathic medication.

Subarachnoid neurolytic block is suitable for patients who have significant cancer pain that is not controlled by any other modalities. The pain should be localized into few sensory segments of the spinal cord. The main goal of the block is selective destruction of the corresponding dorsal root ganglia. This destruction is accomplished by positioning the patient in a way that permits the neurolytic material (either hypo- or hyperbaric) to remain localized in the dorsal surface of the spinal cord. Extremely important for the lower thoracic and lumbar neurolysis is the fact that thoracic and lumbar nerves leave the spinal cord at a higher level than the exiting neural foramina. For example, pain at the level of T9 nerve distribution requires neurolysis at T6, T7, and T8 levels. The usual dose of either agent is 0.6 ml and is injected within 80 to 90 seconds for each level. Complete neurologic examination before and after the block is mandatory to evaluate any neurologic deficits. Common side effects include temporary or permanent weakness of the urinary or rectal sphincters. Postdural puncture headache may occur and is most common in younger patients. Radiofrequency lesioning is the application of electrical current to achieve coagulation of proteins and nerve destruction. It is used to ablate pain pathways in the trigeminal ganglion, spinal cord, dorsal root entry zone, dorsal root ganglion, sympathetic chain, facet joints, and peripheral nerves. Because it causes nerve destruction, this technique is used only as an end-of-the-line therapeutic modality when other measures have failed. Fluoroscopic guidance is a requirement for proper needle placement. Common complications include pneumothorax, postlesioning neuritis, motor paralysis, numbness, and incomplete pain relief.

Neuraxial opioid therapy is often effective for treating cancer pain that has not been adequately controlled by systemic treatment. The close proximity of the opioid receptors in the spinal cord to the injected neuraxial opioids ensures maximum effect with small doses of medication. The preservative-free drug can be delivered via epidural, intrathecal, or intraventricular approach. Opioids can be used alone or in combination with local anesthetics, α -adrenergic agents, or baclofen to achieve synergistic effect and optimal pain relief. The intraventricular approach is used infrequently for neck and head cancer pain.

A tunneled epidural catheter can be placed at any level in the lumbar, thoracic, or cervical level. The indications include

cancer pain anywhere from the neck to the lower extremities and a life expectancy of 3 to 6 months or less. This technique is more advantageous than the nontunneled epidural catheter because of the low incidence of infections. A tunneled epidural catheter can be either a simple, one-piece catheter or consist of two pieces with a Dacron cuff and antibiotic cuff. Administration of epidural medications can be accomplished by continuous infusion via a standard portable infusion pump connected to a port. Patient-controlled epidural analgesia (PCEA) allows delivery of intermittent boluses by the patient or the family and thus some degree of control over the pain management.

Intrathecal delivery of opioids into the CNS has certain advantages over epidural catheters. The doses of medications needed are significantly lower; opioid requirements are approximately 10% of those for epidural administration. The intrathecal drugs act quicker and last longer. Patients experience fewer side effects due to decreased systemic absorption. Implantable intrathecal pumps are considered for patients whose pain becomes increasingly more difficult to manage, who experience significant side effects with increasing doses of enteral and parenteral medications, who cannot tolerate large doses of epidural infusions, and whose life expectancy is longer than 6 months. Morphine is the only opioid approved for intrathecal use by the US Food and Drug Administration (FDA) for treatment of chronic and cancer pain. Other opioids have been used, such as hydromorphone, fentanyl, and sufentanil. The most common nonopioid medications used are clonidine, ziconotide, bupivacaine, and baclofen. Usually one or more of these drugs are added to opioids in the intrathecal delivery system. The infusion regimen is individualized, based on the results from the patient's pain assessment and oral or intravenous opioid requirements. Several companies produce intrathecal pumps. Codman's model 400 (Raynham, MA) is a nonprogrammable, constant-flow infusion pump. Medtronic's Isomed and Synchronomed II (Minneapolis, MN) allow the physician to change the daily rate (mg/d), including options of single bolus, timed-specific boluses, or a complex continuous delivery of drug. Changing the rate is easily performed with a programmer. The implanted pumps require infrequent drug refills.

Surgery

Finally, in some cases, it may be appropriate to perform neurosurgical destructive procedures. Examples include anterolateral cordotomy, stereotactic mesencephalotomy, and midline myelotomy.

Conclusion

Despite the multiple options available for the management of cancer pain, many patients are undertreated or suffer limiting secondary effects. Pain may result from the primary disease process, secondary to treatment, or from sources unrelated to malignancy.

Secondary effects of opioids should be anticipated in all patients and screened for in each encounter as they may affect a

patient's ability to use opioids. Opioids are the mainstay of treatment for cancer pain and should be used at any stage of the disease without concern for life expectancy.

Cardiopulmonary resuscitation

Samuel M. Galvagno Jr.

Introduction

In 2010, the American Heart Association (AHA) revised guidelines for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC). Employing an evidence-based approach, these guidelines are based on the best available scientific evidence and were the result of an international collaboration amongst resuscitation experts. Several changes were made to simplify CPR instructions and ECC algorithms and to emphasize critical, evidence-based assessments and interventions recommended for cardiac arrest or other life-threatening conditions. A thorough discussion of topics covered in courses such as advanced cardiac life support (ACLS), pediatric advanced life support (PALS), or the Neonatal Resuscitation Program (NRP) is beyond the scope of this chapter. An introduction to the essential guidelines for CPR and ECC is presented with an emphasis on critical actions that are most likely to be used within the operating room or intensive care unit.

Basic life support (CPR)

The 2010 guidelines recommend a “Circulation-Airway-Breathing” approach (“C-A-B”) as opposed to the classically taught “Airway-Breathing-Circulation” sequence. Fig. 153.1 depicts the sequence of steps to be followed for an unresponsive adult patient.

For all single rescuers of infant, child, and adult victims (excluding newborns), a universal compressing-ventilation ratio of 30:2 is recommended. This ratio may be altered to 15 compressions to 2 breaths for infant and child 2-rescuer CPR. Rescuers should “push hard and fast,” compressing the chest at least 100 times a minute, while allowing complete chest recoil between compressions and minimizing interruptions. Incomplete recoil during compressions is associated with high intrathoracic pressures and impaired hemodynamics, including decreased coronary perfusion, decreased cardiac index, and decreased myocardial blood flow. Layperson bystanders not trained in CPR should provide “hands only” CPR. A summary of basic life support maneuvers for infants, children, and adults is presented in Table 153.1.

It should be noted that, after an advanced airway is secured, rescue breaths for adults, children, and infants should be

delivered at a rate of approximately 8 to 10 breaths per minute. Hyperventilation during CPR for victims with advanced airways has been shown to decrease cardiac output, decrease coronary perfusion pressure, increase gastric inflation, and worsen outcomes. When an advanced airway is placed, chest compressions should not be interrupted to deliver ventilations. During CPR, cardiac output may be reduced to 25% of normal; hence, lower minute ventilation can maintain effective oxygenation and ventilation. Tidal volumes of 500 to 600 ml (6–7ml/kg) are recommended, and an effective way to ensure adequate tidal volume is to produce a visible chest rise. Vigilance is required during bag-mask ventilation as adult ventilating bags typically contain volumes of 1 to 2 liters. There is inadequate evidence to define the optimal timing of advanced airway placement in relation to other interventions for cardiac arrest. Some studies have shown that patients had better neurologic outcomes after cardiac arrest when intubation was delayed and combined with minimally interrupted chest compressions.

Sudden cardiac death is a leading cause of death in North America, and most victims demonstrate ventricular fibrillation (VF) at some point during their arrest. Early defibrillation is most likely to be effective if delivered during the first 5 minutes of collapse; however, many patients will not be defibrillated within this narrow therapeutic window. CPR performed immediately before and after shock delivery after VF-induced collapse has been shown to confer a nearly threefold improved chance of survival. Consequently, the 2010 guidelines continue to strongly emphasize the proper performance of CPR for victims of cardiac arrest.

Electrical therapies

Survival rates for VF are highest when CPR is initiated promptly with defibrillation within 3 to 5 minutes. For every minute that passes between witnessed VF cardiac arrest and defibrillation, survival rates decrease by approximately 10%; when CPR is provided, the decrease is less rapid and averages approximately 4% per minute from collapse to defibrillation. Whereas CPR may maintain minimal oxygen and substrate delivery to the heart and brain, basic CPR, by itself, is not likely to eliminate VF.

Defibrillation is defined as termination of VF for at least 5 seconds following a monophasic or biphasic electrical shock.

Figure 153.1. Adult Advanced Cardiovascular Life Support (ACLS) Cardiac Arrest Algorithm. Reprinted with permission. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, Part 8: Adult Advanced Cardiovascular Life Support. *Circulation* 2010; 122[suppl 3]: S736, Figure 1. ©2010 American Heart Association, Inc.

Investigators have proposed different hypotheses regarding the mechanism of action; however, the exact mechanism of effective defibrillation is unknown. Defibrillating shocks may cause transient depolarization of myocardial tissue or prolong the refractory period of the cardiac action potential. The ability of an electrical shock to defibrillate the heart depends on its

waveform and energy. Cardioversion, as opposed to defibrillation, involves delivery of a shock synchronized with the QRS complex.

Regardless of the timing, a defibrillation waveform describes the energy, or current, mathematically as a factor of time. A monophasic waveform has a single positive phase that

Table 153.1. Summary of key basic life support components for adults

Component	Recommendation
Pulse check	No more than 10 seconds, healthcare providers only (laypersons should not check for a pulse)
CPR sequence	C-A-B (Circulation/Chest Compressions-Airway-Breathing)
Compression rate	100 compressions/minute
Chest wall recoil	Full chest wall recoil should be allowed between compressions
Compressor rotation interval	Healthcare providers should rotate compressors every 2 minutes to avoid fatigue
Compression-to-ventilation ratio	30:2 (1 or 2 rescuers)
Ventilations (rescue breathing)	1 breath every 6-8 seconds (8-10 breaths/min) 1 second per breath Visible chest rise should be observed Asynchronous with chest compressions

either rapidly or gradually returns to zero voltage with current flowing in the direction between defibrillation electrodes (Fig. 153.2).

Biphasic waveforms have a positive and negative phase reflecting a reversal of current flow between the defibrillation electrodes. Recent clinical trials have compared the use of monophasic and biphasic shocks for external defibrillation, but neither has been consistently associated with a higher rate of return of spontaneous circulation or survival. Biphasic shocks have shown a trend toward equivalent or higher success for termination of VF and are now the standard waveform used in most commercial defibrillators. Multiple prospective studies have failed to demonstrate the ideal biphasic energy level. Current recommendations are to deliver the initial shock at 150 J for biphasic truncated waveforms. If the defibrillator is designed to deliver a rectilinear biphasic waveform, 120 J can be used. For subsequent shocks, the same or a higher energy level can be used. Directions for selection of the appropriate energy level are provided with each specific model of defibrillator. If the type of defibrillator is unknown, current guidelines recommend delivering the first shock at 200 J. Previous guidelines recommended three-shock initial sequences for VF, but because the first shock is most likely to be the most effective, especially when biphasic waveforms are used, the current recommendation is to deliver single shocks in between sequences of high-quality CPR.

Defibrillator electrodes, including automated external defibrillators (AEDs), should be placed in an anterolateral (sternal–apical) position. If an implantable medical device is present, the electrode pads should be positioned at least 1 inch

(2.5 cm) away from the device. Pads should never be placed over transdermal medication patches. Several case reports of fires, ignited by defibrillator current arcing, have been described in the presence of oxygen-rich environments, such as the operating room or intensive care unit. Rescuers should take precautions to minimize arcing by using self-adhering defibrillation pads and by minimizing the flow of oxygen across a patient's chest during defibrillation attempts.

Pulseless cardiac arrest

The four most common lethal rhythms encountered during cardiac arrest include VF, rapid ventricular tachycardia (VT), pulseless electrical activity (PEA), and asystole.

The most critical intervention during the first minutes of pulseless arrest is immediate CPR. Chest compression interruptions should be minimized, and defibrillation should be accomplished as soon as possible. Central venous access for drug administration is not required for most resuscitation attempts, and, if access is identified as a problem, endotracheal administration of drugs or intraosseous (IO) cannulation are reasonable alternatives. IO cannulation is safe and effective for initial fluid resuscitation, drug delivery, and blood sampling. IO access is attainable in all age groups and is likely to be a better route for emergency drug administration than the endotracheal route because multiple studies have shown that lidocaine, epinephrine, atropine, naloxone, and vasopressin are absorbed poorly with lower blood concentrations than would be expected with intravenous (IV) administration.

The survival rate for cardiac arrest from asystole and PEA is poor. A successful resuscitation in such cases is most likely when a reversible cause can be identified and treated. As opposed to treatment for VF and VT, defibrillation is not effective. CPR, with early establishment of an advanced airway, remains the mainstay of treatment.

Despite the prolific use of vasopressor and antiarrhythmics for ECC over the past several decades, to date, there is no evidence that any of these agents increase the rate of neurologically intact survival to hospital discharge. For all lethal arrhythmias encountered during pulseless arrest, high-quality CPR and defibrillation should be initiated before

Figure 153.2. Biphasic and monophasic defibrillation waveforms.

Table 153.2. Pharmacologic agents for use in pulseless arrest

Drug	Initial dose	Frequency	Mechanism	Comment
Epinephrine	1 mg IV/IO for adults (0.01 mg/kg of 1:1000 for children or 0.1 mg/kg 1:10,000)	Every 3–5 min	α - and β -adrenergic; increases cerebral and myocardial perfusion	High-dose epinephrine is no longer recommended
Vasopressin	40 Units IV/IO	One-time dose only	Nonadrenergic peripheral vasoconstrictor	One dose may replace either first or second dose of epinephrine
Atropine	1 mg IV/IO (0.02 mg/kg IV/IO for children, minimum dose 0.1 mg)	Every 3–5 minutes; maximum dose 3.0 mg for adults, 1.0 mg for children	Reversal of cholinergic-mediated decreases in heart rate, systemic vascular resistance, and blood pressure	Only indicated in children with bradycardia due to increased vagal tone or primary AV block
Amiodarone	300 mg IV/IO for arrest (5 mg/kg for children)	First dose can be followed by 150 mg	Sodium, potassium, calcium channel blocker; α - and β -adrenergic blocker	If successful, should be followed with a continuous infusion
Lidocaine	1.5 mg/kg first dose IV/IO (1 mg/kg for children)	1.0 mg/kg at 5- to 10-min intervals to maximum dose of 3 mg/kg	Sodium channel blocker	No proven short-term or long-term efficacy in cardiac arrest
Magnesium	1–2 g IV/IO (50 mg/kg IV/IO, maximum dose 2 g for torsades in children)	Give in 10 ml of D ₅ W over 5–10 min	Calcium channel blocker	Effective for termination of polymorphic VT (torsades de pointes)

AV, atrioventricular; D₅W, 5% dextrose in water.

pharmacotherapeutic therapy. CPR should not be interrupted to give medications. Drugs can be administered before or after defibrillation in a *CPR-RHYTHM CHECK-CPR-SHOCK* sequence, repeated as needed. Epinephrine is the first drug of choice in all instances of pulseless arrest. A summary of medications for cardiac arrest is provided in [Table 153.2](#).

Interventions that are not supported by available evidence include pacing in asystole, norepinephrine, and the precordial thump. Procainamide was shown to be effective in a small study of 20 patients, but its use is limited by the need for slow infusion and limited evidence for effectiveness in emergent situations.

Management of symptomatic bradycardia and tachycardia

The management of symptomatic tachycardia and bradycardia is discussed in [Chapter 155](#). [Figures 153.3](#) and [153.4](#) are the current algorithms for symptomatic tachycardia and bradycardia taught in ACLS.

Pediatric advanced life support

In children, sudden cardiac arrest is uncommon and usually results from a respiratory rather than cardiac event. Impending respiratory failure is indicated by increased respiratory rate, nasal flaring, retractions, gasping, diminished breath sounds, or grunting. Shock is another cause of cardiac arrest in the pediatric population with the most common cause being hypovolemia. The signs of compensated and decompensated shock in pediatric patients are summarized in [Table 153.3](#). Knowledge of the signs of shock and imminent respiratory failure is imperative because early recognition may lead to interventions that can prevent cardiac arrest in pediatric patients. Many of the signs of

shock may be confused with other etiologies, such as pain, fever, or anxiety.

Management of the pulseless arrest in the pediatric patient is similar to management of adults insofar as prompt advanced airway management and CPR remain the cornerstones of care ([Fig. 153.5](#)).

Initial electrical shocks, when indicated, should be delivered with 2 J/kg. AEDs are preferred for patients 1 to 8 years of age. Vasopressin is not indicated for pediatric patients. Possible causes should be considered and treated ([Table 153.4](#)).

If an intubated pediatric patient's condition deteriorates precipitously, the mnemonic "DOPE" should be considered to identify the most common culprits:

- D – Displacement of the endotracheal tube
- O – Obstruction of the tube
- P – Pneumothorax
- E – Equipment failure

During CPR, interruptions in chest compressions should be minimized and hyperventilation should be avoided because pediatric patients, like adults, tend to be overventilated during resuscitation. For a complete review of PALS, it is recommended that anesthesiologists who provide care for pediatric patients take the course offered in conjunction with the American Academy of Pediatrics and the AHA.

Neonatal resuscitation

Approximately 10% of newborns require some assistance with breathing at birth, and 1% require formal resuscitation. Guidelines for neonatal resuscitation are provided in the NRP course offered by the American Academy of Pediatrics. Initial management of a neonatal resuscitation, as taught in the NRP, is outlined in [Fig. 153.6](#).

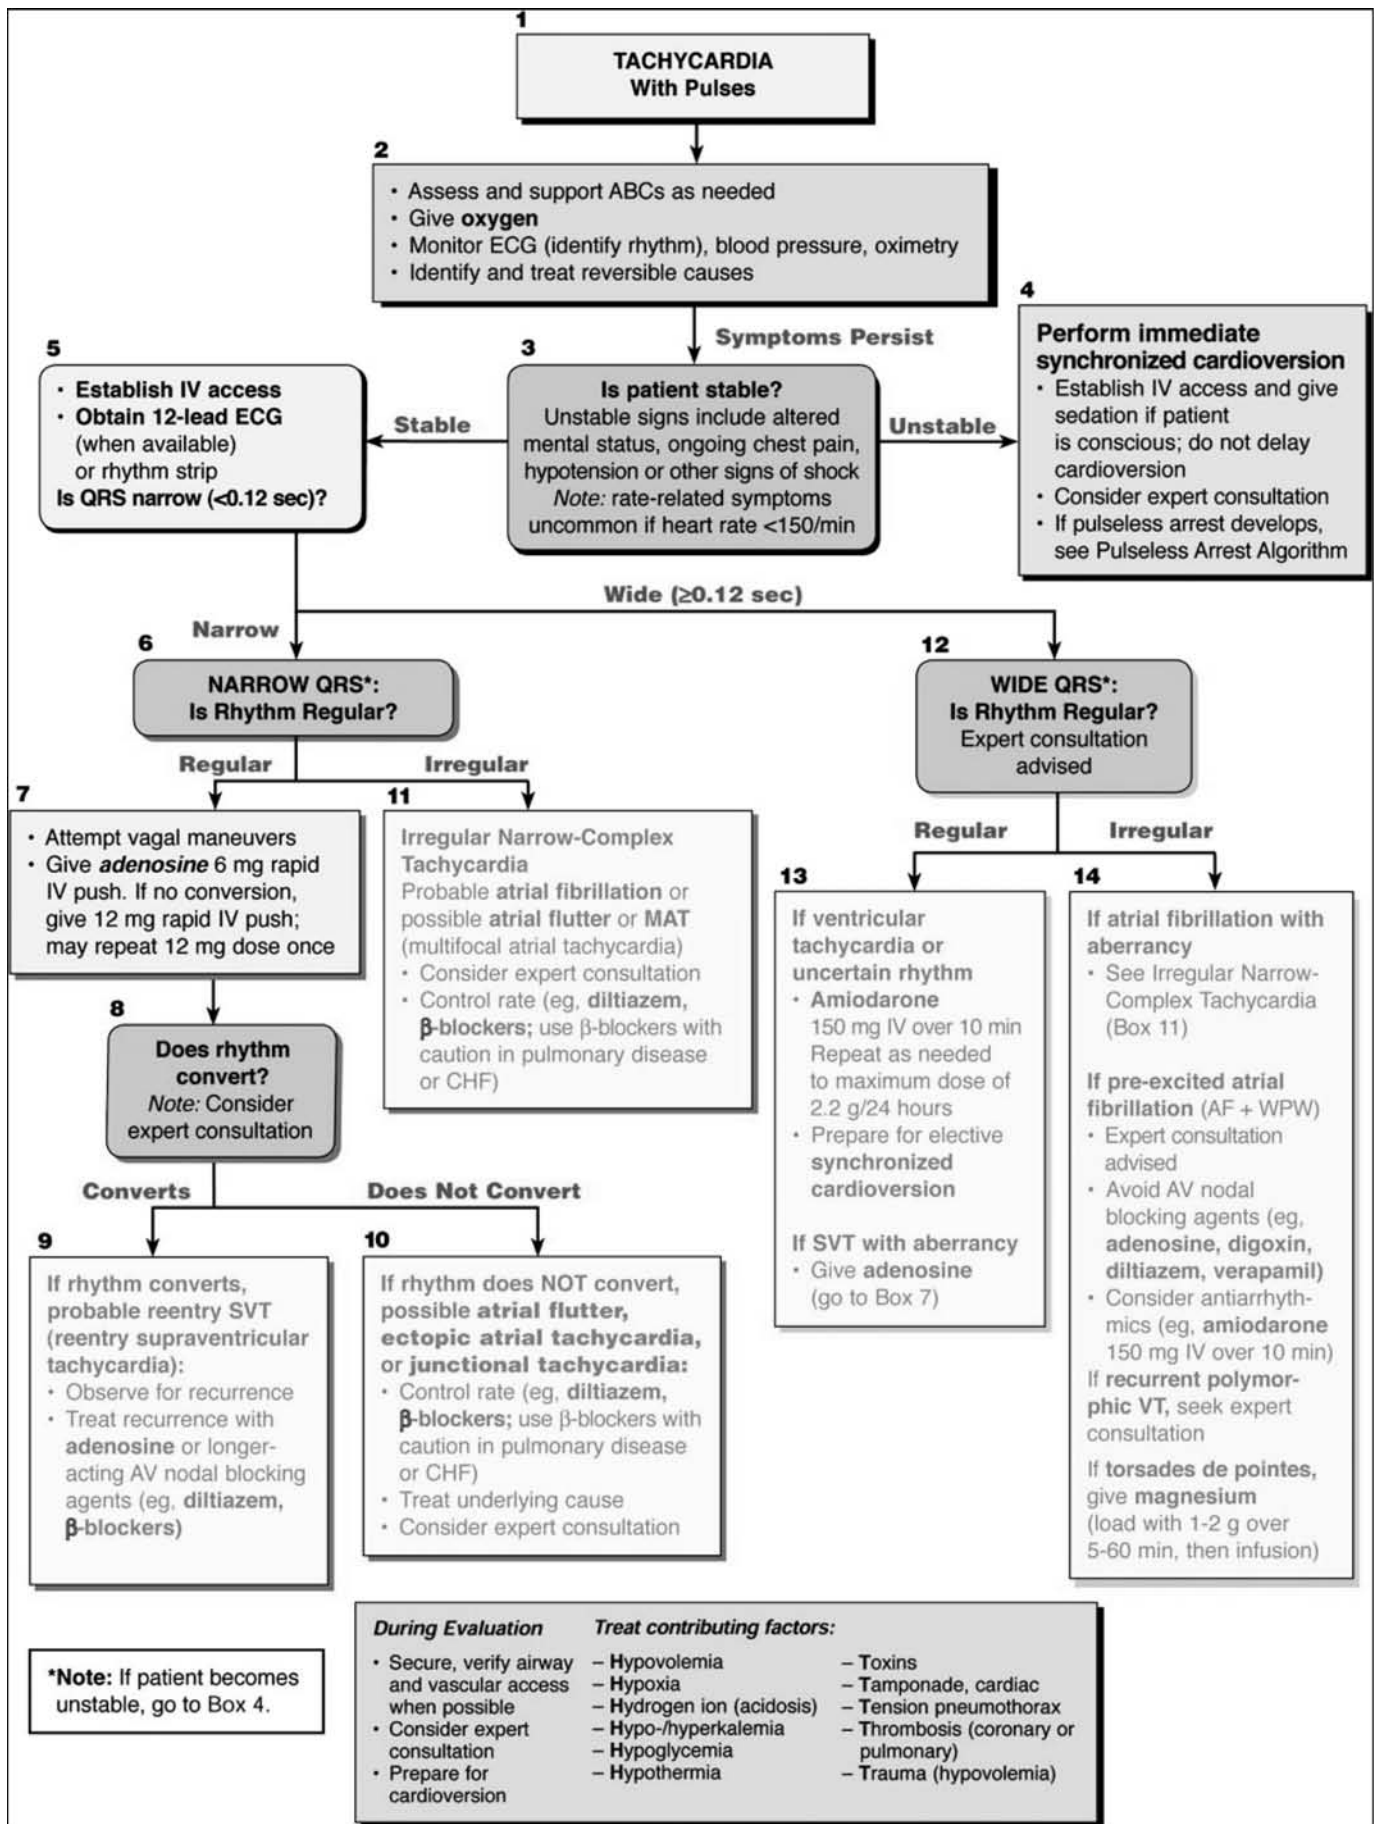

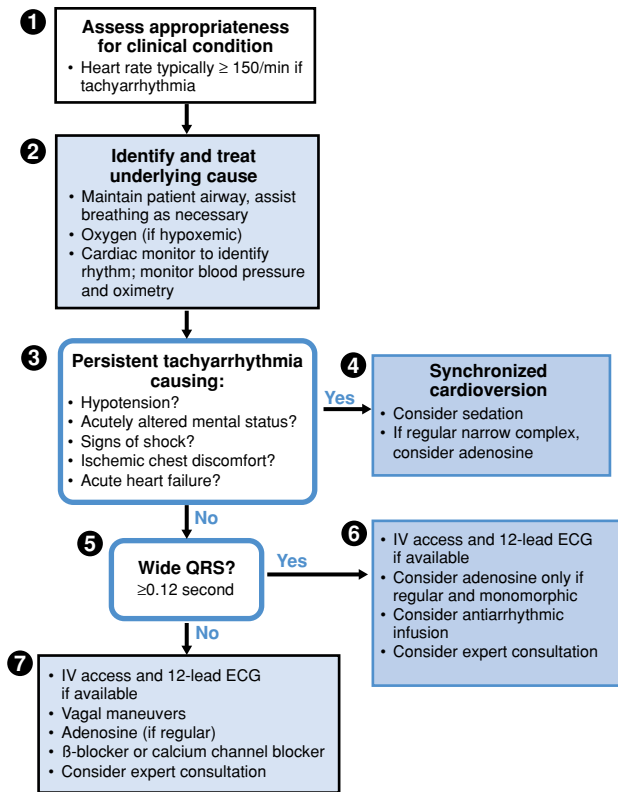

Figure 153.3. Adult Tachycardia (with pulse). Adult Tachycardia (with pulse)

Doses/Details

Synchronized cardioversion
Initial recommended doses:
• Narrow regular: 50-100 J
• Narrow irregular: 120-200 J biphasic or 200 J monophasic
• Wide regular: 100 J
• Wide irregular: defibrillation dose (**NOT** synchronized)

Adenosine IV dose:
• First dose: 6 mg rapid IV push; follow with NS flush
• Second dose: 12 mg if required

Antiarrhythmic Infusions for Stable Wide-QRS Tachycardia

Procainamide IV dose:
• 20-50 mg/min until arrhythmia suppressed, hypotension ensues, QRS duration increases >50%, or maximum dose 17 mg/kg given.
• Maintenance infusion: 1-4 mg/min
• Avoid if prolonged QT or CHF

Amiodarone IV dose:
• First dose: 150 mg over 10 min
• Repeat as needed if VT recurs
• Follow by maintenance infusion of 1 mg/min for first 6 hours

Sotalol IV dose:
• 100 mg (1.5 mg/kg) over 5 min
• Avoid if prolonged QT

Figure 153.4. Adult Bradycardia (with pulse). Reprinted with permission. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, Part 8: Adult Advanced Cardiovascular Life Support. *Circulation* 2010; 122[suppl 3]: S749, Figure 3. ©2010 American Heart Association, Inc.

Table 153.3. Compensated and decompensated shock

Compensated shock	Decompensated shock
Tachycardia	Depressed mental status
Cool extremities	Decreased urine output
Prolonged capillary refill	Metabolic acidosis
Weak peripheral pulses	Tachypnea
Normal blood pressure	Weak central pulses
	Systolic pressure:
	<60 (0–28 d)
	<70 in infants (1–12 mo)
	<70+ (2 × age in years) in children 1–10 y
	<90 in children over age 10

Table 153.4. Possible etiologies for pulseless arrest in both adult and pediatric patients

6 “H’s”	5 “T’s”
Hypovolemia	Toxins
Hypoxia	Thrombosis (coronary or pulmonary)
Hydrogen ion (acidosis)	Tension pneumothorax
Hypoglycemia	Trauma
Hyper- or hypokalemia	Tamponade, cardiac
Hypothermia

Multiorgan failure and its prevention

K. Annette Mizuguchi and Gyorgy Frendl

Introduction

As anesthesiologists, we are routinely asked to care for patients with multiple and complex comorbidities. Few situations, however, can be more challenging than caring for patients with multiorgan dysfunction. These patients are challenging because they have acute functional changes and the potential to deteriorate dramatically. They also present with various combinations of organ involvement and with varying degrees of severity adding another layer of complexity to their management.

Definition of multiorgan dysfunction syndrome and failure

Multiorgan dysfunction syndrome (MODS) and multiorgan failure (MOF) are most commonly seen in the context of critical illness or injury that is often due to sepsis or trauma. Most commonly affected organs are the lungs, kidneys, liver, heart, brain, and the hematopoietic system, but involvement of any organ is possible, and the severity of dysfunction is variable. Unlike other disease processes, organ dysfunction is not caused by a direct disease process involving a particular organ (like infection or trauma); rather the patient's diseased state is thought to indirectly affect the organ.

Incidence, morbidity, and mortality

MOF develops in 15% of all hospital admissions and contributes to up to 80% of all deaths. Patient survival is inversely related to the number of failing organs involved (Table 154.1). When three or more organs are involved, mortality reaches 50%. After five organ systems are affected, mortality is >80%. Therefore, preventing the development of MOD and MOF is desirable and can significantly impact patient survival. Unfortunately, early detection of organ dysfunction by clinical signs and symptoms or by reliable biomarkers is not possible for all organs involved. Early detection of cardiac injury, however, is now possible with the use of troponin as a biomarker.

A MOD score of 5 through 8 is associated with 5% mortality, which increases to 30% with scores of 9 through 12 (Table 154.3). Mortality is further increased to 70% with scores of 13 through 16 and 91% for scores of 17 through 20. Certain combinations of organ dysfunction (i.e., pulmonary and hepatic

dysfunction or cardiac and hepatic dysfunction) carry a high risk of early mortality (Table 154.3).

Dysfunction of key organs

Isolated organ dysfunction is rare. In general, patients with MODS or MOF have combinations of involved organs. Key organs and systems involved are noted in this section.

Lungs

Acute lung injury (ALI), with moderate impairment of lung function, is defined as a $\text{PaO}_2/\text{FiO}_2$ ratio of < 300 ($[\text{SpO}_2/\text{FiO}_2] \leq 315$ if $\text{SpO}_2 \leq 97\%$, where SpO_2 is the oxygen saturation). Severe lung injury is defined as a ratio of $\text{PaO}_2/\text{FiO}_2 < 200$ (or $\text{SpO}_2/\text{FiO}_2 \leq 235$ if $\text{SpO}_2 \leq 97\%$), and it is also known as acute respiratory distress syndrome (ARDS). A detailed discussion of this disease state can be found in Chapter 159.

Cardiovascular

Cardiovascular dysfunction is associated with significantly increased mortality. In mild cardiac dysfunction, elevation of serum troponin is often seen without significant decrease in pump function. In advanced cardiac dysfunction, however, an often severe decrease in left ventricular (LV) pump function (measured as decreased LV ejection fraction [LVEF]) is seen.

Vascular dysfunction manifests as hypotension, due to a profound vasodilatory state that accompanies most forms of MODS or MOF. The combined dysfunction of the cardiac and vascular systems is often apparent as these patients frequently require inotropic agents (i.e., dobutamine) to support their LV pump function as well as vasoconstricting agents to counteract peripheral vasodilation (i.e., norepinephrine or dopamine).

Table 154.1. ICU survival is related to the number of failing organ systems involved

Failing organ systems, <i>n</i>	Mortality, %
0	0.8%
1	6.8
2	26.2
3	48.5
4	68.8
5	83.3

Table 154.2. Risk, injury, failure, loss, and end-stage (RIFLE) kidney criteria

Class	Glomerular filtration rate criteria	Urine output criteria
Risk	Increase in serum creatinine \times 1.5 from baseline	<0.5 ml/kg/h \times 6 h
Injury	Increase in serum creatinine \times 2 from baseline	<0.5 ml/kg/h \times 12 h
Failure	Increase in serum creatinine \times 3 from baseline, or serum creatinine \geq 4 mg/dl with an acute rise $>$ 0.5 mg/dl	<0.3 ml/kg/h \times 24 h, or anuria \times 1
Loss	Persistent acute renal failure = complete loss of kidney function $>$ 4 wk	
End-stage kidney disease	End-stage kidney disease $>$ 3 mo	

Adapted from Bellomo R, Kellum JA, Ronco C. Defining and classifying acute renal failure: from advocacy to consensus and validation of the RIFLE criteria. *Intensive Care Med* 2007; 33:409–413.

Kidneys

Acute kidney injury (AKI) is a major cause of morbidity and mortality in hospitalized patients, and it is consistently associated with increased mortality. AKI can be defined as elevation of serum creatinine greater than 0.3 mg/dl from baseline (pre-diseased state) or the doubling of baseline creatinine. Although there are various definitions for AKI, the two widely accepted criteria are the RIFLE (Table 154.2) and the AKIN classification. The RIFLE criteria provides a graded definition of AKI severity that correlates with outcomes.

Liver

The primary function of the liver is detoxification of internal toxins as well as the production of proteins. It is hypothesized that in MODS or MOF a sepsis-related increased gut permeability and bacterial translocation lead to the development of liver dysfunction. Signs of liver dysfunction consist of persistent elevation of aspartate aminotransferase (AST) and alanine aminotransferase (ALT), elevation of bilirubin to greater than 1.2 mg/dl (mostly due to cholestasis), and persistent unexplained elevation of prothrombin time (PT) indicating a synthetic dysfunction of the liver. Liver failure is noted by hypoglycemia, persistent coagulopathy, ongoing elevation of bilirubin, and elevation of liver enzymes (AST and/or ALT).

Gastrointestinal tract

Gastroparesis (impaired gastric emptying) and postoperative ileus are commonly seen in MODS and/or MOF. Stress ulcers (Curling ulcers) used to occur commonly, but they have been almost completely eliminated with the routine use of acid-suppressing agents (H_2 blockers or proton pump inhibitors).

Brain

Mental status is altered in mild forms of brain dysfunction, and delirium is the most frequent presentation. Delirium is a disoriented state of mind characterized by fluctuation of mental status, inattention, and disorganized thinking. It can be diagnosed with the CAM-ICU (confusion assessment measurement in the intensive care unit) method developed by Ely and colleagues. The benefit of this method is that it can be applied in ventilator-dependent patients. In more severe forms, mental

status can deteriorate to somnolence, stupor, or even coma, even in the absence of organic brain damage.

Hematopoietic system

The most common form of hematologic dysfunction is thrombocytopenia and elevation of prothrombin time (PT) and international normalized ratio (INR). In disseminated intravascular coagulation (DIC), thrombocytopenia and increased PT are seen. Leukocytosis is common, but leukopenia frequently accompanies severe sepsis and septic shock.

Musculoskeletal system

Seen less frequently than other forms of organ dysfunctions, variable degrees of skeletal muscle weakness can develop in the context of critical illness, and it is often referred to as *critical illness myopathy*. Although the cause is often unclear, in certain cases, longer-term use of neuromuscular blocking agents has been suspected.

Assessing the severity of MODS and/or MOF

Two scoring systems have been developed to assess the degree of combined organ dysfunction in MODS and MOF: the MOD score (Table 154.3) and the sequential organ failure assessment

Table 154.3. MOD scores

Organ system	Score				
	0	1	2	3	4
Respiratory: PaO ₂ /FiO ₂	$>$ 300	226–300	151–225	76–150	\leq 75
Renal: creatinine (μ mol/L)	\leq 100	101–200	201–350	251–500	$>$ 500
Hepatic: bilirubin (μ mol/L)	\leq 20	21–60	61–120	121–240	$>$ 240
Cardiovascular: PAR ^a	$<$ 10.0	10.1–15	15.1–20.0	20.1–30.0	$>$ 30.0
Hematologic: platelet count	$>$ 120	81–120	51–80	21–50	\leq 20
Neurologic: Glasgow Coma Scale score	15	13–14	10–12	7–9	\leq 6

^a PAR (pressure-adjusted heart rate) is the product of the heart rate and the ratio of the right atrial pressure to the mean arterial pressure.

Adapted from: Marshall JC, Cook DJ, Christou NV, et al. Multiple organ dysfunction score: a reliable descriptor of a complex clinical outcome. *Crit Care Med* 1995; 23:1638–1652.

Table 154.4. SOFA scores

Organ system	Score				
	0	1	2	3	4
Respiratory: PaO ₂ /FiO ₂	400	≤400	≤300	≤200	≤100
Renal: creatinine (μmol/L)	≤110	101–170	171–299	300–440; urine output ≤500 ml/d	>440; urine output <200
Hepatic: bilirubin (μmol/L)	≤20	20–32	33–101	102–204	>204
Cardiovascular: hypotension	No hypotension	MAP < 70 mm Hg	Dopamine ≤ 5 ^a or dobutamine (any dose)	Dopamine > 5 ^a or epinephrine ≤0.1 ^a or norepinephrine ≤ 0.1 ^a	Dopamine > 15 ^a or epinephrine >0.1 ^a or norepinephrine > 01 ^a
Hematologic: platelet count	150	≤150	≤100	≤50	≤20
Neurologic: Glasgow Coma Scale score	15	13–14	10–12	6–9	<6

^a Adrenergic agents administered for at least 1 h (doses given are in μg/kg/min). MAP, mean arterial pressure.

(SOFA) score (Table 154.4). Both of these score the same six organ systems, using physiologic data, but in a slightly different manner. The SOFA score is calculated based on the most abnormal value during a 24-hour period, whereas the MOD score is calculated using physiologic values measured at the same point in time every day (i.e., first morning values). Importantly, both of these scores, when indicating more severe injury, were found to correlate with poorer outcome and survival.

Clinical conditions commonly leading to MODS and MOF

The most common cause of organ failure is sepsis, and sepsis triggered by a localized inflammatory process can lead to systemic inflammatory response syndrome (SIRS). In 1992, the American College of Chest Physicians and Society of Critical Care Medicine (ACCP/SCCM) consensus conference established the diagnostic criteria for SIRS.

SIRS is present when two or more of the following conditions are met: temperature >38°C or <36°C; heart rate >90 beats/min; respiratory rate >20 breaths/min or PaCO₂ <32 mm Hg; and white blood cell count >12,000/mm³, <4000 cells/mm³, or >10% immature (band) forms. This definition of sepsis (Table 154.5) recognizes the progression of disease status from early inflammation to sepsis, and through severe sepsis and septic shock, ultimately, to MOF (Table 154.3).

Certain critical events seem to be associated with SIRS and MOF: cardiac arrest, congestive heart failure, infection, pneumonia, upper gastrointestinal bleed, surgery, trauma, and

thermal injury. Common surgical procedures associated with SIRS and MOF include surgery for head trauma, elective abdominal aortic aneurysm repair, aortic dissections or ruptures, cardiac valvular surgery, and gastrointestinal surgery for perforation, inflammatory disease, or carcinoma. Other factors associated with the development of SIRS and MOF include delayed or inadequate resuscitation, persistent infection or inflammation, surgical “misadventure,” presence of hematoma, age > 64 years, prior organ dysfunction, steroid use, chronic health problems (i.e., alcoholism, malnutrition, and diabetes), and serious physiologic abnormality on ICU admission.

Other forms of significant (noninfectious) tissue injury (i.e., poly-trauma) can also lead to the development of MODS or MOF in which organ dysfunction develops as a result of tissue hypoperfusion without overwhelming inflammation. Cytokines released from damaged tissues are suspected to play a role in this form of MODS and MOF.

Pathogenesis and suspected mechanism of MODS and/or MOF

Although there is evidence that sepsis- and injury-related hypoperfusion (hypoxemia) of the tissues, in combination with release of mediators, play a role in MODS and MOF, it is yet unclear which of these factors are most important. In fact, it is likely that each of these factors plays a role in the different forms of complex, critically ill states that lead to MODS and MOF. It is hypothesized that both capillary leakiness and the cytokine-induced impaired oxygen extraction further aggravate organ dysfunction and facilitate organ failure.

Sepsis is a disease of the microvascular endothelium that leads to tissue hypoxia and dysoxia even when sufficient oxygen is delivered through the blood. In sepsis, patients are unable to adequately extract oxygen from the blood. Thus, this impaired ability to extract oxygen leads to worsening organ dysfunction. Most likely the combination of tissue hypoxia and inflammatory mediator release triggers the development of organ dysfunction as the clinical signs of sepsis develop.

Table 154.5. Definitions

Sepsis = SIRS as a result of infection
Severe sepsis = sepsis + 2 or more organ dysfunction
Septic shock = severe sepsis + hypotension refractory to volume infusion
MODS = abnormal function in more than one vital organ
MOF = failure in more than one vital organ

Prevention and management

The prevention of MOF requires effective and early management of SIRS. For the management of MODS or MOF related to sepsis, evidence-based guidelines have been developed and are detailed in [Chapter 161](#). These guidelines include early administration of broad-spectrum antibiotic following the submission of appropriate microbial cultures, elimination of known infections focus (i.e., source control), and early, appropriate fluid resuscitation. The success of early volume resuscitation in sepsis is likely due to improved microcirculation and interruption of the vicious cycle of tissue dysoxia, hypoperfusion, and cytokine release. The primary resuscitative fluids should be crystalloids, with judicious supplementation with colloids. Studies have shown that volume resuscitation with albumin can be harmful, particularly for head injured trauma patients, and therefore should be avoided for this patient population. The use of albumin in other populations seems to carry an equipoise and can be used at the discretion of the physicians.

For the management of ALI or ARDS, evidence-based guidelines recommend that a tidal volumes of 6 to 8 ml/kg of ideal body weight be delivered, while keeping the mean airway plateau pressures < 30 mm Hg, combined with the judicious increases of positive end-expiratory pressure (PEEP) to support adequate oxygenation.

For trauma patients, early stabilization of fractures and adequate cardiopulmonary resuscitation play a key role. In burn patients, aggressive fluid resuscitation can significantly reduce secondary organ damage and MODS or MOF.

Early and accurate detection of AKI could lead to improved survival. However, currently available diagnostic tests, which include serum creatinine and blood urea nitrogen, are sub-optimal markers for AKI because they are neither sensitive nor specific for detecting early changes in kidney function. New biomarkers are being evaluated, but none have been approved yet.

The most common cause of AKI is decreased renal perfusion followed by administration of nephrotoxin, contrast administration, and major surgery. Therefore, early institution of prevention strategies in these patients may be helpful. Such strategies include maintenance of adequate blood volume and renal blood flow by providing adequate hydration and avoidance of nephrotoxic drugs. Routine use of diuretics has not been shown to be helpful. Certain forms of AKI (i.e., contrast-induced nephropathy) may benefit from the administration of antioxidants, such as *N*-acetylcysteine.

When AKI progresses to renal failure, renal replacement therapy can be instituted. Continuous renal replacement therapy is commonly used to manage critically ill patients because it seems to be associated with less hemodynamic changes compared to conventional, intermittent hemodialysis. No prospective, randomized studies to date, however, have documented that continuous renal replacement therapy improves clinical outcome when compared with intermittent hemodialysis.

The precise and timely assessment of cardiac dysfunction is difficult even if one uses the combination of hemodynamic and echocardiographic data in combination with vasopressor requirement. The testing of several biomarkers that will provide early detection of cardiac dysfunction is under way. Troponin I and T levels seem to be associated with increased catecholamine requirement, decreased stroke work index, decreased LVEF, and increased mortality. Thus, some institutions follow troponin levels for the assessment of cardiac dysfunction in the ICU. B-type natriuretic peptide has been investigated as another potential biomarker but, as with the troponins, further studies are needed to prove its utility.

At present, the prevention and treatment of cardiovascular dysfunction rest on adequate and early fluid resuscitation with a combined approach of judicious fluid replacement and inotropic support. Maintaining normoglycemia may be beneficial as studies suggest that normoglycemia protects the endothelium, possibly by inhibiting nitric oxide release, and may contribute to the prevention of organ failure and death. Preventative use of statins and β -blockers seem to show promise, but further studies are required.

The future

Prevention and treatment of MOF will improve with availability of acute biomarkers that provide early diagnosis of SIRS and specific organ dysfunction. Such biomarkers could potentially be used to follow disease progression and treatment as well. Development of real-time polymerase chain reaction assays that identify the presence of bacterial or viral infection may replace our current reliance on blood cultures and permit earlier and appropriate antibiotic therapy.

Supraventricular arrhythmias

James P. Hardy and Thomas Edrich

Supraventricular arrhythmias are frequently encountered in the operating room, recovery room, and intensive care unit (ICU). The anesthesiologist and intensivist must recognize the type of arrhythmia and decide on appropriate management, which will depend on the hemodynamic stability of the patient and should be guided by the advanced cardiac life support (ACLS) principles as outlined in [Chapter 153](#). This chapter describes the rationale behind the treatment options and helps prioritize treatment goals.

Classification

A supraventricular tachyarrhythmia is one in which the focus of the dysrhythmias starts above the His bundle. In most cases it provides the ventricles with excitation along the usual pathways (His–Purkinje conduction system), leading to a narrow complex QRS. There may be aberrant conduction of excitation into the ventricles in the case of accessory bundles and rate-responsive bundle blocks leading to wide complex QRS. [Fig. 155.1](#) displays possible mechanisms of the most common supraventricular arrhythmias, and [Table 155.1](#) lists common treatment options.

Sinus tachycardia

Sinus tachycardia is the most common tachycardia seen in the ICU and may have causes listed in [Table 155.2](#).

Identifying characteristics of sinus tachycardia are heart rate (HR) > 100 bpm in an adult and presence of P waves that may be difficult to visualize at a high HR. Uncertainty regarding the P waves may cause difficulty differentiating from paroxysmal supraventricular tachycardia (PSVT) and atrial flutter with 2:1 block. Slowing the HR by vagal maneuvers (carotid sinus massage, Valsalva maneuver) or by medications (β -blocker, adenosine, diltiazem) may help to identify the rhythm via the following mechanisms:

1. Slowing true sinus tachycardia enough to reveal the P waves;
2. Slowing AV-nodal conduction enough to reveal underlying atrial flutter; and
3. Interrupting and possibly terminating PSVT.

Sinus tachycardia is often well tolerated. Tachycardia, however, can lead to poor ventricular filling and compromise cardiac output. Also, the percentage of time that the heart spends in diastole is reduced, thereby reducing perfusion especially to the left ventricle. This reduction can lead to coronary ischemia especially in the setting of left ventricular hypertrophy.

Treatment should focus on reversing underlying mechanisms. Patients perceived as moderate or high risk for rate-related coronary ischemia should receive β -blockade. Frequently used medications are esmolol (short-lasting and easily titratable) or metoprolol.

Atrial fibrillation

Atrial fibrillation (AF) represents chaotic activation of the atria due to the presence of multiple foci of excitation as shown in [Fig. 155.1a](#). The electrocardiogram (ECG) shows irregularly spaced QRS complexes and lacks regular P waves. The ventricular rate depends on the conduction of the irregular atrial depolarizations across the AV-node and into the His bundle. Most often, the QRS will be narrow because the ventricular activation occurs in an orderly fashion along the His–Purkinje conduction system. If the ventricular rate is high enough, a rate-dependent bundle branch block may cause the QRS to widen. AF is the most common dysrhythmia encountered in the surgical ICU. The estimated prevalence is 0.4% to 1% in the general population, and 8% in patients older than 80 years. It occurs in up to 40% after coronary artery bypass graft (CABG) and with a similarly high incidence (8%–60%) after major thoracic surgical procedures. Often, AF will terminate spontaneously when the underlying cause is treated and therefore does not require aggressive attempts at rhythm conversion back to sinus rhythm. [Table 155.3](#) lists common conditions associated with AF.

Symptoms depend on the stiffness or diastolic function of the ventricle. A ventricle with hypertrophy will depend more heavily on the diastolic filling contribution of atrial contraction (the “atrial kick”) and the onset of AF may reduce the stroke volume by 20%.

Postoperative AF has several significant clinical implications:

- Perfusion pressure to vital organs may be lowered critically, requiring more aggressive fluid resuscitation to correct.

Figure 155.1. Simplified mechanisms of common supraventricular tachycardias. **(A)** AF is caused by multiple reentry wavelets that provide high-frequency impulses to the atrioventricular (AV) node that are conducted in an erratic fashion. **(B)** Atrial flutter is caused by a larger reentry circuit within the atrium that provides impulses to the AV node at a rate of approximately 300 beats per minute. Conduction is often regular and limited by a 2:1 or 3:1 blockade due to the refractory period of the AV node. **(C)** AV nodal reciprocating tachycardia (AVNRT) is entertained by two pathways within the AV node that have different refractory periods and conduction velocities. One premature atrial contraction can suddenly initiate this circular pattern of activation (paroxysmal tachycardia), thus activating the ventricles in a rapid regular fashion. **(D)** AV-reentry tachycardia (AVRT) requires an accessory pathway through which excitation can be conducted back to the AV node. Anterograde conduction through the AV node and then circling back through the accessory pathway causes a regular tachycardia with a narrow QRS. Alternatively, conduction may proceed down the accessory pathway first and return retrogradely through the AV node causing a wide-complex tachycardia.

Table 155.1. Treatment options for supraventricular tachycardias (SVTs)

Principle	Intervention	Comments
Mechanical vagal stimulation leading to AV conduction slowing	Carotid sinus massage (CSM)	<i>Method:</i> Steady or pulsatile pressure applied to the carotid sinus for 5–10 s. The carotid sinus is located below the angle of the mandible at the level of the thyroid cartilage. <i>Contraindications:</i> CSM should be avoided in patients with a carotid bruit, a known carotid stenosis > 50%, a history of myocardial infarction or stroke within the preceding 3 months, or a history of ventricular arrhythmias or symptomatic bradyarrhythmias. The risk of neurologic complications attributed to arterio-arterial embolization is low following CSM ranging from 0.28% to 0.9% in patients older than 50 yrs, with most deficits resolving within 24 h (persistent deficits 0.1%).
	Valsalva maneuver	A randomized study of 148 patients with SVT showed termination of the SVT in 18% with Valsalva maneuver compared to 11.8% with CSM. A smaller study of 35 patients also showed that the Valsalva maneuver was more effective than CSM or facial immersion.
Medications blocking fast AV conduction ^a	Esmolol Metoprolol	Short lasting (10 min) – use 20–40 mg IV push or infuse and titrate to effect. Initial dose 1–5 mg IV Onset of action: oral, 20–40 min; IV, within minutes Duration of action: oral, 3–6 h; IV, 2–4 h Conversion IV to PO is 1:2.5 although commonly converted more aggressively (1:5)
	Diltiazem	Initial dose 10–20 mg IV, or infuse 5–15 mg/h Onset: 3 min; duration: 1–3 h Caution: risk of complete AV-block is high when combining both IV metoprolol and IV diltiazem
	Adenosine	Initial dose 6 mg IV rapid push, may repeat with 12 mg Onset: 20 s; duration: <1 min. Note: heart transplant patients are very sensitive.
	Ibutilide Amiodarone and procainamide	Caveat: Torsades de pointes risk = 1.7%. Pretreatment with magnesium may reduce this risk. Useful for tachycardia with wide QRS of uncertain etiology that could be supraventricular with conduction aberrancy, WPW or ventricular. Choose amiodarone if low EF (<45%). Caveat: lung toxicity (2%–7%) and hepatic toxicity (<3%) with amiodarone
	Electrical cardioversion	Recommended energy levels are not yet uniform for biphasic defibrillators. Biphasic 50–100–200 J for AF, atrial flutter, and wide complex tachycardia Biphasic 100–200 J for SVT Monophasic energy levels are approximately 2x higher (ceiling at 360 J). Caveats: Sedation before cardioversion if possible. Remember to SYNCHRONIZE before shocking to avoid shocking in the vulnerable phase of the T wave, which could induce ventricular fibrillation. It is important to recheck for synchronization before each new shock as the defibrillator may default to a nonsynchronized mode.

IV, intravenous; PO, oral; WPW, Wolff–Parkinson–White syndrome

^a β -blockers, diltiazem, verapamil, adenosine, and digoxin may enhance conduction through accessory pathways in WPW and other pre-excitation syndromes and are therefore contraindicated.

Table 155.2. Causes of sinus tachycardia

Pain, anxiety
 Absolute or relative intravascular volume depletion (e.g., hemorrhagic, neurogenic, or septic shock)
 Exposure to positive chronotropic medications, such as dopamine
 Fever
 Heart failure, acute coronary ischemia
 Uncommon: hyperthyroidism, pheochromocytoma

Certain patients, such as those who have had lung resections, may not tolerate the increased intravascular volume and develop edema leading to non-compliant lungs, increased work of breathing, and respiratory failure. Alternatively, vasopressors may become necessary but may compromise perfusion of vital organs with complications such as acidosis.

- Prolonged AF raises the risk of clot formation in the atria, leading to embolic complications such as strokes. The annual risk of stroke is 3% to 8%. Anticoagulation may become necessary, but increases the risk of bleeding complications in the postoperative patient.

Prevention of postoperative AF

Studies of patients undergoing cardiac surgery have shown an overall reduction in the rate of postoperative AF following the use of prophylactic β -blockade and, to a lesser extent, calcium channel blockers. Dosing schedules and type of β -blocker vary in these studies. Ideally, preoperative β -blockade should be initiated in collaboration with the patient's primary care physician, if indicated.

In general, perioperative β -blockade has been shown to reduce postoperative cardiac complications for *high-risk* patients undergoing *high-risk* surgery. However, titration is critical to avoid morbidity due to hypotension. Patients who already take β -blockers should continue them in the perioperative period, as withdrawal of these medications doubles the risk of postoperative AF. Contraindications to perioperative β -blockade include patients who are hemodynamically unstable and possibly requiring inotropic support and patients with second- or third-degree AV block. Cardioselective β -blockers that predominantly antagonize β -1 receptors (e.g., esmolol, metoprolol, atenolol) have been found to be safe even in patients

Table 155.3. Risk factors for atrial fibrillation

Electrolyte disturbances (hypokalemia, hypomagnesemia)
 Hyperadrenergic state
 β -adrenergic drugs, such as dopamine
 Absence of β -blocker therapy or withdrawal of previous β -blockade
 Atrial manipulation (cardiac or thoracic surgery)
 COPD
 Obesity
 Atrial enlargement (e.g., mitral stenosis)
 Age
 Valve surgery

with chronic obstructive pulmonary disease (COPD) and reactive airway disease, with no changes in forced expiratory volume in the first second of expiration (FEV₁) or symptoms in a large meta-analysis.

Treatment of AF

Patients with hemodynamic instability

Rapid AF may compromise perfusion severely, with hypotension leading to mental status deterioration, oliguria, chest pain, or signs of coronary ischemia in the ECG. These patients should be treated emergently with electric cardioversion as described in [Table 155.1](#). Vasopressors, such as phenylephrine, that do not increase HR may be useful to restore adequate perfusion pressure while awaiting cardioversion. If possible, a heparin bolus and infusion to attain a 1.5- to 2-fold prolongation of PTT should be performed concurrently with cardioversion, unless contraindicated due to risk of post-surgical bleeding. Anticoagulation is recommended for 4 weeks even after successful cardioversion, as will be discussed below.

Patients who are hemodynamically stable – rate control versus rhythm control

A decision must be made whether to lower the HR to a tolerable range without converting to sinus rhythm (rate control), or to attempt electrical or chemical cardioversion back to sinus rhythm (rhythm control). Even when pursuing rate control only, a large proportion of postoperative patients will spontaneously convert back to sinus rhythm once the insult of surgery has passed without requiring anti-arrhythmic medications. A review of the largest prospective randomized trials found that pharmacologic rhythm control was not superior to rate control, but did result in a higher rate of hospitalization and a trend towards more strokes although the increased stroke rate did not become apparent until following patients for 3.5 years. Certain malignant dysrhythmias were significantly more likely to occur in the rhythm control group. A subsequent review of electrical cardioversion compared to rate control did not show a mortality difference but found a non-significant increase in strokes in the cardioversion group. Several indices of quality of life, however, improved significantly after cardioversion. These studies may be less applicable to the surgical patient population where the insult of surgery, and presumed cause of AF, is expected to resolve over time.

Rate control

Most frequently, rate control is initiated with a β -blocker (e.g., metoprolol) or calcium antagonist (e.g., diltiazem). These agents lower the HR but have no intrinsic ability to cardiovert. Nevertheless, spontaneous cardioversion to sinus rhythm often occurs after hours or days as the conditions underlying the arrhythmia resolve (see [Table 155.3](#)). Once in sinus rhythm, β -blockers or calcium antagonists are known to reduce the likelihood of recurrent AF (secondary prevention).

Rhythm control

Unsatisfactory rate control in patients with an elevated risk posed by tachycardia (e.g., coexisting coronary artery disease) may necessitate cardioversion. Both electrical and chemical cardioversion carry the risk of dislodging blood clots from the heart and causing a stroke. The risk of stroke increases after AF has persisted for more than 48 hours. Thus, after the 48-hour limit, patients require either 3 weeks of full anticoagulation before the cardioversion attempt or, alternatively, transesophageal echocardiography (TEE) to rule out a clot before immediate cardioversion. Even when using TEE, initiation of heparin therapy with an IV bolus and infusion to attain an elevated PTT (1.5–2 times normal) is recommended immediately before cardioversion (unless contraindicated). Thrombi can be found in the left atrial appendage where inadequate atrial contraction has allowed stasis of blood. Thus, TEE is the best method to rule out clots because the esophageal positioning of the probe brings it closest to the left atrium for optimal imaging quality.

Special considerations for patients with AF and Wolff–Parkinson–White Syndrome (WPW)

As described below, patients with WPW syndrome have an accessory conduction pathway between the atria and the ventricles. They may exhibit a delta wave on a resting ECG. Agents that slow conduction across the AV node are contraindicated in patients with WPW and AF. These include β -blockers, adenosine, calcium channel blockers, and digitalis. Slowing AV conduction in these patients can enhance anterograde conduction along the accessory pathway during AF, leading to acceleration of the ventricular rate with subsequent hypotension and possible degeneration into ventricular fibrillation. Hemodynamically unstable patients should be cardioverted. Stable patients may be treated with amiodarone, procainamide, or ibutilide.

Anticoagulation after AF

AF carries the risk of clot formation and subsequent thromboembolism due to loss of mechanical function of the atrium and stasis of blood. Return to sinus rhythm enhances the risk of dislodging a clot, particularly from the left atrial appendage. This risk exists after both electrical and chemical cardioversion. In both cases, the complete recovery of atrial mechanical function may be delayed by several weeks. In addition, there is an elevated risk of recurrent AF, which may be asymptomatic and therefore go unnoticed. Thus, these patients require full anticoagulation for 4 weeks after cardioversion. If AF recurs, the need for continued anticoagulation will depend on the patient's risk factors for stroke, and either full anticoagulation (e.g., coumadin) or aspirin will be needed.

Atrial flutter

Atrial flutter most commonly results from a macro-reentry phenomenon with an excitatory wave-front circling through the right atrium in a regular pattern as illustrated in Fig. 155.1b. The ventricular rate can appear regular because atrioventricular conduction may be blocked for every second or third atrial beat leading to 1:2 or 1:3 conduction. Symptoms, management, and prevention of perioperative atrial flutter are similar to AF. Treatment typically begins with a β -blocker. Rate control can be challenging because a lower atrial rate may match the AV-refractory period better and actually cause a 3:1 block to “improve” to a 2:1 block with an undesirable *increase* in ventricular rate. This is more likely when using class I antiarrhythmic drugs, such as procainamide, flecainide, or propafenone, because these agents do not prolong the AV-node refractory period and thus do not protect against the switch to a lower conduction ratio. Therefore, simultaneous rate control with AV-nodal blocking agents, such as esmolol, metoprolol, or diltiazem, is advisable. Although the risk of stroke may be lower with atrial flutter than with AF, the same anticoagulation strategies are recommended. Atrial flutter can be treated with catheter ablation.

Atrioventricular nodal reciprocating tachycardia

Atrioventricular nodal reciprocating tachycardia (AVNRT) is the most common cause of narrow-QRS tachycardia with a regular rate, accounting for up to 60% of cases (see Fig. 155.1c). In AVNRT there are two functionally different pathways within the AV node: one with a short refractory period and slow conduction, and the other with a longer refractory period but faster conduction. In sinus rhythm, only the faster pathway is used. An irregular atrial contraction (e.g., a premature atrial beat), however, can be transmitted to the ventricle via the slow pathway if the fast pathway is still refractory and then circle back through the fast pathway when it has recovered from its refractory period. This triggers a sudden onset of tachycardia, typically at a rate of 140 to 250 beats per minute. The QRS remains narrow because the ventricular activation is triggered from the AV node, unless a rate-dependent bundle branch block also occurs. Because the atria and ventricles are activated almost simultaneously, the P wave is obscured by the QRS and cannot be seen on the surface ECG. Acute management is the same as for AVRT and will be discussed in the next paragraph.

Atrioventricular reentry tachycardia

Atrioventricular reentry tachycardia (AVRT) requires the presence of both the normal AV node, as well as an anatomically distinct conduction pathway between the atria and the ventricles called an accessory pathway (see Fig. 155.1d). The most common such accessory pathway is the Kent bundle. Both the AV node and the accessory pathway can conduct in both directions so that paroxysmal onset of circular excitation is possible. When

excitation progresses down the regular AV node to the ventricles and then returns to the atria via the accessory pathway, it is termed *orthodromic* AVRT. The QRS complex is typically narrow because the ventricles are depolarized in an orderly fashion starting with the AV node and progressing through the His–Purkinje conduction system. In *antidromic* AVRT, anterograde conduction occurs via the accessory pathway and returns via retrograde conduction through the AV node. Because depolarization of the ventricles is initiated outside the His–Purkinje system, the QRS is wide. When an accessory pathway allows anterograde conduction *at rest* while the HR is normal, the QRS can be slightly widened with a slurred upstroke of the QRS complex called a *delta wave*. This occurs because there is fusion of ventricular depolarization emanating from both the His–Purkinje system (narrow QRS) as well as via the accessory pathway (pre-excitation of the ventricle causing widening of the QRS via the delta wave). If the accessory pathway allows only retrograde conduction at rest, then there is no manifestation on the surface ECG. This is called a *concealed accessory pathway*. The combination of delta waves and a short PR interval in the ECG at rest, and a history of palpitations is referred to as the Wolff–Parkinson–White (WPW) syndrome.

Treatment of AVNRT and AVRT

If initial assessment indicates an unstable hemodynamic state or if tachycardia poses a significant risk of exacerbation of underlying disease such as coronary artery disease, then immediate cardioversion may be indicated. Otherwise, therapy hinges on the assessment of the ECG and the patient's previous medical history.

Narrow QRS complex

Regular tachycardia with a narrow QRS complex poses a diagnostic dilemma because it could represent orthodromic AVRT, AVNRT, or atrial flutter with a fixed conduction ratio. Adenosine can be considered the first choice for all regular narrow complex tachycardias. The other nodal blocking agents listed in Table 155.1 (esmolol, metoprolol, diltiazem) are also appropriate. In patients with pacemakers, overdrive atrial pacing may also terminate narrow complex tachycardias, but with the risk of inducing AF.

Wide QRS complex

Differential diagnosis of regular tachycardia with a wide QRS is more problematic, and management depends on the etiology. Possibilities include:

- Ventricular tachycardia
- Antidromic AVRT
- Orthodromic AVRT, AVNRT, atrial flutter, or atrial tachycardia, all with coexisting bundle branch block (preexisting block or a rate-dependent block)

If in doubt regarding the etiology of regular-rate wide-complex tachycardia, ventricular tachycardia (VT) should be assumed and treated with amiodarone (150 mg IV over 10 minutes, repeated as needed to a total of 2.2 g over 24 hours) or elective synchronized cardioversion. Treatment with nodal-blocking agents, particularly verapamil or diltiazem, may be deleterious because they may precipitate hemodynamic collapse in a patient with VT.

With antidromic AVRT, nodal blocking agents (e.g., adenosine, esmolol, metoprolol, diltiazem) do not slow conduction via the accessory pathway but may actually enhance conduction over the accessory pathway. This can lead to ventricular arrhythmia, even ventricular fibrillation, in AVRT as well as in the setting of AF/flutter or atrial tachycardias. Procainamide is the drug of choice because it slows conduction over the accessory pathway more than over the AV node, although amiodarone is preferred in patients with a low ejection fraction (EF). Cardioversion is an alternative.

Treatment for known orthodromic AVRT, AVNRT, atrial flutter, or atrial tachycardia remains as described in the previous sections regardless of the presence of a bundle branch block.

Multifocal atrial tachycardia

Multifocal atrial tachycardia (MAT) is an uncommon arrhythmia usually seen in critically ill patients with electrolyte abnormalities or COPD. It is an irregular narrow complex tachycardia, with a variable P-wave appearance and is considered to be a transitional rhythm between atrial tachycardia and AF. Treatment should be focused on correction of precipitating causes. β -blockers or channel blockers may be used for rate control.

Cardiac failure in the intensive care unit

Maxwell Weinmann

Introduction

There are more than 1 million hospital admissions per year in the United States of patients suffering from acute decompensated congestive heart failure (CHF); the most common etiology is ischemic heart disease. As pump failure develops, the physician is often confronted with competing therapeutic demands to optimize oxygenation and perfusion in an attempt to prevent organ failure and reduce mortality. This is of particular importance when the anesthesiologist is faced with stabilizing the uncompensated cardiac failure patient requiring emergent surgery.

Epidemiology

CHF affects approximately 2% of the population. Almost half a million new cases are diagnosed nationally per annum – 10 times that of newly diagnosed HIV infection and twice that of breast carcinoma. Despite advances in the field, admission rates have actually grown over time and are responsible for in excess of more than \$20 billion in health care expenditures annually in the United States alone.

Etiology

The most common etiology of CHF is underlying ischemic heart disease. While these patients frequently have a history of angina, myocardial infarction, and an array of associated risk factors (e.g., diabetes, hypertension, smoking), coronary vascular disease often progresses silently, and CHF can be the first clinical manifestation of the disease. Other less common conditions include idiopathic dilated cardiomyopathy, valvular heart disease, myocarditis, drugs (e.g., doxorubicin, cocaine), HIV infection, and so forth.

Pathophysiology

Neurohumoral dysregulation

A neurohumoral cardio–cerebro–renal axis exists that regulates cardiovascular homeostasis through cardiac filling/output and systemic perfusion. In CHF, this homeostatic mechanism breaks down. As the heart begins to fail, its output declines, as does systemic organ perfusion. The body interprets this low cardiac output as hypovolemia, and compensatory mechanisms are

initiated which produce vasoconstriction and fluid retention. Consequently, sympathetic activity is increased to maintain cardiac output, via elevated catecholamine levels, while the renin–angiotensin–aldosterone system (RAAS) acts to retain fluid and Na^+ . In the setting of progressive cardiac disease, a chronic hyperstimulatory state results which is self-perpetuating, leading to progressive myocardial wall stress, fibrosis, and ventricular remodeling. These changes culminate in a shift to anaerobic myocardial metabolism, electrolyte abnormalities and diminished myocardial reserve, leading to a propensity for arrhythmias, worsening cardiac failure, and increased mortality.

Diastolic dysfunction

Diastolic dysfunction refers to an abnormality of ventricular relaxation that impairs filling, and can occur in the presence or absence of an abnormal left ventricular ejection fraction. Ventricular relaxation is an active process and thus energy dependent. Myocardial ischemia will therefore lead to nonhomogeneity of diastolic filling.

It is estimated that up to one-third of patients presenting in decompensated heart failure (HF) demonstrate diastolic dysfunction. This estimate rises with increasing age such that approximately 70% of patients older than 70 years of age have findings consistent with this condition.

Systolic dysfunction

Classically, systolic dysfunction and failure refer to the progressive decline in left ventricular ejection fraction due to ventricular remodeling in the face of injury or increased afterload. The most common etiologies contributing to ventricular remodeling are coronary vascular disease and hypertension.

Myocardial injury is characterized by an imbalance of collagen degradation and production, perivascular fibrosis, and myocardial scarring, which may occur despite recanalization of the infarct-related vessel. Myocardial scarring is, in part, due to changes in the neurohumoral environment with activation of the renin–angiotensin system, which has been shown to be profibrotic and proinflammatory. In the absence of intervention, a chronic inflammatory state and ongoing myocardial remodeling ensue. Ultimately, the left ventricle begins to fail both mechanically and in terms of its electrophysiologic integrity and homogeneity.

Systolic and diastolic dysfunction have emerged as two distinct clinical entities such that diastolic failure demonstrates initial preservation of ejection fraction in the absence of ventricular dilatation, whereas systolic failure is characterized by profound remodeling and progressive decline in output.

Right ventricular failure

Unlike the left ventricle, the right ventricle functions in a relatively low-pressure milieu. Functioning as a crescentic “bellows” adjacent to the more muscular left ventricle, its pressure–volume relationship is much flatter, demonstrating that it can accommodate large variations in venous return in the absence of large pressure swings. This relationship also has implications for contractility, which is preload-dependent. In the presence of acute increases in afterload, but in the absence of changes in preload, the ventricle responds with increased inotropy. As afterload continues to increase, however, right ventricular dilatation will occur, and its declining mechanical reserves will lead to right heart failure. At this point, the elevated right ventricular pressure will impair coronary perfusion, and worsen mechanical failure. Although ischemia does affect the right ventricle, it is extremely rare in isolation (the anterior wall of the right ventricle has dual blood supply from both the right coronary and the left anterior descending arteries), and it occurs more commonly in association with inferior wall ischemic events (up to 50% of cases).

Cardiogenic shock

Cardiogenic shock is life-threatening ventricular failure and a sign of a profound acute myocardial decompensation. Cardiogenic shock is typically due to acute ischemia or infarction. This can occur with or without preexisting ventricular dysfunction. Measuring systemic vascular resistance and cardiac contractility may help discern where in the clinical spectrum ranging from ventricular dysfunction to failure a particular patient lies. For these patients the therapeutic goal in the intensive care unit (ICU) will be myocardial preservation, optimization of function, and organ salvage.

Diagnosis

Electrocardiogram

While an electrocardiogram (ECG) is not diagnostic of CHF, it does allude to the underlying etiology, associated complications, and need for intervention. The left ventricular hypertrophy of chronic hypertension, the S-T changes of acute ischemia, and the evolution of conduction abnormalities which would benefit from pacing are some examples. Additionally, evolutionary changes are particularly helpful if an acute ischemic event is suspected, such that serial ECGs may be clinically relevant on admission to the ICU, in addition to biochemical markers, such as troponins, to confirm one’s clinical suspicions. Furthermore, as therapy is initiated and progresses, continuous ECG monitoring is important due to the inherent risk of

arrhythmias, which may be exacerbated by the electrolyte shifts accompanying therapy.

Chest radiograph

The radiologic findings accompanying CHF are well known. The heart may appear enlarged and globular, which may suggest the presence of pericardial fluid which, if suspected, should prompt echocardiographic investigation. Interstitial pulmonary edema may range from blunting of the costophrenic angles through to gross CHF with pleural effusions and fluid in the fissures.

Hemodynamic monitoring

The pulmonary artery catheter is less frequently used in the ICU due to its associated morbidity, the lack of outcome benefits, and the availability of less invasive measures of heart function, such as echocardiography. While the pulmonary artery catheter does provide an assessment of the left ventricular end diastolic pressure, its correlation with left ventricular end diastolic volume is skewed by acute changes in ventricular compliance, especially in the setting of an acute ischemic syndrome. The intensivist should take this into account when titrating volume status to a particular wedge pressure.

Echocardiography

Both transthoracic and transesophageal echocardiography are useful, noninvasive tools to measure contractility and wall motion, wall thickness, valvular and intraluminal pathology, as well as any pericardial disease. Both may be performed within the ICU rapidly, easily, and without the need for transport of a critically ill patient. It is, nevertheless only a snapshot of an evolving clinical syndrome and does not exclude the absence of transient ischemia should wall motion be seen to be normal.

Biochemical markers

Troponin

The I and T subunits of troponin are considered specific for myocardial injury and should be evaluated whenever failure is considered secondary to acute ischemia. However, the intensivist should be wary of other clinical situations that may complicate the interpretation of elevated levels, such as severe sepsis, renal failure, pulmonary embolism, pulmonary hypertension, and acute liver failure, to name a few. The exact mechanisms of troponin elevation in these noncardiac diseases remain unclear but include myocardial injury and inflammation due to elevated free fatty acid levels in sepsis, reduced filtration of troponin fragments in renal failure, and endothelial injury or dysfunction in critical illness and systemic inflammatory response syndrome (SIRS). Of importance, however, is recent evidence supporting that critical illness–related troponin elevation is of prognostic value, implicating incipient organ failure and increased mortality.

Brain natriuretic peptide

Progressive understanding of the mechanisms of action of natriuretic peptides has demonstrated their key role in a cardio–cerebro–renal axis of fluid and electrolyte homeostasis within the body. Natriuretic peptides gained particular relevance in the diagnosis, management, and prognostication of patients with CHF. Levels > 100 pg/ml are considered to have good sensitivity and specificity in diagnosing CHF in acutely dyspneic patients who present to the emergency room.

Additionally, natriuretic peptides have been implicated in the regulation of myocardial perfusion by promoting coronary vasodilation in the presence of ischemia. This theory has been supported by elevations of brain natriuretic peptide (BNP) proportional to underlying coronary vascular disease even in the absence of ventricular dysfunction. Presumably, by stimulating both coronary vasodilatation and systemic afterload reduction, myocardial work is reduced and the effects of ischemia blunted. Similarly, successful revascularization has been associated with a reduction in BNP levels postoperatively.

Therapy

Airway management and oxygenation

The application of positive airway pressure (via both noninvasive or invasive modes delivering continuous positive airway pressure [CPAP] or bilevel positive airway pressure [BiPAP]) has been shown to be effective in the acute management of decompensated CHF. By reducing work of breathing, increasing afterload reduction, and improving oxygenation, there is a marked reduction in intubation rates, mortality and improved cardiac performance compared to oxygen by mask alone. Adequacy of oxygenation should be determined not only by pulse oximetry, but also by arterial blood gas studies, which can provide information on the adequacy of circulation (through pH, lactate, the presence of associated carbon dioxide retention, and so forth). If work of breathing and hypoxia do not respond to noninvasive ventilatory support, the patient should be intubated to optimize systemic oxygenation.

Pharmacotherapy

Reperfusion strategies

Treatment of CHF in the ICU is governed by optimizing myocardial function, perfusion, preservation, and salvage. If acute ischemia or infarction is identified as the underlying etiology, then the patient should be assessed as a potential candidate for reperfusion via percutaneous coronary intervention (PCI), thrombolysis, or even surgery. Previous studies have demonstrated that in patients with ST elevation myocardial infarction PCI is superior to thrombolysis in terms of mortality and morbidity, leading to the conclusion by some investigators that reperfusion by stenting should be the standard approach.

Although primary intervention with thrombolysis is relatively easy compared to PCI, it nevertheless presents challenges in terms of the risk of hemorrhagic complications

(particularly in elderly patients), the relatively short window of optimal opportunity (4 hours), re-occlusion rates, inadequate restoration of flow in the infarct-related segment, and the lack of efficacy in those patients who present with cardiogenic shock. PCI or coronary artery bypass grafting is recommended in the latter. In those patients not considered candidates for thrombolysis, emergent PCI offers a significant opportunity for myocardial salvage.

Diuretic therapy

Although diuretics have not been shown to affect mortality, they are typically used to alleviate the symptoms of volume overload. Outpatient oral dose may be changed to the intravenous dose by dividing the oral dose by 2 to 2.5 and observing the response. Diuretics reduce left ventricular filling pressures, and commencement of diuretic therapy will also enhance the action of angiotensin-converting enzyme (ACE) inhibitors through volume contraction. Although bolus dosing diuretics is commonly implemented, an infusion is also an alternative if one wishes to titrate a response or achieve a gentler, consistent diuresis in a fragile patient. Electrolyte imbalances must be watched for, as arrhythmias may be easily precipitated in these patients. By evaluating urinary K^+ , for example, K^+ replacements may be preempted. Additionally, K^+ losses may be ameliorated by aldosterone antagonists.

Digoxin

Although well known, digoxin is certainly not outmoded in the approach to CHF. It has been shown to provide symptomatic relief even in the presence of a conventional therapeutic regimen including ACE inhibitors, diuretics, and low dose β -blockers. It was not, however, found to improve survival. Anuric renal failure is not a contraindication to fully loading digoxin, and serum levels should be used to assess and follow the potential for toxicity, particularly in the presence of renal dysfunction.

Vasodilators

Nitroglycerin

Nitrates are typically part of the first line of therapy in acute decompensated HF. They serve to produce venodilatation predominantly, although they are active, but weaker, arteriodilators. This is particularly relevant to the coronary arteries. The combined result is a reduction in preload, reduced ventricular wall tension, enhanced myocardial perfusion, and, ultimately, reduced myocardial oxygen consumption. In acute syndromes, perfusion is also enhanced by their antiplatelet activity, which is mediated via nitric oxide (NO) mechanisms, a property of all nitrovasodilators. Unfortunately, tolerance develops rapidly, particularly to high doses of nitrates, such that these medications cannot be relied on to provide a sustained clinico-pharmacologic impact.

ACE inhibitors

ACE inhibitors are potent vasodilators. Through their action on aldosterone and antidiuretic hormone (ADH), salt and water

reabsorption are inhibited in CHF patients. The consequent increase in angiotensin-I levels acts to reduce norepinephrine release by binding to sympathetic nerve terminals. Acute administration also helps to correct myocardial β -sympathetic insensitivity associated with CHF, reduces myocardial inflammation and remodeling, and helps to restore endothelial NO responsiveness and synthesis.

Abundant evidence exists confirming the decreased mortality benefits of these agents in the chronic patient and recently in the asymptomatic high-risk patient as well. These agents should be administered cautiously, however, in patients with renal dysfunction and in those who may already be volume-depleted by concomitant diuretic administration. Additional concerns have been raised perioperatively where ACE inhibitors may potentiate the renal toxicity of aprotinin (note that aprotinin is no longer in clinical use). Cessation is not associated with rebound phenomena.

Nitroprusside

A potent “balanced” vasodilator, nitroprusside is administered as an infusion. A half-life measured in minutes translates to rapid titratability clinically. Its metabolites, although pharmacologically inactive, are potentially toxic. Nitroprusside is metabolized by combining with hemoglobin to form cyanmethemoglobin and cyanide ions. The intensivist must, therefore, monitor for the development of metabolic acidosis and methemoglobinemia in these patients. Although uncommon in the acute phase (<48 hours), it is more common in patients with renal insufficiency. Methemoglobinemia responds rapidly to vitamin B12 and/or thiosulfate administration.

β -blockers

CHF is characterized, in part, by a chronic sympathetic hyperautonomic state. This has been shown to lead to a downregulation of myocardial β -receptor number and sensitivity with a reduction in myocardial performance, altered myocardial energetics, and reduced myocardial efficiency. This biochemical and metabolic disarray can be modulated by the introduction of low-dose β -blockade. By affecting substrate utilization, energetics are improved, allowing enhanced myocardial performance. The intramyocardial inflammatory state is also antagonized, with a reversal of myocardial remodeling. As a result, morbidity and mortality are reduced. Importantly, impact on morbidity and mortality appears to be drug specific, rather than an inherent feature of all β -blockers (Table 156.1).

Nesiritide

Characterization of the physiologic actions of natriuretic peptides has demonstrated that they appear to be extremely important to cardiovascular homeostasis. Properties include potent vasodilator activity, with preferential arterial activity via modulation of Ca^{2+} through cyclic guanosine monophosphate (cGMP) and NO synthesis. They also produce renal afferent vasodilatation and efferent vessel vasoconstriction that

culminates in an enhanced glomerular filtration rate (GFR). Suppression of renin and aldosterone and modulation of sympathetic activity is also evident. Most recently, modulation of coronary artery vasculature, through NO, implicates them as part of the myocardial paracrine response to ischemia. Studies of nesiritide have remained controversial, in part due to the lack of any clear dose–response relationship for the agent. These findings hindered therapeutic predictability and limited the use of nesiritide. New evidence using more circumspect dosing is emerging, suggesting that the peptide possesses a dose–response relationship that warrants reinvestigation of its utility.

Inotropes

Inotropes are usually considered when end-organ damage has evolved due to persistent hypoperfusion. Unfortunately, there is no method to determine the inherent physiologic cost to the myocardium (induction of ischemia) by pharmacologically induced increased performance. Therefore, the intensivist risks stressing oxygen dynamics in an already compromised myocardium and may exacerbate underlying ischemia and arrhythmogenesis. Such detrimental effects were borne out by previous trials in which morbidity was found to increase with the administration of milrinone thus raising questions regarding the safety of this agent in CHF. Indeed, in a recent comparison of therapy in acutely decompensated HF patients, nesiritide was found to be more innocuous, being associated with less morbidity and mortality, reduced length of stay, and a lower likelihood of readmission with recurrent symptoms when compared to treatment with milrinone or dobutamine.

Mechanical support

Intra-aortic balloon counterpulsation

Should medical therapy be unsuccessful in providing adequate circulatory support, mechanical means may be considered. The utility of intra-aortic balloon counterpulsation (IABP) depends on the overall salvageability of the myocardium. In other words, can the etiology of the refractory HF or cardiogenic shock ultimately be reversed by revascularization, valve repair, or even transplant in an appropriate candidate? IABP therapy produces a reduction in ventricular wall tension with an associated reduction in myocardial oxygen demands. In fact, in those patients undergoing emergent revascularization or acute myocardial infarction complicated by shock, the implementation of an IABP has been shown to be associated with a lower mortality. Efficacy of the balloon is dependent on correct placement and timing of insufflation and deflation. The balloon is placed just distal to the origin of the left subclavian artery to avoid ischemic complications. Contraindications to placement include severe aortic regurgitation, where augmentation cannot be achieved and the regurgitant fraction is increased. The presence of severe atheromatous disease, aortic dissection, aortic aneurysm, and mild aortic regurgitation are relative contraindications. The physician must be vigilant for potential complications related to placement of the IABP, including ischemia, vascular injury, and bleeding. The overall complication rate is < 8%.

Table 156.1. Large-scale, placebo-controlled mortality trials of β -blockade in HF

Trial	Drug	HF severity	Patients, <i>n</i>	Target dose, mg	Effect on all-cause	
					Mortality	Hospitalization
US Carvedilol (94)	Carvedilol	NYHA II-III	1094	6.25–50 BID	↓ 65%	↓ 27%

^e Destination therapy.

From Richards NM, Stahl MA. Ventricular Assist Devices in The Adult. *Crit Care Nurs Q* 2007; 30:104–18.

Ventricular assist devices

The application of ventricular assist devices (VADs) in patients with refractory CHF has increased with time, particularly as recent evidence has indicated that survival and quality of life are enhanced. Indeed, at 1 year, survival has been shown to be 52% versus 25% with conventional medical therapy ($P = 0.002$). As a result, the devices are used not only as bridges to transplantation or to facilitate heart recovery, but also as “destination” therapy.

Presently, devices are defined by position (extracorporeal [external] pumps or implantable pumps) and by the nature of flow (pulsatile or nonpulsatile) (Table 156.2).

VAD insertion is associated with improved myocardial metabolic profiles. Additionally, local neurohumoral activity and adrenergic receptor density and responsiveness return, facilitating myocardial function. Complications include hemorrhage, hemolysis, sepsis, malfunction, embolic phenomena, and infection. The latter may predispose to HLA sensitization. Overall, outcome is determined by the indication for VAD support and the associated comorbidities.

Future therapies

Novel therapies are on the horizon for the treatment of CHF. These therapies range from the delivery of stem cells used to enhance myocardial recovery and healing postacute infarction to neurohormonal manipulation. Even myocyte reprogramming of energy metabolism through gene transfer therapy is currently being investigated in the laboratory as a novel and unique therapeutic option. All present both controversy and promise but reflect the aggressive and imaginative pursuits required to address a medical epidemic that challenges the intensivist.

Summary

- CHF is a medical epidemic.
- Etiology is typically due to the advancement of coronary artery disease.
- The pathophysiology can be considered in terms of intrinsic myocardial and extrinsic factors. Intrinsically, there is no longer an ability to contract and relax normally due to inflammation, ischemia, and loss of actual myocytes. Extrinsically, disordered neurohumoral homeostatic mechanisms contribute to fluid accumulation and loss of cardio–renal balance.
- There are a host of investigational tests that can confirm CHF. None can replace clinical history and examination.
- Primary critical care therapy is always aimed at organ preservation and salvage through oxygenation and restoration or preservation of perfusion
- No therapy is without potential side effects. One example is arrhythmogenesis due to inotropes.

- Try to avoid polypharmacy, which often leads to drug combinations that are conflicting. Rationalize the use of medications, realizing that dose response is often altered by disease and, as the intensivist, you may have to titrate to effect.
- Be clear with therapeutic goals and communicate closely with the family and patient.

Sedation in the surgical intensive care unit

David A. Silver

Introduction

Most patients admitted to the surgical intensive care unit (SICU) require analgesia as part of their treatment; many also require sedation and anxiolysis. The medications used to provide analgesia and sedation are not without significant side effects, however, and the intensivist must at all times be mindful of the overall goals of care both in choosing which medications to use and in dosing these medications.

The following recommendations are intended to apply primarily to intubated patients. Although most of the medications discussed may be safely administered to spontaneously breathing patients in need of analgesia and anxiolysis, the focus of this chapter is the effective maintenance and weaning of sedation in the mechanically ventilated patient.

Goals of sedation

Patient safety and comfort are the two primary concerns in the titration of sedation in the ICU. A patient is ideally sedated if he or she lies quietly, without attempting to remove lines or tubes; does not pose a threat to his or her own safety; and has a fairly normal sleep–wake cycle. Several objective instruments have been designed as tools to help guide ICU sedation, including the Ramsay Sedation Scale and sedation–agitation scales. In our SICUs, we use the Richmond Agitation–Sedation Scale (RASS) (Table 157.1), which is easy to perform, has excellent inter-rater reliability, and has been clinically well-validated. Our goal for most patients is a RASS score of 0 to –2.

Commonly used pharmacologic agents

Analogous to the concept of a balanced anesthetic, the appropriate sedation regimen usually comprises a combination of medications. Opioids and other analgesics minimize pain and relieve a sense of dyspnea or the need to cough, both common in patients undergoing mechanical ventilation. Central neuraxial and regional anesthesia techniques, in particular epidural analgesia, can be vital in ensuring patient comfort while minimizing exposure to systemic opioids, which can contribute to delirium. Propofol, benzodiazepines (BZDs; lorazepam and midazolam), and dexmedetomidine add sedation and anxiolysis, important in critical illness, which is inherently fraught with

emotional stress. Traditional antipsychotic medications, such as haloperidol, and atypicals, such as olanzapine, risperidone, and quetiapine fumarate, may be added to treat delirium and agitation. In addition, ketamine hydrochloride, a phencyclidine derivative, is a potent analgesic and sedative at low doses and is a useful adjunctive agent in certain situations.

Analgesia

SICU patients have obvious needs for analgesia related to surgical procedures as well as to pain related to care (e.g., mechanical ventilation, dressing changes, suctioning) and rehabilitation (physical therapy, limited mobility). Many surgical patients, especially those with malignancy, have chronic pain issues as well. The approach to the agitated patient in the SICU must begin with an assessment of analgesic requirement; undertreated pain is common in the critically ill, especially those who are hemodynamically unstable, and administration of adequate analgesia can significantly reduce sedation requirements.

We begin our approach to analgesia with regional anesthetic options. Where appropriate and not contraindicated, our patients have epidural catheters (especially after major thoracic, abdominal, or orthopedic surgery and in trauma patients with rib fractures or pulmonary contusions). In elderly patients, most epidural infusions contain only local anesthetic, typically dilute bupivacaine. In younger patients, we add a small amount of hydromorphone, but systemic levels are still far lower than those seen with parenterally administered opioids. Nerve block catheters may be appropriate for patients whose anticoagulation status precludes central neuraxial blockade; this approach includes the use of paravertebral catheters as well as peripheral nerve blocks in thoracic surgery and trauma patients. Many of our cardiac surgery patients have pumps that continuously infuse bupivacaine through surgically placed catheters at the site of sternotomy. Finally, where appropriate, we often apply transdermal lidocaine patches to identifiable sites of patients' pain.

For enteral and parenteral analgesia, we begin with non-opioid medications, such as acetaminophen, ketorolac tromethamine, and ibuprofen. We supplement these medications with opioids as needed, whether via a nurse-titrated continuous infusion, intermittent dosing, or a patient-controlled

Table 157.1. The Richmond Agitation-Sedation Scale (RASS)

Term	Description	Score
Aggressive	Overly combative, violent, immediate danger to staff	+4
Very agitated	Pulls or removes tube(s) or catheter(s); aggressive	+3
Agitated	Frequent nonpurposeful movement, fights ventilator	+2
Restless	Anxious but movements not aggressive or vigorous	+1
Alert + calm		0
Drowsy	Not fully alert, but has sustained awakening (eye opening/eye contact) to voice (10+ seconds)	-1
Light sedation	Briefly awakens with eye contact to voice (under 10 seconds)	-2
Moderate sedation	Movement or eye opening to voice (but no eye contact)	-3
Deep sedation	No response to voice, but movement or eye opening to physical stimulation	-4
Unarousable	No response to voice or physical stimulation	-5

Procedure for RASS assessment

- Observe patient
Patient is alert, restless, or agitated. Score 0 to +4
- If not alert, state patient's name and instruct the patient to open eyes and look at speaker
Patient awakens with sustained eye opening and eye contact Score -1
Patient awakens with eye opening and eye contact, but not sustained Score -2
Patient has any movement in response to voice but no eye contact Score -3
- If there is no response to verbal stimulation, physically stimulate patient by shaking or rubbing shoulder
Patient has any movement to physical stimulation Score -4
Patient has no response to any stimulation Score -5

Adapted from Ely EW, Shintani A, Truman B, et al. Delirium as a predictor of mortality in mechanically ventilated patients in the intensive care unit. *JAMA* 2004; 291(14):1753–1762.

analgesia (PCA) device for the awake patient. Due to its attractive pharmacokinetics, a fentanyl infusion is our preferred method of providing analgesia to intubated patients with ongoing opioid requirements. Similarly, fentanyl's rapid onset and short duration make it the opioid of choice for brief procedures, such as bronchoscopy, dressing changes, and burn debridement. It is important to remember, however, that intermittent boluses of fentanyl are generally *not* appropriate for analgesia in the patient being weaned off an infusion: A longer-lasting opioid, such as morphine or hydromorphone, should be used to ensure consistent analgesia.

For patients with chronic opioid requirements, we continue their home regimens as much as possible and add additional medication for acute pain. For those who use morphine or hydromorphone at home, we generally respond to acute pain issues by increased doses of the medications they are already taking. Oral-to-parenteral conversion instruments are useful tools and are easily located on the Internet and elsewhere.

Finally, we find that a low-dose continuous infusion of ketamine (0.1–0.3 mg/kg/h) can be an excellent supplemental agent for patients who may complain of significant pain despite maximal opioid therapy limited by respiratory depression or other side effects or who require escalating doses of sedatives. Ketamine provides potent analgesia without respiratory depression, can significantly reduce both opioid and BZD requirements, and can be continued through extubation in patients weaning from mechanical ventilation. Careful monitoring for hallucinations and other psychiatric side effects is important, especially at the upper end of the infusion range; if these develop, we decrease or stop the infusion.

Anxiolysis and sedation

Once adequate analgesia has been established, the addition of sedatives helps the intensivist achieve the desired level of sedation to ensure the patient's comfort and safety.

The most commonly employed sedatives in the ICU are propofol, midazolam, and lorazepam – all of which are relatively inexpensive and effective. None of these drugs has any analgesic properties, and they should not be used as sole agents in patients who have significant pain.

Propofol (and a prodrug form currently undergoing testing, fospropofol) is an intravenous anesthetic agent that is particularly attractive as a sedative because its short redistribution half-life (on the order of minutes) allows for rapid lightening of sedation to allow frequent assessment of patients' mental status, which is particularly useful in patients with neurologic injuries. In addition, daily lightening of sedation (a sedation "holiday") has been demonstrated to reduce duration of mechanical ventilation and ICU stay and is easily achieved with propofol sedation.

In contrast to the other sedative agents discussed later in this chapter, propofol is primarily a general anesthetic agent that has sedative effects at low doses. For its safe use and titration, it should be administered only by persons experienced in its use.

Disadvantages of the use of propofol include pain on peripheral injection, hypotension (at least in part due to dose-dependent vasodilatation), elevated serum triglycerides with long-term infusion, and risk of infection and bacterial contamination of the emulsion. A rare but serious complication,

propofol infusion syndrome, has been described in patients undergoing long-term propofol infusion at high doses. Prominent features of the syndrome include cardiac and renal failure, rhabdomyolysis, and severe metabolic acidosis, and it has been reported most frequently in patients (especially children) receiving corticosteroids and catecholamines in addition to propofol. Clinicians should be cautious in administering high doses of propofol (in the range of 5 mg/kg/h) for >48 hours, especially in patients receiving these concomitant medications.

Propofol is initially redistributed to peripheral tissues, then metabolized in the liver via the cytochrome P450 system (CYP450) to inactive conjugates that are renally excreted. Significant hepatic dysfunction may lead to prolonged effects, but if infusions are titrated via the RASS, hepatic and renal dysfunction often do not mandate significant dosing adjustments.

BZDs, in particular lorazepam and midazolam, have long been mainstays of ICU sedation as they are potent anxiolytic and sedative agents. These drugs exert their effects primarily through binding to inhibitory γ -aminobutyric acid (GABA)-A receptors (as does propofol), have anticonvulsant properties, and can be used to treat the withdrawal syndrome associated with ethanol dependence.

Midazolam traditionally has been used in short-term sedation, whereas lorazepam, historically less expensive and with a longer half-life, has been used for long-term sedation. Each has advantages and disadvantages: Midazolam is a more potent amnestic agent, a “hypnotic” BZD, whereas lorazepam is primarily an “anxiolytic” BZD. Although the amnestic effect of midazolam may be initially desirable in critically ill patients, it may contribute to disorientation and the development of delirium over time. The long half-life of lorazepam can be a disadvantage in attempts to lighten sedation, and its preparation in a base of propylene glycol can lead to toxicity and acidosis when administered over time at high doses. Midazolam can also demonstrate prolonged sedative effects, however, particularly in elderly patients and in patients with hepatic dysfunction, and the variability of the effects of midazolam is greater than that seen with lorazepam.

Midazolam has useful properties as a long-term infusion or when bolused for procedures (rapid onset, rapid offset), but like fentanyl, it is inappropriate to use bolus administration for sedation in the patient being weaned from mechanical ventilation; however, abrupt withdrawal after long-term infusion of BZD is well-described and should be avoided. A smooth transition may be accomplished by switching from midazolam to propofol approximately 24 hours before the anticipated discontinuation of sedation or by initiating a tapered regimen of intermittent doses of lorazepam after the discontinuation of the midazolam infusion (because the goal is to prevent withdrawal symptoms, not to provide ongoing sedation).

Midazolam and lorazepam are both metabolized via CYP450 and excreted in the urine. Significantly impaired hepatic or renal function should lead the clinician to reduce the doses used or to select another sedative agent.

Dexmedetomidine, a highly specific α_2 -agonist with both anxiolytic and analgesic properties, is quickly gaining acceptance in ICU care and in many ways has begun to revolutionize the approach to ICU sedation. The use of dexmedetomidine requires an initial paradigm shift regarding the perception of adequate sedation: Whereas patients receiving opioids plus propofol or BZDs are often asleep or unresponsive (RASS < -2), patients receiving dexmedetomidine are commonly awake and respond to questions and commands. Appropriate dosing means that the patient is not uncomfortable, trying to remove lines or tubes, or expressing pain. Many critical care nurses at first find dexmedetomidine anxiolysis to be disquieting, perceiving it as inadequate sedation, but with experience they come to prefer it as facilitating patient assessment and avoiding overmedication.

Although dexmedetomidine is significantly more expensive per dose than propofol, midazolam, or lorazepam, it has recently been shown in mechanically ventilated patients to result in more days alive without delirium or coma than lorazepam, with no overall increase in cost, adding to literature showing the agent to be cost-effective when overall costs of hospitalization are considered. Dexmedetomidine is US Food and Drug Administration (FDA)-approved for 24 hours of use at doses up to 0.7 μ g/kg/h, although longer infusions and higher doses have both been documented to be well-tolerated. Common side effects include initial hypertension and bradycardia with rapid bolus dosing (avoided by administering the initial loading dose [1 μ g/kg] over 30–45 minutes), followed by bradycardia and hypotension during the maintenance phase.

In contrast to propofol and opioid-BZD combinations, dexmedetomidine is not a respiratory depressant. This makes its use in nonintubated patients safer than use of the other agents and allows for weaning and discontinuation of mechanical ventilation without adjusting or stopping the sedative/analgesic agent, which may enhance patient comfort and smooth the transition to spontaneous, unassisted ventilation.

Like propofol and the BZDs, dexmedetomidine undergoes hepatic CYP450 metabolism and renal excretion, and dosing should be carefully adjusted to clinical targets in patients with significant dysfunction of these organs.

Ketamine is a useful adjunct to sedative as well as analgesic medications. We add it to the regimen when the standard approach is not providing adequate analgesia and sedation, and wean it in parallel with other medications or with the development of undesirable side effects, especially delirium. Ketamine has sympathomimetic effects, which can be especially problematic in patients with significant cardiovascular disease, and, like the sedatives listed earlier in text, dosing should be reduced in patients with significant hepatic and renal dysfunction.

Processed electroencephalograph monitoring

For patients whose condition requires the administration of neuromuscular blockers (NMBs), which preclude traditional

The diagnosis of delirium requires the presence of acute onset of changes or fluctuations in the course of mental status, and inattention, and either disorganized thinking or an altered level of consciousness.

Figure 157.1. Flow diagram of CAM-ICU. From Ely EW, Inouye SK, Bernard GR, et al. Delirium in mechanically ventilated patients: validity and reliability of the confusion assessment method for the intensive care unit (CAM-ICU). *JAMA* 2001; 286(21):2703–2710.

assessment of adequacy of sedation through patient movement and interaction, the processed electroencephalograph (EEG) score provided by the BIS monitor (Aspect Medical Systems, Newton, MA) or similar devices can be helpful in reassuring clinicians that the patient's level of sedation is adequate and that recall is unlikely to occur.

Delirium in the ICU

ICU delirium (also referred to as *acute brain dysfunction*) is an increasingly appreciated contributor to morbidity and mortality in critically ill patients, with a prevalence of up to 85% and long-term implications for patient outcomes. Hyperactive delirium, formerly known as “ICU psychosis,” is more dramatic but less common than hypoactive delirium (characterized by negative symptoms [inattention, flat affect]), which is associated with a worse prognosis. Delirium is more common in the elderly population and among patients with underlying neurologic disease, and its causes are multifactorial. Frequent assessment for the presence of delirium as well as efforts to minimize patients' exposure to medications known to cause delirium should be part of daily rounds.

To screen for delirium, we combine the RASS with the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) tool (Fig. 157.1 and Table 157.2), administered at least once per shift by our critical care nurses.

Restoring a normal sleep–wake cycle is important in preventing or treating delirium, and this restoration may be approached in various ways. Nocturnal ambient lighting in the ICU should be reduced to a minimum, as should noise and other stimuli. The administration of a sedating psychoactive medication at bedtime (trazodone, olanzapine, quetiapine) can help patients fall asleep without the disruption of delta-wave sleep and risk of delirium associated with the use of BZDs. Propofol anesthesia has been shown to be restful and to share EEG traits with normal sleep, and we sometimes use nocturnal propofol infusions to help our critically ill patients “sleep” at night.

Finally, the conventional antipsychotic medication haloperidol remains a mainstay in the treatment of ICU delirium, particularly in agitated patients, and has been joined in recent years by the atypical antipsychotic medications mentioned earlier in this text. Haloperidol has the advantage of easy intravenous or intramuscular administration, which is

Table 157.2. The Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) part i

1. Acute onset or fluctuating course

Is there evidence of an *acute change in mental status* from the baseline?

Or, did the (abnormal) behavior fluctuate during the past 24 hours, that is, tend to come and go or increase and decrease in severity as evidenced by fluctuations on the Richmond Agitation Sedation Scale (RASS) or the Glasgow Coma Scale?

2. Inattention

Did the patient have *difficulty focusing attention* as evidenced by a score of less than 8 correct answers on either the visual or auditory components of the Attention Screening Examination (ASE)?

3. Disorganized thinking

Is there evidence of *disorganized or incoherent thinking* as evidenced by incorrect answers to 3 or more of the 4 questions and inability to follow the commands?

Questions:

1. Will a stone float on water?
2. Are there fish in the sea?
3. Does 1 pound weigh more than 2 pounds?
4. Can you use a hammer to pound a nail?

Commands:

1. Are you having unclear thinking?
2. Hold up this many fingers. (Examiner holds 2 fingers in front of the patient.)
3. Now do the same thing with the other hand (without holding the 2 fingers in front of the patient)

(If the patient is already extubated from the ventilator, determine whether the patient's thinking is disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject.)

Adapted from Ely EW, Inouye SK, Bernard GR, et al. Delirium in mechanically ventilated patients: validity and reliability of the confusion assessment method for the intensive care unit (CAM-ICU). *JAMA* 2001; 286(21):2703–2710.

Table 157.3. Summary points on management of delirium in the ICU

Monitor delirium regularly in ICU patients using a valid, reliable tool (e.g., the Delirium Screening Checklist or the CAM-ICU). Remember that the most is hypoactive and will be missed if not actively “looked for.”

Discuss results of delirium assessments on all patients daily on interdisciplinary rounds.

Identify patients with a high number of risk factors for the development or persistence of delirium (e.g., electrolyte imbalance, fever, addition of new medications; especially those with anticholinergic properties, uncontrolled pain, new onset of congestive heart failure or nosocomial infection, prolonged immobility and restraint use, sleep/wake cycle disturbance).

Review sedation and analgesia therapy, and ensure that the patient is receiving the minimum doses needed to achieve comfort, recognizing that narcotics are often used for the double effect of analgesia and sedation. Implement strategies for tight titration (e.g., nurse-driven, patient-targeted sedation delivery with daily sedation vacations).

Consider the benefit and risk profile of adding medications that might spare the use of sedatives and avoid respiratory suppression (e.g., haloperidol or atypical antipsychotics).

Adapted from Pun BT, Ely EW. The importance of diagnosing and managing ICU delirium. *Chest* 2007; 132:624–636.

useful in the agitated patient, although the risk of QT prolongation and precipitation of torsades de pointes, a potentially lethal arrhythmia, must be recognized and the electrocardiogram (ECG) monitored. Our preference is to avoid the use of antipsychotic medications, but when their administration is deemed necessary, we use haloperidol in patients who require parenteral administration, and switch to enterally administered atypical medications as soon as possible, basing our choice on desired attributes, such as degree of sedation, and so forth. For a summary of management of delirium in the ICU, see Table 157.3.

The ICU patient in the operating room

Critically ill patients may require various surgical procedures, from the relatively minor (tracheostomy and percutaneous enteral access) to more significant (exploratory laparotomy, wound debridements, completion of staged procedures). The anesthesiologist will often find it easiest to continue the patient's existing regimen through the operating room course, integrating it into the general anesthetic plan, as long as the patient's clinical stability allows it. Often the anesthesiologist will simply add a small amount of volatile anesthetic and an NMB to the ICU sedation regimen to achieve an adequate balanced anes-

thetic. For longer procedures, it may be more appropriate to suspend the ICU sedation during the general anesthetic and restart it for the return to the ICU.

Weaning sedation

As mentioned previously, a daily wake-up test has been shown to improve outcomes in sedated, critically ill patients. A ventilator bundle, which includes frequent reassessment of the patient's readiness to separate from mechanical ventilation, should also drive a regular assessment of the ability to lighten or discontinue sedation. Critically ill patients metabolize and recover from the effects of sedating medications differently over time, and frequent reassessment of mental status and depth of sedation are critical to avoiding overmedication and its attendant ill effects, including prolonged ventilation and ICU stay, increased risk of ventilator-associated pneumonia and acute brain dysfunction, and poor long-term outcome. The increasing use of validated sedation scales, delirium screening tools, and algorithm-driven sedation and ventilator weaning protocols have all helped to improve outcomes in critically ill patients.

Weaning from mechanical ventilation

Maxwell Weinmann

There is little agreement regarding the optimal method for weaning patients from mechanical ventilator support. No single mode has been identified as ideal for this purpose other than that which achieves optimal patient comfort while not sacrificing gains in oxygenation and ventilation made during the acute illness. Indeed, it has been estimated that some patients spend approximately 40% of their ventilator time committed to the weaning process. Additionally, the literature is replete with the search for indices which can predict patient weaning capability from mechanical ventilation; however, a gold standard has yet to emerge. It is not surprising therefore that no single test has supplanted clinical evaluation, possibly because such tests represent physiologic “snapshots” rather than an evaluation of pulmonary reserve. The capacity to wean is not merely a function of pulmonary status but is a codependent dynamic process affected by fluid balance, cardiac function, neurologic status, coexistent abdominal pathology, and associated therapy (such as sedatives), to name a few. This has led some clinicians to challenge the practicality of such indices which are considered to be only modest predictors of the need for reintubation, tracheostomy and mortality, and in some cases thought only to prolong the weaning process.

In light of the ongoing confusion, a collaboration among the American College of Chest Physicians, the Society of Critical Care Medicine, and the American Association of Respiratory Physicians produced evidenced-based guidelines for weaning from mechanical ventilation.

Pathology of ventilator dependence

All aspects of the underlying disease which necessitated intubation, potential reversibility, and associated complications must be identified and treated. Prolonged mechanical ventilation may be associated with ventilator-induced lung injury, respiratory muscle deconditioning, pneumonia, tracheal injury, prolonged sedation, and so forth. Removal from ventilatory support, must be balanced against the patient’s ability to protect his/her airway, clear secretions, demonstrate a consistently clear sensorium, maintain hemodynamic stability, and cope with the often increased work of breathing. For example, regarding the latter, many patients with underlying chronic obstructive pulmonary disease (COPD) develop a compensated hypercapnic acidosis during their acute illness that persists in the recov-

ery phase despite ventilatory support. Acetazolamide has been used in these cases to produce a metabolic acidosis to stimulate respiratory drive. The potential for success of such a strategy, however, is a function of the underlying physiologic reserve of the patient. The physiologic cost of “normalizing” gas values often translates to increased work of breathing, which may not be sustainable due to diminished pulmonary reserve. This may be secondary to incomplete resolution of the patient’s illness, respiratory muscle deconditioning, and/or complicating pathology. This approach has had limited success and demonstrates the potential dangers of “treating the numbers.”

Assessing patient potential to wean

With resolution of the acute phase of the illness and stabilization of the patient, the clinician must determine if those factors necessitating implementation of mechanical ventilation have resolved sufficiently for the commencement of weaning. This determination is fraught with clinical subjectivity and the absence of any clear predictor.

Today, central to the success of liberating patients from ventilator support is regular and meticulous clinical assessment. The following indices have been developed and tested, with varying successes, for the ventilator weaning process (Table 158.1).

Frequency-to-tidal volume ratio: rapid shallow breathing index (RSBI)

Application of this parameter is based on the observation that those patients who failed weaning demonstrated increasing respiratory rates with declining tidal volumes. Although the sensitivity and specificity of this parameter have varied within the literature, it remains among the most common evaluations and is considered quite reliable. A threshold of approximately 100 breaths/min/L is becoming generally accepted as predictive of successful weaning. Clinical reliability, however, will depend on additional factors, such as the presence or absence of ongoing support, the level of support, the size of the endotracheal tube, and so forth.

Minute ventilation

Normal minute ventilation is approximately 6 L/min. Its use as a predictor of weanability has a sensitivity and specificity of

Table 158.1. Selected recommendations from the ACCP–SCCM–AARC Evidence-Based Weaning Guidelines Task Force

Recommendation 1: Patients receiving mechanical ventilation for respiratory failure should undergo a formal assessment of discontinuation potential if the following criteria are satisfied:

1. Evidence of some reversal of the underlying cause of respiratory failure
2. Adequate oxygenation: PaO₂/FiO₂ 150–200 mm Hg, required PEEP ≤ 5–8 cm H₂O, FiO₂ ≤ 0.4–0.5, and pH ≥ 7.25
3. Hemodynamic stability as defined by the absence of clinically important hypotension and requiring no vasopressors or only low-dose vasopressors (e.g., dopamine or dobutamine < 5 µg/kg/min)
4. Patient is able to initiate an inspiratory effort

The decision to use these criteria must be individualized. Some patients who do not satisfy all the criteria may, nevertheless, be ready for an attempt to discontinue mechanical ventilation.

Recommendation 2: Formal discontinuation assessments should be done during spontaneous breathing rather than while the patient is still receiving substantial ventilatory support. An initial brief period of spontaneous breathing can be used to assess the patient's ability to do a formal SBT.

Criteria to assess patient tolerance during SBT are the respiratory pattern, adequacy of gas exchange, hemodynamic stability, and subjective comfort. Patients who tolerate a 30- to 120-min SBT should promptly be considered for ventilator discontinuation.

Recommendation 3: With patients whose ventilatory support has been successfully discontinued, the decision of whether to remove the artificial airway should be based on assessment of airway patency and the patient's ability to protect the airway.

Recommendation 4: If the patient fails an SBT, determine the reasons the patient continues to require ventilatory support. When the reversible causes of failure are corrected, an SBT should be performed every 24 h.

Recommendation 5: Patients who fail SBT should receive a stable, nonfatiguing, comfortable form of ventilatory support.

Recommendation 6: Weaning/discontinuation protocols designed for nonphysician clinicians should be developed and implemented by ICUs. Protocols should aim to optimize sedation.

Recommendation 7: Critical care practitioners should be familiar with facilities in their communities or units in their hospital that specialize in managing patients who suffer prolonged ventilator dependence, and practitioners should stay abreast of peer-reviewed reports from such units. When medically stable enough for transfer, patients who have failed discontinuation attempts in the ICU should be transferred to facilities that have demonstrated success and safety in accomplishing ventilator discontinuation.

Recommendation 8: Unless there is evidence of clearly irreversible disease (e.g., high spinal cord injury, advanced amyotrophic lateral sclerosis), a patient who requires prolonged ventilatory support for respiratory failure should not be considered permanently ventilator-dependent until 3 months of weaning attempts have failed.

Recommendation 9: With a patient who requires prolonged ventilation, the weaning should be slow paced and should include gradually lengthening SBTs.

ACCP, American College of Chest Physicians; SCCM, Society for Critical Care Medicine; AARC, American Association for Respiratory Care; PaO₂/FiO₂, ratio of arterial partial pressure of oxygen to fraction of inspired oxygen; SBT, spontaneous breathing trial.

Adapted from Meade M, Guyatt G, Cook D, et al. Predicting success in weaning from mechanical ventilation. *Chest* 2001; 120(6 Suppl):400S.

approximately 0.96 and 0.47, respectively, and while considered to be a reflection of the potential of the patient to deal with a respiratory burden, it nevertheless has to be placed in the perspective of how the patient achieves it. In other words, if the minute ventilation is >6 L/min but predominantly due to a high respiratory rate, then sustainability and potential for successful weaning must be questioned.

Vital capacity

Vital capacity is not considered particularly reliable as it depends, in part, on patient cooperation and does not correlate with sustainability.

Maximum inspiratory pressure

Measurements of this parameter demonstrate substantial variability, and it has not become clearly established as a reliable guide for weaning. The ratio of the inspiratory pressure to the airway occlusion pressure has been proposed as more reliable (the latter reflecting ventilatory drive and muscle strength), but requires further assessment.

Work of breathing

Typically, indirect markers have been used as surrogates of work of breathing, such as respiratory rate, use of accessory

muscles, and tachycardia. Direct measures have proven to be rather cumbersome and clinically impractical. A definitive predictive value has remained elusive. Consequently, the interactions between Compliance, Respiratory rate, Oxygenation and inspiratory Pressure have been proposed as an alternative, the so-called CROP index. Its clinical utility remains to be determined.

Arterial blood gases

Contrary to what might be expected, arterial blood gas values have not been shown to correlate with weanability, despite their reflection of underlying gas exchange capacity. One would not attempt, however, to reduce the level of support and consider weaning if hypoxia and/or hypercapnia were ongoing issues.

Overall

No single parameter has been shown to be the gold standard by which successful weaning and liberation from mechanical ventilation can be predicted. Nor has any been shown to impact on or predict in-hospital mortality, extubation failure, or need for tracheostomy. The key to effective weaning is regular assessment of the patient's comfort, in close collaboration with intensive care unit (ICU) nursing staff and respiratory therapists, and individualized care tempered by clinical perspective (Fig. 158.1).

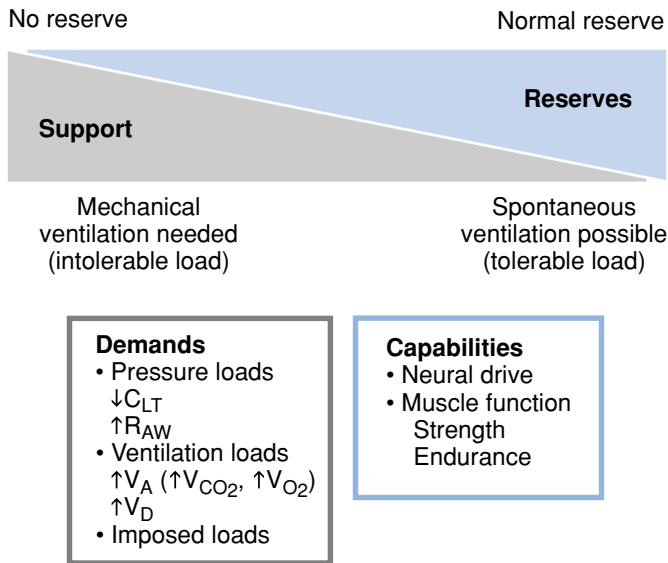

Figure 158.1. Determinants of need for mechanical ventilatory support.

Weaning strategies

A key to determining the appropriateness and success of a particular mode of support during weaning is patient comfort. A balance must be achieved between patient demand and the level of support. This should be achieved in the absence of distress and deterioration in physiologic function and therapeutic gains that accompany change in ventilator settings. Patient synchrony, indirect markers of work of breathing, cardiovascular status, oxygenation and ventilation status must be regularly evaluated to avoid the onset of fatigue and derecruitment. Potential traps include “treating the numbers” (e.g., when patients demonstrate abnormal blood gases but are nonetheless well compensated despite diminished pulmonary reserve). Many algorithms have been proposed to achieve weaning. These algorithms vary from regularly exercising the respiratory muscles, to rapidly reducing support to avoid respiratory muscle deconditioning, to T-tube trials and extubation. No single approach has been shown to be superior to another. The physician must, therefore, tailor a therapeutic strategy based on patient capabilities. Clearly, the respiratory reserve of a patient with an uncomplicated drug overdose may allow rapid weaning to extubation, whereas a patient with Guillain-Barré syndrome provides an ongoing challenge of progressive slow reduction in support during neurologic recovery and rehabilitation. Similarly, basing weaning to an acceptable respiratory rate of 18 to 24 may be impossible in a patient who has developed restrictive lung physiology following severe acute respiratory distress syndrome (ARDS).

Traditional weaning methods

Pressure support

Pressure support ventilation (PSV) is a pressure targeted, or limited, mode supporting each patient breath in a synchro-

nized fashion. Detection of the onset of inspiration is either by the generation of a negative pressure or a rapid increase in flow, whereas the onset of expiration is indirectly heralded by a reduction in inspiratory flow. It is the patient who regulates rate and has partial control over tidal volume. PSV has been shown to efficiently reduce work of breathing as evidenced by increased tidal volumes, reduced respiratory rates, and parallel reductions in transdiaphragmatic pressure swings. Support is not necessarily linear, such that above a certain pressure, volume increments are not as great, and work of breathing is not decreased. To wean, therefore, the physician must establish sustainable patterns of respiratory rate and tidal volume confirming that patient comfort may be achieved. If successful, a strategy of progressive scheduled reductions in support can be instituted until extubation is accomplished while the patient is closely monitored. It is important to recall that this includes regular blood gas analysis, as pulse oximetry is not a measure of ventilatory status.

Synchronized intermittent mandatory ventilation

In this mode, an underlying mandatory rate is set, at a fixed volume. The rationale is that the patient’s respiratory muscles are progressively exercised and reconditioned during spontaneous effort, while resting during mandatory breaths. Typically, the mandatory rate is gradually reduced as the patient’s work progressively increases to the point of extubation. Pressure support has recently been added to the spontaneous cycle to further assist in patient work of breathing. Evaluation of this mode has shown, however, that the theoretical impact on work of breathing is not borne out in practice and that effort is similar in both assisted and unassisted breaths. This has been attributed to the inability of the respiratory center to adapt to breath-to-breath changes in work load, culminating in ventilator dyssynchrony and respiratory muscle fatigue.

Spontaneous breathing trials

T-piece weaning is the oldest weaning technique. It consists of the initiation of progressively increasing intervals of spontaneous breathing while the patient is connected to a T-piece circuit consisting of a high flow, humidified gas source. During the evaluation, the patient is not connected to the ventilator, hence the term *spontaneous breathing trial*. Typically, evaluation was based on repeated efforts over hours; however, the current understanding that respiratory muscle recovery requires approximately 24 hours has limited such trials to once a day for periods of less than 2 hours.

Currently, spontaneous breathing trials are the recommended final step in the weaning process and for evaluating patient readiness for extubation. These are most commonly performed while the patients are on the ventilator. This provides the advantage that all parameters of respiration can be continuously monitored and evaluated during the weaning process. Such trials are performed once daily and only for eligible patients who meet standard criteria ($RSBI < 105$, adequate oxygenation [$PaO_2 > 60$ mm Hg on FiO_2 of 40%, presence

of spontaneous effort for breathing, PEEP < 5–10, PaO₂/FiO₂ > 300], stable cardiovascular status, T < 38°C, no significant respiratory acidosis, adequate mentation, no other contraindications [such as intracranial hypertension, etc.]). When performed via the ventilator, the patient is placed on continuous positive airway pressure (CPAP) mode with activation of alarms providing additional monitoring benefits. On occasion, positive end-expiratory pressure (PEEP) has been added to compensate for the perceived loss of any physiologic PEEP, but in reality is of no benefit and counterintuitive to our current understanding of respiratory physiology.

Role of PEEP

Conventionally, PEEP is used as a tool to optimize oxygenation by alveolar recruitment. It is therefore considered more physiologic than merely increasing FiO₂ by achieving greater homogeneity within the lung. It does so at some cost, however, and may potentially impact on cardiovascular function by impeding venous return and therefore cardiac output. This impact is in part dependent on lung compliance and may be estimated by esophageal pressure measurements and fluctuations in the central venous pressure (CVP). The more compliant the lung, the more likely it is that pressure changes will be transmitted to the central veins. PEEP has also been purported to potentially increase intracranial pressure (ICP); however, this increase can only occur when venous pressure exceeds intracerebral tissue pressure.

In terms of its relationship to weaning, PEEP can also impact on work of breathing. This is particularly true in patients with obstructive lung disease who demonstrate gas trapping due to delayed expiration, with a failure to exhale down to functional residual capacity (FRC) of the lung. As volume accumulates, expiratory pressure increases and effectively splints open the airways until a new equilibrium is reached at both a higher overall pressure and FRC. The resultant pressure is termed *auto PEEP*, or *intrinsic PEEP*, as it acts much in the same way as extrinsic or ventilator-derived PEEP. At end expiration, total PEEP is therefore the sum of both these values: one set by the operator, the other, an inadvertent consequence of impaired exhalation, due to intrinsic lung and/or airway disease or an inappropriate adjustment of inspiratory and/or expiratory times. In weaning such a patient, airflow will not commence until the intrinsic pressure is exceeded. This becomes an added respiratory muscle load and increases the work of breathing, thereby hampering weaning unless the physician is vigilant for its presence. This may be clinically apparent as ventilator asynchrony or dyspnea, as there is a delay between overcoming auto-PEEP and triggering the ventilator.

Overall assessment of traditional methods

Studies have failed to demonstrate the superiority of any particular mode over another in terms of successful extubation, in-hospital mortality, ventilator-associated complications, or the requirement for reintubation. The key patient comfort

and titrating weaning parameters in a physiologically sensitive manner. This translates to the clinician's assessment of the patient's underlying respiratory reserve and the patient's response to reduced support, in collaboration with respiratory therapists and ICU nursing staff.

New modes of ventilation

Some new modes of ventilation may ease the process of weaning due to their enhanced responsiveness to the patient's needs. However, it is yet unclear if these new modes can help shorten the time patients spend on the ventilator.

Tube compensation

Tube compensation was designed to overcome the problem of breathing against the resistance of an artificial airway and its accompanying work load. The flow resistance qualities of the endotracheal tube size are known and are associated with a pressure drop across the length of the tube during inspiration. The ventilator, in turn, compensates for this pressure drop, making tracheal pressure constant, depending on the degree of assist required by the patient (100% and lower). Potentially, this mode enhances patient ventilator synchrony, increases patient comfort, reduces risk of gas trapping (through expiratory resistance by the tube), and reduces respiratory muscle fatigue.

Proportional assist

The level of assistance in this new mode of ventilation is proportional to patient effort and is therefore a positive feedback loop. The patient determines pressure, flow, and volume, which are then amplified according to clinical assessment. This mode is considered by some investigators to be more physiologic but its superiority as a support and a weaning mode has yet to be demonstrated.

Mandatory minute ventilation

Mandatory minute ventilation was one of the earliest forms of closed loop ventilation support. The clinician presets minimum minute ventilation; should the patient be unable to achieve or maintain it, the ventilator augments support by increasing either respiratory rate or tidal volume (depending on the machine). Alternately, if the patient begins to exceed the minimum preset level, support diminishes. Unfortunately, the ventilator is indifferent to how minute ventilation is achieved, so that 10 breaths per minute of 450 ml each would be viewed as identical to 30 breaths per minute of 150 ml each.

Airway pressure release ventilation

Two levels of positive pressure are applied for preset times; the high pressure dictates lung volumes during inhalation, which is longer in duration than exhalation (and is therefore a form of inverse ratio ventilation), whereas the lower pressure is the exhalation baseline. Due to the very short duration of the expiratory phase, the lung does not completely deflate such that

auto PEEP maintains alveolar recruitment. The patient may breathe spontaneously during the inspiratory phase, but no additional support is provided, unlike bilevel ventilation (see below). This mode, despite being an inverse ratio, is well tolerated by patients.

Bilevel ventilation

Unlike airway pressure release ventilation, bilevel ventilation is not necessarily an inverse mode, although it is an option depending on the inspiratory time, which the clinician may determine. It may be easier to consider bilevel ventilation as a pressure-regulated synchronized intermittent mandatory ventilation (SIMV) mode that runs in the background, while any additional spontaneous breaths may be supported by the addition of pressure support. Weaning is achieved by a reduction in the mandatory rate and high pressure level (which determines tidal volume) with a transition to pure pressure support.

Pressure-regulated volume control and/or volume support

Here a set tidal volume is predetermined by the clinician while the ventilator delivers the volume to a maximum pressure level; in other words, it is volume targeted and pressure regulated. The ventilator delivers a pressure-controlled breath to calculate the patient's lung compliance. Based on this calculation, the ventilator delivers the appropriate pressure to generate the desired volume. The ventilator will continue to titrate pressure to volume within its set pressure range. If the rate is set, the mode is identified as "volume control," while if the rate is determined solely by the patient, it is termed "volume support." Although this method is attractive, if the patient increases tidal volume in response to worsening of the underlying pathology, the ventilator will interpret this increase as an improvement in lung status and consequently reduce support.

Assessment of new weaning modes

Many new modes incorporate a closed loop system in which the ventilator reacts to changes in a target variable by the initiation of a rapid compensatory response (as in volume support, mentioned earlier in text). These techniques are therefore considered to be more physiologic than traditional methods, and hold promise. Their overall superiority in terms of weaning, or reducing the time spent on the ventilator, remains to be determined.

Extubation

After the patient has demonstrated that he or she meets weaning criteria, extubation follows. The clinician must be wary of the facts that such criteria (as outlined earlier in the text) do not necessarily correlate with sustainability of liberation from

the ventilator and that close monitoring must continue if reintubation is to be avoided. Additionally, problems may surface that were not readily apparent during weaning, such as subglottic edema, postextubation laryngospasm, and aspiration, to name a few. Edema and laryngospasm often respond to nebulized racemic epinephrine, and the risk of aspiration may be diminished by discontinuing feeds prior to extubation. Some clinicians also perform a cuff leak test to evaluate postextubation airway patency. This test has not been shown to be reliable because leak volume is also a function of system compliance, inspiratory flow, and expiratory resistance.

For those patients who still struggle postextubation, noninvasive positive pressure ventilation may be a temporizing measure rather than resorting to immediate reintubation. To be effective, however, the patient must be cooperative, anxiety should be minimal, the patient must have an effective cough, secretions should be minimal, and the condition that necessitates the ventilator support has to be reversible in the short term (hours to days). Finally, nonrespiratory factors should always be evaluated and treated in the patient who either struggles to meet extubation criteria or develops respiratory distress on extubation as outlined in [Table 158.2](#).

Tracheostomy

Tracheostomy should be considered when it is evident that the patient requires either long-term ventilator support or airway protection, despite the capacity to wean, and is at risk of ongoing aspiration. Tracheostomies may be performed either surgically or at the bedside using the percutaneous technique. The patient may be reassured that comfort and tolerance of an artificial airway is greater with a tracheostomy and that it is not necessarily permanent and can be easily removed when normal respiratory function returns.

Summary

- As yet, no particular method has emerged as the gold standard for successful patient weaning.
- Similarly, there is no ideal index of weanability.
- Indices reflect moments in time rather than a true assessment of respiratory reserve and the capacity to remain extubated for a protracted period.
- Liberating the patient from mechanical ventilator support requires regular and meticulous assessment of the patient's readiness to separate from the ventilator, and observation postextubation.
- Weaning presupposes that the acute precipitating event has resolved.
- Weaning is a collaborative effort involving the physician, respiratory therapist, ICU nursing staff, and the patient.
- Patient comfort is the key that dictates the methodology and rate of declining support.
- Clinical acumen determines timing, avoidance of complications, and reversibility of confounding factors.

Table 158.2. Nonrespiratory factors in weaning patients from mechanical ventilation

Category	Factor	Mechanism	Clinical presentation
Cardiac status	Acute left-ventricular failure	Increased preload because of increased venous return and decreased pulmonary capillary compression as intrathoracic pressure is reduced	Patient fails weaning, often after initially doing well for 30-60 minutes; may develop acute respiratory and/or metabolic acidosis, hypoxemia, hypotension, chest pain, and cardiac dysrhythmias
Acid-base status	Acute alkalosis in patient with underlying carbon dioxide (CO ₂) retention	Loss of preexisting metabolic compensation for hypercapnia; inability to sustain required V _E and WOB	Patient with COPD or other cause of chronic respiratory acidosis before acute insult fails weaning after several days of ventilation to a PCO ₂ lower than the patient's pH-compensated level
	Respiratory alkalosis	Depression of ventilatory drives by hypocapnia and alkalemia	PCO ₂ rises and pH falls during weaning attempt; patient is said to fail weaning if some arbitrary change in these values (e.g. 10 mm Hg increase in PCO ₂) is used as a criterion for failure.
	Metabolic acidosis	Increase in ventilatory demand to compensate for respiratory alkalosis	Patient may be unable to sustain required increase in V _E and WOB to maintain a lower PCO ₂ to compensate for a lower HCO ₃
Metabolic status	Hypophosphatemia and hypomagnesemia	Ventilatory muscle weakness	Patient fails weaning because of rapid shallow breathing, respiratory distress, and acute respiratory acidosis; maximal inspiratory pressure is decreased.
	Hypothyroidism	Decreased ventilatory drive with possible ventilatory muscle weakness	Rare cause of weaning failure that occurs because of acute respiratory distress.
Drugs	Narcotics, sedatives, tranquilizers, and hypnotics	Depression of ventilatory drive	Patient fails weaning because of acute respiratory acidosis in the absence of tachypnea and respiratory distress
	Neuromuscular blocking agents	Ventilatory muscle weakness; delayed clearance in patient with renal insufficiency	Patient fails weaning because of rapid shallow breathing, respiratory distress, and acute respiratory acidosis; maximal inspiratory pressure is reduced.
		Ventilatory muscle weakness caused by acute myopathy, especially in patients who have received high-dose systemic corticosteroids	Same as above; may have elevated muscle enzymes; can last for weeks or months.
	Aminoglycosides	Neuromuscular blockade	Very rare cause of weaning failure that occurs because of rapid shallow breathing, respiratory distress, and acute respiratory acidosis; maximal inspiratory force is reduced.
Nutrition	Overfeeding	Increased CO ₂ production, especially with excessive carbohydrate calories	Patient fails weaning because of excessive ventilatory demand (high V _E requirement to keep PCO ₂ normal); unusual cause of weaning failure unless very large caloric loads are administered.
	Malnutrition	Effects of acute illness; preexisting nutritional deficiencies	May contribute to ventilatory muscle weakness, decreased ventilatory drive, impaired immunologic function, fluid retention, depression, distinguishing this from other factors is difficult
Psychological status	Agitation: "psychological ventilator dependence"	Anxiety, fear, delirium, ICU psychosis, or influence of preexisting personality factors	Patient becomes agitated and panicky during attempt to reduce or discontinue ventilatory support; can be said to cause weaning failure when other factors are absent
	Lack of motivation	Depression, effects of drugs, organic brain dysfunction, or influence of preexisting personality factors	Patient refuses to participate in care (e.g., mobilization, bronchial hygiene, physiologic measurements); flat affect and immobility in bed; considered when other factors are absent

V_E, minute ventilation; WOB, work of breathing; PCO₂, partial pressure of carbon dioxide; pH, hydrogen ion concentration; HCO₃⁻, bicarbonate.

Acute lung injury and acute respiratory distress syndrome

David A. Silver

Diagnostic criteria

The clinical syndromes of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) represent degrees of severity along the continuum of noncardiogenic respiratory failure, and present significant management challenges to the anesthesiologist and intensivist.

ALI is a clinical syndrome defined by the rapid onset of severe hypoxemia ($\text{PaO}_2/\text{FiO}_2$ [P/F ratio] ≤ 300) regardless of positive end-expiratory pressure (PEEP), bilateral infiltrates on frontal chest radiograph, and lack of cardiogenic etiology for these findings. In the presence of a pulmonary artery catheter (PAC), this “noncardiogenic” is generally defined by a pulmonary artery occlusion pressure (PAOP) ≤ 18 mm Hg; otherwise, the diagnosis is based on absence of stigmata of elevated left atrial pressure. ARDS is defined by the same criteria, but with more severe hypoxemia, a P/F ratio ≤ 200 (Table 159.1).

A recent study from the National Institutes of Health, National Heart, Lung, and Blood Institute ARDS Network (ARDSnet) has validated the use of pulse oximetric saturation in a ratio of $\text{SpO}_2/\text{FiO}_2$ (S/F ratio) in patients with $\text{SpO}_2 \leq 97\%$, with an S/F ratio of 315 correlating with a P/F ratio of 300, and an $\text{SpO}_2/\text{FiO}_2$ (S/F) ratio of 235 correlating with a P/F ratio of 200. This new convention appears to have excellent sensitivity and fair specificity and may allow less invasive screening for and rapid diagnosis of ALI/ARDS, facilitating the initiation of appropriate therapy and entry into clinical trials of patients at the onset of the disease syndrome. It is also consistent with the concerns in modern critical care to minimize blood draws (and resultant iatrogenic anemia) as well as the costs associated with processing arterial blood gas (ABG) samples.

Many patients will meet some criteria for both clinical heart failure (e.g., due to volume overload after resuscitation for severe sepsis) and for ALI. Thus there may be uncertainty as to how to categorize respiratory failure in patients with multiorgan system failure. The diagnosis of ALI is not based on purely objective tests, and lacks a pathognomonic clinical finding. As a result, for instance, since different clinicians interpret patients’ chest radiographs differently, they may or may not make the diagnosis of ALI. In clinical practice, it is important to have a high index of suspicion for the development of ALI and to treat patients appropriately as soon as the diagnosis is made. It is also

crucial, however, to ensure that another disease process with a specific treatment is not missed (Table 159.2).

Markers of inflammation

Although levels of various biomarkers of inflammation, including tumor necrosis factor-alpha (TNF- α), transforming growth factor-beta-1 (TGF- β 1), angiostatin, and interleukins 1 and 8 (IL-1 and -8), are elevated in bronchoalveolar lavage (BAL) specimens from ALI patients, their roles in the pathophysiology of the disease process are still under investigation, and routine BAL is not required for the diagnosis of ALI. It is clear that pulmonary neutrophils are important in the development of ALI, as their increased activation of the transcriptional regulatory factor nuclear factor-kappa B (NF- κ B) leads to the increased production of many of the factors listed above, as well as the kinases p38 and phosphoinositide 3-kinase (PI3-K).

Epidemiology

Risk for the development of ALI/ARDS is particularly high in older patients, in patients with significant medical comorbidities (such as chronic hepatic and pulmonary disease), and possibly in patients with a genetic predisposition to severe inflammation. Once labeled “adult respiratory distress syndrome” to distinguish it from the infant respiratory distress syndrome, it is now called “acute” and is well-described in patients 15 years of age or older.

Recent studies of the epidemiology of ALI have demonstrated that it is much more common than previously thought,

Table 159.1. Defining ALI and ARDS

Timing: Acute onset
Hypoxemia (regardless of PEEP)
ALI: $\text{PaO}_2/\text{FiO}_2 \leq 300$ (or $\text{SpO}_2/\text{FiO}_2 \leq 315$ if $\text{SpO}_2 \leq 97\%$)
ARDS: $\text{PaO}_2/\text{FiO}_2 \leq 200$ (or $\text{SpO}_2/\text{FiO}_2 \leq 235$ if $\text{SpO}_2 \leq 97\%$)
Frontal chest radiograph: Bilateral infiltrates present
Noncardiogenic: PAOP (when measured) ≤ 18 mm Hg; otherwise, no clinical evidence of elevated left atrial pressure

and represents a significant public health issue. The reported incidence of and mortality associated with ALI and ARDS vary significantly among trials.

In 2002, the Australian and New Zealand Intensive Care Society Clinical Trials Group reported an overall incidence of ALI and ARDS of 34 and 28 cases per 100,000 per annum, respectively. The overall 28-day intensive care unit (ICU) mortality rate was 28% for patients with ALI/ARDS; mortality was 30% with the subgroup that met ARDS criteria, and mortality was only 10% (a significant difference) in the ALI without ARDS group.

The King County Lung Injury Project (KCLIP) reported in 2005 a higher incidence of ALI/ARDS (combined) of 78.9 cases per 100,000 person-years, with an age-adjusted incidence of 86.2 per 100,000 person-years, and an overall in-hospital mortality of 38.5%. This study confirmed a dramatic increase in incidence with age, from 16 per 100,000 person-years for patients 15 to 19 years old to 306 per 100,000 person-years for those 75 to 84 years old. Mortality similarly ranged from 24% for teenagers to 60% for patients 85 years or older. The authors extrapolated their findings to estimate 190,600 cases of ALI in the United States each year, associated with 74,500 deaths and 3.6 million hospital days. Although the incidence the authors describe is higher than that reported from the Australia/New Zealand group, their standardized methods of review may have uncovered a much higher incidence of these syndromes than had previously been appreciated, and they reinforce an appreciation for the persistently high mortality of ALI/ARDS even after the advent of low-tidal-volume ventilation.

As the diagnosis of ALI may not be made in up to 48% of patients who meet criteria, the KCLIP study results are credible in revealing a significant incidence of ALI. Various risk factors have been examined in epidemiologic studies, and investigation continues into the genetic and other factors involved in a complex and heterogenous disease process. Table 159.3 lists some factors that have been implicated as risk factors for the development of, or mortality from ALI/ARDS. Some are not surprising – for instance, patients admitted to the hospital with greater severity of illness (as measured by the Acute Physiology And Chronic Health Evaluation II [APACHE-II] or similar scores) have a higher mortality. Others, such as a seemingly protective effect of diabetes, are less clear. It may be that diabetic patients

Table 159.3. Risk factors in the development of mortality from ALI

Obesity	Decreased mortality
Diabetes	Decreased risk of developing ARDS
Chronic alcoholism	Increased risk of developing ARDS
Increasing age up to 69 y	Increased incidence and mortality
Worse physiologic severity of illness	Increased mortality
Shock on hospital admission	Increased mortality
African-American race	Increased mortality
Low body mass index (below-average weight)	Increased mortality
Male gender	Increased mortality
Longer hospitalization before ALI	Increased mortality
Shorter ICU stay with ALI	Increased mortality
Increased radiographic opacity	Increased mortality
Immunosuppression	Increased mortality
Various genetic factors	Variable effects

From Rubenfeld GD, Herridge MS. Epidemiology and outcomes of acute lung injury. *Chest* 2007; 131:554–562.

are more likely to have nonpulmonary (and more easily treated) sources of sepsis (e.g., genitourinary, soft tissue infections), but there may be another yet-unelucidated protective effect. Obese patients diagnosed with ALI may have better reserves to deal with critical illness, or they may not have lung injury at all, just significant atelectasis, the rapid resolution of which may lead to the appearance of lower mortality in this patient population.

Pathophysiology

ALI is not a primary disease process, but is rather a reaction to a direct or indirect insult to the lungs (Table 159.4).

Direct injury (e.g., pneumonia, aspiration) or indirect injury due to systemic inflammation (especially with severe sepsis) leads to a common pathway of generalized inflammation and subsequent increased pulmonary vascular permeability. In early ALI, a protein-rich pulmonary edema characterizes what has been called the *exudative phase*, during which inflammation

Table 159.4. Causes of ALI

Direct injury
Pneumonia
Gastric aspiration
Drowning
Fat and amniotic-fluid embolism
Pulmonary contusion
Alveolar haemorrhage
Smoke and toxic gas inhalation
Reperfusion (pleural effusion drainage, embolectomy)
Unilateral lung re-implantation
Indirect injury
Severe sepsis

Shock
Salicylate or narcotic overdose
Pancreatitis

From Wheeler AP, Bernard GR. Acute lung injury and the acute respiratory distress syndrome: a clinical review. *Lancet* 2007; 369:1553–1565.

Figure 159.1. The Alveolus in Acute Lung Injury. In the acute phase of the syndrome, there is sloughing of both the bronchial and alveolar epithelial cells, with the formation of protein-rich hyaline membranes on the denuded basement membrane and filling of the air space with protein-rich edema fluid which inactivates surfactant. Macrophages in the air space secrete cytokines, which (among other effects) stimulate chemotaxis and activation of neutrophils and a subsequent inflammatory cascade.

predominates, surfactant production decreases, existing surfactant is inactivated, and widespread atelectasis results (Fig. 159.1). Elastases damage the structural framework of the lung (both alveolar–capillary and epithelial cell injury are seen), and a procoagulant environment likely leads to capillary thrombosis.

In some patients, the histopathologic changes of ALI resolve completely after the acute phase. In others, the disease progresses to a prolonged *fibroproliferative phase*, characterized by chronic fibrosing alveolitis, increased alveolar dead space, persistent hypoxemia, and, in some patients, pulmonary hypertension and right ventricular failure.

In the *recovery phase*, improvements in lung compliance and oxygenation are seen. Pulmonary function may return to normal, as may the appearance of the chest radiograph. Long-term recovery and prognosis after ALI vary.

Treatment

The ARDSnet trial, published in May 2000 in the *New England Journal of Medicine*, showed great benefits of low-tidal-volume ventilation to patients with ALI/ARDS. The trial was stopped early, after the enrollment of 861 patients, when an interim analysis showed significantly decreased mortality (31.0% vs.

39.8%, $P = 0.007$) in the low-tidal-volume group. This group also had significantly more ventilator-free days (days 1–28), a significantly better chance of being off the ventilator by day 28, and a significant reduction in nonpulmonary organ failure. The ARDSnet protocol assigned to patients in the intervention group a target tidal volume of 6 cc/kg of predicted body weight, to be reduced to as little as 4 cc/kg if inspiratory plateau pressures exceeded 30 cm H₂O. PEEP and FiO₂ were adjusted per the protocol (and Table 159.5), as was pressure support weaning.

Whereas the ARDSnet publication demonstrated the efficacy of low-tidal-volume ventilation in the management of patients with ALI/ARDS, many investigations have attempted to find the best levels of PEEP, acceptable hypercapnia, and so forth, in these critically ill patients.

Although high PEEP levels have been associated with deleterious effects, such as circulatory compromise and overdistension, PEEP may help with recruitment of some areas of atelectasis and improve oxygenation. Following the observation that the ARDSnet low-tidal-volume strategy resulted in intrinsic PEEP and higher PEEP_{total} in patients in the study, the ARDSnet investigators pursued a comparison of a high- versus low-PEEP strategy in patients with ARDS. They found no

Table 159.5. ARDSnet protocol^a

Variable	Group receiving traditional total volumes	Group receiving lower total volumes
Ventilator mode	Volume assist-control	Volume assist-control
Initial tidal volume (ml/kg of predicted body weight) ^b	12	6
Plateau pressure (cm of water)	< 50	< 30
Ventilator rate setting needed to achieve a pH goal of 7.3 to 7.45 (breaths/min)	6–35	6–35
Ratio of the duration of inspiration to the duration of expiration	1:1–1:3	1:1–1:3
Oxygenation goal	PaO ₂ , 55–80 mm Hg, or SpO ₂ , 88–95%	PaO ₂ 55–80 mm Hg, or SpO ₂ , 88–95%
Allowable combinations of FiO ₂ and PEEP (cm of water) ^c	0.3 and 5	0.3 and 5
	0.4 and 5	0.4 and 5
	0.4 and 8	0.4 and 8
	0.5 and 8	0.5 and 8
	0.5 and 10	0.5 and 10
	0.6 and 10	0.6 and 10
	0.7 and 10	0.7 and 10
	0.7 and 12	0.7 and 12
	0.7 and 14	0.7 and 14
	0.8 and 14	0.8 and 14
	0.9 and 14	0.9 and 14
	0.9 and 16	0.9 and 16
	0.9 and 18	0.9 and 18
	1.0 and 18	1.0 and 18
1.0 and 20	1.0 and 20	
1.0 and 22	1.0 and 22	
1.0 and 24	1.0 and 24	
Weaning	By pressure support; required by protocol when FiO ₂ < 0.4	By pressure support; required by protocol when FiO ₂ < 0.4

^a PaO₂ denotes partial pressure of arterial oxygen, SpO₂ oxyhemoglobin saturation measured by pulse oximetry, FiO₂ fraction of inspired oxygen, and PEEP positive end-expiratory pressure.

^b Subsequent adjustments in tidal volume were made to maintain a plateau pressure of < 50 cm of water in the group receiving traditional tidal volumes and < 30 cm of water in the group receiving lower tidal volumes.

^c Further increases in PEEP, to 34 cm of water, were allowed but were not required.

From The Acute Respiratory Distress Syndrome Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med* 2000; 342:1301–1308.

difference in clinical outcome (breathing unassisted, death before hospital discharge) in patients assigned to a high- versus low-PEEP strategy, as long as plateau pressures remained \leq 30 cm H₂O. The study was stopped early for futility, although some feel that this was a premature termination based on careful post-unblinding assessment of the patient groups in the study. Perhaps the most important information from this study was the reinforcement of a mortality benchmark of 25% to 30% in patients treated with low-tidal-volume ventilation, much lower than the expected mortality of approximately 40% in the pre-ARDSnet ICU.

Rouby and colleagues have urged that “a pragmatic, rather than a dogmatic approach” be used to select the “right” level of PEEP for each individual patient, balancing the clinician’s assessment of the need for recruitment against the risk of over-inflation. They recommend considering three clinical elements: the lung morphology pattern (much better demonstrated by CT of the chest than by plain-film chest radiograph), the shape of the pressure–volume (P–V) curve, and the changes in gas exchange resulting from different PEEP levels. We find that this practical approach of “building a PEEP curve” for each individ-

ual patient helps to fine tune ventilator settings and guides the continual process of reassessment as the patient’s disease progresses.

The use of esophageal balloon manometry to calculate transpulmonary pressure (as [airway pressure – pleural pressure]) also can be useful in guiding ventilator adjustment, as many of the most critically ill patients have markedly increased intra-abdominal pressures, diminished chest wall elastance, and so forth. Balloon measurements of pleural pressure can reassure the intensivist that, although total airway pressures may be high, the transpleural (and thus the transalveolar) pressure is not dangerously elevated. Esophageal balloon manometry thus may help to guide recruitment maneuvers and PEEP adjustment in patients with ALI/ARDS.

Further attempts at recruitment through the use of cyclic “sighs,” prone positioning of patients, the use of chest weights or sandbags, high-frequency oscillatory ventilation (HFOV), airway pressure release ventilation (APRV), and biologically variable or “fractal” ventilation using low tidal volumes have variously been shown to improve oxygenation, and continue to attract research attention as potentially beneficial. None of these

small studies, however, has shown improvement in mortality as has the ARDSnet protocol, which must still be considered the gold standard treatment in this patient population.

It is interesting that, while volume- and pressure-limited ventilation has been convincingly shown to reduce morbidity and mortality in patients with ALI/ARDS, the preemptive use of this ventilatory strategy in patients at high risk for lung injury has not been shown to be beneficial, and may actually increase morbidity.

Permissive hypercapnia (PHY) is the concept of allowing the partial pressure of carbon dioxide to exceed normal levels to maintain low-tidal-volume ventilation, even when patients develop moderate associated acidemia. Hypercapnia is not a therapeutic goal in itself – indeed, many patients will tolerate a high enough respiratory rate that they will not become hypercapnic, with tidal volumes limited to 6 ml/kg. With the large amount of dead-space ventilation and limited gas exchange common in ARDS, allowing the PaCO₂ to increase and the pH to decrease may be necessary to enable a lung-protective ventilatory strategy. As long as right heart failure does not develop, even sudden PHY and its associated transitory hyperdynamic cardiovascular state and pulmonary hypertension are well-tolerated, especially by younger patients.

Pharmacologic interventions

Steroids and ARDS

The use of steroids in ARDS remains controversial. In 2006, the ARDSnet investigators reported no mortality benefit from administration of methylprednisolone (2 mg/kg × 1, followed by 0.5 mg/kg every 6 hours for 14 days), although patients who received steroids had more ventilator-free and shock-free days during the first 28 days, improved oxygenation and respiratory system compliance, and more days free of vasopressor therapy. Patients who were started on steroids after 14 days of ARDS had higher mortality than those randomized to placebo. The authors concluded that the routine use of methylprednisolone for persistent ARDS was not supported by the results of the study.

In 2007, however, Meduri and colleagues reported the results of a multicenter, randomized, double-blind, placebo-controlled study of methylprednisolone infusion (1 mg/kg/d) in early severe ARDS which showed reductions in ventilation time, ICU stay, and ICU mortality. In an accompanying editorial, Djillali Annane argued that, despite the attributable risks of gastrointestinal (GI) bleeding, ICU myopathy, hyperglycemia, and so forth, the results of this and several other studies justify the routine use of a low-dose steroid infusion in patients with severe ARDS of < 2 weeks duration.

The use of exogenous surfactant in ARDS has not been shown to improve ventilator-free days or mortality, although, in a 2004 report in the *New England Journal of Medicine*, patients randomized to surfactant had greater improvements in gas exchange than did those receiving standard therapy. Similarly, exogenous nitric oxide therapy has not been shown to provide

survival or other significant benefit in the management of ventilated patients with ARDS.

Fluid management and transfusion

A conservative fluid-management strategy is increasingly supported by evidence in ARDS as improving oxygenation and ventilator-free days, although no mortality benefit has yet been shown. Fluid resuscitation may of course be needed for the appropriate treatment of an underlying disease process, such as pancreatitis, sepsis, and so forth, but as soon as is practical, a conservative approach to fluid administration to minimize pulmonary edema and optimize oxygenation seems prudent. Guidance of resuscitation with a central venous line (CVL) alone is adequate; a trial of PAC use in ARDS has added to the overwhelming weight of evidence against PAC use, showing approximately twice as many catheter-related complications and no outcome benefit in the PAC group.

Transfusion of red blood cells and other blood products is well-recognized as a risk factor for the development of ALI/ARDS in critically ill patients, and the body of evidence demonstrating poor outcomes with aggressive transfusion practices continues to grow. Evidence-based conservative transfusion practices are certainly warranted, and blood products should never be used to “spare” crystalloid infusion in fluid-requiring patients with ALI/ARDS.

Outcomes

Several investigators are now looking at quality of life and outcomes in survivors of ARDS and have found significant physiologic, neurocognitive, and emotional deficits that persist for years after ICU discharge and result in decreased quality of life. Many patients show a significant loss of body mass (average 18% loss of baseline body weight), complain of persistent muscle weakness and fatigue, and, although they have normal lung volume and spirometric measurements by 6-month follow-up, DLCO (diffusing capacity of lung for carbon monoxide) generally remains low a year after discharge, reflecting abnormal gas exchange capacity at the alveolar level. Patients usually do not require supplemental oxygen at follow-up, but may have significant desaturation with exercise to below 88%. Patients who did not receive corticosteroids, did not acquire additional illnesses during their hospital stay, and had rapid resolution of their multiorgan and pulmonary dysfunction have better functional status at 1-year follow-up.

A Canadian study has reported that 85% of patients who are discharged from the ICU survive to 2-year follow-up, and the initial hospital stay accounts for the majority of the costs associated with the disease. Although 65% of these patients had returned to work at 2-year follow-up, most continued to have exercise limitation, and although emotional and mental health improved in the 1- to 2-year postdischarge interval, all other quality-of-life measures remained below those of the general population and did not show statistically significant improvement from 1 to 2 years.

Future study

Although significant improvements in the management of ALI/ARDS and its underlying causes have been made in the past decade, mortality remains high at 30% to 50%. The National Heart, Lung, and Blood Institute Working Group, among others, is working to develop new approaches to the management of this heterogeneous disease process through a multimodal approach combining the use of biologic, genomic, and genetic approaches in animal and clinical studies, with the goal of improving detection and treatment of the disease syndrome.

Nosocomial infections

David Oxman, Shannon S. McKenna, and Gyorgy Frenzl

Health care–associated (hereto referred to as *nosocomial*) infections are considered to be infections acquired in acute or chronic health care settings (in hospitals and rehabilitation or chronic care facilities). They are an increasing problem and constitute a major source of morbidity and mortality. In addition, these infections significantly increase the cost and duration of hospital care. Ventilator-associated pneumonia (VAP) and catheter-related bloodstream infections (CRBSI) represent two of the most serious nosocomial infections and will be the focus of this chapter. Both of these infections can easily progress to sepsis and death. Other nosocomial infections, such as urinary tract and wound infections, are typically more easily treatable and less likely to increase patient mortality, and therefore are not discussed here.

A common feature of all these nosocomial infections is that they are preventable, and the most successful strategy for fighting them is prevention. It is essential for the anesthesiologist to be comfortable managing patients who develop these complications and to be aware of proven methods for preventing their occurrence.

Ventilator-associated pneumonia

Incidence, morbidity and, mortality

VAP is one of the most commonly occurring intensive care unit (ICU) infections. Anywhere from 5% to 20% – depending on definitions used – of mechanically ventilated patients develop VAP. Compared to patients with similar initial degrees of illness, patients who acquire VAP stay in the hospital longer, stay on the ventilator more days, and die at a higher rate. Additionally, the costs associated with VAP are significant, with estimated excess hospital costs of at least \$40,000 per case.

Pathogenesis

The prolonged presence of an endotracheal tube (greater than 48 hours) is the major contributor to the pathogenesis of VAP. Although other factors contribute to the risk, the endotracheal tube and the alterations in host-defense mechanisms it engenders, as well as the reservoir for pathogenic organisms it creates, are the major causative factors in the development of VAP.

The first protection of the lower respiratory tract against aspiration and microbial colonization are mechanical defenses,

including cough reflexes and mucociliary clearance. The presence of an endotracheal tube impairs both of these mechanisms. It also creates a direct conduit by which bacteria from the upper airway and oropharynx can access the lungs. Aspiration of oropharyngeal secretions is the major route by which bacteria gain access to the lower respiratory tract. Although aspiration of gastric contents with bacterial overgrowth plays some role in the acquisition of VAP, it is probably less important. Bacteria can also enter the lungs via other routes: (1) direct extension of a contiguous infection, (2) hematogenous spread from distant sites, and (3) inhalation of contaminated aerosols. The most common route by which organisms enter the lungs is aspiration. The typical organisms causing VAP are listed in [Table 160.1](#).

Clinical manifestations

Signs and symptoms of VAP can be obvious or subtle. Systemic signs such as fever or leukocytosis should, when present in the mechanically ventilated patient, always lead to the consideration of VAP. An increase in the amount of secretions suctioned from the endotracheal tube may also be an early sign of VAP. Changes in a patient's respiratory parameters, such as a decreasing partial pressure of arterial oxygen (PaO_2) as measured by arterial blood gas, or the need to increase the fraction of inspired oxygen content (FiO_2) or positive end-expiratory pressure (PEEP) to maintain normal oxygen saturation, may be the first indication of VAP and should prompt further investigation.

Although chest radiography is often helpful, it is unreliable for ruling in or ruling out the diagnosis of VAP by itself. Other common conditions in mechanically ventilated patients, such as ARDS, atelectasis, or lung contusion, may mimic or obscure VAP ([Table 160.2](#)). If the clinical suspicion is high and chest radiograph is inconclusive, CT of the chest may be helpful. A new infiltrate on chest radiograph, however, when

Table 160.1. Typical organisms causing VAP

Pulmonary edema
ARDS
Atelectasis
Pulmonary hemorrhage
Pulmonary contusion
Pulmonary infarct

coupled with other findings (e.g., fever and/or an increase in sputum production or a change in a patient's respiratory status) are together highly suggestive of VAP.

Microbiology of VAP

With critical illness, the microbiologic flora of the oropharynx changes dramatically. In healthy people the oropharynx is overwhelmingly colonized with streptococci and anaerobes. The mouth flora of a critically ill patient becomes colonized with Gram-negative bacteria and *Staphylococcus aureus*. Predictably, Gram-negative organisms and *S. aureus* are the most common pathogens responsible for VAP (Table 160.1). Drug-resistant organisms, such as *Pseudomonas aeruginosa* and methicillin-resistant *S. aureus* (MRSA), pose added danger to critically ill patients. Anaerobic bacteria, *Legionella*, and viruses, such as herpes simplex virus, can cause VAP as well but are much more uncommon.

Diagnosis

Unfortunately, there is no gold standard diagnostic test for VAP, and diagnosis can be challenging. Clinical characteristics, such as fever, sputum production, increased oxygen requirements, and a new infiltrate seen on chest radiograph, are suggestive of VAP, but they are not specific (Table 160.3). Sampling of the lower respiratory tract for pathogenic organisms increases diagnostic accuracy. Several methods exist for obtaining a microbiological specimen – including tracheal aspiration, nonbronchoscopic “min-BALs,” and fiber-optic bronchoscopy with bronchoalveolar lavage or a protected brush sampling. Which method is the most accurate and cost-effective is an area of some controversy. Whenever VAP is suspected, however, some type of lower respiratory specimen should be sent for Gram stain and culture.

The Clinical Pulmonary Infection Score (CPIS; Table 160.4) is a prediction tool designed to help make the diagnosis of VAP based on clinical variables. It incorporates variables such as the presence or absence of fever, purulent sputum, or leukocytosis, as well as the degree of hypoxemia, character of radiographic abnormalities, and microbiologic findings. A score of > 6 is typically used to diagnose VAP. Although the CPIS may be helpful in clinical decision making, its positive predictive value is modest – approximately 60% – and should not be overly relied on.

Treatment

Treatment for VAP should begin as soon as VAP is suspected and not be delayed for definitive diagnostic testing, as delays in

Table 160.3. Centers for Disease Control and Prevention surveillance definition for clinical diagnosis of hospital-acquired pneumonia

Radiologic signs

Two or more serial chest radiographs with at least one of the following^a:

- New or progressive and persistent infiltrate
- Consolidation
- Cavitation

Clinical signs

At least one of the following:

- Fever (temperature >38°C) with no other recognized cause
 - Leukopenia (leukocyte count <4.0 × 10⁹ cells/L) or leukocytosis (leukocyte count >12.0 × 10⁹ cells/L)
 - For adults ≥70 y, altered mental status with no other recognized cause
- And at least two of the following:
- New onset of purulent sputum, change in character of sputum, increased respiratory secretions, or increased suctioning requirements
 - New onset or worsening cough, dyspnea, tachypnea
 - Rales or bronchial breath sounds
 - Worsening gas exchange (e.g., O₂ desaturations [e.g., PaO₂/FiO₂ ≤240], increased oxygen requirements, or increased ventilation demand)

^a In patients without underlying pulmonary or cardiac disease (e.g., respiratory distress syndrome, bronchopulmonary dysplasia, pulmonary edema, or chronic obstructive pulmonary disease), one definitive chest radiograph is acceptable.

Table 160.4. CPIS scoring

Temperature

≥36.5 and ≤38.4 = 0 points
≥38.5 and ≤38.9 = 1 point
≥39 or <36.5 = 2 points

Blood leukocytes, micro/L

≥4000 and ≤11,000 = 0 points
<4000 or >11,000 = 1 point
Band forms ≥50% = add 1 point

Tracheal secretions

Absence of tracheal secretions = 0 point
Presence of nonpurulent tracheal secretions = 1 point
Presence of purulent tracheal secretions = 2 points

Oxygenation

PaO₂/FiO₂, mm Hg >240 or ARDS (defined as PaO₂/FiO₂ ≤200, PAWP ≤18 mm Hg and acute bilateral infiltrates) = 0 points
PaO₂/FiO₂ ≤240 and no ARDS = 2 points

Pulmonary radiography

No infiltrate = 0 points
Diffuse (patchy) infiltrate = 1 point
Localized infiltrate = 2 points

Progression of pulmonary infiltrate

No radiographic progression = 0 points
Radiographic progression (after HF and ARDS excluded) = 2 points

Culture of tracheal aspirate

Pathogenic bacteria cultured in rare or few quantities or no growth = 0 points
Pathogenic bacteria cultured in moderate or heavy quantity = 1 point
Same pathogenic bacteria seen on Gram stain, add 1 point
Total score of >6 suggestive of VAP

PAWP, pulmonary arterial wedge pressure; HF, heart failure. From Pugin J, Auckenthaler R, Mili N, Janssens JP, Lew PD, Suter PM. treatment lead to poorer outcomes. Initial antibiotic therapy should be broad and directed at the typical nosocomial organisms causing pneumonia in the ICU. VAP is most often caused by Gram-negative bacteria, such as *P. aeruginosa* – but Gram-positive bacteria, particularly *S. aureus*, are increasingly common pathogens. Given the high rates of antibiotic resistance in VAP, combination therapy is almost always indicated initially, and it should include two different classes of antibiotics directed to Gram-negative bacteria and an agent active against MRSA (Table 160.5). After microbiological data become available, antibiotic therapy should be tailored to the specific pathogen and combination therapy can be stopped. Furthermore, in patients who turn out to have an alternative diagnosis and who do not have VAP, antibiotics should be stopped as soon as possible. Exposure to unnecessary antibiotics leads to colonization with drug-resistant organisms in the patient and the entire ICU, and makes future episodes of VAP much more difficult to treat. Adjunctive measures such as lung-protective, low-tidal-volume ventilation strategies may be helpful in patients developing decreased lung compliance from their infection (for details, see Chapter 159).

Prevention

The best way to prevent VAP is to avoid intubation or, if that is not possible, minimize the duration of mechanical ventilation. Therefore, in patients who meet criteria, noninvasive positive pressure ventilation should always be considered. In patients who must be endotracheally intubated, moving toward extubation as soon as the patient is ready prevents many episodes of VAP. Limiting sedation and performing daily spontaneous breathing trials help to identify those patients early who are capable of being liberated from mechanical ventilation.

Several additional simple and inexpensive measures have been proven to reduce rates of VAP. They include maintaining head-of-bed elevation (above 30°) in mechanically ventilated patients, hand washing before physical examination, and limiting respiratory circuit tubing changes. Other measures,

Table 160.6. Strategies to prevent VAP

Hand washing before physical examination
Head-of-bed elevation >30°
Limit sedation and perform “daily wake-ups”
Perform daily spontaneous breathing trials
Oropharyngeal decontamination (conflicting evidence)
Continuous subglottic suctioning (some evidence)
Silver-coated endotracheal tubes (some evidence)

such as continual oral decontamination, continual subglottic suctioning, and the use of silver-coated endotracheal tubes, are promising but not yet definitively proven (Table 160.6).

Catheter-related bloodstream infections

Incidence, morbidity, and mortality

CRBSIs are among the most common hospital-acquired infections. Each year up to 250,000 patients in the United States develop nosocomial bloodstream infections, the majority of which are catheter-related, with an attributable mortality anywhere from 12% to 25%. Understanding the pathogenesis, clinical presentation, and management of CRBSI is vital for the anesthesiologist taking care of patients at risk for CRBSI. Additionally, anesthesiologists should be aware of the state-of-the-art practice for preventing these infections from occurring.

Pathogenesis

Microorganisms causing CRBSI enter the bloodstream via one of four mechanisms. The first is through colonization of the skin at the catheter entry site. Microorganisms can then enter the bloodstream via migration along the catheter itself. The second route of infection is via contamination of the catheter hub or stopcock. These two mechanisms account for the vast majority of all catheter-related bloodstream infections. Seeding of the catheter through the blood from an infection at a distant site, and contamination of intravenous infusates are the two other means by which CRBSI occur, but are much less common. Short-term, noncuffed central venous catheters have the highest rates of infection but arterial catheters and peripherally inserted central venous catheters (PICC lines) can also cause infection at high rates.

Clinical manifestations

The clinical manifestations of CRBSI are generally indistinguishable from bloodstream infections originating from any other source. Fever, rigors, hypotension, or other early signs of sepsis (such as tachycardia or tachypnea) often occur. Catheter entry sites and tunneled catheter tracts should be examined, as infrequently there may be signs such as erythema, local tenderness, or purulent drainage.

Microbiology of CRBSI

S. aureus and coagulase-negative *Staphylococcus* (such as *S. epidermidis*) are the most common organisms responsible for

CRBSI. *Enterococci* and *Candida* species are the next most common with assorted Gram-negative bacteria responsible for most of the remaining infections.

Diagnosis

Blood culture is the definitive diagnostic test for CRBSI. In the patient with an intravascular catheter, if two sets of blood cultures drawn from two separate venopuncture sites are positive, it is highly suggestive of a CRBSI. An additional set drawn from the intravascular catheter may also be helpful in pinpointing the intravascular catheter as the source of the bacteremia. As the lumens of intravascular catheters are frequently colonized with bacteria, sending blood cultures drawn through the catheter alone will lead to a high false-positive rate and the removal of many catheters that are not infected. Differences in the speed at which blood cultures obtained peripherally and those obtained through the intravascular catheter turn positive may help to distinguish between a line-related and a non-line-related bacteremia. Semiquantitative cultures of the tip of the central line, using either the roll plate method or sonication, may help to further define the etiology of a bacteremia. Line tip culture, however, requires removal of the suspected line before a CRBSI is proven. It is important to note that the roll plate method, which is the most commonly used culture technique, examines the outside of the line only and will not identify infections originating from the internal lumen of the line.

Treatment

As CRBSI carries a high rate of morbidity and mortality, treatment should not be delayed until blood cultures become positive. In patients with an intravascular catheter displaying typical signs and symptoms of CRBSI, empiric antibiotics directed at typical pathogens should be started immediately, and, if possible, the catheter should be removed. As Gram-positive organisms, including MRSA, cause the majority of infections, vancomycin is the typical first-line agent. In the immunocompromised or septic patient, empiric treatment should be broadened to cover typical nosocomial Gram-negative organisms. Fungal CRBSI, although increasing in incidence, is still relatively uncommon, and empiric antifungal coverage should be reserved for high-risk patients. After the causative organism is identified, antibiotic therapy should be tailored accordingly and the line should be removed if it has not been already. Exchange of an infected catheter over a guidewire is not effective for managing CRBSI and should be discouraged.

Prevention

Fortunately, CRBSIs are preventable, and recent studies have shown that with careful attention to prevention techniques, rates of CRBSI can be reduced to near zero. When placing intravascular catheters, maximum barrier precautions – including sterile gloves, surgical mask and gown, and a large

sterile drape – should be used. Cleansing of the patient's skin with chlorhexidine has been shown to be superior to povidine-iodine. Use of a real-time standardized checklist has been shown to be an effective method of ensuring that appropriate sterile technique is used with each and every line insertion. Standardized sterile technique with maximum barrier precautions should be used for all line insertions, including line insertions in the operating room, emergency department, and ICU. Any central line placed without observance of standard sterile technique should be appropriately identified as such and needs to be removed within 48 hours of placement.

Proper hand hygiene, using either antiseptic soap and water or an alcohol-based hand sanitizer, is essential prior to both line insertion and the handling of catheter hubs and stopcocks and is the backbone of infection prevention. Additionally, access ports must be cleaned with an antiseptic, such as an alcohol swab, immediately prior to use, and only sterile access devices may be used.

Whenever possible, the femoral insertion site should be avoided as this site is associated with higher infection rates. Similarly, several studies have shown that the subclavian approach is associated with a slightly lower risk of infection than is internal jugular catheterization. Although it is true that the longer an intravascular catheter stays in place the higher the risk of bloodstream infection, there is no evidence to support the routine replacement of catheters after an arbitrary duration of time. Any indwelling catheter that is no longer essential for patient care, however, should be removed immediately. When a CRBSI is suspected, or confirmed, the associated line must be removed. If central access is still required, a new line must be inserted at a new site. Ideally, the patient will be given a period of time with antibiotic treatment before the new central venous catheter is inserted to diminish the risk of seeding the new line.

Septic shock and sepsis syndromes

Maxwell Weinmann

Introduction

Sepsis and septic shock are causes of substantial morbidity and mortality. Of the 1 million patients diagnosed annually in the United States with septic shock, mortality is approximately 50%, but may increase to as high as 80% in the setting of complicating organ failure. As such, early diagnosis and timely intervention are critical if outcome is to be favorably altered.

Pathogenesis

Pathophysiologically, irrespective of the offending organism, sepsis is a systemic disease with significant involvement of the endothelium. Intravascular recognition of bacterial antigens initiates both inflammatory and procoagulant responses that are intimately associated. Subendothelial injury generates thrombin, which fuels an accelerating and potentially systemic proinflammatory and procoagulant state. Microvascular thrombosis and ischemia ensue with systemic progression of diffuse endovascular inflammation and injury, and, ultimately, vascular autoregulatory collapse. Microvascular thrombosis produces disordered perfusion and oxygen delivery at a time of increased oxygen demand. Unabated, this cycle is self-perpetuating and may culminate in irreversible ischemic organ failure and death. Despite apparent early global stability, the body attempts to shunt blood from nonessential vascular beds to vital organs; a phenomenon known as *compensated shock*. After organ reserve is depleted, systemic failure becomes clinically evident. If therapy is to be successful and either reverse or mitigate the ensuing organ injury and collapse, intervention must be both timely and comprehensive.

Spectrum of disease and definitions

Sepsis presents a spectrum of clinicopathologic phenomena, so a number of clinical definitions have emerged in an attempt to both better understand the phenomena and develop therapeutic strategies. These definitions include the following:

1. Systemic inflammatory response syndrome (SIRS): requires at least two of the following:

Temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$

Heart rate >90 bpm

Respiration $>20/\text{min}$ or $\text{PCO}_2 >32$ mm Hg

White cell count $>12,000/\text{mm}^3$

10% immature neutrophils

2. Sepsis: requires SIRS with a presumed or confirmed septic focus
3. Severe sepsis: requires sepsis with >1 sign of organ dysfunction in the presence of hypotension. Examples include:

Pulmonary	Hypoxia ($\text{PaO}_2/\text{FiO}_2 <300$), tachypnea
Renal	Oliguria (urine output <0.5 ml/kg/h) Creatinine increase <0.5 mg/dl
Hematologic	Coagulopathy (international normalized ratio [INR] <1.5 , partial thromboplastin time [PTT] >60 s) Thrombocytopenia (platelets $<100,000/\mu\text{l}$)
Hepatic	Elevation in transaminases and bilirubin
Neurologic	Confusion/delirium
Metabolic	Hyperglycemia, lactic acidosis
Cardiac	Tachycardia

As organ systems fail, the potential for reversibility diminishes, and mortality rises. The progressively increasing risk of mortality emphasizes the importance for timely diagnosis and intervention as shown in Fig. 161.1.

4. Septic shock: defined as persistent hypotension, despite adequate fluid resuscitation, which is not explained by other causes. Hypotension is defined as a systolic blood

Figure 161.1. Organ system failure and mortality. (Source: Angus DC, Linde-Zwirble WT, Lidicker J, et al. Epidemiology of severe sepsis in the United States: analysis of incidence, outcome and associated costs of care. Adapted, with permission, from *Crit Care Med* 2001; 29:1303–1310.)

Figure 161.2. Clinical markers of sepsis.

pressure (BP) of <90 mm Hg and a mean arterial pressure (MAP) of <60 mm Hg, or a reduction in systolic BP of >40 mm Hg from baseline (Fig. 161.2).

Therapy

The following recommendations emerge largely from the Surviving Sepsis Campaign (SSC), an international effort to decrease the mortality of sepsis consisting of 11 international societies. Recommendations were classified according to literature support or expert opinion.

Fluid resuscitation

The presence of hypotension signals that septic pathophysiology is already well established. If accompanied by systemic lactic acidosis, anaerobic metabolism has commenced (at least in some organ beds) and resuscitation is urgent.

The SSC recommends that resuscitation goals within the first 6 hours include

- Central venous pressure (CVP) 8 to 12 mm Hg,
- MAP >65 mm Hg,
- Urine output >0.5 ml/kg/h,
- Central venous or mixed venous O₂ saturation >70%, and
- Consideration of a blood transfusion if venous saturation is unresponsive to fluids alone, despite a CVP of 8 to 12 mm Hg.

However, the clinician must place this information into clinical perspective. Conditions that influence the pressure–volume relationship of the heart will necessitate review of these values. For example, a patient with chronic obstructive pulmonary disease (COPD) and pulmonary hypertension may require a CVP of 14 to 16 mm Hg to achieve the same degree of filling compared to a previously healthy person. Similarly, a venous saturation of >70% may still be a cause of concern in a patient with an increasing lactate, suggesting that shunting or disordered oxygen uptake is persisting despite intervention, requiring a modification of therapeutic strategy.

Additionally, the long-standing controversy over the superiority of either colloid or crystalloid as a resuscitation strategy continues. The Saline versus Albumin Fluid Evaluation Study (SAFE Study) was a prospective analysis of approximately 7000 patients, each patient being randomized to either normal saline or 4% albumin. Results demonstrated that there was no significant difference in mortality, hospital stay, duration of mechanical ventilatory support, incidence of organ failure, or need for continuous renal support between the two therapies. Subgroup analysis suggested a trend toward reduced mortality in patients receiving albumin with severe sepsis but increased mortality when administered with severe head trauma. Whether these effects are through immune modulation, altered microcirculatory performance, and oxygen delivery, both globally and on a microcirculatory level, is yet to be determined (Fig. 161.3).

Figure 161.3. Relative mortality risk of administering albumin versus saline during resuscitation. (Source: The SAFE Study Investigators. A comparison of albumin and saline for fluid resuscitation in the intensive care unit. *N Engl J Med* 2004; 350(22):2247–2256.)

Diagnosis and source control

Diagnostic procedures should proceed contemporaneously with resuscitation. Two or more blood cultures (preferably drawn from peripheral blood via venipuncture) are advised. Additional blood cultures from the lumen of each intravascular device may be desirable. Other sites should also be cultured, including sputum, urine, and cerebrospinal fluid (CSF), if clinically warranted. Imaging studies should be pursued based on clinical indication, such as recent surgery, premorbid conditions, and preexisting intravascular devices, in order to determine if a distinct focus of infection exists. If so, a determination of the viability of drainage, removal, exploration, and debridement follows. The successful treatment of sepsis hinges on effective source control.

Antibiotic therapy

Antibiotic therapy is considered part of the resuscitative effort and must be instituted as a matter of urgency, ideally within the first hour of arrival. Empiric therapy is therefore often unavoidable. The choice of antibiotics is a function of the clinical scenario encountered: the patient's immunocompetence, clinical history (including recent antibiotic therapy), and susceptibility patterns in the patient's community and hospital of admission.

Typically, broad-spectrum coverage is initiated and tailored to more specific regimens after susceptibilities are determined. This practice helps prevent not only resistance but also superinfection by resistant organisms.

As only 5% of cases of severe sepsis or septic shock have been shown to be due to fungal infection, it is not warranted to commence empiric anti fungal therapy, except when the likelihood of fungal infection is exceedingly high (patient on TPN, immunocompromised patient, and when fungal cultures are positive from multiple sites or fungus is seen on Gram stain of blood).

Vasopressor and inotropic therapy

The mortality of sepsis can be significantly reduced using the early fluid resuscitation strategy (Rivers et al.) combined with

the judicious use of inotropic agent (dobutamine) and vasopressors.

If hypotension persists despite fluid resuscitation and adequate circulatory filling as determined by the CVP, vasopressors should be commenced. An ideal vasopressor has yet to emerge, as all have potential side effects, namely exacerbation of ischemia, arrhythmias, etc. Reestablishment of perfusion pressure is vital if organ failure is to be prevented or reversed. The clinician must therefore titrate the dose to effect, while being watchful for any untoward complications. The need to titrate to effect is largely due to the profound alteration of dose-response relationships in severe sepsis.

The drug of first choice is a function of the clinical scenario and the clinician's assessment of the patient's potential to respond (i.e., the patient's clinical reserve). For example, in the setting of associated coronary vascular disease, the physician may be wary of epinephrine's potential for tachycardia and choose phenylephrine. Irrespective of which agent is ultimately selected, restoration of perfusion pressure is the resuscitative goal as long as the intensivist is watchful for the "physiologic cost" of therapy. For example, if the addition of vasopressors produces a decline in venous saturation and raises concerns regarding oxygen dynamics, observation of the lactate response will be a clue to the potential cost of intervention. Elevation of lactate would suggest iatrogenic worsening, requiring a new strategy, whereas a decline in lactate would suggest that the degree of shunting has been reduced. Clinical perspective is the key because, at present, the technology to actually evaluate the microcirculation remains largely in the realm of research.

Vasopressor strategies and ongoing controversies

While no vasopressor agent has been shown to be clearly superior for the management of septic shock, norepinephrine and epinephrine have moderate advantages over the use of dopamine. Phenylephrine appears to have no role (other than a temporizing agent) in the management of septic shock. Studies have shown a moderate benefit of the use of vasopressin (in the 0.04–0.08 U/min range) for the management of early (less severe) septic shock.

Conventional clinical dogma dictates stabilization of systemic BP in resuscitation of the critically ill septic patient. However, despite the efforts to stabilize systolic BP, mortality remains high and prognosis poor. Evaluation of the circulatory response to sepsis has strongly supported that sepsis is primarily a disease of the microcirculation and the endothelium in particular, where endothelial integrity and function are predictive of both organ function and patient survival. Consequently, systemic parameters cannot be considered a reliable reflection of events in key vascular beds.

Traditionally, lactate levels have been the conventional indirect measure of the onset of anaerobic metabolism and organ stress in the intensive care unit (ICU). Sole reliance on lactate, however, is inadequate as a marker of tissue hypoxia, as a critical fraction of tissue must be rendered ischemic before serum lactate levels increase. The absence of lactic acidosis therefore does not exclude the presence of tissue ischemia. Conversely, the presence of lactate does not always confirm ischemia. Lactate elevation is due to biochemical derangements accompanying both sepsis (such as disordered pyruvate dehydrogenase activity) and treatment (such as occurs with the induction of aerobic glycolysis by vasopressor therapy). Thus serum lactate levels may be artificially elevated in the absence of hypoxia. Additionally, lactate levels may continue to increase despite aggressive resuscitation due to a washout effect with the restoration of perfusion. Lactate must therefore be considered a rather late and insensitive marker of ischemia that does not adequately reflect regional or organ-specific events.

Correlation with other markers of oxygen dynamics has included the oximetric pulmonary artery catheter, which has allowed estimation of mixed venous oxygen saturation (SvO₂) in real time. The adequacy of global oxygen use and delivery is determined as outlined by manipulation of the Fick equation:

$$\text{SvO}_2 = \text{SaO}_2 - \text{VO}_2 / (\text{CO} \times 1.34 \times [\text{Hb}])$$

where SaO₂ is arterial oxygen saturation, VO₂ is oxygen consumed per minute, CO is cardiac output, and Hb is hemoglobin concentration.

In the absence of anemia or hypoxia, the measure of SvO₂ will therefore reflect the relationship between VO₂ and CO, or oxygen delivery (DO₂), such that reductions in SvO₂ are presumably due to an imbalance between DO₂ and VO₂:

$$\text{SvO}_2 \propto \text{VO}_2 / \text{CO} \text{ or } \text{SvO}_2 \propto \text{VO}_2 / \text{DO}_2.$$

Unfortunately, this mathematic expression of a physiologic relationship breaks down in the presence of anemia and hypoxia, which are almost universal in the critically ill. Therefore, regional ischemia and incipient organ failure can occur despite normalization of SvO₂, a *global* measure. Consequently, large studies have not demonstrated a survival advantage to normalization of SvO₂.

By contrast, almost all patients undergoing resuscitation have a central venous catheter placed for fluid management, vasopressor administration, and so forth, as part of the standard of care. As a result, central venous oxygen saturation (ScvO₂)

has been advocated as a surrogate measure of oxygen dynamics. The validity of the SvO₂–ScvO₂ relationship remains in question as the capacity of systemic markers to accurately reflect microcirculatory events is dubious.

Overall, if clinical interventions are to effect morbidity and mortality, they must be initiated prior to irreversibility of organ failure, and titrated according to physiologic reserve to avoid inducing or exacerbating further ischemia and organ injury.

Steroid therapy

The application of steroids in shock has long been debated. Recent studies have demonstrated the secondary adrenal failure of sepsis, where both the synthesis of cortisol is inhibited and its metabolism is enhanced. Evidence of relative adrenal insufficiency is considered present when serum cortisol levels demonstrate a <9 μg/dl increase in response to a 250-μg stimulation of adrenocorticotropic hormone (ACTH) and is also supported by a random basal serum cortisol of <20 μg/dl. Whether or not the decision to commence steroid therapy should be based on this response has been debated, largely because of the variability of the adrenal response in critical illness, the fact that free cortisol (the biologically important hormone) is not measured. Therefore, it is now believed that adrenal testing is unlikely to identify steroid responders and is not warranted.

Where does this leave the clinician in deciding who, if anyone, would benefit from steroids? Review of the latest clinical evidence suggests that, in severe septic shock, where the patient is unresponsive to resuscitation with both fluids and vasopressors, the addition of steroid therapy hastens the reestablishment of hemodynamic stability and reversal of shock. In terms of mortality, however, conflicting results make this an area of ongoing debate.

As for the recommended dose, low dose or physiologic steroid replacement is the current approach (i.e., 200–300 mg of hydrocortisone in three to four divided doses, or by continuous infusion). Higher doses have been associated with worsening mortality and untoward complications including secondary infection, myopathy, and so forth, and are not recommended. The addition of fludrocortisone remains questionable, as hydrocortisone possesses mineralocorticoid activity (20 mg of hydrocortisone is equivalent to 0.05 mg of fludrocortisone), and is currently under investigation.

As to weaning, no clear protocol has emerged due to the phenomenon of *rebound*, where there is a contemporaneous decline in cardiovascular improvements and increased evidence of inflammation with reduction in dose. The clinician must therefore be guided by the clinical picture and consider gradual reduction in dose only after establishment and maintenance of stability.

Recombinant activated protein C

In sepsis, loss of thrombin modulation perpetuates a procoagulant state with systemic progression of diffuse endovascular

inflammation and injury, vascular autoregulatory collapse, and organ ischemia. It is therefore apparent that, if outcome is to be effected, one must target the endothelium. The recent therapeutic introduction of exogenous activated protein C in patients with severe sepsis has been associated with a significant reduction in mortality. By restoring levels of protein C, thrombin regulation is reestablished with a subsequent reduction in its systemic inflammatory, procoagulant, and antifibrinolytic activity. As a result, microvascular integrity is restored, attenuating the propagation of inflammatory and ischemic organ injury and culminating in lowered morbidity and enhanced survival in patients with septic shock. It is important to note that activated protein C therapy carries the risk of increased bleeding, and for that reason has not gained wide acceptance in the perioperative setting. Some clinicians have questioned the clinical effectiveness of this intervention, and further large scale clinical trials are under way to confirm the utility of this therapy in sepsis.

Ancillary therapies

Metabolic management

For some time it has been considered intuitive that excellent glycemic control would positively impact morbidity and, possibly, mortality in critically ill patients. However, the relationship between glucose control, the level of hyperglycemia, the amount of administered exogenous insulin, morbidity, and mortality has remained a contentious and hotly debated issue. This debate is emphasized by recent observations of increased mortality despite aggressive insulin regimens in critically ill patients. Additionally, it has been suggested that the role of insulin resistance, the apparent cause of hyperglycemia in critically ill patients, is emerging as a potentially more important predictor and marker of mortality than is glycemic control. This finding has led some researchers to conclude that glucose stability (as opposed to absolute levels) is of greater therapeutic benefit. Indeed, recent meta analyses showed that tight glycemic control did not, in fact, confer any mortality benefit in critically ill patients, in part due to the incidence of hypoglycemic events.

Hypoglycemia may be the physiologic complication of striving for euglycemia, but the clinical cost may often be catastrophic, particularly in those patients with acute neurologic injury. The avoidance of hypoglycemia is therefore critical. The clinician must be aware that many of the clinical signs of hypoglycemia will be masked by intubation, vasoactive agents, sedation, and paralyzing agents, to name a few. Therefore, vigilant biochemical monitoring is often the sole means of avoiding potentially tragic complications.

Ventilator management

Since sepsis is often associated with the injury of multiple organs, it is not uncommon to see acute respiratory distress syndrome or acute lung injury in septic patients. In the absence

of any specific pharmacologic intervention in the treatment of acute respiratory distress syndrome and/or acute lung injury (ARDS/ALI), the mainstay of therapy has revolved around mechanical ventilatory strategies. Whereas ARDS/ALI may be diffuse, it is not necessarily uniform. Subsequently, different areas of lung are subjected, and vulnerable to barotrauma and inflammation-mediated alveolar trauma, producing heterogeneous injury. Using a lung-protective strategy (i.e., tidal volumes of 6 ml/kg of predicted body weight with a range of 4–8 ml/kg, and plateau pressures of ≤ 30 cm H₂O), mortality has been found to be reduced by 9%. This approach has now become the cornerstone for ventilatory management in these patients. The additional impact of recruitment maneuvers, optimal levels of positive end-expiratory pressure (PEEP), optimal ventilatory mode, and effect of sedation continue to be debated.

Future issues

If sepsis is a disease of the endothelium, then timely intervention will be dependent on moving beyond conventional macrophysiologic monitoring. Real-time assessment of organ-specific microcirculatory events remains largely experimental, but promising. With the evolution of oximetry to near-infrared spectroscopy (NIRS; using near-infrared light of 700–1100 nm wavelength), tissue now becomes virtually translucent. Cytochromes of the respiratory chain now act as chromophores in this spectrum, in relation to their oxidation status allowing real-time assessment of oxygen dynamics at the mitochondrial level.

Similar promise has been demonstrated with reflectance spectrophotometry, optode microsensors, and oxygen electrodes, to name a few.

As such technologies continue to shed light on these clinical syndromes, our understanding of, and the potential for meaningful interventions will continue to evolve.

Summary

1. Sepsis is a significant cause of morbidity and mortality in critically ill patients.
2. Rapid diagnosis and intervention are required if sepsis syndromes are to be successfully treated and organ injury prevented or reversed.
3. It is important to realize that, when clinical evidence of sepsis manifests, the disease process is already well established.
4. The “surviving sepsis guidelines” (see Dillinger 2004) provide the best available evidence for the treatment of sepsis. These guidelines are also evolving as mechanisms of disease and the impact of new therapies are analyzed.
5. Conventional global markers of perfusion are unreliable in evaluating organ injury, since sepsis is a disease of the microcirculation. Therefore, trends of these markers are often more important than their absolute values.

6. There is no clearly superior vasopressor in the treatment of septic shock. The key to the success of resuscitation remains the provision of sufficient perfusion pressure.
7. One must always be aware that dose–response relationships are severely distorted by sepsis. Titrate the dose of the vasoactive agents to effect and be aware of potential side effects.
8. Sepsis is a systemic condition and therefore requires a systemic approach: endocrine, ventilatory, nutritional aspects of care, and so forth should all be carefully monitored and addressed.

Anesthetic management of the brain-dead organ donor

J. Matthias Walz and Stephen O. Heard

As of August 2010, more than 107,000 individuals were on the waiting list for organ transplantation (Table 162.1). The total number of transplants performed in the United States during the preceding year was 28,463, of which 21,854 were from deceased donors, and approximately 6,609 were from living donors. There has been an increasing disparity over the last decade between patients on the waiting list for organ transplantation and available organs, despite governmental, private, and public initiatives to raise awareness about this crisis in health care. One of the most promising strategies to increase the number of available organs for transplantation is to maximize the retrieval of organs from cadaveric donors, which relies on optimal donor management in the preoperative and intraoperative period, because up to 25% of potential organ donors are lost to hemodynamic instability and other complications. Protocol-driven perioperative management has been validated in prospective clinical trials to significantly increase the number of transplantable organs and will be outlined in this chapter.

The legal framework for organ transplantation in the United States is defined in the National Organ Transplant Act (NOTA). Regional agencies under the auspices of the United Network for Organ Sharing (UNOS) are responsible for the allocation of organs and the administration of waiting lists and are called organ procurement organizations (OPOs). For example, the New England Organ Bank (NEOB) is the OPO responsible for the New England region.

The two principal sources of organs for solid organ transplantation are living donors (related or unrelated) and cadavers (cardiac death donors and brain death donors). This chapter will focus on cadaveric transplantation after the brain death of the potential organ donor.

Definition of brain death and management prior to organ donation

The most common cause of brain death in the adult potential organ donor is catastrophic brain injury due to anoxia, trauma, subarachnoid hemorrhage (SAH), or ischemic stroke. In children, the most common causes are abuse, motor vehicle accidents, and asphyxia. The exact definition of brain death may vary from state to state but always requires the absence of brainstem reflexes, motor responses, and respiratory drive in a

comatose patient with irreversible brain injury. Furthermore, the patient has to be normothermic, and metabolic abnormalities and drug intoxication as a cause of coma have to be excluded. In addition to the physical examination, a number of confirmatory tests, including nuclear medicine flow studies and electroencephalogram (EEG), are available to complement the physical examination in the diagnosis. The utility of four-vessel angiography to document lack of blood flow to the brain is limited because of the potential of end organ damage related to the contrast agent (e.g., contrast-induced nephropathy) but may be required for the patient who is in a pentobarbital coma or in situations where the diagnosis of brain death remains in doubt. One example of the key elements of the protocol used for the documentation of brain death shown in Table 162.2 (Source: UMass Memorial Medical Center). The documentation of brain death requires two separate structured examinations documenting the irreversible cessation of all cerebral and brainstem function. The two physical examinations have to be performed at least 6 hours apart, and some centers require that these examinations be performed by two different physicians. In addition to the physical examinations, an apnea test has to be performed to document the absence of any spontaneous breathing activity. For a more detailed discussion of the concept and diagnosis of brain death, see Nathan and Greer. If a patient is declared brain dead according to state and institutional criteria, the focus of critical care therapy shifts from restoring and maintaining brain function (which at this point is irreversibly lost and equates to the death of an individual) to the preservation of end organ function of the potential organ donor. Although patients with overwhelming infection are not

Table 162.1. Patients on transplant waiting lists by organ system

All	107,882
Kidney	85,511
Pancreas	1,434
Kidney/pancreas	2,179
Liver	15,923
Intestine	256
Heart	3,112
Lung	1,772

Table 162.2. Clinical examination

Motor response	No cerebral motor response to pain in all extremities, sternal rub, supraorbital pressure; no posturing; no grimacing (spinal reflexes do not preclude diagnosis of brain death)
Pupils	No response to bright light; pupils fixed and dilated (rule out preexisting pupillary abnormalities)
Corneal reflex	No response/blink to stimulation of corneas with wisp of cotton
Cough	No cough to deep tracheal/bronchial suctioning
Gag	No gag response to stimulation of posterior pharynx
Oculocephalic	No eye movements to rapid turning of the head (eliminate test if cervical spine injury is suspected)
Ocuvestibular	No deviation of eyes to irrigation in each ear with ~30 ml of ice water (allow 1 min after injection and at least 5 min between testing on each side; ensure intact, unobstructed tympanic membrane)
Absence of respiratory drive at a PaCO ₂ of 60 mm Hg (or 20 mm Hg above patient's baseline values)	Apnea test should be done last, after all other brainstem reflexes are absent, according to institutional guidelines

considered for organ donation, patients with meningitis, bacteremia, or fungemia (as well as hepatitis B or C virus infection) may be eligible. It is important to involve the local OPO early in the process to determine the eligibility of an individual to donate, because eligibility criteria for organ donation are always in flux. Some patients who may not seem to be candidates can go on to successful donation after careful evaluation by a team of experts. For a list of absolute contraindications to organ donation see [Table 162.3](#).

Intraoperative anesthetic management

The progression to brain death will result in a number of pathophysiological changes that can cause profound hemodynamic instability. Left untreated, this instability would result in multi-system organ failure and cardiovascular collapse in 70% to 80% of brain-dead individuals within 3 to 5 days and include cardiovascular, respiratory, hematologic, and metabolic changes. There is good evidence to support the use of protocol-driven pre- and intraoperative management of the potential organ donor. One of the challenges of providing intraoperative care for the potential organ donor is the competing interests of participating transplant specialties. For example, the team retriev-

ing the kidneys for transplantation will be interested in brisk urine output, whereas the surgeon recovering the lungs may be concerned about volume overload and impaired gas exchange. It is crucially important to maintain excellent communication with the participating providers to prioritize and discuss resuscitation strategies that will result in optimal organ function for the recipients.

Anesthetic management in the operating room is a continuation of therapies started in the intensive care unit with the aim of maintaining end organ perfusion and oxygenation, as well as maintaining optimal electrolyte and acid base status. Monitoring should include American Society of Anesthesiologists (ASA) standard monitors as well as invasive arterial blood pressure management, a central venous catheter, two large-bore peripheral venous catheters, a urinary catheter, blood gas analysis at regular intervals, as well as electrolyte panels as indicated. Because there is no perception of pain in a brain-dead individual (complete loss of cortical function), there is no absolute need for opioids or inhalational anesthetics. Due to the loss of inhibitory signals from the brainstem to the spinal cord, there may be hyperreflexia in response to somatic and visceral stimulation during the surgical procedure. Muscle relaxation should be maintained to optimize surgical conditions, and signs of high sympathetic tone, such as hypertension, tachycardia, and diaphoresis, can be managed with short-acting β -blockers and antihypertensives. After the onset of brain death, the individual is prone to hypothermia due to the loss of hypothalamic thermoregulation. Multimodal warming strategies will help to avoid adverse effects, such as coagulopathy, cardiac dysfunction, arrhythmia, and cold-induced diuresis. Additionally, hypothermia can shift the oxygen-hemoglobin dissociation curve to the left, resulting in impaired oxygen delivery to the tissues. Ideally, core temperature of the potential organ donor should be maintained above 35°C.

Cardiovascular

Ischemia of the brain secondary to irreversible injury results in markedly increased sympathetic tone to maintain cerebral perfusion pressure. This increase in sympathetic outflow can initially lead to hypertension, arrhythmia (bradyarrhythmia), and subendocardial ischemia, predominantly of the left ventricle. After brain herniation is complete, sympathetic outflow will cease, resulting in marked hypotension, often exacerbated by relative hypovolemia as a result of osmotic therapy to lower intracranial pressure. To maintain adequate end organ perfusion prior to organ retrieval, fluid, vasopressor, and inotropic therapy should be titrated to hemodynamic targets as outlined in [Table 162.4](#). Patients eligible for cardiac donation will undergo transthoracic or esophageal echocardiography or cardiac catheterization in the preoperative period to assess cardiac performance or disease. Unstable patients will require advanced hemodynamic monitoring based on thermodilution methods (pulmonary artery catheter), invasive arterial blood pressure monitoring, and/or hemodynamic monitoring based

Table 162.3. Absolute contraindications to organ donation

HIV infection (donation is possible if recipient is also HIV positive)
Human T-cell leukemia-lymphoma virus infection
Systemic viral infections (e.g., measles, rabies, adenovirus, parvovirus, enterovirus)
Prion-related diseases
Herpetic meningoencephalitis
Advanced malignant disease

Table 162.4. Hemodynamic and physiologic endpoints during anesthetic management of the potential organ donor

Systolic/mean arterial blood pressure	≥90 mm Hg / ≥60 mm Hg
Central venous pressure	≤12 mm Hg
Pulmonary capillary wedge pressure	≤12 mm Hg
Cardiac index	>2.5 L/min/M ²
Left ventricular stroke work index	> 15 g.m/M ²
Systemic vascular resistance	800–1200 dyn·s·cm ⁻⁵
Urine output	> 1 and <4 ml/kg/h
Core temperature	>35°C
Hematocrit	≥25%
Oxygen saturation	>95%
pH	7.35–7.45

on ultrasound techniques (transesophageal echocardiography, esophageal Doppler ultrasound). For patients who remain hemodynamically unstable despite conventional resuscitative measures as evidenced by poor cardiac output (CO), inadequate end organ perfusion, and increasing lactate levels, three-drug hormonal resuscitation should be initiated. This strategy includes a methylprednisolone bolus and infusion of arginine-vasopressin and thyroid hormone (Table 162.5). Intravenous administration of thyroid hormone appears to improve myocardial contractility, resulting in an increase of mean arterial pressure (MAP) and CO as well as decreased catecholamine requirements and arrhythmias. Although earlier studies have not documented improved cardiac performance with hormone replacement therapy, more recent studies have been encouraging. Rosendale and coworkers were able to show in a group of 701 brain-dead organ donors a 22.5% increase in the number of organs transplanted per donor, and hormonal resuscitation appears to be beneficial for donors both younger and older than 40 years. For a hydraulic model of the circulation in the potential organ donor, see Fig. 162.1.

Fluid management

The principal choice of fluids for intraoperative management of the potential organ donor includes crystalloids, either isotonic or hypotonic, and colloids, including plasma and red cell products. The type of organ(s) scheduled for retrieval will impact the fluid resuscitation strategy. If the lungs are to be procured, a

minimally positive fluid balance has been shown to be beneficial for organ function, whereas more aggressive fluid administration results in improved renal function. In cases where both kidneys and lungs are to be procured, targeted hemodynamic management as outlined earlier in the text is advisable. Frequently, patients with devastating head injuries as the cause of brain death will present to the operating room with marked hypernatremia and a free water deficit. These abnormalities should not be corrected with large amounts of dextrose-containing solutions because of resulting hyperglycemia, osmotic diuresis, and other electrolyte abnormalities. Instead, hypotonic solutions should be infused to normalize sodium levels to avoid graft damage (liver) related to high sodium levels. Hyperoncotic colloids containing hydroxyethyl starch have been implicated in renal tubular damage and impaired early graft function and should be avoided. Although there is insufficient evidence to recommend a certain transfusion trigger, it seems reasonable to keep hematocrit levels between 25% and 30% to ensure adequate oxygen delivery and hemodynamic stability. In the case of pronounced metabolic acidosis, sodium bicarbonate may be added to half-normal saline solution (50 mmol/L) to optimize acid-base status. It is important that all fluids be warmed to avoid patient hypothermia.

Respiratory

Respiratory complications are common in the potential organ donor and are related to prolonged mechanical ventilation, neurogenic pulmonary edema secondary to brain death, or aspiration and pulmonary contusion in patients with multiple trauma. In the absence of controlled trials in this patient population, lung-protective ventilation strategies as applied in patients with acute respiratory distress syndrome (ARDS) should be continued through the perioperative period. These strategies include tidal volumes of 6 to 8 ml/kg of ideal body weight and the application of positive end-expiratory pressure to prevent atelectasis and optimize gas exchange. High fractions of inspired oxygen should be avoided, if possible, to prevent oxygen toxicity to the lung. Plateau pressures should not exceed 30 cm H₂O. Bronchoscopy may be necessary to remove airway secretions and evaluate bronchial anatomy prior to transplantation. The use of colloids in patients scheduled for lung retrieval should be considered to avoid a positive fluid balance. Diuresis may be necessary in patients with frank volume overload. Hypocapnia should be avoided after the diagnosis of brain death because it will shift the oxygen-hemoglobin dissociation curve to the left and impair oxygen delivery to the tissues. It is important to remember that a brain-dead individual has a lower metabolic rate, which translates into decreased minute ventilation to maintain normocarbica.

Metabolic

Approximately 80% of patients with brain death will develop diabetes insipidus (DI) due to the destruction of the posterior pituitary gland and the resultant antidiuretic hormone

Figure 162.1. Hydraulic model of the circulation in the potential organ donor. Hypotension frequently occurs as a result of many factors and requires a structured approach to the differential diagnosis. Hypovolemia can be either absolute or effective, and an accurate assessment frequently requires the use of invasive monitoring techniques. Cardiac dysfunction and vasodilation commonly occur together, but they can arise from disparate processes that should be sought and corrected. Reprinted with permission from *N Engl J Med* 2004; 351(26):2730–2739.

(ADH) deficiency. The diagnostic features of DI are outlined in Table 162.6. To avoid hemodynamic instability and marked alterations in electrolyte balance, urine output should be matched with crystalloid infusions while monitoring electrolyte levels. If hourly urine output is greater than 200 ml, pharmacologic treatment with desmopressin acetate (DDAVP), a V_2 -receptor agonist causing renal water conservation, is indicated. The drug is available for intravenous (IV), subcutaneous (SC),

and intranasal administration. The dose for SC or IV administration is 1 to 2 μg twice daily; the intranasal dose required to maintain normal urine volume is more variable and ranges between 10 and 40 μg daily. A continuous infusion of vasopressin can also be used to treat DI.

Endocrine synthetic function of the pancreas is sufficient after the onset of brain death; however, insulin resistance will result in hyperglycemia in the majority of potential organ donors. Blood glucose levels should be maintained in the range of 80 to 150 mg/dl with a continuous insulin infusion.

Hematologic

Coagulopathy is a common problem in the potential organ donor and can be caused by hypothermia, acidosis, and the release of procoagulant substances from traumatized brain tissue (i.e., thromboplastin and cerebral gangliosides). Disseminated intravascular coagulation (DIC), which can be further exacerbated by dilutional coagulopathy from resuscitation with crystalloid, may ensue. In addition, there is evidence

Table 162.6. Diagnostic features of DI

Urine output	≥ 5 ml/kg/h
Urine specific gravity	≤ 1005
Urine osmolarity	< 300 mOsm/L
Serum osmolarity	> 310 mOsm/L

Hypocalcemia	

that patients with severe traumatic brain injury (TBI) develop platelet dysfunction, and a bleeding tendency can be present even if circulating platelet counts are normal. The effect of DIC on transplantation appears to be minimal as no significant differences between the number of retrieved organs among donors suffering from severe TBI with or without DIC have been shown. Treatment of clinical coagulopathy should include correction of the international normalized ratio (INR) to < 2.0 , maintenance of a platelet count $\geq 80,000$ per cubic centimeter, and maintenance of hematocrit levels between 25% and 30%. Thromboelastography may be helpful in addition to routine laboratory testing to guide treatment of coagulopathy in the perioperative period.

In summary, the key elements of anesthetic management for the potential organ donor include maintenance of adequate end organ perfusion by aggressively treating hemodynamic and electrolyte instability. If conventional measures directed at maintaining hemodynamic stability are unsuccessful, the addition of hormonal resuscitation may improve outcomes. The implementation of evidence-based treatment protocols in centers involved in organ donation is recommended to improve function of transplanted organs.

Principles of trauma management

Mallory Williams and Selwyn O. Rogers Jr.

Introduction

Trauma is a surgical disease that results in more than 5 million deaths worldwide each year. In the United States, standardized management principles have evolved to address variations in processes of care to improve the outcomes of traumatized patients. The American College of Surgeons developed the Advanced Trauma Life Support (ATLS) and tiered levels of trauma care to improve trauma outcomes across the United States. In many settings, surgeons and emergency medicine physicians participate in the initial workup of trauma patients. The principle of the *golden hour* refers to the limited time available to intervene effectively to salvage life and limb. The golden hour calls for the immediate prioritization and management of the trauma patient according to ATLS principles. The ABCDE mnemonic was developed to enforce prioritization in trauma management in descending order of importance:

- Airway and cervical spine protection
- Breathing
- Circulation and hemorrhage control
- Disability and neurologic status
- Exposure and environmental aspects

ATLS outlines the fundamental management concepts of the trauma patient:

1. Treat injuries that have the greatest risk to life first.
2. Lack of definitive diagnosis should never impede the application of an indicated treatment.
3. A detailed history is not essential in the evaluation and treatment of the injured patient.

We will review the components of the primary survey in the evaluation of the trauma patient, focusing on what an anesthesiologist should know.

The primary survey

During the primary survey, life-threatening injuries are identified and managed. Careful attention to the ABCDEs provides an opportunity to rapidly evaluate a critically ill trauma patient while stabilizing the patient hemodynamically. This initial assessment must be completed on all trauma patients before moving on to a more detailed history and physical examination, called the secondary survey.

Airway and cervical spine protection

In trauma management, the highest priority is to obtain and maintain a patent airway. Failure to do so leads to increased mortality. The evaluation begins by placing the patient in an appropriately sized cervical spine collar and assessing airway patency. Appropriate voice quality usually indicates a patent airway. A hoarse or breathless response may indicate airway compromise. Disorderly or confused conduct and language may also be indicator of hypoxia, whereas no response may indicate neurologic disturbance. For patients who are unable to protect their own airway, the airway should be inspected for an edematous tongue, foreign body, secretions, and blood. The simple maneuvers of chin lift and jaw thrust can be performed to secure airway patency. For patients with airway compromise or for those in a coma, it is essential to secure a definitive airway. Unless contraindicated, direct laryngoscopy with passage of a cuffed endotracheal tube is the primary approach to securing the airway. Appropriate placement has to be confirmed by both end-tidal carbon dioxide (CO₂) monitor and auscultation of breath sounds. Recent experience indicates that airway patency may be improved by the use of laryngeal mask airways (LMAs); however, these devices should not be considered a secure and definitive airway for the management of trauma patients because of their significant risk of aspiration (due to delayed gastric emptying). In some circumstances, fiberoptic bronchoscopic intubation may be attempted but should not delay the primary survey and the delivery of life-saving interventions. If securing the airway via direct laryngoscopy is unsuccessful in an expeditious manner for patients in need of a definitive airway, surgical airway by cricothyroidotomy has to be performed by an experienced provider. Cricothyroidotomy should be performed at the bedside, preferably by a surgeon. Airway compromise is a threat to life and must be treated emergently. Hypoxia also represents a secondary insult to patients with brain injury and worsens prognosis.

Breathing

The ability to breathe requires a patent airway, functional lung parenchyma, and appropriate chest wall and diaphragm dynamics. Trauma may interfere with all of the above. Pneumothorax or hemothorax both can be life threatening, and

should be evacuated with a thoracostomy tube. For patients who present with a deviated trachea, hypotension, distended neck veins, and absent breath sounds, tension pneumothorax should be suspected. Tube thoracotomy should be immediately performed on the side with the absent breath sounds. A tension pneumothorax can be transiently decompressed with the placement of a 14-gauge angiocatheter in the 2nd intercostal space in the midclavicular line. Following this maneuver, a thoracotomy tube has to be placed for continued air evacuation. Occasionally, the chest wall may be violated secondary to penetrating trauma, creating a sucking chest wound. Bandaging this wound with a 4 × 4 gauze taped on three sides will improve chest wall dynamics for breathing.

More commonly, chest wall trauma produces injuries such as pulmonary contusions. A flail chest wall results from multiple contiguous rib fractures along two lines (that are either located bilaterally or in anterior and posterior positions on one side of the chest). Flail chest will lead to poor ventilatory mechanics (due to an unstable chest wall), increased work of breathing, and pain. Although these injuries are not immediately life threatening, they are formidable causes of prolonged intensive care unit (ICU) stay, especially in the elderly population. Pain control is essential. Rib fractures are an important cause of morbidity and mortality, particularly in elderly patients. Elderly patients suffer twice the mortality of younger patients with rib fractures. Rib fractures, due to their accompanying pulmonary compromise, should be identified early as life threatening in the elderly patient. ICU admission for appropriate pain management is recommended, in addition to a thoracic epidural or paravertebral catheter placement, adequate pulmonary toilet, and early mobilization.

Circulation and hemorrhage control

Hypotension is the most ominous sign in the trauma patient. Hypotension is used in the field as a key vital sign to triage patients to Level 1 trauma centers. Prevention and prompt treatment of hypovolemic (hemorrhagic) shock is an essential component of early and successful management of trauma patients. In the hypotensive patient, the primary survey evaluation with ABCDE prioritization is performed with a rapid assessment and correction of life-threatening injuries, such as airway compromise, tension pneumothorax, flail chest, or open exsanguinating wounds. Soft tissue injuries such as scalp lacerations, complex perineal wounds, or vascular bleeding from extremity wounds may all be sources of hypotension. Orthopedic injuries, such as long bone fractures in the lower extremities, can be responsible for two or more units of blood loss per thigh compartment. The primary concern of the trauma surgeon is the rapid identification of the source(s) of hypotension and appropriate therapeutic intervention(s).

The development of trauma systems to rapidly identify and prioritize these patients as critical and rapidly transport them to American College of Surgeons' Committee on Trauma verified trauma centers has been shown to save lives. The hypotensive

trauma patient undergoes a primary survey with ABCDE prioritization. After access has been established, response to bolus crystalloid infusion is evaluated. Appropriate large-bore intravenous access should be established in anticipation of large fluid and blood product requirements. Peripherally placed 14-gauge angiocatheters in bilateral upper extremities should be the minimal standard. Patients may be characterized in the following manner: responders, transient responders, or nonresponders. Patients who are transient or nonresponders and who do not have spinal shock must be assumed to have ongoing hemorrhage. Focused assessment with sonography for trauma (FAST) may be done as an adjunct to the primary survey to rule out intra-abdominal bleeding. Resuscitation should not be delayed due to the lack of crossmatched blood. "Emergency release" O negative blood can be used for blood transfusion of these patients (see more refined details on the rules governing emergency transfusions in Part 12). Early identification of patients who will require large amounts of blood transfusion should prompt activation of a massive transfusion protocol for efficient delivery of blood for transfusion until hemorrhage control has been achieved. Patients with signs and symptoms of intra-abdominal injury, such as a distended and tender abdomen, should undergo emergent celiotomy.

A circumstance needing special discussion is that of the multitrauma patient with pelvic fractures. Pelvic fractures should be appropriately reduced. The patient with a pelvic fracture may have severe hypotension and need angiographic embolization as an initial therapeutic intervention, instead of laparotomy. Patients with pelvic fractures will occasionally require both celiotomy for intra-abdominal injury and embolization for the control of bleeding. Sequencing and timing require surgical judgment as well as timely availability of resources, such as the angiography team.

Compression of actively bleeding open wounds should continue until arrival to the operating room. The radiology suite may not be an appropriate location for unstable patients. Transfusion of red blood cells should prompt an early prioritization of replacing clotting factors with fresh frozen plasma. Massive transfusion can be defined as more than 10 units of packed red blood cells (pRBCs; a patient's total blood volume) over a 24-hour period of time. This definition has been expanded to mean 50 units of pRBCs over 24 to 48 hours. Massive transfusion protocols guide therapy with the aim of rapid restoration of intravascular blood volume with effective oxygen carrying capacity and hemostasis. Dilutional thrombocytopenia becomes a problem after replacement of 1.5 times the blood volume. Thrombocytopenia can occur with smaller transfusion quantities if disseminated intravascular coagulation (DIC) occurs or if there is preexisting thrombocytopenia. Platelets are given when levels fall below 50,000. Fresh frozen plasma is administered concomitantly with the aim of maintaining the prothrombin time (PT) and partial thromboplastin time (PTT) below 1.5 times normal. Cryoprecipitate may be given for fibrinogen levels less than 0.8 g/L. Coagulopathy often results from DIC, metabolic derangements, and hypothermia, which is

Table 163.1. Glasgow Coma Scale

further exacerbated by delayed or inadequate resuscitation. New enthusiasm for the use of whole blood has been precipitated by the casualties suffered in the Iraq war. The attractiveness of this approach stems from the fact that whole blood contains all essential clotting factors and maintains oxygen carrying capacity. Retrospective studies suggest the use of fresh frozen plasma and platelets in low ratios with packed red blood cells for resuscitation enhances survival.

Disability and exposure

Assessment of neurologic status is important. Early documentation of neurologic function is valuable, especially for prognostic purposes. The initial neurologic assessment in the trauma bay is often based on the Glasgow Coma Scale (GCS). The GCS is a summation score based on best eye opening, best motor, and best verbal responses (Table 163.1). The GCS can be altered by systematic factors such as drug intoxication, hypoxia, and hypotension.

Trauma patients should be fully exposed to identify all sources of external injury. The exit pathway of projectiles is particularly crucial in establishing whether midline structures have been violated. Ruling out perforation of critical aerodigestive and vascular structures is important, as these missed injuries lead to significant morbidity and delayed mortality. As soon as possible following the secondary survey, the patient's body should be covered. The trauma bay should be maintained at a warm temperature.

Trauma patients are often exposed to the external environment for long periods of time. When the ambient temperature is less than 98.6°F, loss of body heat occurs. Hypothermia by itself increases mortality, contributes to coagulopathy, and must be avoided at all costs. The key factors to consider are body surface area, temperature gradient, and time of exposure.

Conduction, convection, and evaporation are important potential sources of heat loss for trauma patients. Conduction is heat loss through direct contact between objects. Water conducts heat away from the body 25 times faster than air. Wet clothes are an important source of loss of body heat. Convection is a process of conduction during which one of the objects is in motion. Molecules against the surface are heated, move away, and are replaced by new molecules that are also heated. Wind chill is an example of convection heat loss. Finally,

evaporation is heat loss from converting water to a liquid to a gas. Examples of evaporative heat loss are perspiration and respiration.

This chapter has covered the essentials of the initial trauma care in the hospital setting, especially related to the assessment and management of the trauma patient. ATLS addresses the approach to the trauma patient in a structured and systematic manner.

Venous thromboembolic disease in the critically ill patient

Mallory Williams, Naomi Shimizu, and Jonathan D. Gates

Deep venous thrombosis

Rudolf Ludwig Karl Virchow in 1856 described the triad of stasis, injury to the blood vessel (endothelial cell dysfunction), and change in the composition of the blood (hypercoagulability) as factors predisposing patients to pulmonary thromboembolism. He coined the term *embolia* and described the process of emboli breaking off and traveling to the lungs from the deep veins. Virchow understood that the etiology of pulmonary emboli was deep venous thrombosis (DVT). Patients in the intensive care unit (ICU) are at particularly high risk of venous thromboembolic disease. Their overall immobility, high predilection for indwelling venous catheters, and disease processes that induce inflammatory states causing endothelial damage are the basis for a high-risk profile and increased morbidity and mortality from DVT and pulmonary embolism (PE).

Epidemiology

DVT and PE, known collectively as venous thromboembolic events (VTE), are the number one cause of preventable in-hospital mortality. Goldhaber and colleagues reported a 33% incidence of DVT in medical ICU patients despite 61% having prophylaxis. Several studies using Doppler ultrasonography demonstrated that 6.4% of patients had DVT on admission to the ICU. Considering that more than 2 million people are admitted to an ICU each year in the United States, there are possibly 128,000 patients who are admitted to the ICU with DVT. These projections are consistent with the estimated 2 million DVTs per year in the United States. The only study to use contrast venography (the gold standard) to diagnose DVT detected 28% DVT and 8% proximal DVT in the 85 patients with chronic obstructive pulmonary disease (COPD) exacerbations. PE has been reported in 7% to 27% of postmortem examinations of ICU patients.

Pathophysiology

The tendency toward thrombosis occurs when the physiologic balance favors coagulation over anticoagulation. The pathophysiology of venous thrombosis is therefore an accumulation of factors that stimulate coagulation and inhibit anticoagulation and fibrinolysis. Immobility is the principle causative factor

for thrombosis in the ICU. Inactivity inhibits the fibrinolytic system. An overall increase in blood viscosity causes reduced blood flow that facilitates coagulation and venous thrombosis. Tissue damage impairs fibrinolysis through inflammation and cytokine production. Patients who have inherited deficiencies of the circulating anticoagulants, antithrombin and proteins C and S, are more likely to suffer from venous thrombosis. These inherited deficiencies are found in 20% of patients who have a history of venous thrombosis and whose first DVT occurs before age 41. Factor V Leiden deficiency has been established as the most common cause of inherited venous thrombophilia. The second most common cause is a mutation in the prothrombin gene G20210A. Most patients with thromboembolism, however, have no identifiable causes of hypercoagulability.

Venous thrombi are primarily composed of fibrin and red blood cells. Venous thrombus formation principally occurs at sites of vessel damage and at valve cusp pockets in the deep veins of the calves. Veins often do recanalize as the thrombus is resorbed, but they leave behind incompetent venous valves. Destruction of venous valves after venous thrombosis leads to a postphlebotic syndrome that may present as pain, swelling, discoloration, skin pigmentation, and venous ulcers. These veins with damaged valves are susceptible to recurrent thrombosis.

The soleal veins of the lower extremity are the most common sites of thrombosis. Although these thrombi rarely embolize, 15% to 20% do propagate. Venous thrombosis that propagates to the femoral and iliac veins may cause massive swelling, discoloration, and pain. This syndrome is called *phlegmasia cerulea dolans*. If thrombosis is complete in the leg, distal venous pressure will increase to the point at which arterial inflow is reduced and the limb becomes ischemic. This syndrome is called *phlegmasia cerulea albicans* and may be seen with disseminated malignancy and sepsis.

Upper extremity venous thrombosis in the ICU is often related to the presence of indwelling central venous catheters. The expanded use of peripherally inserted central catheters has made secondary thrombosis of the upper extremity more prominent. In a prospective registry of 592 patients, it was found that 324 (or 55%) of patients had central venous catheter-associated DVT, and 268 patients had noncentral

venous catheter-associated DVT. PE, however, was as likely in both groups. Upper extremity DVT now accounts for 8% to 10% of all DVTs in the United States. Other causes of upper extremity venous thrombosis are intravenous drug abuse, congenital malformations, neoplasia, or upper extremity trauma.

Diagnosis

Clinical examination

The classic signs of unilateral leg swelling and pain with forced dorsiflexion of the foot (Homan's sign) are only 35% sensitive for DVT. Scoring systems that are often used for outpatients have not been validated in the ICU.

Duplex ultrasonography

The diagnostic test of choice for DVT is duplex ultrasonography. The sensitivity for proximal DVT is 97%, but it decreases to 73% for calf DVT. The specificity for proximal vein DVT is 94% with a negative predictive value of 99%. The overall weakness of this imaging study is in detecting DVT in the calf and DVT proximal to the inguinal ligament. Duplex ultrasonography also cannot detect new clots in patients with known DVT. Ultrasonography has not been found to be cost effective when used as a screening tool for all ICU patients. Only patients with a high degree of clinical suspicion (high pretest probability) should be tested.

The following are the diagnostic criteria of DVT by duplex ultrasonography:

1. Noncompressibility of the vein,
2. Presence of echogenic material in lumen,
3. Loss of phasicity and augmentation of spontaneous flow, and
4. Venous distention.

Contrast venography

Contrast venography is now seldom used in the diagnosis of DVT. The potential for renal toxicity from the contrast dye adds to patient morbidity, which is a concern in the ICU setting. However, it is the accepted gold standard for diagnosis of DVT. Due to its high sensitivity and specificity, only 1.3% of patients with DVT will have negative venography. The morbidity of venography can be reduced by using isotonic radiographic dye.

MRI

Sometimes there are difficulties in obtaining an accurate duplex ultrasound of the extremities for the diagnosis of DVT in ICU patients. Factors such as body habitus, injured extremities, patient hardware, and medical equipment may interfere with the images. While costly and more time consuming, one option is to use MRI, which has a sensitivity of 92% and a specificity of 95% for detecting DVT. Compared to duplex ultrasound, MRI is more sensitive for proximal than distal DVT.

Perioperative management of anticoagulation

Venous thromboembolism

Perioperative management of anticoagulation for venous thromboembolism is determined by the number of months that have passed since the VTE. After an acute episode of venous thromboembolism, the risk of recurrence decreases rapidly over the next 3 months. This risk of recurrent DVT 3 months after a proximal DVT is approximately 50% without anticoagulation therapy. One month of warfarin therapy reduces this risk to 10%, and 3 months of warfarin therapy reduces this risk to 5%. Considering these data, stopping anticoagulants in the first month after an acute DVT is associated with a 40% risk of VTE. Stopping anticoagulants in the second or third month after an acute DVT is associated with a 10% risk of VTE. For patients who are on long-term anticoagulation for multiple episodes of VTE, hypercoagulable state, or cancer, discontinuation of warfarin therapy is associated with a 15% per year risk of thromboembolism.

For patients who present after an acute venous thromboembolism, each day without anticoagulation is associated with a 1% absolute increase in the risk of recurrence. Despite the risk of increasing the rate of bleeding, immediate postoperative intravenous heparin therapy reduces the serious morbidity in these patients because of the extremely high thromboembolic risk. In the second and third months after venous thromboembolism, immediate postoperative intravenous heparin therapy is justified. Three months after a venous thromboembolism, full postoperative anticoagulation measures are no longer required. Only prophylactic measures, such as subcutaneous low-molecular-weight heparin (LMWH) given with or without graduated compression stockings and intermittent pneumatic compression boots, should be used.

Bridge therapy with low-molecular-weight-heparin

Bridge therapy is a therapeutic strategy employed when a patient who is at high risk of VTE needs to have warfarin therapy interrupted for a period of time for surgery. There are no available randomized, prospective trials validating this strategy. Patients would stop taking their warfarin 5 days before their procedure. Full-dose LMWH would be started at this time. On the day of surgery, only a prophylactic LMWH dose would be given. On postoperative day 1, both warfarin and LMWH full-dose therapy would be restarted. Some protocols are more aggressive and start LMWH in the immediate postoperative period.

Prevention and treatment

In the management of patients at high risk for the development of DVT, one should focus on effective prevention. In its 2001 policy statement, the Agency for Healthcare Research and Quality identified DVT prophylaxis as one of the top

priorities among 79 patient safety interventions, all based on strong evidence. In 2005, the Institute for Healthcare Improvement developed care bundles, which grouped evidence-based interventions that reduced the morbidity, mortality, and health care costs from a disease process. DVT prophylaxis is now an integral component in the *ventilator bundle* order sets applied to all ventilated ICU patients, unless contraindicated.

Patients at risk for DVT may be identified by surveillance for risk factors and associated comorbidities. One study by Goldhaber and colleagues designed a prospective registry of 5451 patients with ultrasound-confirmed DVT to identify comorbidities. The five most frequent comorbidities were hypertension (50%), surgery within 3 months (38%), immobility within 30 days (34%), cancer (32%), and obesity (27%). Rogers and colleagues used data from the Patient Safety in Surgery Study to develop a predictive model for venous thromboembolism. Fifteen variables were independently associated with increased risk of DVT. These variables included patient gender (female), higher American Society of Anesthesiologists (ASA) class (2–5), ventilator dependence, preoperative dyspnea, wound classification (infected/contaminated), disseminated cancer, chemotherapy within 30 days, transfusion of more than 4 units of packed red blood cells in the 72 hours before operation, preoperative laboratory values (albumin < 3.5 mg/dl, bilirubin > 1.0 mg/dl, sodium > 145 mmol/L, and hematocrit < 38%), and operation characteristics (type of surgical procedure, emergency operation, work relative value units). A multifactorial risk index for DVT may guide our decision on DVT prophylaxis and may improve quality in patient care.

The best method of DVT prevention is early ambulation. Because early ambulation is not an option in the ICU setting, other prophylactic therapy is used.

Compression devices

Compression devices are simple and are without adverse risk. Early studies by Knight and Dawson in 1976 suggested that compression devices work by promoting fibrinolysis. Both pneumatic compression and compression stockings are now used to prevent blood stasis in the deep vein. Although intermittent compression has been thought to work in the prevention of DVT by promoting venous flow, there is no evidence that devices that produce higher velocities are more effective.

Goldhaber and colleagues prospectively studied 330 cardiac surgery patients by using two mechanical regimens of DVT prophylaxis. The primary endpoint in their study was ultrasound assessment of lower extremity DVT on hospital discharge. They found that patients assigned to intermittent pneumatic compression and graduated compression stockings had a DVT rate of 19% versus 22% in patients assigned to graduated compression stockings only.

Chemical prophylaxis

Heparin is the standard of treatment for DVT and for the prevention of DVT and thrombus extension. A more effective

chemical prophylaxis for DVT can be accomplished with the use of LMWH, which has been proven to be safe and effective both in prevention and treatment of acute proximal DVT. The advantages of LMWH over unfractionated heparin are better bioavailability, a longer half-life, and more predictable anticoagulant activity. The disadvantages are the higher risk of major bleeding and the inability to monitor and titrate the dosage. Fixed doses of LMWH are used for VTE prophylaxis regardless of body mass index, but weight-based dosing with larger doses for obese patients may be more effective. The even more effective pentasaccharide, fondaparinux, is a synthetic agent introduced for VTE prophylaxis and treatment. Both LMWH and fondaparinux pose an increased risk of bleeding complications with the administration of neuraxial (spinal and epidural) analgesia.

Vena cava filter

There is a subgroup of patients whose risk of thromboembolic complications is high but their treatment with any anticoagulants may increase their risk of bleeding. These patients have either failed previous anticoagulation therapy or have an increased risk of hemorrhage with chemical prophylaxis. One particular subgroup of patients is the trauma population with sustained closed head injury, pelvic fracture, solid organ injury, or spinal cord injury. These patients benefit from a vena cava filter placement early in their hospital course. Other patient subgroups at high risk of VTEs include surgical oncology patients, patients who have a history of hypercoagulable state (Factor V Leiden, lupus anticoagulant, and protein C and S deficiency), and bariatric patients. There is a growing trend in the use of removable preoperative vena cava filters in bariatric patients as a way of reducing morbidity and mortality from PE.

Thrombolytic therapy

Thrombolytic therapy is pursued as a treatment for DVT with the goal of maintaining vein patency and avoiding postthrombotic syndromes. These agents are serine proteases, and they work by converting plasminogen to plasmin, a natural fibrinolytic agent. Plasmin breaks down the fibrinogen and fibrin in the clot. Alteplase, the first recombinant tissue-type plasminogen activator (tPA), is identical to native tPA. Reteplase is a faster-acting second-generation tPA. Because reteplase does not bind fibrin as tightly as native tPA, the drug diffuses more freely through the thrombus. Reteplase also has a faster plasma clearance and shorter half-life (approximately 11–19 min) than does alteplase. Reteplase undergoes renal (and some hepatic) clearance. Both urokinase, a fibrinolytic agent recently reintroduced to the market, and prourokinase, a clot-specific fibrinolytic agent, are also available.

In 2007, the Cochrane Review published results from randomized studies of 668 patients with DVT treated with anticoagulation or thrombolytic therapy. Patients receiving thrombolysis had significantly more bleeding complications

([RR] = 1.73). There was, however, a reduction in postthrombotic syndrome (RR = 0.66) and a complete clot lysis in the thrombolytic group (RR = 0.24). There was no significant effect on mortality.

Long-term treatment

It is important that patients diagnosed with DVT in the ICU have appropriate long-term care. Often the appropriate treatment plans during the hospital course depend on accurate ICU documentation. Guidelines for the treatment of DVT include a short-term course of LMWH or unfractionated heparin therapy plus long-term oral warfarin sodium therapy. LMWH has been shown to be as effective as intravenous unfractionated heparin in the treatment of DVT. The following are recommendations of the American College of Chest Physicians on the treatment of DVT:

1. Patients diagnosed with DVT and who have identifiable risk factors should receive 3 months of anticoagulation therapy.
2. Patients who have an initial episode with an idiopathic cause should receive 6 months of anticoagulation.
3. Patients with symptomatic isolated calf vein thrombosis should receive 6 to 12 weeks of anticoagulation therapy.
4. Patients with recurrent idiopathic venous thromboembolic disease should receive 12 months of anticoagulation therapy.

Accurate documentation of long-term goals and treatment plans before patients leave the ICU setting is a form of quality care.

Pulmonary embolism

Pathophysiology

The circulatory failure secondary to PE is caused by mechanical obstruction of the pulmonary outflow tract. The resulting hypoxemia induces hypoxic vasoconstriction that further reduces the cross-sectional area of the pulmonary vascular bed. This vasoconstriction leads to an increase in both pulmonary artery pressure and right ventricular afterload and, ultimately, to right ventricular strain, increased right ventricular wall tension, and oxygen consumption. Depression of right ventricular function reduces cardiac output and blood pressure despite increased right ventricular end diastolic pressure. Left ventricular filling may also be impeded by an overdistended right ventricle.

Diagnosis

The Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) showed that the high-resolution multidetector computed tomographic angiography (MDCTA) has sensitivity and specificity comparable to that of contrast pulmonary angiography. The study was performed with a 4-row, 8-row, and

Figure 164.1. CT angiography showing large proximal pulmonary embolism (arrow) in the right pulmonary artery.

16-row multidetector CT. The acquisition time was usually less than 30 seconds. The diagnostic criteria for PE was intraluminal filling defect (Fig. 164.1). The sensitivity of CTA for PE was 83%, and the specificity was 96%. The positive predictive value was 86%, and the negative predictive value was 95%. The positive predictive values for PE were 97% for main or lobar vessel, 68% for segmental vessels, and 25% for subsegmental vessels. The complications from CTA were dye allergy (<1%), urticaria (<1%), and extravasation of contrast material (<1%). Although pulmonary angiography is the gold standard diagnostic modality for PE, it is being replaced by MDCTA, because the latter modality is significantly less invasive, is easier to perform, and offers equal sensitivity and specificity.

Now that CTA has become an accepted diagnostic tool, appropriate hydration and renal protection strategies are important to avoid contrast nephropathy. ICU patients receive large dye loads during diagnostic workup in their first 48 hours in the hospital. They may also be exposed to other pharmacologic agents that are nephrotoxic. The intensivist should be aware of the total contrast load that patients are receiving and provide the maximum intervention for the protection of kidney function for these patients.

D-dimer measures fibrin breakdown products. This laboratory test is highly sensitive (>95%) for the presence of acute venous thrombosis or PE. Because patients in the ICU have many different illnesses, a nonspecific test like D-dimer will often be positive. The utility of this test is in the negative result, which is used to exclude the presence of venous thrombosis or PE.

Prevention and treatment

Vena cava interruption

The idea of placing a barrier in the inferior vena cava (IVC) to prevent PE from a venous thrombus was first introduced by Trousseau in 1868. In 1998, a multicenter group in France conducted the first published, randomized, prospective study of IVC filters in the prevention of PE. They studied 400 patients with known proximal DVT and randomized patients into an IVC filter or no filter group. Additionally, these same patients were randomized to receive LMWH or unfractionated heparin. The primary outcome event was radiographic PE within the first 12 days after randomization and during the 2-year follow-up period. Although they found a statistically significant decrease in the incidence of PE in patients with IVC filter at 12 days, this was not true in the long term. After 2 years, the incidence of symptomatic PE in the filter group was 3.4%. This study suggested that early use of an IVC filter is an effective barrier to PE, yet, over the long term, this protection becomes less effective. After 8 years, although the cumulative incidence of PE was significantly reduced (6% vs. 15%, $P = 0.008$), there was an increased incidence of DVT in the filter group (35% vs. 27%, $P = 0.042$). Studies have also been done to determine whether IVC filters can prevent PE in critically ill trauma patients with known DVTs. In a retrospective review of 200 patients, Carlin and colleagues examined the rate of PE in patients with DVTs, patients with PE, and patients with both DVT and PE. None of the patients with DVT developed a PE. Arguments can be made against the prophylactic use of IVC filters in both trauma and ICU patients. Long-term IVC filters have been associated with risk of thrombosis and postphlebotic venous insufficiency.

Retrievable filters

With the technical advances in the Greenfield IVC filter and percutaneous deployment devices, filters have become easier and safer to place (Fig. 164.2). The newer designs have allowed

Figure 164.2. Conical shape of a retrievable IVC filter.

retrieval of the filters, which decrease the known complications of caval thrombosis and postphlebotic venous insufficiency. Studies have demonstrated a 51% filter removal rate with no complications. These patients had no proximal thrombus, had a normal venogram prior to filter retrieval, and were anticoagulated with heparin or warfarin. Early retrieval is preferred to decrease the known complications of indwelling filters. These long-term complications include filter migration, occlusion, perforation, IVC thrombosis, and postthrombotic syndrome.

IVC filter placement is now being done in the interventional radiology suite or under ultrasound guidance at the patient's bedside. The safety of IVC filter placement at the bedside using duplex ultrasound in critically ill trauma patients has been proven to be feasible. In one study in 2003, 94 patients with multiple traumas whose injuries precluded them from anticoagulation had temporary IVC filters placed in the ICU. Ninety-six percent had insertions without complications. Complications included hematomas (2%) and filter misplacement (3%). Other reported insertion-related complications include *de novo* thrombosis (26%) and arteriovenous fistula (<3%). Similar studies in critically ill populations have confirmed the safety of bedside ultrasound-guided insertion of an IVC filter.

Anticoagulation

When a PE is diagnosed, treatment modalities are designed to prevent propagation, worsening obstruction, right ventricular failure, or a second embolism. With PE, the obstruction causes dilation of the right ventricle and displacement of the interventricular septum. As the strain and oxygen demands increase, the ventricle becomes ischemic due to poor oxygen supply. Ischemia eventually leads to cardiac arrest. This fatal progression can be stopped by complete removal of the obstruction to allow normalization of right heart pressures.

Heparin is the first-line of therapy for PE. The effectiveness of heparin is in its prevention of thrombus progression and reduction of embolization. This intervention reduces the mortality rate associated with PE from 30% to 10%. Early anticoagulation is important. Hospital-based heparin protocols were implemented to reduce the number of patients receiving subtherapeutic doses of heparin. In one clinical trial, patients were given either intravenous heparin followed by warfarin or intravenous heparin and simultaneous warfarin. Only 1% to 2% of patients were subtherapeutic for more than 24 hours with respect to the activated partial thromboplastin time (aPTT) level in both groups. When comparing weight-based heparin dosing versus standard-care nomogram, a higher percentage of patients using the weight-based heparin dosing achieved therapeutic range in 24 hours. The weight-based group was dosed with 80 U/kg as a bolus and then 18 U/kg/h infusion. The standard-care nomogram group received a 5000-U bolus followed by 1000 U/h infusion. Eighty-nine percent of weight-based patients achieved the therapeutic range for aPTT (1.5–2.3) versus 75% of standard-care nomogram patients in 24 hours. The risk of recurrent thromboembolism was more

frequent in the standard-care group. Subtherapeutic heparin in the initial 24 hours is associated with a higher incidence of recurrences.

In the same study comparing intravenous heparin followed by warfarin versus intravenous heparin and warfarin given concurrently, 69 of 99 (69%) patients had supertherapeutic values (aPTT = 2.5) that persisted for 24 hours. These patients belonged to the group receiving heparin and warfarin together. Despite this more intensive therapy and supertherapeutic values, bleeding complications occurred at similar frequencies in both groups (9.1% combined therapy vs. 12% heparin alone).

Thrombolysis

Thrombolysis is the established treatment for patients with hemodynamic instability following PE because of its ability to lyse the obstructing emboli and improve right ventricular function. There is, however, an ongoing controversy in the use of thrombolytics in patients with hemodynamically stable PE. In 2002, a multicenter, prospective, double-blind, randomized study in Germany studied the effectiveness of heparin and a thrombolytic agent, alteplase, in patients with hemodynamically stable PE. They found that thrombolysis with anticoagulation therapy reduced the need for escalation of therapy (increased heparin dose) and lowered the risk of death threefold.

Embolectomy

Both thrombolytic therapy and catheter-directed fibrinolysis can be used to treat PE. Many critically ill patients are not eligible for thrombolysis, however, because of the risk for bleeding. Suction pulmonary embolectomy is increasingly used to treat PE as it is still less invasive than is an open embolectomy. Although the American College of Chest Physicians recommended against the use of mechanical methods of thrombectomy, many authors agree on the following three criteria for performing catheter thrombectomy in acute PE:

1. Hemodynamic instability, defined as a systolic pressure ≤ 90 mm Hg, a drop in systolic pressure ≥ 40 mm Hg for ≥ 15 minutes, or ongoing administration of vasopressors for the treatment of hypotension;
2. Subtotal or total filling defect in the left and/or right main pulmonary artery; and
3. The presence of one of the following contraindications to thrombolysis: history of intracranial bleeding, head injury, neurosurgery, ischemic stroke, or brain tumor; surgery or organ biopsy; active bleeding, cancer with hemorrhagic risk, gastrointestinal bleeding or major trauma within

15 days; pregnancy or recent delivery; platelet $< 50,000$ cells/ μl , international normalized ratio (INR) > 2.0 .

The goal of embolectomy is to reverse right heart failure. Surgical pulmonary embolectomy is the last resort after less invasive methods have failed or the patient progresses to hemodynamic instability or arrest. The overall survivability and outcomes of embolectomy are better when earlier approaches are chosen. Surgical embolectomy should be considered only when an experienced cardiothoracic team is immediately available.

The overall mortality of pulmonary embolus is between 6% and 8% and increases to as high as 30% when complicated by hypotension. Of those patients with fatal PE, 67% die within 1 hour of onset of symptoms. Early definitive treatment for those patients who are hemodynamically unstable is essential.

Traumatic brain injury

Albert H. Kim, Meredith R. Brooks, Ian F. Dunn, Shaheen F. Shaikh, and William B. Gormley

Traumatic brain injury (TBI) remains a significant global health care problem and, in the United States, affects 2% of the population per year. Despite significant advances in our understanding of the pathophysiology of TBI, mortality remains high at 20%, with significant long-term neurologic deficits in 35% of survivors. A joint task force of the Brain Trauma Foundation and the American Association of Neurological Surgeons (AANS) has developed evidence-based guidelines in an attempt to address systematically the care of these patients. The results of such collaborative efforts have focused management on both the primary injury – the initial traumatic insult—and secondary injuries, the pathophysiologic events subsequent to the primary insult.

Our goal is to help practicing anesthesiologists understand the pathophysiology of TBI to allow them to develop perioperative management strategies most consistent with available evidence and current guidelines. TBI is often a key element of multitrauma. Hence, anesthesiologists are often asked to provide care for these patients while surgeons tend to their associated injuries.

In this chapter, we review current concepts in TBI. First, we address the diagnosis and assessment of TBI. Second, we focus on the pathophysiology and management paradigms of both primary and secondary brain injury.

Assessment of traumatic brain injury

Glasgow Coma Score

Developed in 1974 by Jennett and Teasdale, the Glasgow Coma Score (GCS; see [Table 163.1](#)) is the most widely used scale for determining the severity of TBI. Included in the scale are the patient's eye opening, verbal response, and motor response. Although the GCS has been widely criticized by many clinicians as being excessively simplistic, it remains the primary assessment tool in this population. In fact, its simplicity allows accurate communication regarding initial impressions of a patient between observers with different levels of expertise.

The GCS helps to classify injuries according to their clinical severity. Two broad categories include minor head injury (GCS 9–15) and severe head injury (GCS 3–8). A simple guide to the management of minor head injuries is highlighted in [Fig. 165.1](#).

Minor head injuries can be further divided into minimal, mild, and moderate head injury. Patients who are neurologically intact, have suffered no amnesia or loss of consciousness, and have a GCS of 15 are categorized as having minimal head injury. These patients generally do not require brain CT scanning except in select cases ([Fig. 165.1](#) for CT indications) and are discharged home with instructions to return should signs or symptoms of brain injury develop. Patients with a GCS of 14 are categorized as having mild brain injury and may experience a brief (<5 minutes) loss of consciousness or memory impairment. Our institution routinely obtains CT scans on these patients. In one of the largest retrospective studies of mild head-injured patients, 16% of patients with a GCS of 14 exhibited abnormal CT scans. A GCS score of 9 to 13 indicates moderate injury. Such patients are able to follow commands at the time of examination but have had longer periods of loss of consciousness (>5 minutes) and have abnormal findings on neurologic examination. This group of patients requires careful monitoring because more than 30% of patients in this subgroup demonstrate abnormal CT scans. Therefore, patients should have emergent CT scans with prompt neurosurgical consultation if findings are abnormal on examination ([Fig. 165.1](#)). GCS scores from 3 to 8 indicate severe TBI with worse outcomes. Within this group, nearly 80% of patients with an initial hospital GCS of 3 to 5 eventually die, have severe disability, or are vegetative.

Primary and secondary traumatic brain injury

Significant morbidity and mortality are caused not only by the original insult but also by ensuing pathophysiologic processes evolving over a period of hours to days. This has led to the distinction between primary and secondary brain injury.

Table 165.1. Types of primary brain injury

Focal	Diffuse
Hematoma	Concussion
Epidural	Multifocal contusion
Subdural	DAI
Intraparenchymal	
Contusion	
Concussion	
Lacerations	

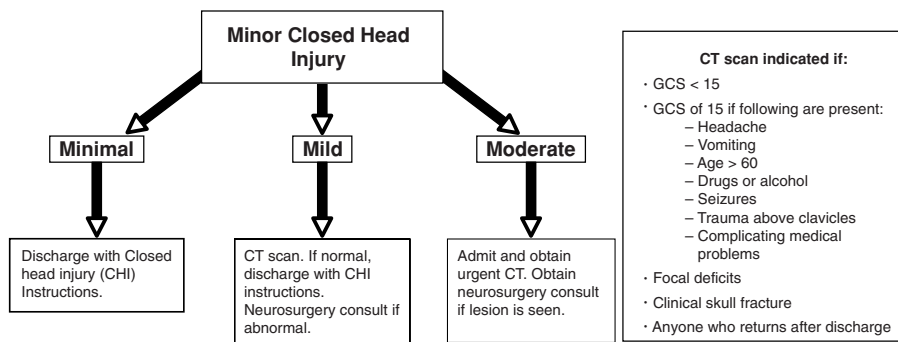

Figure 165.1. Minor head injury management.

Primary brain injury

Primary brain injury can be broadly divided into focal and diffuse injuries (Table 165.1). Focal injuries are related to a narrow force vector delivered to a delimited intracranial region. This type of an injury tends to produce intracranial hemorrhages, including epidural and subdural hematomas, or cerebral contusions and intracerebral hematomas. Diffuse injuries are more often related to wide force vectors and high acceleration or deceleration injuries as seen with motor vehicle accidents. Diffuse injuries range from concussion to diffuse axonal injury (DAI) with widespread long tract signs and posttraumatic coma.

The first critical step in the management of TBI is to determine the nature and severity of the primary injury by using the clinical examination and radiographic evaluation. It is during this assessment of the primary injury that the decision for emergent surgical intervention is made. After the primary injury is considered and addressed, the patient moves into the phase of secondary injury prevention. The general management of TBI can thus be considered in two phases: identification and management of primary brain injury followed by the prevention of secondary brain injury.

Hemorrhages

Acute blood can be readily identified on noncontrast CT of the head, an important component in the initial evaluation of a patient with TBI, as mentioned earlier in the text. The main types of traumatic brain hemorrhage requiring surgery are epidural, subdural, and intracerebral.

Acute epidural hematomas are managed, when surgically appropriate, by craniotomy due to the gelatinous consistency of an acute blood clot, which is difficult to remove without complete bony exposure of the area of bleeding. Expectant management can be an option if mass effect is minimal and the patient's neurologic status is normal, especially in the pediatric population. However, the disadvantage of conservative management is that the patient must be monitored carefully in the intensive care unit (ICU) for several days.

Accumulation of blood in the subdural space can occur in an acute or chronic manner. The acute subdural hematoma can be surgically treated by craniotomy or craniectomy. In a

subset of individuals with no neurologic compromise and a stable, limited amount of blood, the subdural collection can be allowed to liquefy over a few weeks and then drained by burr-hole evacuation. In fact, many patients present with a liquefied, subacute or chronic subdural hematoma, often due to (1) persistent oozing or (2) the accumulation of multiple, small subdural bleeds. The advantage of the burr-hole is the low surgical risk, as some cases may even be performed under local anesthesia. The acute-on-chronic subdural hematoma, often the consequence of systemic anticoagulation, can have a significant and sudden acute component on top of an otherwise indolent and inconsequential chronic accumulation. The important first step in the management of these patients is to stop ongoing bleeding by discontinuing anticoagulation and correcting any coagulopathy. Correcting the coagulopathy will become the responsibility of anesthesiologists managing the trauma patient intraoperatively if a decision to perform an emergent operation is made.

Intraparenchymal hemorrhages occur commonly following brain trauma, and most are treated nonoperatively. Often these hemorrhages present as contusions on the surfaces of the inferior frontal lobe and the anterior temporal lobe adjacent to the greater sphenoid wing, sites where the brain strikes bony margins. They may increase dramatically in size over the first few days, creating significant mass lesions where only small lesions were present initially. Therefore, small contusions seen on initial CT scans should be followed closely for the first 3 days. This problem can be much more dramatic in elderly patients on traditional anticoagulation or antiplatelet agents or in patients with a coagulopathy. A recent randomized, controlled trial (Surgical Trial in Intracerebral Haemorrhage [STICH]) suggests that early craniotomy for traumatic intraparenchymal hemorrhages is no better than medical management. Opinion is still divided, however, regarding craniotomy or craniectomy for intraparenchymal hemorrhages associated with refractory, high intracranial pressure (ICP), especially later in the course of the hemorrhage.

Secondary brain injury

Surgery typically is performed in response to the primary brain injury. Secondary brain injury, however, refers to

regional cellular processes that take place over hours to days after the initial brain injury. Secondary brain injury results not only from the delayed effects of primary brain injury but also from contributing factors, such as hypotension, hypoxia, intracranial hypertension, and inadequate cerebral perfusion pressure (CPP). Untreated, severe secondary injury ultimately leads to intracranial hypertension and cerebral ischemia, which can significantly compound the effects of the initial injury. Critical care physicians and anesthesiologists play key roles in the prevention of secondary brain injuries as they are most often responsible for managing these patients in this period.

Seizure prophylaxis

TBI clearly increases the risk of seizures, which have been traditionally divided into early (within 1 week) and late posttraumatic seizures. Seizure control is critical in TBI patients, given the effects of epileptiform activity on brain metabolism and the potential systemic complications of seizure, which may exacerbate secondary injury. Temkin and colleagues demonstrated that phenytoin treatment for 7 days in patients with intracranial blood or depressed skull fractures decreased the incidence of early but not late posttraumatic seizures. More recently, levetiracetam, with its favorable side-effect profile, has been employed as prophylaxis against early posttraumatic seizures. Although early seizure control following TBI appears equivalent between phenytoin and levetiracetam, it is important to note that TBI patients on levetiracetam have a higher tendency to exhibit an abnormal electroencephalogram (EEG). Beyond the early posttraumatic period, a TBI patient with seizures is treated as would be any patient with new-onset seizures.

Intracranial hypertension

Pathophysiology

Intracranial hypertension is a common complication of severe head injury, and its management is essential to the control of secondary injury. Nearly half of head-injured patients with intracranial mass lesions have persistently elevated ICP. ICP is determined by the contents of the intracranial vault, the physiology of which was codified by the Monro–Kellie doctrine. An uncompensated increase in one or more compartments in that vault results in ICP above the normal range (5–15 mm Hg). In the absence of a mass, increased ICP in severe TBI can result from aberrations in cerebrospinal fluid (CSF) flow, cerebral blood volume, and the development of vasogenic and cytotoxic edema. When endogenous mechanisms for volume buffering are exhausted, ICP increases in an exponential fashion. The steep nature of the volume–pressure curve complicates ICP management because an increase in ICP signifies a sudden and significant reduction in intracranial compliance (Fig. 165.2). Sustained ICP readings of greater than 20 mm Hg are abnormal. ICP greater than 40 mm Hg represents severe preterminal intracranial hypertension.

Figure 165.2. ICP–volume relationships.

The two main consequences of elevated ICP are brain herniation and compromised cerebral perfusion ($CPP = \text{mean arterial pressure [MAP]} - \text{ICP}$). The three principal forms of herniation are uncal, central diencephalic, and tonsillar herniation. Uncal herniation is produced by medial displacement of the temporal lobe by middle fossa lesions with subsequent midbrain compression, leading to a clinical syndrome involving coma, ipsilateral fixed and dilated pupil, and, commonly, contralateral hemiparesis. Uncal herniation can progress to include brainstem hemorrhages and posterior cerebral artery compression with consequent infarction in this territory. Central diencephalic herniation results from generalized bilateral intracranial hypertension with caudal displacement of the diencephalon through the tentorial incisura, deformation of the brainstem, and progressive decrease in consciousness. In tonsillar herniation, a posterior fossa mass, such as a cerebellar hemorrhage, exerts pressure in the confined space of the posterior fossa, leading to brainstem compression and coma. Cushing's triad of bradycardia, hypertension, and respiratory irregularity may indicate imminent brainstem herniation.

Cerebral perfusion

The management of ischemia focuses on maintaining an adequate CPP and avoiding systemic hypotension, hypoxia, and anemia to ensure adequate cerebral blood flow (CBF). Normally, CBF is relatively constant in a range of CPP between 40 and 160 mm Hg due to autoregulation. At low perfusion pressures within this range, the arteriolar bed dilates to decrease cerebral vascular resistance (CVR) and increase blood flow to normal levels. Below the autoregulatory threshold, arterioles passively collapse and CBF falls. Above the autoregulatory limits, vessels are maximally constricted and CBF increases.

Pressure autoregulation is impaired in many patients following TBI, and even when it is intact, the parameters at which it is operative may be shifted. Most notably, the lower limit of autoregulation may increase from CPPs around 40 to 50 mm

Figure 165.3. CPP–ICP relationship with preserved autoregulation.

Hg, meaning that perfusion pressures that are normally adequate may cause ischemia in these patients. The clinician must assume that, in patients with severe TBI, CBF is directly proportional to CPP, and therefore CPP must be closely monitored and maintained. Prospective studies have demonstrated that mean mortality is reduced by 50% when CPPs are maintained above 70 mm Hg in patients with severe TBI. The Brain Trauma Foundation supports maintaining CPP of 50 mm to 70 mm Hg, whereas other centers, such as ours, advocate a CPP above 70 mm Hg.

Besides the fact that increased ICP can decrease CPP, it is also true that decreases in CPP can increase ICP, leading to a deleterious positive feedback loop. As CPP decreases, pial arterioles dilate to accommodate larger blood volumes (diagrammed in Rosner's vasodilatory cascade; see Fig. 165.3). Increased blood volume can increase ICP. Restoration of CPP can therefore lead to pial arteriolar constriction and decreased ICP.

Systemic hypotension and hypoxia can also contribute to secondary injury by compromising cerebral oxygenation. Miller and others showed a 150% increased risk of mortality in patients with severe TBI who had at least one episode of hypotension as defined by systolic blood pressure < 90 mm Hg when compared with patients without hypotension. Similarly, Stochetti and colleagues showed that severe TBI patients with hypoxic episodes prior to intubation had a 77% mortality rate. Therefore, it is advisable to avoid periods of hypotension and hypoxemia should TBI patients require anesthesia for surgery.

Anemia may also decrease tissue oxygenation, and thus the hematocrit deserves particular attention in the head-injured patient. Kee has suggested that brain tissue oxygen delivery begins to decrease below a hematocrit of 33%, but most centers transfuse packed red blood cells below hematocrits of 30%. These recommendations are similar to those used in acute coronary syndromes and differ with recent reports outside of these two populations where lower hematocrits are felt to be acceptable.

Monitoring

The indications for placing an ICP monitor in patients with TBI are based on the identification of groups at risk for developing intracranial hypertension or for whom a neurologic examination cannot be followed, such as pharmacologically paralyzed

patients or patients under general anesthesia. Patients at highest risk are those with GCS \leq 8 and an abnormal CT scan. All patients with GCS \leq 8 should have an ICP-monitoring device placed unless there is a coexisting coagulopathy. We also consider ICP monitoring in TBI patients with a GCS > 8 who are undergoing anesthesia for extensive extracranial surgery.

Management of increased intracranial pressure

The goals of intracranial hypertension management are the maintenance of adequate CPP and the avoidance of brain herniation. Elevated ICP is an independent predictor of poor neurologic outcome in patients with severe head injury. The Brain Trauma Foundation supports initiating treatment at ICP readings of 20 to 25 mm Hg with preservation of adequate CBF. A caveat to dogmatic adherence to these values is that herniation may occur at ICP readings below 20 mm Hg, particularly in patients with temporal lesions. Also, a therapeutic CPP target may be reached with ICP readings as high as 25 mm Hg. At our institution, we initiate treatment for ICP readings greater than 25 mm Hg, unless CPP is compromised at lower pressures. We use a stepwise approach, from conservative to more invasive, beginning with head elevation to optimize cerebral venous outflow, followed by pharmacotherapy and CSF drainage (Fig. 165.4).

Specific maneuvers to decrease ICP

Conservative measures: positioning, CO₂, and sedation

We advocate elevating the head of the bed to 30° and maintaining a neutral head position to maximize venous return from the brain and thereby reduce CBV. Additionally, if a cervical collar is present, we confirm that the collar is not so tight as to impede jugular venous flow. This needs to be carefully and repeatedly verified both in the ICU and in the operating room as these

Figure 165.4. Stepwise protocol for ICP management.

patients may require prolonged procedures and passive positioning.

Changes in arterial carbon dioxide (CO_2) are known to affect CBF and vascular caliber. While pressure autoregulation may be dysfunctional in severe TBI, CO_2 reactivity is preserved. Hypoventilation raises PaCO_2 and ICP by increasing vascular caliber and CBF, whereas PaCO_2 levels below 35 mm Hg may lower ICP but compromise CBF. The ideal PaCO_2 level in head-injured patients is thus normocapnia. In emergency situations, such as with acute neurologic deterioration and impending herniation, acute hyperventilation can be considered but should be maintained only until other treatments are expeditiously initiated. The only circumstance in which mild chronic hyperventilation may be considered as a therapy is when cerebral hyperemia (more prevalent in the pediatric population) is shown by either jugular bulb venous saturation (SjVO_2) or CBF measurements.

Sedation and analgesia may help to blunt the sympathetic stimulation activated by pain or agitation, endotracheal irritation, or routine nursing care and help to decrease ICP. The short-acting sedative propofol is being used with increasing frequency because its short half-life permits frequent neurologic examinations and because it appears to have superior effects on ICP reduction compared to narcotics. Propofol is a potent vasodilator, however, and careful attention must be paid to MAP and CPP during its administration. Also, propofol is contraindicated in the pediatric population due to the possibility of *propofol syndrome*, characterized by metabolic acidosis, cardiac conduction abnormalities, and rhabdomyolysis. Severe intracranial hypertension may require pharmacologic paralysis by neuromuscular blockade for maximum muscle relaxation.

CSF drainage by ventriculostomy

CSF drainage via an external ventricular drain (EVD) or ventriculostomy is an effective method of ICP reduction in head-injured patients. After placement, the EVD is leveled or “zeroed” to the tragus. With a ventriculostomy in place, we drain CSF to its maximal capacity for increased ICP control prior to starting osmotherapy. We, therefore, recommend the use of a ventricular catheter, whenever possible, prior to the use of osmotherapy and paralysis, and certainly before the initiation of barbiturate coma. When an intraparenchymal monitor without drainage capability is already in place, however, osmotherapy may be instituted before CSF drainage.

Osmotherapy

The osmotic diuretic mannitol is a mainstay in the armamentarium of ICP management. Mannitol was commonly thought to reduce ICP by reducing intracranial water content but is now recognized to also expand plasma volume and decrease viscosity. Experiments have demonstrated that mannitol increases CBF and decreases ICP by autoregulatory vasoconstriction. Furosemide, which can inhibit the production of

CSF, may potentiate the effects of mannitol. When using mannitol, intravascular volume, serum osmolarity, sodium, blood urea nitrogen (BUN), and creatinine must be vigilantly watched for possible adverse effects. When the serum osmolarity is above 320 Osm, mannitol may precipitate acute renal failure, especially in patients with already compromised kidney function. With prolonged use, mannitol can also disrupt the blood–brain barrier and may pass into the brain parenchyma, causing a rebound effect with subsequent increases in ICP.

Hypertonic saline may be used as an adjunct or alternative to mannitol. Hypertonic saline has the advantage of a lower risk of rebound intracranial hypertension and renal failure. At hyperosmolar concentrations, sodium chloride creates a gradient, which drives water from interstitial and intracellular compartments into the intravascular space, reducing brain water and thus ICP. More recent work has suggested that hypertonic saline also exerts anti-inflammatory effects. Qureshi’s group has reported that 23.4% saline in doses of 30 to 60 ml over 20 minutes can markedly reduce ICP when standard treatments fail. Hartl and colleagues demonstrated that 7.5% hypertonic saline was particularly effective in ICP reduction and CPP elevation in patients with severe TBI when ICPs were refractory to other measures. Hyponatremia is commonly observed but resolves as renal free water clearance is reduced. Possible adverse consequences include central pontine myelinolysis, seizures, as well as congestive heart failure from fluid shifts and coagulopathy.

Intracranial hypertension refractory to standard treatment

The measures just mentioned are routinely used to manage intracranial hypertension. When ICP begins to increase despite maximal treatment, however, other measures, such as decompressive craniectomy or barbiturate-induced burst suppression, can be considered. We use these measures in select situations only, after careful consideration and discussion with family members regarding the advantages and disadvantages of each.

Barbiturates

Barbiturates potentiate the effects of γ -aminobutyric acid (GABA) at GABA receptors, which inhibit neuronal transmission and thereby reduce the cerebral metabolic rate of oxygen consumption (CMRO_2). Barbiturates may also decrease ICP by limiting free radical–mediated lipid peroxidation and resultant cerebral edema. The routine use of barbiturates in the treatment of high ICP is not indicated, especially because outcomes have not been shown to improve with this therapy. Although barbiturates have been shown to decrease ICP, there are important side effects of this therapy. The most clinically significant side effects of barbiturate administration are hypotension and global oligemic hypoxia, followed by hypokalemia, respiratory depression, hepatic dysfunction, and renal dysfunction. For these reasons, this treatment should always be used in conjunction with a

Swan–Ganz catheter. Plasma and CSF pentobarbital levels correlate poorly with physiologic effects; therefore, pentobarbital dosing is best followed by EEG monitoring with titration to achieve burst suppression. Barbiturates, because of their neuroprotective effects, are the first choice for the induction of general anesthesia for TBI patients.

Decompressive hemicraniectomy

In decompressive hemicraniectomy, the bone is removed and the dura is opened to increase the size of the intracranial vault. In a trial consisting of 27 pediatric patients, Taylor and colleagues demonstrated a reduction in risk ratio of 0.54 for death in the acute period as well as for death, vegetative state, and severe disability 6 to 12 months after the event in patients who underwent bitemporal decompressive craniectomy for high ICP. Evidence from the ischemic stroke field also has shown that decompressive craniectomy, especially when performed early, can greatly decrease mortality. Future class I studies in TBI patients are eagerly awaited.

Anesthetic considerations

Analgesia and sedation

Patients with persistent ICP elevation should receive little or no premedication to avoid hypercapnia and hypoxemia. Sedation without control of the airway should be avoided. The agitated patient may require general anesthesia.

Positioning

Please see subsection on conservative measures. In patients who are hypovolemic, elevation of the head may be associated with a decrease in blood pressure; therefore, blood pressure must be maintained so that CPP is not compromised.

Monitoring

Intra-arterial blood pressure monitoring is helpful so that hemodynamic changes may be monitored closely. Central venous pressure or pulmonary artery pressure monitoring may be necessary in patients with significant cardiac or pulmonary comorbidities, but should not delay surgery. The position of the pressure transducers will need to be adjusted to the height of the patient's right atrium to ensure reliable measurements.

Blood pressure management

Hypotension (systolic < 90 mm Hg) at any point during treatment has been identified as one of the primary factors that worsen prognosis. Arterial hypotension attributed to hypovolemia should be rapidly corrected with fluid administration. Placement of two large-bore intravenous (IV) cannulae is necessary. These patients should undergo aggressive fluid resuscitation with isotonic fluids until euvolemia is achieved. Isolated head trauma rarely leads to severe hypotension. Other

possible injuries, such as spinal cord trauma and blunt abdominal and/or chest trauma, should be identified and treated. Combined inotropes/vasopressors, such as dopamine or norepinephrine, may be required to sustain arterial pressure in hypotension persisting despite fluid administration, although these agents should be used with caution, as their vasoconstriction effects potentially may impair local CBF despite improving CPP. Norepinephrine may be the vasopressor of choice in these situations.

Induction

All patients with TBI should be regarded as having a full stomach and should have a rapid-sequence induction with cricoid pressure. Intubation without anesthetics may cause coughing and bucking and increase ICP, hence IV anesthetic agents and muscle relaxants must be used to secure the airway. Thiopental at 3 to 5 mg/kg IV or propofol at 1 to 2 mg/kg IV is the drug of choice, along with a short-acting neuromuscular agent. Barbiturates and propofol are effective in lowering ICP by decreasing CBF. Hypotension is a potential side effect of both of these agents and can compromise CPP. The use of succinylcholine in intracranial hypertension is controversial. Animal and human studies have shown an increase in ICP presumably due to fasciculations. This effect can be avoided by using a defasciculating dose of a nondepolarizing drug prior to succinylcholine. Securing the airway promptly with succinylcholine avoids the deleterious effects of hypoxia and hypercarbia and a subsequent increase in ICP. If the airway assessment reveals that intubation may be easy, then rocuronium at 0.6 to 1.2 mg/kg may be used.

Fentanyl, at 3 to 5 μ g/kg IV, is administered to blunt the hemodynamic response to laryngoscopy and intubation. Lidocaine, at 1.5 mg/kg IV given 90 seconds before laryngoscopy, can help to prevent the increase in ICP. If a difficult intubation is anticipated, awake fiberoptic intubation, which produces substantial, but transient, increases in ICP, may be necessary, but should be used with caution. Sedation, analgesia, paralysis, and topical tracheal anesthesia do not completely prevent this increase. Blind nasal intubation is contraindicated in patients with a basilar skull fracture, which is suggested in patients with CSF otorrhea, rhinorrhea, hemotympanum, periorbital ecchymosis (raccoon eyes), or ecchymosis behind the ear (Battle's sign).

Sedation, analgesia, and neuromuscular blockade

It is important to maintain neuromuscular blockade during surgery. Care should be taken when suctioning the endotracheal tube because it can increase ICP in the nonrelaxed patient. Coughing and bucking may increase ICP by increasing intrathoracic pressure and obstructing cerebral venous outflow. Agitation and pain may significantly increase blood pressure and ICP. Hence postoperatively adequate sedation and analgesia is an important adjunct treatment. Hypovolemia predisposes to hypotensive side effects and should be treated promptly.

Selection of shorter-acting agents allows for a brief interruption of sedation to examine the neurologic status.

Hyperventilation and PEEP

Hypoxemia is associated with increased morbidity and mortality. Oxygen administration should be generous to maintain an oxygen saturation of hemoglobin (SpO_2) $> 90\%$ or $\text{PaO}_2 > 60$ mm Hg. The use of prophylactic hyperventilation therapy ($\text{PaCO}_2 \leq 20$ – 25 mm Hg) during the first 24 hours after severe TBI should be avoided because it can compromise cerebral perfusion during a time when CBF is reduced. High tidal volumes and high respiratory rates are independent predictors of acute lung injury or acute respiratory distress syndrome. Neurogenic pulmonary edema can also contribute to hypoxemia. Alternative ventilator strategies should be considered to protect the lung and maintain tight PaCO_2 control. In patients with severe brain injury and acute lung injury, the use of positive end-expiratory pressure (PEEP) is limited by conflicting results on its effect on ICP. With higher levels of PEEP (10–12 cm H_2O), there is a slight increase in ICP in patients with normal ICP. For PEEP to increase cerebral venous pressure to levels that would increase ICP, the cerebral venous pressure must at least equal the ICP. The higher the ICP, the higher the PEEP must be to have such a hydraulic effect on ICP.

Management of brain oxygenation

Therapy following severe TBI is directed toward preventing secondary brain injury. Delivery of oxygen (O_2) to the brain is a function of the oxygen content and CBF. Hypoxemia, usually a PaO_2 below 50 mm Hg or 60 mm Hg, is associated with cerebral vasodilation. The optimal PaO_2 in a brain-injured patient is currently unestablished. Brain tissue monitoring allows one to provide minimal fraction of inspired oxygen (FiO_2) to avoid lung toxicity from hyperoxia that permits the optimal (not too high, not too low) brain tissue oxygen level. Low brain tissue oxygen (P_{btO_2}), less than 15 mm Hg, has been associated with increased mortality.

Glucose management

Glucose is essential to cerebral metabolism, and hypoglycemia should be avoided because, under anaerobic conditions in poorly perfused ischemic areas, lactate levels may increase, contributing to worsening of neuronal damage. Hyperglycemia has been associated with longer length of stay and increased mortality rate. Euglycemia should be maintained.

Temperature management

Hypothermia is associated with better neurologic outcomes. There is evidence of improved neurologic outcome after induced hypothermia to 33°C for 12 to 24 hours in out-of-hospital cardiac arrests. Preliminary studies suggest that decreased mortality may be seen when target temperatures are

maintained for more than 48 hours. Clifton and colleagues, however, were unable to show a beneficial effect of induction of hypothermia after TBI.

Fluid management

Please see the earlier sections on hyperosmolar agents and blood pressure management. Hypo-osmolar solutions, such as 5% dextrose in water, reduce serum sodium and increase brain water and ICP. Colloid solutions exert little influence on either variable. Fluid restriction minimally affects cerebral edema and, if pursued to excess, may result in episodes of hypotension, which may increase ICP and worsen neurologic outcome. Although there is no single best fluid for patients with TBI, isotonic crystalloids are widely used.

Systemic sequelae

Fluid therapy used to support CPP may cause visceral edema, increasing intra-abdominal pressure, which increases ICP. Ventilatory maneuvers used to treat respiratory failure may increase intrathoracic pressure, limiting venous return and thereby increasing ICP and decreasing CPP. In severely injured patients with head trauma, treatment decisions may create a cycle that increases pressure in various body compartments.

Antiseizure prophylaxis

Seizures can occur in 15% to 20% of patients after TBI and can increase cerebral metabolic rate and ICP. In patients with severe TBI, 50% of seizures can be subclinical and can be detected only by continuous EEG monitoring. Posttraumatic seizures can occur early (within 7 days) or late (after 7 days) following injury. Anticonvulsants are indicated to decrease the incidence of early seizures. Routine seizure prophylaxis later than 7 days is not recommended.

Postoperative management

If the patient is not responsive to analgesia and sedation alone after surgery, neuromuscular blockade should be considered. The prophylactic use of neuromuscular blockers in patients with intracranial hypertension has not been shown to improve outcome, may be associated with increased risk of pneumonia and sepsis, and may obscure seizure activity.

Conclusion

To conclude, the principal goals of severe TBI management are addressing the primary injury and then limiting secondary brain injury. The avoidance of intracranial hypertension is essential for the latter as it prevents brain herniation and cerebral ischemia. An *ICP-based approach* to patients with severe TBI includes stepwise measures as shown in Fig. 165.4. Just as important is a *CPP-based approach*, in which maintenance of a particular CPP (rather than a particular ICP) guides management.

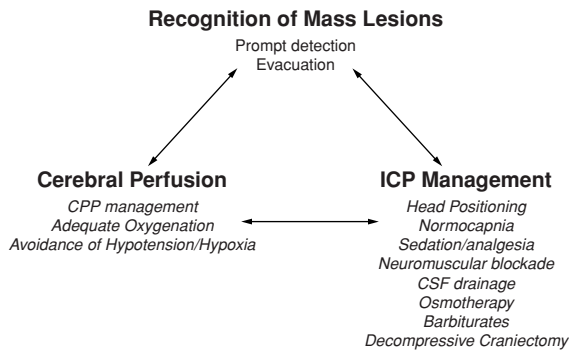

Figure 165.5. Cornerstone of severe TBI management.

An integrated management paradigm that monitors and controls both ICP and CPP is thus strongly recommended. The cornerstones of such a strategy include (1) rapid identification and management of intra- or extradural mass lesions, (2) ICP monitoring and management, and (3) CPP maintenance for avoidance of cerebral ischemia (Fig. 165.5). Finally, meticulous systemic medical management of these patients, including appropriate seizure prophylaxis, is a requirement for successful outcomes.

Burn management

Mark Chrostowski and Edward A. Bittner

Epidemiology

Of the estimated 500,000 patients treated for burns every year in the United States, approximately 40,000 are admitted into the hospital. Of these patients, more than half are sent to specialized regional burn centers. Survival and quality of life for patients with severe thermal injury have significantly improved over the last few decades due to advances in critical care and surgical technique. Today, except for the most severe cases, burn victims are expected to survive their initial injuries. Recent estimates from the American Burn Association show a 94.4% survival rate for all patients admitted to burn centers. As more patients survive, therapy for postburn deformity has increasingly become a major clinical problem. Consequently, more operative cases are now devoted to addressing reconstructive problems. Available data suggest that, by resuscitating patients through postburn shock and managing burn sepsis, patients can survive their burns and maintain a satisfying quality of life.

Pathophysiology

Severe burn injury causes extensive physiologic changes (Table 166.1). Changes begin when significant tissue trauma leads to widespread release of both local and systemic inflammatory mediators. Inflammatory mediators, including histamine, free O₂ radicals, and prostaglandins, cause burn shock through generalized capillary leak, intravascular volume depletion, and myocardial dysfunction. Although evaporative and direct fluid loss from the site of burn injury play a role, it is the extensive systemic capillary leak and protein loss that lead to edema formation and intravascular depletion. This fluid and protein loss occurs both locally at the burn site and at more distant, non-burned tissues. The end result is burn shock that requires large volume resuscitation for stabilization and prevention of tissue ischemia.

To complicate matters further, other mediators, including epinephrine, norepinephrine, vasopressin, angiotensin II, and serotonin, cause an increase in systemic and pulmonary vascular resistance. The vasoconstriction increases afterload and contributes to the decreased cardiac output. This vasoconstriction results in decreased flow to vascular beds that are already underperfused. Tissue ischemia and secondary organ injury can result without early, aggressive fluid resuscitation. After burn shock is successfully treated and capillary integrity is

restored, a hypermetabolic response develops with associated fever, tachycardia, and severe fat and muscle wasting. In the hypermetabolic phase of burn injury, resting metabolic rates can double and remain elevated for up to 9 to 12 months post-injury.

Classification of burns

Classification of burns is important because the extent of injury correlates with the severity of pathophysiologic changes and the

Table 166.1. Systemic effects of burn injury

System	Pathophysiologic changes and complications
Respiratory	Airway edema Reduced pulmonary and chest wall compliance Bronchospasm Pneumonia, pulmonary edema, and ARDS
Cardiovascular	Hypovolemia Myocardial dysfunction and decreased cardiac output (early) Increased cardiac output and hypertension (late)
Renal	Decreased renal blood flow (early) Increased renal blood flow (late) Myoglobinemia
Metabolic	Increased metabolic rate Impaired thermoregulation Protein catabolism Electrolyte imbalances (from resuscitation and topical antibiotics)
Gastrointestinal	Curling ulcers Ileus and delayed gastric emptying Impaired intestinal barrier
Hematologic	Hemoconcentration (initially) Chronic anemia (later) Thrombocytopenia (dilutional and consumptive) Coagulopathy and disseminated intravascular coagulopathy (in severe cases)
Infectious	Postburn sepsis
Neurologic	Encephalopathy Acute and chronic pain Cyanide and carbon monoxide poisoning
Skin	Increased fluid and heat loss Need for escharotomy in severe cases Contracture and scar formation
Pharmacologic	Altered pharmacokinetics and pharmacodynamics Increased tolerance to sedatives and opioids Altered response to muscle relaxants

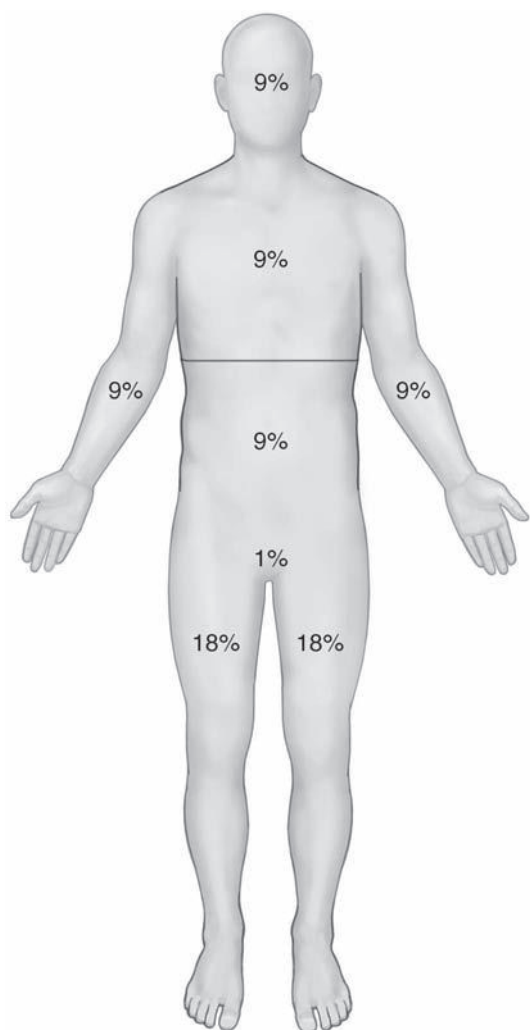

Figure 166.1. The rule of nines for estimating TBSA. Note: Not accurate for all age groups.

need for resuscitation. It also helps to predict how the injury will progress and whether surgical intervention may be needed. The extent of burn injury is assessed in relation to total body surface area (TBSA) involved with either the rule of nines (Fig. 166.1) or Lund and Browder burn diagrams. Although the rule of nines provides useful initial estimates of TBSA in the acute setting for adults, it underestimates the TBSA for children. More accurate characterizations should be obtained through the use of comprehensive and age-specific burn diagrams once the patient is stabilized.

It is also important to assess the depth of burns (Table 166.2). The classical description of burn injury in terms of first, second, and third degree has given way to a new system that is more descriptive of burn depth. The new characterizations (superficial, superficial partial-thickness, deep partial-thickness, and full thickness burns) help to determine the need for inpatient admission and surgical intervention. It often takes 2 to 3 weeks, however, to determine whether the wound will heal primarily or be severe enough to require surgical intervention.

Table 166.2. Classification of burn depth

Depth	Level of injury	Clinical features
Superficial	Epidermis	Dry, red Blanches Painful
Superficial partial-thickness	Papillary dermis	Blisters Moist, red, weeping Blanches Painful Return to full function
Deep partial-thickness	Reticular dermis	Blisters Wet or waxy dry Does not blanch Absent pain sensation Possible need for surgical excision and grafting
Full thickness	Subcutaneous fat, fascia, muscle, or bone	Waxy white to leathery Dry and inelastic Does not blanch Absent pain sensation Surgical excision and grafting as early as possible

Modified from Bittner EA, Grecu L, Martyn JAJ. Evaluation of the burn patient. In: Longnecker DE, et al., eds. *Anesthesiology*. New York: McGraw-Hill Professional; 2008.

Management

Initial evaluation

Treating patients with burn injuries requires a complex, multidisciplinary approach. As with any other trauma admission, the patient with acute burn injury should be managed to ensure adequate airway, breathing, and circulation. After the airway and hemodynamics are stabilized, a secondary survey is done to look for associated nonthermal injuries, and a comprehensive history and physical examination are performed. The cervical spine should be evaluated for potential injury in the appropriate clinical setting. A Foley catheter, nasogastric tube, and adequate intravenous (IV) access for resuscitation are all needed for major thermal injury.

Patients with electrical injury require immediate hospital admission, often to a specialized burn center. Electrical burns can have massive amounts of tissue destruction that often cannot be predicted by the burn size alone. Although the events that lead to injury can be either obvious or subtle, high-voltage burns cause injury one of three ways: (1) thermal burns to skin, (2) destruction of muscle and nerves, and (3) arrhythmias and cardiac arrest. Extensive deep tissue damage can also cause myoglobinuria and compartment syndromes. Standard resuscitation endpoints must be monitored closely because fluid resuscitation formulae are often inaccurate when hidden, deeper injuries exist.

Airway and respiratory issues

Patients should immediately be assessed for inhalation injury and any evidence of airway compromise. Inhalation injury is a major source of mortality in burn patients. Signs of hoarseness,

brassy cough, or stridor indicate laryngeal edema and constitute an emergency. Because edema formation occurs in non-burned tissues after major thermal injury, respiratory failure can develop even in the absence of inhalation injury.

The respiratory status often deteriorates in the setting of massive fluid resuscitation. In these cases, it is generally safer to intubate the patient early than risk a difficult intubation later when airway swelling has occurred. With burn injuries of the face or neck, direct laryngoscopy may be difficult or impossible and a surgical airway may be needed. The difficult airway should ideally be managed in the operating room with resources for obtaining a direct surgical airway readily available.

Severe injury complicated by deep, circumferential chest wall wounds can significantly reduce pulmonary and chest wall compliance, causing high airway pressures and significant ventilatory difficulties. Escharotomy should improve ventilation in this situation. Indirect respiratory injury resulting from pulmonary edema, pneumonia, or acute respiratory distress syndrome (ARDS) may develop in the days following the initial burn injury. Many patients are now managed with a low-tidal-volume ventilation of 6 ml/kg. This low-tidal-volume ventilation strategy is thought to help reduce alveolar distention and barotrauma. Permissive hypercapnia is used if not contraindicated by pulmonary hypertension, hemodynamic instability, or intracranial hypertension.

Cardiovascular issues

Hemodynamics in burn injury are initially characterized by a reduction in cardiac output and an increase in systemic and pulmonary vascular resistance. Approximately 3 to 5 days after major burn injury, a hypermetabolic response develops with associated fevers, increased cardiac output, and increased energy expenditure. Severe fat and muscle wasting results.

Although multiple fluid resuscitation formulae exist for estimating fluid needs, no single formula has proved to be superior in improving outcomes. The *Parkland formula* is perhaps the most known and remains a gold standard in guiding fluid resuscitation requirements for burn victims. The formula calls for 4 ml/kg/%TBSA of lactated Ringer's in the first 24 hours, with one half of this amount administered over the first 8 hours. As a general rule, burns of <15% TBSA are not associated with extensive capillary leak and can be managed with fluid of 1.5 times the maintenance rate. Resuscitation formulae should be used only as guidelines. Actual fluid administration should be individualized for each patient and titrated to physiologic endpoints (Table 166.3).

If the total fluid requirement exceeds 6 ml/kg/%TBSA/24 hours, it may be advisable to obtain more information regarding intravascular volume and cardiac function thru measurement of central venous and cardiac filling pressures. After 24 to 48 hours, capillary integrity is restored in nonburned areas and fluid requirements dramatically decrease. It is important to decrease fluid administration at this time because overresuscitation can be associated with substantial morbidity.

Table 166.3. Burn resuscitation endpoints

Arousable and comfortable
Warm extremities
Systolic blood pressure: for infants, 60 mm Hg; for older children, 70–90 + 2 × age (y); for adults, mean arterial pressure > 65 or within 20% of baseline
HR 80–150 bpm (age dependent)
Urine output 0.5 ml/kg/h
Lactate levels < 2 mmol/L

Although the benefits of resuscitation are obvious, the type of fluid used in resuscitation of burn victims has always been controversial. Theoretically, resuscitation with colloid should improve outcomes by preserving plasma oncotic pressure and replacing intravascular volumes with less tissue and pulmonary edema. Clinical studies have not shown improved outcomes, however. Given their significant extra cost but no improvement in survival, many clinicians question the continual use of colloids, especially for burns of < 40% TBSA. If they are used, many advocate waiting until capillary integrity is restored.

Renal issues

Inadequate resuscitation after major thermal injury complicated by hypotension and myoglobinemia contributes to the development of early acute renal failure (ARF). A urine output of at least 0.5 ml/kg/h is one indicator of the adequacy of resuscitation. Late ARF is associated more with multisystem organ failure, sepsis, and the effects of nephrotoxic drugs. The development of ARF is associated with increased mortality in burn patients.

Gastrointestinal and nutritional issues

Patients with severe burns often develop a paralytic ileus and require nasogastric decompression. Gastroduodenal ulceration (Curling ulcers), likely due to reduced splanchnic blood flow, is a risk after severe burn injury. Ulcer prophylaxis with H₂-receptor antagonists or proton pump inhibitors should be initiated early.

The presence of circumferential abdominal burns and accumulation of intraperitoneal fluid and/or bowel edema from large volume resuscitation can lead to abdominal compartment syndrome (ACS). Signs of ACS include diminished urine output, decreased pulmonary compliance, and hemodynamic instability. Bladder pressures can be obtained to make the diagnosis. Surgical decompression may be necessary in some cases.

Severe burn injury results in a hypermetabolic response with profound wasting of lean body mass that can last for more than a year after injury. Strategies used to minimize this catabolic response include early wound excision and grafting, early institution of feeding, prompt treatment of sepsis, and maintenance of high environmental temperature. Nutritional support can partially abate the hypermetabolic response to burns and help maintain muscle mass. Enteral feeding is preferable to parenteral feeding because it maintains gastrointestinal

(GI) motility and reduces bacterial translocation and sepsis. Parenteral nutrition is reserved for patients with intolerance for enteral feeding or prolonged ileus. Some evidence suggests that β -blockade may attenuate this hypermetabolic response and associated muscle wasting. Propranolol has been shown to decrease heart rate (HR) and resting energy expenditures as well as reverse muscle–protein catabolism.

Neurologic and pain issues

Mental status changes can develop in the setting of hypoxia, hypotension, or the inhalation of neurotoxic chemicals. Therapies for anxiety and pain cause sedation and complicate efforts to diagnose the etiology of acute neurologic changes. Signs of central nervous system dysfunction include delirium, hallucinations, personality changes, seizures, and coma. Radiologic imaging should be obtained if intracranial injury is suspected.

Pain management in the burned patient provides many challenges. Nearly every therapy for burn injury is associated with pain. Surgery, dressing changes, physical therapy, and transport exacerbate baseline pain and anxiety levels. Standardized pain and anxiety guidelines are used in many burn centers to provide appropriate and consistent patient comfort. IV morphine and versed are commonly used medications for intubated patients or for those who are NPO. Ketamine has also proved to be a useful adjunct because of its effects as an analgesic acting via the *N*-methyl-D-aspartate (NMDA) receptor. Transition to oral medications when possible helps to provide more constant therapeutic levels. Burn patients develop tolerance to most opioids and sedatives, so they require higher doses than do patients without thermal injury. Continuous administration of analgesics by themselves can result in opioid-induced hyperalgesia, which will accentuate the need for higher opioid levels.

Infection issues

Infection is a leading cause of morbidity and mortality in burn patients. Sepsis in burn injury can be difficult to diagnose because, even in the absence of sepsis, patients are already hypermetabolic and have hyperdynamic physiology. Prevention, early diagnosis, and treatment of infection is essential. Prophylactic antibiotics have no proven role in burn care and are not routinely given. Topical antimicrobials, however, provide high concentrations of drug at the wound surface, reduce the levels of wound flora, and delay the interval between injury and colonization. Tetanus toxoid should be given to burn patients because all burn injuries have potentially contaminated soft-tissue wounds. Maintaining sterile technique both in the operating room and during transport through the use of a mask and sterile gloves and dressings is essential to preventing infection.

Surgical considerations

Blood loss during burn wound excision can be deceptively large with published estimates ranging from 3.5% to 5% of the blood volume for every 1% TBSA excised. It is not difficult for the surgical team to remove eschar so rapidly that the patient becomes

hypovolemic and unstable. Limiting the operative duration and extent of excision can prevent such problems. Techniques to minimize blood loss include intraoperative tourniquets for limb surgery, injection of dilute epinephrine, and brisk operative pace.

Altered pharmacokinetics and pharmacodynamics

The altered physiologic state in burn injury and changes in concentrations of plasma proteins cause changes to the pharmacokinetic and pharmacodynamic response to drugs. Hypotension and low cardiac output decrease hepatic and renal blood flow and function. Standard dosing of drugs should be adjusted accordingly.

Anesthetic considerations

Preoperative evaluation and transport

Given the enormous physiologic changes seen in burn injury, careful planning is essential for safe intraoperative care (Table 166.4). As with any surgical procedure, the preoperative evaluation should consist of gathering information about the patient's history and performing a thorough physical examination. Reviewing details of the patient's burn injury – with special attention to the time since injury, extent of injury, adequacy of resuscitation, and presence of an inhalational component – provides insight into expected physiologic changes and possible anesthetic difficulties. Previous anesthetics, especially those already completed in the postburn period, can provide information on difficulties in airway management, ventilation, hemodynamic stability, or pain control. Coexisting diseases, associated injuries, current medications, and allergies must be reviewed. Standard laboratory tests include electrolytes, blood urea nitrogen (BUN), creatinine, hematocrit, coagulation status, and a blood bank sample. Blood products should be available in the operating room for larger cases where blood loss is expected.

The airway is assessed for the possibility of difficult intubation. Facial wounds often create difficulties for mask ventilation. Likewise, edema formation and scarring can complicate intubating conditions by decreasing neck mobility and mouth opening. There is always a risk for endotracheal tube (ETT) dislodgement during patient transport or intraoperative positioning. Tape alone is usually insufficient to secure the ETT if facial burns are present. Common practices are to either tie the ETT securely around the neck or use wire to secure the tube to a tooth.

The neurologic examination should be focused on baseline mental status and adequacy of anxiety and pain control. The baseline pain and sedation regimen should be known to help guide the need for premedication and intraoperative pain control. Assessment of cardiovascular status should focus on hemodynamic function in response to stage of burn injury (early hypodynamic vs. later hyperdynamic), adequacy of resuscitation, and vasopressor dependence. Given the risk for large

Table 166.4. Perioperative concerns specific to burn patients

Preoperative	
Initial evaluation	History and physical examination, including: Extent of burn injury (TBSA, depth, and location) Mechanism of injury, elapsed time from injury, adequacy of resuscitation Associated injuries Presence of inhalation injury Presence of organ dysfunction Presence of infection Coexisting diseases Surgical plan
Airway	Assess for airway patency and possibility of difficult intubation.
Neurologic	Assess baseline mental status and pain control.
Cardiovascular	Assess adequacy of resuscitation. Consider hemodynamic response to injury (hypo- vs. hyperdynamic).
Pulmonary	Assess for evidence of inhalation injury. Adequacy of oxygenation and ventilation Significant ventilatory support may require ICU ventilator.
Renal	Assess for renal failure and electrolyte imbalances.
Gastrointestinal	Assess NPO status (limit NPO time given increased metabolic requirements).
Laboratory data	CBC, electrolytes, and coagulation studies Blood bank sample and availability of blood products
Transport issues	Ensure the ETT is well secured. Check all equipment prior to departure. Ambu bag, O ₂ cylinder, monitors, infusion pumps Equipment and medications for reintubation and resuscitation Maintain patient comfort and sedation.
Intraoperative	
Monitoring	Standard ASA monitors; invasive monitoring as dictated by patient's condition and operative procedure
Airway	Anticipate potential difficulty. If injuries do not preclude standard airway management (mask fit, mouth opening, neck extension), direct laryngoscopy and intubation can be performed. Gastric emptying may be delayed in burn patients.
IV access	Anticipate difficulty locating vessels; ultrasound guidance can be helpful. Central venous access is usually necessary in patients with large burn injuries. Securing adequate vascular access before the surgical procedure begins is necessary because blood loss can be rapid and substantial.
Temperature	Massive heat loss can occur through the open wounds. Keep ambient temperature elevated. Use warming blankets, radiant warmers, and blood and fluid warmers.
Hemodynamics	Response varies with extent of burn, elapsed time from injury, and adequacy of resuscitation. Early (days 1–3): reduction in CO, increased SVR and PVR; later (>3 days): hyperdynamic state with increased CO
Ventilator management	Provide adequate oxygenation and ventilation without inducing further morbidity from oxygen toxicity, hemodynamic compromise, barotrauma, or alveolar overdistension.
Anesthetics	Many anesthetic agents have been used successfully. Choice of agent should be based on the patient's hemodynamic and pulmonary status and potential difficulty in securing the patient's airway.
Muscle relaxants	Succinylcholine can result in an exaggerated hyperkalemic response and should be avoided in patients 24 hours after burn injury. Dose of nondepolarizing muscle relaxant necessary to achieve paralysis in burn patients can be substantially elevated.
Pain management	Anticipate tolerance to sedatives and opioids. Continue baseline pain regimen; multimodal adjuncts (e.g., ketamine) are likely to be useful.
Postoperative	
	Assess potential for extubation at end of case. Call to the burn unit in adequate time for them to warm the room and obtain necessary supplies and equipment (e.g., infusions, ventilator). Ongoing fluid resuscitation and transfusion of blood products is expected after extensive excision and grafting. Presence of newly excised tissue and harvested donor sites can be painful and require higher doses of analgesics and sedatives. Determine new pain requirements. Maintain normothermia.

CBC, complete blood count; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

volume blood loss during surgery and significant fluid shifts, in nonurgent cases it is prudent to postpone surgery until hemodynamic stability is achieved. Pulmonary assessment includes evaluation of oxygenation and ventilation, causes of impaired gas exchange, and mechanical ventilatory requirements. Significant pulmonary injury and poor compliance result in auto-

PEEP (positive end-expiratory pressure) and breath stacking. Ventilatory requirements may exceed 20 L/min in adults during the hypermetabolic state. The high ventilatory needs combined with high peak inspiratory pressures and PEEP often cannot be sustained on traditional operating room ventilators. An ICU ventilator should be made available in these cases.

The need for aggressive intraoperative resuscitation necessitates adequate IV access. The presence of burn injury, together with tissue edema and hypovolemia, often makes this a challenge. Central lines are not routinely used unless there is a need for administration of vasoactive medications or in severe cases where invasive monitoring is needed. For example, large burns complicated by coexisting heart disease may benefit from the monitoring of central venous pressures, pulmonary artery pressures, or mixed venous oxygen saturation. Because central lines increase the risk for infection and are associated with complications during placement, they should be used only when needed. Most patients with burn injury can safely be managed with only large-bore peripheral IV catheters and invasive arterial pressure monitoring.

Managing the patient during transport is often more complicated. All equipment (including a functioning ambu bag, a full oxygen cylinder, charged batteries for monitors and infusion pumps, and any equipment needed for reintubation) should be checked prior to departure. Fluids and resuscitative medications are also needed. Optimization of the patient's respiratory and hemodynamic status is essential prior to transport. The patient should remain comfortable and sedated to prevent agitation, which can cause ventilator dyssynchrony, hemodynamic changes, and dislodging of lines or tubes. Paralysis during transport is rarely necessary and often undesirable if the patient can breathe spontaneously.

Intraoperative management

Standard American Society of Anesthesiologists (ASA) monitoring including electrocardiogram (ECG), blood pressure, pulse oximetry, capnography, inspired oxygen concentration, and temperature is required. The location of wounds and intraoperative positioning often create difficulties as monitors do not adhere well to injured areas with topical ointments. ECG leads can be secured with staples or placed under dependent portions of the patient's body. A Foley catheter is required to help assess the adequacy of resuscitation.

Given the significant nutritional needs of some patients, careful attention must be paid to scheduling surgeries and limiting NPO status. In patients with suspected ileus and delayed gastric emptying, a rapid-sequence intubation with cricoid pressure is warranted.

It is important to remember that patients have marked changes in their response to muscle relaxants. There is general agreement that succinylcholine administration to patients > 12 hours after injury is unsafe. Significant increases in extrajunctional acetylcholine receptors develop in these cases, placing the patient at risk for severe hyperkalemia and cardiac arrhythmias. This response can exist more than a year after injury. Because burn victims also develop significant resistance to nondepolarizing muscle relaxants, rocuronium may have a delayed onset of action even when dosed at 1.2 mg/kg. Intraoperative monitoring of neuromuscular function must be done frequently.

As stated earlier, tangential excision and grafting of burn wounds leads to significant intraoperative blood loss. The

adequacy of resuscitation can usually be monitored by physiologic endpoints (Table 166.3). Blood products should be readily available for transfusion. Fluids should be warmed because burn patients are prone to heat loss. Hypothermia increases the risk for coagulopathies and arrhythmias, and shivering increases metabolic demand and may compromise the viability of newly placed grafts. Other measures to take include increasing ambient temperatures, wrapping the head, and using forced-air warming devices.

Many anesthetic agents have been used successfully in patients with burn injury. Ketamine is frequently used for intraoperative management because of its analgesic properties, relative hemodynamic stability, and tendency to preserve ventilatory efforts. It is a useful adjunct to the patient's baseline pain and sedation regimen, which often consists of morphine and midazolam.

Postoperative care

The potential for extubation is assessed at the end of surgery. Standard extubation criteria are used with significant attention given to the presence of airway edema, hemodynamic stability, need for ongoing resuscitation, and the presence of sepsis. Patients who received significant fluid resuscitation or who were positioned prone for an extended amount of time may benefit from remaining intubated until edema resolves. Chest radiographs may be needed to confirm ETT placement.

As stated earlier, extreme care must be taken during transport. The intensive care unit should have ample time to prepare prior to accepting the patient. Vasoactive medications, blood products, and a ventilator should be available if needed. Both the operating room and the patient's room should be warmed to help maintain normothermia. Finally, changes in the patient's level of pain may develop after extensive excision and grafting. The baseline pain regimen should be adjusted accordingly.

Key points to remember

- Burn injury results in pathophysiologic changes in most organ systems. The perioperative care of burn patients requires knowledge of these pathophysiologic changes from the initial period of injury until wounds have healed.
- The magnitude of burn injury is classified according to the TBSA involved, depth of the burn, and presence of inhalation injury. The rule of nines or age-specific burn diagrams are used to estimate the TBSA burned.
- The Parkland formula is perhaps the most widely used resuscitation formula for burn injury. The formula calls for 4 ml/kg/%TBSA of lactated Ringer's in the first 24 hours, with one half of this amount administered over the first 8 hours. Actual fluid administration should be individualized for each patient and titrated to physiologic endpoints.
- As with any other trauma admission, the patient with acute burn injury should be managed to ensure adequate airway, breathing, and circulation. After the airway and

hemodynamics are stabilized, a secondary survey is done to look for associated nonthermal injuries.

- Severe burn injury results in a hypermetabolic response with profound wasting of lean body mass. Strategies used to minimize this catabolic response include early wound excision and grafting, early aggressive nutritional support, prompt treatment of sepsis, and maintenance of high environmental temperature.
- Pain management in the burned patient provides many challenges. Surgery, dressing changes, physical therapy, and transport exacerbate baseline pain and anxiety levels. Burn patients develop tolerance to most opioids and sedatives, so they require higher doses than do patients without thermal injury.

Common ethical issues in the intensive care unit

Nicholas Sadvnikoff

Ethical issues, questions, and concerns are common in the intensive care unit (ICU) setting and occur more frequently than in the operative anesthesia setting. The reasons are readily apparent, as patients cared for in the ICU are generally the most ill in the hospital or have undergone the most high-risk surgeries. Mortality in ICU patients varies depending on a hospital's size and the acuity of its population. In major tertiary care teaching hospital settings, ICU mortality may exceed 10%, with a substantial toll in terms of morbidity and loss of function as well. It is no wonder, then, that ethical concerns arise frequently around such issues as decisional capacity, informed consent, surrogate decision making, withdrawing and withholding life-sustaining therapies, and futility. Given the imprecise nature of medical prognostication, decisions must often be made in the context of less than clear-cut parameters and consequences. Compounding the difficulty of such decision making is the profound emotional stress associated with critical illness, on both the caregivers and the decision makers. A rapid decline in a patient's medical condition or a failure to recover well after a surgical intervention can be a sudden event for which little planning or preparation has taken place on the part of the patients or their proxy agents. Fortunately, there has been a recent widespread recognition of the need for guidance and dispassionate appraisal in the context of ethical challenges, and this recognition has resulted in a proliferation of ethics support services. Most hospitals now have an ethics committee, an ethics consultation service, or both; many ethics consultation services are available on a full-time, 24-hour basis. Use of these resources can provide substantial comfort and resolution to caregivers, families, and patients alike.

General principles

Ethics can be distilled in many instances to the body of thought or philosophy that addresses the question "What is the right thing to do?" It is important, however, to recognize that the answer to that question may vary greatly depending on the frame of reference of the questioner or the responder. The pursuit of an absolute set of ethical rules that can be expected to be shared across all cultural and religious contexts has proven challenging, if not an outright failure. It is for this reason that Englehardt is fond of pointing out that the word *ethics* is, in fact, plural. Persons coming from different moral communities

may answer an ethical question differently. The fact of this ethical diversity must be acknowledged a priori when considering ethical questions, and all efforts should be made to understand the ethical context of the individual asking the question without imposing the ethical context of the responder and vice versa.

In the context of moral and ethical diversity, we have, as a society, nevertheless had to achieve enough of a consensus on certain moral questions to write and enforce laws. Legal and ethical questions frequently intersect, but should never be confused for one another. Frequently, an ethics consultation may be accompanied by a consultation with the hospital's legal department, but it is important to clarify the difference between the two. It is important as well to remember that legal statutes in the medical domain often vary substantially from state to state, reflecting the ethical stance of the prevailing communities in the states' legislatures.

In general, the secular ethical community in the United States has embraced a set of four ethical principles popularized by Beauchamp and Childress, often referred to as *the four principles*, which are comprised of autonomy, beneficence, non-maleficence, and justice.

Autonomy

The right of patients to dictate those medical interventions they will accept and those that they will not is the predominant theme in current ethical practice. This concept is in contradistinction to paternalism, still practiced in many other countries (including some Western societies), wherein physicians may exercise decisions regarding treatments on the basis of the "best interest of the patient." In this line of thinking, physicians' medical knowledge and experience equip them the best to decide on medical interventions.

The argument in favor of autonomy includes the codicil of informed consent, which calls on physicians to use their medical knowledge and experience to fully inform the patient of the potential benefits and risks of an intervention, but then allows patients, in the context of their own predicament, goals, preferences, and culture, to have unimpeded control over what is done to their bodies. As will be explored later in this chapter, patients in the ICU are frequently unable to express their autonomous sentiments. The decision making must then be transferred to a substitute whose duty it is to attempt to advocate for what the

patient would want done, given the circumstances, preserving the patient's autonomous wishes.

Beneficence

Beneficence refers to the obligation of physicians to do or promote the most possible good for patients. In instances in which a therapy comports both benefit and harm, the benefit should outweigh the harm. It is thus that it is easy to justify the pain of a surgical incision in order to remove an infected appendix. The concept of beneficence is extended to the obligation to remove harm (e.g., treat pain) as well as to prevent harm (e.g., administer vaccines). Beneficence, which prioritizes the “best interest of the patient,” can thus conflict with autonomy. In most cases, the principle of autonomy prevails, as when Jehovah's Witnesses are allowed to refuse blood in situations in which this clearly is not in their best interest. Exceptions occur when there is reason to question the decisional capacity of the patient, such as when suicidal individuals are involuntarily hospitalized for treatment of clinical depression.

Nonmaleficence

Nonmaleficence is the companion concept to beneficence that is summarized by the Latin aphorism *primum non nocere* (“above all, do no harm”). This obligation not to do harm to patients is obviously couched in the same context that the harm cannot exceed the good, and that a certain amount of harm can be acceptable if it is proportionally exceeded by benefit. Unfortunately, quantitating and weighing benefit and harm are at times difficult and sometimes even impossible tasks due to prognostic imprecision. Furthermore, to respect autonomy, patients' preferences must be considered in this calculus. An acceptable harm for one patient may be completely untenable for another (e.g., amputation of a gangrenous leg).

Justice

Justice refers primarily to distributive justice, in which the obligation of the physician, or more widely the health care delivery system, is to ensure that care is delivered fairly, equitably, and appropriately to all individuals. This concept conflicts strongly with the concept of beneficence, which promotes the greatest possible good for the individual patient. This issue is most effectively addressed at the societal and governmental level, rather than through rationing by individual physicians. Unfortunately, despite the fact that health care expenditures constitute an ever-increasing and progressively unaffordable portion of the United States' economic output, there has been, with only a few exceptions, little legislative appetite for limiting health care expenditures. Even the recent legislation passed by the US Congress, mandating certain reforms of the national healthcare delivery system, is characterized by substantial dilution and compromise, such that the net impact on the equitable distribution of health care services is likely to be small. The fact that distributive justice is given so low a national priority is difficult to defend by ethical arguments.

Competence and decisional capacity

The terms *competence* and *decisional capacity* differ in terms of their definition, but for the purpose of this chapter are interchangeable in that neither an incompetent patient nor a patient lacking decisional capacity should dictate his or her own medical decision making. These are conditions in which patients are stripped of their autonomy as a consequence of cognitive impairment that prevents them from fully understanding, considering, and processing information involved in consenting for or refusing medical interventions.

As has previously been noted, a substantial proportion of ICU patients are unable to participate in decision making about their medical treatment. The reasons for this are numerous, but the main issues are now discussed.

Delirium

Delirium is defined as a disturbance of consciousness with inattention accompanied by a change in cognition or perceptual disturbance that develops over a short period of time (hours to days) and fluctuates over time. Depending on how stringently testing is done, delirium is present in as many as 50% to 80% of ICU patients. Risk factors for delirium include advanced age, severity of illness, and medications (in particular, benzodiazepines). Delirium is fairly readily diagnosed by simple testing and, if present, impairs patients from having the capacity to give informed consent or participate in their own health care decisions.

Intubation

Patients who are intubated and receiving mechanical ventilation cannot talk, which substantially impairs discussions regarding medical choices. Although they may be awake and able to write notes, this is a much less rich form of communication as it may not capture emotional content. Furthermore, studies have found that at least 80% of mechanically ventilated patients are delirious, and most are in fact receiving sedative medications. Although there may be exceptions, in general it is prudent to have a proxy decision maker participate in medical decisions for intubated patients.

Dementia

Dementia is defined as the loss (usually progressive) of cognitive and intellectual functions, without impairment of perception or consciousness, caused by a variety of disorders, including severe infections and toxins, but most commonly associated with structural brain disease. It is a diagnosis that needs to have been made before a patient becomes critically ill, as it is a risk factor for, and commonly coexists with, delirium. ICU patients with an established diagnosis of dementia should not be asked to make decisions regarding their medical care.

Depression

Depression frequently coexists with and complicates both chronic and critical illness. It may cause patients to have

distorted interpretations of the value of medical therapies and of the value of their own well-being. A formal psychiatric evaluation should be performed if a patient seems to be making decisions that appear not to be made in the best self-interest and are not based on cultural or religious beliefs. A clinical diagnosis of depression may warrant the temporary designation of a proxy decision maker while the depression is treated.

Assessment of competence to consent for treatment can be challenging, and there are no formal guidelines from professional societies regarding this process. There are indeed degrees of impairment that may affect competence, such that it may be reasonable for a moderately impaired patient to give informed consent for procedures where the stakes are low (anesthesia for drainage of a superficial abscess) but not appropriate to give consent for high-risk procedures (organ transplantation). Standardized tools, such as the MacArthur Competence Assessment Tool for Treatment, have been developed that can be administered expeditiously and have shown high inter-rater agreement. Psychiatric evaluation can also be helpful when the question of competency is unclear. Ethics consultations are frequently useful in settings where there is uncertainty, particularly when patients refuse potentially beneficial therapy.

Substituted judgment

When a patient does not possess decisional capacity, the goal is to extend as accurately as possible that person's autonomy through a surrogate decision maker (SDM). The mandate of the SDM is to advocate on behalf of the patient for what the SDM believes that patient wanted when capable of autonomous decision making. SDMs may also have guidance from other documentation, such as living wills and advance directives.

Designated health care proxy agents

Ideally the SDM is someone who was designated by the patient and who has had previous in-depth discussions with the patient regarding wishes and goals for health care. Such a person is called a *designated health care agent*, and there must be a proxy document signed by both parties acknowledging this choice. In the absence of a formal process having taken place to designate a health care agent, there may be a hierarchy of persons to whom that role may fall by default. The exact priority varies from state to state, and some states do not recognize a hierarchy at all. Almost universally, the spouse is the first default, followed by parents, children, siblings, more distant relatives, and close friends. Often the role may be assumed by a less closely related individual (e.g., nephew) who happens to know the patient the best.

Living wills

These documents are generally broad statements completed by patients in anticipation of the possibility of losing decisional capacity. They often contain such conditional language as “if there is no reasonable hope of recovery” or “if I am permanently dependent on machines to stay alive.” These phrases are vague

and subject to interpretation and the vagaries of prognostication. The instructions often include prohibition of “heroic measures” or other similarly poorly specified interventions. Thus, living wills serve more as indications of the general spirit of the patient's wishes, rather than as detailed instructions for future care.

Advance care directives

Advance care directives are more detailed documents completed by patients in advance of their possibly losing decisional capacity. There is a widespread effort to encourage patients to use advance directives, the purpose of which is to elucidate more clearly than living wills their wishes for their future care. They are useful in that they provide guidance both to physicians and to SDMs. Their strength is that they do not depend on hearsay and are not clouded by the personal bias that an SDM may, whether intentionally or not, impose on the decision-making process. Advance directives are, however, limited by the specifics of their language, which may not apply to the specifics of the predicaments patients ultimately come to face. That is, the more specific are the instructions, the less they are likely to apply to the actual clinical situation that ultimately affects the patient.

The best practical solution is for patients to identify a health care agent who is aware of the spirit (living will) and specifics (advance directive) that characterize that individual's goals for care should decisional capacity be lost. Ideally, decisions are made with advance directive or living will documents and the health care agent present.

Synthetic judgment

There are instances in which critically ill patients have not completed any sort of advance directive or living will and have no known living relatives or close friends who might act as SDM. In these instances, exhaustive efforts should be pursued to learn of the patient's social and medical history, all attempts should be made to identify any previously articulated wishes, the best interests of the patient should be objectively assessed, and all treatment options should be considered. A *synthetic judgment* may then be formulated that takes into account all of the information that has been gathered. In scenarios such as these, consultation of the hospital ethics and legal resources is often of substantial value to help achieve an objective assessment that is free of bias or paternalism and is legally defensible. If consensus as to a reasonable assessment of the patient's wishes cannot be achieved, it may be necessary to engage the legal system to appoint a guardian.

Informed consent

When the issue of who shall consent for treatment decisions is established, it is the ethical duty of a physician to acquaint the patient or proxy with information regarding the risks and benefits of the proposed treatment, so that the autonomy of the patient can be respected in accepting or declining. The

exact nature of the information in terms of detail, volume, and exhaustiveness may vary depending on the needs and preferences of the patient or SDM. Clearly, describing every possible outcome of a proposed treatment would be burdensome and potentially frightening to patients, but some important subset of all possible outcomes should be presented to the patient or SDM. Several standards have been proposed to describe this subset.

Reasonable person standard

This standard is used to describe the amount and type of information that a reasonable person would be expected to want to know before deciding on a treatment plan. It assumes that the vast majority of patients would want to hear the same information, and it is somewhat hamstrung as a guide when patients themselves are unreasonable.

Standard of care

This concept, which can also be called the reasonable physician standard, implies that there is a set of information that a prudent, responsible physician in that patient's community should tell a patient or SDM. Although it seems superficially attractive, this concept has been challenged as focusing on the needs of the physician.

Subjective standard

This standard implies a titration of the level and quantity of information given to the patient in proportion to his or her ability to process and use it. The physician decides how much to tell the patient based on the patient's intellectual, emotional, and spiritual characteristics. Some highly intelligent patients may request to be spared a detailed description of potential harm from a treatment; in such cases it is ethical to honor their request, so long as they have a basic understanding of the treatment. Similarly, relatively uneducated patients or SDMs may require risks and benefits described in exquisite detail before they are ready to decide. Here the physician is ethically bound to be thorough but may set limits should the process become overly burdensome.

Waiver of consent

Only under highly stringent conditions is it acceptable to forgo the informed consent process. The most obvious is in the setting of a medical emergency wherein delay in treatment for the purpose of obtaining consent might genuinely risk causing harm to the patient. The more difficult cases occur when the patient has lost decisional capacity and has no health care proxy. Here the terms *presumed consent* and/or *implied consent* have been used. As previously noted in the discussion of competence, these scenarios mandate careful attempts to ascertain the patient's own wishes, and the involvement of hospital ethics resources is often warranted.

End-of-life care

As noted earlier in the text, many patients die in the ICU, often after a long and protracted course during which the clinical picture has changed many times, fostering periods of both optimism and despair. The most common ethical challenges in this setting surround changing the goals of medical care from cure oriented to comfort focused. Several issues frequently arise in this regard.

Withholding life-sustaining therapies

The decision to forgo life-sustaining therapy may be made by a competent patient, in which case the physician is ethically bound to honor this decision. Psychiatric consultation to rule out depression with suicidal ideation may be appropriate in this setting. If a physician feels that he or she cannot ethically continue to care for the patient who refuses a life-sustaining intervention, that physician is ethically obligated to identify and transfer care to a physician who is willing to care for the patient.

The decision to withhold life-sustaining therapy from the incompetent patient is more complicated. Although a SDM may make this decision based on previous discussions with the patient, it is no longer the patient speaking, and a high degree of certainty is warranted given that the consequence of forgoing life-sustaining therapy is usually death. In many states, the power of the SDM is somewhat limited, and decisions to withhold life-sustaining therapy must be supported by "convincing evidence" that this decision accurately reflects the patient's previously stated wishes. On occasion, there may be disagreement between the medical care team and the SDM as to whether life-sustaining therapy should be initiated. The medical care team is not ethically or legally obligated to provide treatment that it does not believe will benefit the patient simply because such treatment is requested; in these instances, ethics consultation is recommended as well as engagement of the hospital legal department to provide an objective assessment of the contradictory opinions. Ethics consultation services are generally not expected to settle decisions, but rather to ensure that all voices have been heard and then to provide non-binding recommendations for ethically defensible courses of action.

Do not resuscitate (DNR) orders constitute a specific prescription of rescue measures taken in a setting of impending or actual cardiac arrest. Cardiopulmonary resuscitation (CPR) and advanced cardiac life support (ACLS) protocols were designed to rescue individuals suffering from reversible medical events such as acute myocardial infarction, yet the concept has been extended to the default assumption that this is desired by all hospitalized patients. That is, unless a patient or SDM requests that resuscitation not be performed, it is assumed that the patient desires or would desire this intervention. The scenario is unusual in that there are few, if any, other interventions that patients are assumed to elect or accept, and yet it is clear that, for a great many critically ill patients, this intervention has no potential for benefit, whether desired or not. Indeed, many

patients and SDMs choose to decline CPR and ACLS at the end of life, once they understand the procedures and their potential benefits (or lack thereof). Frank discussions between the care team and the patient or SDM should be held whenever possible to establish the patient's goals and preferences for treatment. Furthermore, it should be clarified that the decision to forego interventions such as CPR and ACLS is not equivalent to declining aggressive care, but rather applies specifically to those particular interventions.

Withdrawing life-sustaining therapies

It is widely accepted both ethically and legally that there is no a priori difference between withholding and withdrawing life-sustaining therapies. That is not to say, however, that there is no difference between the two *processes*. Studies of physician attitudes have shown that physicians have greater misgivings about withdrawing therapies that have already been instituted than about withholding the same therapies to begin with. This distinction naturally extends to family members and SDMs as well. The psychological stigma of taking life-sustaining therapy away – “pulling the plug” – rather than never initiating it in the first place clearly resonates, even if it has no ethical or moral basis. Further complicating the withdrawal of life-sustaining therapies is the fact that this process will often require sedative and/or analgesic medication to ensure the patient's comfort, and the administration of these medications may hasten death.

Providing comfort at the end of life

When the decision is made to seek comfort as a primary goal rather than to pursue a curative therapeutic approach, the objectives become the control of pain and prevention of the discomfort of respiratory distress. Analgesic medications, most commonly opioids, are widely used to achieve these goals, but they comport the additional effect of potentially hastening death through respiratory depression or conceivably hypotension. The tension between the goal of achieving comfort for the patient and the ethical duty not to cause a patient's death is traditionally resolved philosophically by the principle of the *double effect*. First espoused by Roman Catholic theologians in the Middle Ages, this concept permits an otherwise morally unacceptable effect (hastening death) even if it is foreseeable, when the primary intent is inherently good (relief of suffering). The concept of proportionality is important in that the good effect must outweigh the bad, with a net benefit being realized by the patient. This concept is helpful in resolving many ethical dilemmas in end-of-life care, but it must be acknowledged that not all situations lend themselves to being resolved via this line of reasoning. For example, the decision to withdraw mechanical ventilation from a ventilator-dependent patient, an action that would typically be accompanied by heavy sedation to prevent the suffering of respiratory distress (*terminal sedation*), is not permitted under the principle of double effect. The rationale is that the primary act (removal of the ventilator) is not inherently good (results in the death of the patient), hence the use

Table 167.1. The “slippery slope”

Relief of pain and suffering
Comfort measures only
Physician-assisted suicide
Voluntary euthanasia
Nonvoluntary euthanasia
Involuntary euthanasia
Killing/murder

of sedation to prevent the possibility of suffering is not permissible. Thus the acceptability of a physician potentially hastening a patient's death depends on a number of factors and will vary substantially depending on the moral community within which the physician functions. A gradient of possible behaviors in terms of physicians' hastening of death can be described and is sometimes referred to as a *slippery slope* (see Table 167.1).

Relief of pain and suffering, even while carrying out an aggressive curative treatment approach, is an ethical obligation for the physician to pursue. *Comfort measures only* refers to the abandonment of a curative approach with an emphasis on achieving comfort, though recent data suggest that early palliative care may even prolong life. As mentioned before, such measures may secondarily hasten the death of the patient. Here already, some physicians may feel uncomfortable, believing that every possible effort must be expended to preserve life and that the quest for cure should never be abandoned. *Physician-assisted suicide* refers to a physician aiding a patient who requests assistance in hastening death, usually by providing the patient the means with which to commit suicide. Although this practice is not widely considered ethically acceptable in the United States, it is legal in two states and is known to occur on an undocumented basis with some frequency. *Voluntary euthanasia*, in which a physician commits an act that hastens death at the request of the patient, is illegal and not widely practiced in this country but is permitted in some Western societies, such as the Netherlands. *Nonvoluntary euthanasia* is the hastening of death by a physician of a patient who has not expressed a wish to die, and *involuntary euthanasia* is the hastening of death of a patient who has specifically expressed a wish not to die. Neither of these actions is ethically acceptable in Western societies. Killing and murder are generally morally and ethically forbidden for physicians, but even here societal exceptions may exist in the setting of capital punishment or war.

The concern arises that if hastening death is permissible in the context of providing comfort for terminally ill and suffering patients, then the rather subjective criteria by which such patients are identified (terminal, suffering) might become sufficiently flexible that euthanasia also becomes permissible. Although there is substance to this argument (when taken to the extreme), extending it could prohibit relief of suffering and obstruct the responsibility of the physician to do what is within his or her power to attenuate suffering when cure is not possible. The position taken by most practitioners in this country involves the liberal use of opioids for patients who carry a terminal diagnosis with a life expectancy that is measured in days

to weeks, but there is scant legal or professional support for more aggressive measures, such as physician-assisted suicide or euthanasia.

Futility

Much controversy has surrounded the concept of medical futility. Attempts in recent decades to define futility in an objective and non-value-based context have essentially been unsuccessful. The goal of defining futility has at its core the observation that, with advances in life-sustaining therapies, patients could be kept from dying almost indefinitely but could fail as well to make any progress toward recovery. This use of expensive and intensive medical resources tends to have a demoralizing effect on care teams, and efforts to define futile care have been undertaken. A declaration of futility would then justify the withdrawal of aggressive, life-sustaining therapy. The process of defining futility is fraught with problems, however. First, it ignores the generally dominant principle of autonomy. That is, if a patient or SDM desires to continue life-sustaining therapy, the declaration of futility would override this preference; this selective violation of autonomy does not have, in the United States, much traction, although it is accepted and practiced in many other Western countries. Second, a declaration of futility requires some prognostic certainty. It is an uncomfortable truth that physicians' abilities to prognosticate, however refined and aided by advanced technology, are imperfect and subject to error. When the consequences of decisions based on such predictions frequently involve death through withdrawal of life-sustaining therapies, the prognostic certainty must be high indeed. Third, the argument that such use of intensive therapies places a financial burden on the health care system has not been borne out in economic analyses. The number of patients in such predicaments is so small as to have a trivial effect on overall health care expenditures. Finally, inherent in the notion of futility is a predefined assumption of what constitutes a *life worth living*. This is so deeply subjective that it in fact defies definition; existences that many would define as completely intolerable are in fact perfectly acceptable to those inhabiting them.

Keeping all of these issues in mind, there are clear cases of medical futility wherein the likelihood of recovery is so minute as to be dismissed. In these cases, there is often concern on the part of the care team that far more suffering is being inflicted than benefit being obtained by the patient. Typically, these scenarios involve SDMs who insist that the patient would have wanted every attempt made to sustain life. These situations are particularly challenging to care team members, not only because of the sense that they are participating in care that is ultimately more harmful than good, but because, despite their expertise, they are disempowered to change the course of care. Care team members may feel that their integrity is being compromised, leading to resentment and creation of an oppositional relationship with the patient, SDM and/or family members. Given these challenges, most institutions have established futility policies that are to be used when consensus cannot be reached as to the appropriateness of discontinuing

life-sustaining therapies. These policies tend, for the reasons just mentioned, to be extremely stringent, requiring objective second medical opinions, extensive involvement of ethics and legal services, and significant mandatory waiting periods. The state of Texas is currently unique in having codified such procedures through legislation; of note is that the law has been called upon only infrequently since its passage, and so far it has not been subjected to judicial challenge.

Truth telling and disclosure

The last decade has seen a sweeping change in attitudes toward disclosure of medical errors, events that occur with higher frequency and with higher stakes in the ICU due to the severity of the patients' conditions. The patient safety movement, spurred by the Institute of Medicine report in 1996 that suggested that between 44,000 and 98,000 patients a year die as a result of medical errors, has revolutionized the approach to medical error. The widespread culture of secrecy and silence in the wake of a medical error was largely fueled by a concern for medicolegal and professional liability. When investigations of errors were performed, the goal was commonly to identify an individual to blame and censure, further reinforcing the desire on the part of physicians for secrecy and evasion. The result of this culture was that the systems of care that were actually to blame were not identified, but rather allowed to persist. Error, rather than being accepted as an inevitable characteristic of human behavior, was reviled and prosecuted. As a more enlightened realm of thought has evolved over the last decade, the attitude toward human error has undergone a complete reversal, and most institutions are now embracing the concept of disclosure of adverse medical events to patients when they occur. Disclosure policies generally consist of three components: a prompt and honest acknowledgment that an error has taken place, an apology or expression of sympathy for its consequences, and a pledge that work is underway to identify the cause of the error and prevent the same event from occurring again. The obvious concern is that this disclosure exposes physicians to the risk of embarrassment, professional censure, and litigation. This risk is felt to be outweighed by the benefits, which begin with the fact that telling patients the truth is the only morally and ethically defensible action. Furthermore, openness and transparency enhance trust on the part of the patient, family, and care team. Reviews of litigation have shown that a majority of patients seek legal redress because of communication failures involving the patient, family, and physician. Ultimately, this act of disclosure begins the process of investigating how the system or process of care can be better designed to prevent similar adverse events from recurring in the future. As this is a relatively new approach within the culture of medicine, it is not yet clear what the overall effect will be on rates of litigation or on overall costs to the health care system.

Middlemen (and women)

No discussion of ethics in the ICU would be complete without acknowledging the position of middlemen. These individuals

are members of the health care team, most commonly nurses, fellows, and resident physicians who may be asked to provide patient care that they feel is unethical or causes moral distress, but whose position in the hierarchy does not permit them to express their sentiments or to participate in decisions regarding trajectory of care. This scenario is particularly common in surgical ICUs, where the team in the ICU may have a perspective on a patient's condition that differs from that of the operative surgeon. These conflicts are not easily resolved, for there often is a plethora of ethical viewpoints represented within an ICU care team. Consensus as to what the patient would want, or even what is in the patient's best interest, can be difficult to achieve. In such instances, an institutional mechanism should be available so that individuals who are experiencing moral discomfort or who feel that ethical principles are being violated can express their concerns. In many institutions, use of the ethics consultation service provides such a mechanism; ideally the service can be engaged by anyone, from patient to caregivers to family members to housekeepers, when a question of ethical concern is raised. This resource is extremely important for middlemen, who, due to their intermediary positions in the hierarchy, cannot act as independent agents. Ethics consultation provides a protected and acceptable route for such morally stressed individuals to express their concerns. Again, although ethics consultants do not have the authority to dictate care, they do have the experience and knowledge to consider the concerns of all of the stakeholders and to provide recommendations for ethically defensible plans of care. Even in the absence of a resultant change in the plan for a patient's care, middlemen are often substantially relieved simply to have had their voice heard.

Considerations for the operative anesthesiologist

For the operative anesthesiologist, the ethical issues involving ICU patients come into play most commonly when operative interventions are needed or when assistance with airway management is requested. The circumstances surrounding these events are often characterized by an emergent need for intervention, with little time available for assessment of ethical concerns. In such instances, such as when a patient's wishes regarding endotracheal intubation are unclear, it is ethical for the anesthesiologist to intervene if it appears that the patient is in danger of harm or death in the absence of immediate action. If time permits, however, the anesthesiologist should ascertain that such issues as the goals of therapy and consent for treatment, have been adequately discussed with the patient or SDM. If this is not the case, the process of obtaining informed consent for anesthesia constitutes an opportunity to discuss those issues.

The specific instance of a patient who has asked not to be resuscitated at the end of life (DNR), but who has agreed to a

surgical procedure merits specific mention. A clear discussion regarding whether to continue or suspend the DNR status for the time of the procedure and recovery is critical. Patients or surrogates who ask to continue the DNR status while undergoing general anesthesia and surgery present a particular problem for the anesthesiologist. Agreeing to such an arrangement means agreeing to not resuscitating the patient from many potentially reversible complications in the course of surgery and anesthesia. It is ethically defensible for an anesthesiologist to agree to these terms; however, it is also ethically sound for an anesthesiologist to refuse to care for a patient under such circumstances, so long as he or she can identify another anesthesiologist who is willing to assume the care of the patient under those constraints.

Conclusion

This review of common ethical problems in the ICU is meant to be neither exhaustive nor definitive, but rather is meant to highlight the ethical issues commonly faced in this setting. There is a recent overall trend toward identifying and addressing ethical questions head-on within health care institutions, and this has led to the formalization of ethics consultation services and committees in most hospitals. As the volume of this work has increased, so has the skill and experience of its practitioners, and the value of their contributions to the overall medical care environment cannot be overestimated. The fundamental messages of this chapter are simple: the intersection of extreme severity of disease and the diversity of moral communities present in our society will lead to the frequent emergence of complicated ethical questions in the ICU. Although no canonical guidelines for ethical actions can be identified, practical general principles exist, and local expertise in this realm within health care institutions is rapidly burgeoning. Robust use of the guidance provided by ethics services in situations of uncertainty can be of immense value, and their perspective and input should be pursued with impunity.

Appendix: Pre-use checking of anesthesia equipment

Yasodananda Kumar Areti

A major contributory cause of anesthesia misadventure has been the use of anesthesia machines and/or breathing systems that have not been adequately checked by an anesthesiologist before use. The following is the U.S. Food and Drug Administration (FDA)-recommended pre-use checkout procedure.

Anesthesia apparatus checkout recommendations: US FDA, 1993

This checkout, or a reasonable equivalent, should be conducted before the administration of anesthesia. These recommendations are only valid for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing system pressure monitor with high- and low-pressure alarms. This is a guideline that users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should undergo appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low-pressure leak test (step 5).

Emergency ventilation equipment

- *1. Verify backup ventilation equipment is available and functioning.

High-pressure system

- *2. Check oxygen cylinder supply.
 - a. Open O₂ cylinder and verify at least half full (about 1000 psi).
 - b. Close cylinder.
- *3. Check central pipeline supplies.
 - a. Check that hoses are connected and pipeline gauges read about 50 psi.

Low-pressure system

- *4. Check initial status of low-pressure system.
 - a. Close flow control valves and turn vaporizers off.
 - b. Check fill level and tighten vaporizer's filler caps.
- *5. Perform leak check of machine's low-pressure system.
 - a. Verify that the machine master switch and flow control valves are OFF.
 - b. Attach "Suction Bulb" to common (fresh) gas outlet.
 - c. Squeeze bulb repeatedly until fully collapsed.
 - d. Verify that bulb stays fully collapsed for at least 10 seconds.
 - e. Open one vaporizer at a time and repeat "a" and "b" as above.
 - f. Remove suction bulb and reconnect fresh gas hose.
- *6. Turn on machine master switch and all other necessary equipment.
- *7. Test flowmeters.
 - a. Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flowtubes.
 - b. Attempt to create a hypoxic O₂/N₂O mixture and verify correct changes in flow and/or alarm.

Scavenging system

- *8. Adjust and check scavenging system.
 - a. Ensure proper connections between the scavenging system and both APL (pop-off) valve and ventilator relief valve.
 - b. Adjust waste gas vacuum (if possible).
 - c. Fully open APL valve and occlude Y-piece.
 - d. With minimum O₂ flow, allow scavenger reservoir bag to collapse completely and verify that absorber pressure gauge reads about zero.
 - e. With the O₂ flush activated, allow the scavenger reservoir bag to distend fully, and then verify that absorber pressure gauge reads >10 cm H₂O.

Breathing system

- *9. Calibrate O₂ monitor.
 - a. Ensure monitor reads 21% in room air.
 - b. Verify low O₂ alarm is enabled and functioning.
 - c. Reinstall sensor in circuit and flush breathing system with O₂.
 - d. Verify that monitor now reads > 90%.
10. Check initial status of breathing system.
 - a. Set selector switch to “Bag” mode.
 - b. Check that breathing circuit is complete, undamaged, and unobstructed.
 - c. Verify that CO₂ absorbent is adequate.
 - d. Install breathing circuit accessory equipment (e.g., humidifier, PEEP valve) to be used during the case.
11. Perform leak check of the breathing system.
 - a. Set all gas flows to zero (or minimum).
 - b. Close APL (pop-off) valve and occlude Y-piece.
 - c. Pressurize breathing system to about 30 cm H₂O with O₂ flush.
 - d. Ensure that pressure remains fixed for at least 10 seconds.
 - e. Open APL (pop-off) valve and ensure that pressure decreases.

Manual and automatic ventilation systems

12. Test ventilation systems and unidirectional valves.
 - a. Place a second breathing bag on Y-piece.
 - b. Set appropriate ventilator parameters for next patient.
 - c. Switch to automatic ventilation (Ventilator) mode.
 - d. Fill bellows and breathing bag with O₂ flush and then turn ventilator ON.
 - e. Set O₂ flow to minimum, other gas flows to zero.
 - f. Verify that during inspiration bellows delivers appropriate tidal volume and that during expiration bellows fills completely.
 - g. Set fresh gas flow to about 5 L/min.
 - h. Verify that the ventilator bellows and simulated lungs fill and empty appropriately without sustained pressure at end expiration.
 - i. Check for proper action of unidirectional valves.
 - j. Exercise breathing circuit accessories to ensure proper function.
 - k. Turn ventilator OFF and switch to manual ventilation (Bag/APL) mode.
 - l. Ventilate manually and assure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.
 - m. Remove second breathing bag from Y-piece.

Monitors

13. Check, calibrate, and/or set alarm limits of all monitors.
 - a. Capnometer
 - b. Oxygen analyzer
 - c. Pressure monitor with high and low airway alarms
 - d. Pulse oximeter
 - e. Respiratory volume monitor (spirometer)

Final position

14. Check final status of machine.
 - a. Vaporizers off
 - b. APL valve open
 - c. Selector switch to “Bag”
 - d. All flowmeters to zero
 - e. Patient suction level adequate
 - f. Breathing system ready to use

***If an anesthesia provider uses the same machine in successive cases, these steps (1 to 9) do not need to be repeated or may be abbreviated after the initial checkout.**

Automated checkout

Clinicians fail to check their equipment thoroughly, are often not successful in detecting machine faults, or they do not check their machines at all. Despite extensive instruction, anesthesia residents, at best, could only perform 81% of a checkout procedure. Hence, automated checkout is incorporated in newer machines (Datex-Ohmeda S/5 ADU, Dräger Julian, NM 6000, Fabius GS). They are unique in having a system checkout routine that is electronic and automated. The operator follows instructions to activate flows of gases, occlude the breathing circuit during the leak check, switch from manual to mechanical ventilation, open and close the pop-off valve, or manually check various functions (suction, or emergency oxygen cylinder supply). It covers all the steps of the FDA checklist. The system checkout is logged, but may be bypassed in an emergency.

Despite these automated procedures, not every fault, obstruction, crossed connection, disconnection, or incompetent valve may be detected. It may not be obvious to the clinician as to what the machine is testing. Hence in addition to automated checkouts, anesthesiologists must develop appropriate manual checklists to suit the apparatus being used. The anesthesia delivery systems have evolved to the point that one checkout procedure is not applicable to all anesthesia delivery systems currently on the market. Hence the ASA (American Society of Anesthesiologists) subcommittee on equipment and facilities in 2008 recommended a template for developing checkout procedures that are appropriate for each individual anesthesia machine design and practice setting (Tables A1 and A2). Items that are not evaluated by the automated checkout

Table A1. Summary of checkout recommendations by frequency and responsible party (to be completed daily)

Item to be completed	Responsible party
Item #1: Verify auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning	Provider and Tech
Item #2: Verify patient suction is adequate to clear the airway	Provider and Tech
Item #3: Turn on anesthesia delivery system and confirm that AC power is available	Provider or Tech
Item #4: Verify availability of required monitors, including alarms	Provider or Tech
Item #5: Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine	Provider and Tech
Item #6: Verify that the piped gas pressures are ≥ 50 psig	Provider and Tech
Item #7: Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed	Provider or Tech
Item #8: Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet	Provider or Tech
Item #9: Test scavenging system function	Provider or Tech
Item #10: Calibrate, or verify calibration of, the oxygen monitor and check the low oxygen alarm	Provider or Tech
Item #11: Verify carbon dioxide absorbent is not exhausted	Provider or Tech
Item #12: Breathing system pressure and leak testing	Provider and Tech
Item #13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider and Tech
Item #14: Document completion of checkout procedures	Provider and Tech
Item #15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care (ANESTHESIA TIME OUT)	Provider

need to be identified, and supplemental manual checkout procedures included as needed. Adaptation of the pre-anesthesia checkout to local needs, assignment of responsibility for the checkout procedures, and training are the responsibilities of the individual anesthesia department. These guidelines and examples of institution-specific procedures for current anesthesia delivery systems are available on the ASA website (see list).

Table A2. Summary of checkout recommendations by frequency and responsible party (to be completed prior to each procedure)

Item to be completed	Responsible party
Item #2: Verify patient suction is adequate to clear the airway	Provider and Tech
Item #4: Verify availability of required monitors, including alarms	Provider or Tech
Item #7: Verify that vaporizers are adequately filled and if applicable that the filler ports are tightly closed	Provider
Item #11: Verify carbon dioxide absorbent is not exhausted	Provider or Tech
Item #12: Breathing system pressure and leak testing	Provider and Tech
Item #13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider and Tech
Item #14: Document completion of checkout procedures	Provider and Tech
Item #15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care (ANESTHESIA TIME OUT)	Provider

Special Topics

Bhavani S. Kodali, editor

Bronchopleural fistula

Ju-Mei Ng and Peter Gerner

A bronchopleural fistula (BPF) is a pathologic connection between an airway and the surrounding pleural cavity. A BPF may occur by breakdown of a bronchial suture line after pulmonary resection; from spontaneous rupture of a lung abscess, bulla, or cyst; or by erosion of a bronchus by carcinoma or chronic inflammatory disease of the lung parenchyma. More commonly, it is a postoperative complication following lobectomy or pneumonectomy. Predisposing factors for postoperative BPF include preoperative radiation therapy, infection, right-sided pneumonectomy, residual neoplasm, a long bronchial stump without coverage, and prolonged intubation. Symptoms may include intermittent (small BPF) or persistent (large BPF) air leak, subcutaneous emphysema, dyspnea, and purulent drainage from the chest tube, or development of an empyema.

Surgical management

Small fistulas may close spontaneously. If surgical intervention is necessary, it ranges from application of fibrin glue via bronchoscopy to thoracotomy requiring flap closure of the stump. Surgical repair may either be primary (early cases) or require drainage of an empyema followed by delayed corrective surgery.

Anesthesia management

Preoperative management

Determination of the size of the BPF

These patients should have a chest tube in place already. If the air bubbling through the water seal chamber of the chest tube drainage system occurs only intermittently with deep breathing or coughing, then one can reasonably assume that the fistula is small. A continuous, persistent leak indicates involvement of a larger fistula. A more quantitative approach is to determine the difference between inspired and expired tidal volumes. This is easy in a ventilated patient, but can be done in a spontaneously breathing patient using a tight-fitting mask and a fast-responding spirometer.

If the patient is mechanically ventilated preoperatively, the ventilator settings should be determined and the amount of tidal volume lost via the leak assessed. It is important to make

sure it will be possible to take the patient off that specific ventilator to transport him or her to the operating room (OR) and it will be possible to ventilate the patient with the OR ventilator. Some older models do not provide enough gas flow to compensate for the leak. In rare cases, an intensive care unit (ICU) ventilator might have to be brought to the OR.

Review of chest radiographs

BPFs may result in entrainment of pleural fluid (often infected) into the bronchus with spillage to the other lung. If there is additional injury to the contralateral lung, it may greatly impair the ability to insure adequate oxygenation during the procedure.

If the patient is not ventilated and the BPF is determined to be small, it is necessary to decide whether the patient will tolerate a brief period of positive pressure ventilation prior to lung separation. Even if the BPF is thought to be small, the anesthesia provider must be ready to provide lung isolation immediately. A small BPF may be larger than anticipated or may open up with positive pressure, making it impossible to ventilate the patient without lung isolation. Lung isolation as early as possible is also necessary if there is potential for spillage of the nonaffected lung with empyema fluid from the lung with the BPF.

Intraoperative management

There are several considerations for induction if the patient is not already on the ventilator. If there is a small leak and the plan is to have a period of positive pressure ventilation prior to lung isolation, it is useful to take the chest tubes off suction and place them on water seal. This will decrease the air leak but still prevent a tension pneumothorax from developing. If the patient does not yet have a chest tube, it is imperative to talk to the surgeons about placing one under local anesthesia prior to induction of anesthesia and commencement of positive pressure ventilation. Even an inhalational induction with spontaneous ventilation is problematic as breath holding or laryngospasm may require unplanned institution of positive pressure ventilation, which may lead to the development of a tension pneumothorax. If the surgical plan requires a diagnostic bronchoscopy, a single-lumen tube (SLT) is needed for bronchoscopy. Depending on the size of the BPF, a massive air leak might be

encountered. Therefore, in such cases it is preferable to perform an awake surgical bronchoscopy (through a laryngeal mask airway, if necessary), prior to induction of anesthesia. If a large leak through the BPF is anticipated, a sevoflurane mask induction or a combination of low-dose propofol, remifentanyl, and sevoflurane are both useful techniques. While maintaining spontaneous ventilation, intubation with a double-lumen tube (DLT) should be performed and one-lung ventilation (OLV) initiated. This approach avoids the situation of being unable to ventilate the nonaffected lung secondary to all gas escaping through the BPF. If a very large leak is present, the safest method is to perform an awake fiberoptic intubation with a DLT. If positive pressure ventilation is applied prior to lung isolation, mean and peak airway pressures should be minimized and the time spent ventilating the fistula limited. Thoracic epidural anesthesia reportedly has been used as the only mode of anesthesia and may be considered under certain circumstances.

Lung isolation techniques

DLTs, bronchial blockers, and selective intubation of the left mainstem bronchus with an SLT (if the BPF is right-sided) are all options for lung isolation. Generally, intubation of the right mainstem bronchus with an SLT for a left-sided BPF is not optimal, as the right mainstem is too short to accommodate the cuff without obstructing the take-off for the right upper lobe bronchus.

If the BPF is recent and not infected, it may be possible to perform a primary repair. Otherwise, the surgeon will simply drain the empyema and pack the fistula. In most cases, this approach will significantly decrease, but not eliminate, the air leak. For all cases in which the BPF is not repaired, the anesthesiologist will need to discuss postoperative management with the recovery unit or ICU team. If there is still a significant air leak, it may be necessary to continue OLV in the ICU. If the patient is too hypoxic to tolerate prolonged OLV, one possible approach is to ventilate both lungs independently using a DLT and separate ventilators.

It may be difficult to determine optimal ventilation by tidal volume measurements alone. Whenever there is a large air leak, much of the tidal volume exits via the chest tubes. The tidal volumes reported by the ventilator are measured in the expiratory limb and thus exclude the inspiratory volume lost via the chest tubes. Likewise, end-tidal CO₂ measurements also will be inaccurate. Frequent blood gas monitoring is required for optimum adjustment of the ventilator. Many ventilators have spirometry readings that permit a reasonably accurate assessment of the inspiratory tidal volume derived from the graphic display of volume versus time plot.

High-frequency jet ventilation for the management of BPF

Conventional intermittent positive pressure ventilation delivers relatively large tidal volumes at relatively low respiratory rates. High-frequency jet ventilation (HFJV) has been used based on the theory that it minimizes air leaks and mediastinal emphysema due to lower inspiratory pressures and tidal

volumes, leading to less gas leak through the BPF. However, several authors found that with HFJV, PaCO₂ was unacceptably high, or that no clinically important decreases in airway pressure and flow across the fistula occurred. In addition, HFJV is rather ineffective in patients with stiff (noncompliant) lungs, such as in acute respiratory distress syndrome or pulmonary fibrosis. Continuous positive airway pressure (CPAP) is an alternative to the treatment of hypoxia during OLV. The equipment and setup are more straightforward, and most anesthesiologists have experience with CPAP. For this reason, it is the more prudent first choice for treating hypoxia during OLV.

Postoperative management

It is usually best to resume spontaneous ventilation as soon as possible, because in many cases it significantly decreases the remaining leak. When it is not possible to extubate the patient, and the BPF is not completely repaired, ventilatory pressures must be minimized. Continuous high flow across a packed, but not completely repaired, fistula will simply prevent healing and closure. Pressure control ventilation may be quite useful, as the ventilator will not alarm for failure to deliver the set tidal volume and will cease inspiration reliably because expiration is time-triggered rather than flow-triggered (as in pressure support ventilation). Usually, the suction on the chest tube is also minimized as much as possible.

If the patient is to remain intubated, the care team must decide whether to leave the DLT in place or change to an SLT. The small internal diameter of the DLT causes a problem with pulmonary toilet. It is difficult to suction effectively, and bronchoscopy can be performed only with a pediatric scope. However, a DLT allows continuation of OLV, or immediate resumption of OLV if necessary. If the decision is made to change the tube, the anesthesiologist must avoid contact with the area of repair. This is of particular concern if the use of a tube changer is planned.

Inhaled nitric oxide

Wolfgang Steudel and Warren M. Zapol

In the fields of neonatology, critical care, and cardiothoracic anesthesia, nitric oxide (NO) has become a useful inhaled therapeutic agent over the past two decades. NO is a gaseous free radical with a short half-life (seconds) in blood and interstitial fluid. Inhaled NO binds rapidly to hemoglobin in the pulmonary vasculature of ventilated lung areas and induces selective pulmonary vasodilation. When low doses of NO are inhaled (~0.1–10 parts per million [ppm]), the distribution of ventilation to perfusion (V/Q) improves and PaO₂ increases. Inhaling higher concentrations of NO (~10–100 ppm) may decrease pulmonary artery pressure without lowering systemic vascular resistance (SVR) or systemic blood pressure.

Smooth muscle relaxation by NO

Inhaled NO stimulates the enzyme-soluble guanylate cyclase, which is responsible for conversion of guanosine 5'-triphosphate to cyclic guanosine monophosphate (cGMP). cGMP activates cGMP-dependent protein kinases, leading to vascular relaxation. The actions of cGMP are limited via its rapid catabolism by phosphodiesterases (Fig. 169.1).

Besides cGMP-dependent mechanisms, NO interacts independently of cGMP with heme-containing molecules and proteins containing reactive thiol groups. Also, NO interacts with superoxide radical, thereby limiting NO bioavailability and resulting in the formation of the potent oxidant peroxynitrite (ONOO⁻). In the presence of oxygenated hemoglobin (Hb), NO is rapidly metabolized to nitrate with formation of methemoglobin (met-Hb). Met-Hb in erythrocytes is rapidly reduced to ferrous-Hb by met-Hb reductase within the red cell.

Laboratory experiments

Pulmonary vasoconstriction

The ability of NO to selectively dilate the pulmonary vasculature was initially demonstrated in lamb acute pulmonary hypertension models using alveolar hypoxia (breathing 10% oxygen) or U46619 infusion (a synthetic thromboxane analogue) as the vasoconstrictor stimulus. Both cause pulmonary vasoconstriction and increase mean pulmonary artery pressure (MPAP). After inhaling NO at 40 ppm, the MPAP was decreased after a few breaths. The lamb's cardiac output and systemic arterial

pressure were not affected by NO inhalation. These results were later confirmed in healthy adult volunteers breathing hypoxic gas mixtures both at ambient pressure and in a high-altitude laboratory.

V/Q matching and oxygenation

The intrapulmonary distribution of blood flow and ventilation is a major determinant of the efficiency of transpulmonary oxygenation and results in high PaO₂. In a normal healthy lung, the best-ventilated areas are well perfused. The venous shunt (from the right to the left side of the circulation) is mainly extrapulmonary (e.g., via bronchial veins) and accounts for less than 5% to 8% of cardiac output. Local alveolar hypoxia constricts the vascular bed adjacent to the hypoxic region and redistributes blood flow toward lung regions with better ventilation, producing a higher PaO₂. It has been shown experimentally that inhaling NO in models of acute lung injury activates this mechanism, increasing PaO₂ by increasing the blood flow perfusing well-ventilated lung areas (Fig. 169.2).

Clinical uses

Neonatology

Full-term newborn babies

Persistent pulmonary hypertension of the newborn (PPHN) is a clinical syndrome characterized by sustained pulmonary hypertension and severe hypoxemia, often resulting in cyanosis unresponsive to oxygen therapy. PPHN may be caused by a variety of common etiologies (e.g., aspiration) or may be idiopathic. Diagnostic confirmation of PPHN includes echocardiographic observation of a right-to-left shunt through the ductus arteriosus or foramen ovale and is usually caused by an increased pulmonary vascular resistance (PVR) in the absence of congenital heart disease. Treatment strategies have included breathing at high inspired oxygen concentrations, hyperventilation, intravenous infusion of bicarbonate solutions to produce alkalosis, and surfactant administration. Extracorporeal membrane oxygenation (ECMO) is a high-risk therapy employed as a last resort to treat hypoxemia. However, the anticoagulation and cannulation of large vessels required for ECMO may produce hemorrhagic and ischemic complications, respectively.

Figure 169.1. NO signaling pathway in the lung. PKG, cGMP-dependent protein kinases; NOS, NO synthase; L-arg, L-arginine; sGC, soluble guanylate cyclases; RSNO, S-nitrosothiol. (Reprinted with permission from Ichinose et al. Inhaled nitric oxide. A selective pulmonary vasodilator. Current uses and therapeutic potential. *Circulation* 2004; 109: 3106–3111.)

In 1990, it was discovered that inhaled NO (1–80 ppm) rapidly improved arterial oxygenation in many newborns with PPHN. The magnitude of the increase in arterial oxygen tensions of babies treated with inhaled NO was directly proportional to the degree of hypoxia before NO inhalation, and in a large percentage of infants breathing NO, the increased systemic oxygenation was maintained over time, even after NO inhalation was discontinued. Subsequently, several large controlled, randomized multicenter trials using inhaled NO in near-term and term hypoxic newborn patients were performed.

In most patients with PPHN and hypoxic respiratory failure, NO improved oxygenation and decreased the requirement for ECMO. These studies of term gestation newborns with PPHN led the US Food and Drug Administration to approve NO inhalation for this indication in December 1999.

Premature babies and newborns with bronchopulmonary dysplasia

Bronchopulmonary dysplasia (BPD) is a severe lung disease of premature babies that results from the absence or interruption of normal pulmonary alveolar/microvascular development. Ventilator-induced lung injury can produce additional lung damage. Several multicenter studies with encouraging results in more than 2000 babies reported that NO inhalation may decrease the incidence of BPD and death in prematurely born infants. Further trials are ongoing.

Critical care

Acute respiratory distress syndrome

Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are conditions involving acutely impaired arterial oxygenation. They are defined by the European–American Consensus Conference on ARDS as a ratio of PaO₂ to fraction of inspired oxygen (FiO₂) of 300 and 200, respectively, regardless of whether or how much positive end-expiratory pressure is used. Additional criteria are bilateral pulmonary infiltrates on the frontal chest radiograph and pulmonary capillary wedge pressure (PCWP) < 18 mm Hg without clinical evidence of

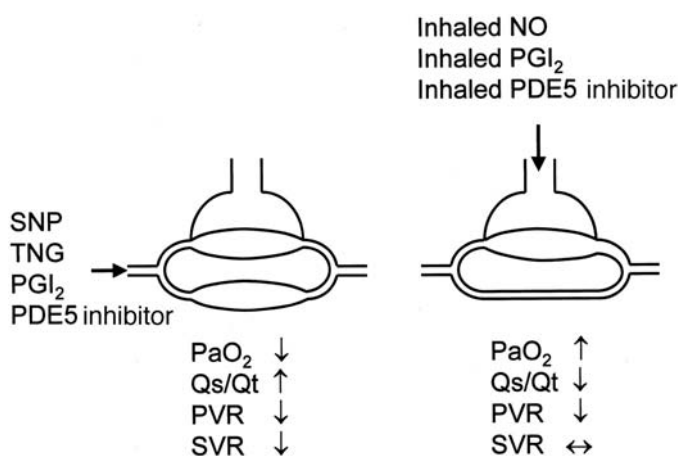

Figure 169.2. Differing pathophysiologic effects of inhaled pulmonary vasodilators and intravenous vasodilators. SNP, sodium nitroprusside; TNG, nitroglycerin; PGI₂, prostaglandin I₂; Qs/Qt, right-to-left shunt fraction; SVR, systemic vascular resistance. (Reprinted with permission from Ichinose et al. Inhaled nitric oxide. A selective pulmonary vasodilator. Current uses and therapeutic potential. *Circulation* 2004; 109:3106–3111.)

an elevated left atrial pressure on the chest radiograph. Predisposing factors for ALI/ARDS include chest trauma, aspiration and inhalation injury (causing direct lung injury), sepsis, pancreatitis, and massive blood transfusions (causing indirect lung injury). Although a downward mortality trend has been observed over the past few decades, the overall mortality of ARDS remains high and is estimated to be 40% to 50%.

Selective pulmonary vasodilation in ARDS

In severe ARDS, pulmonary hypertension augments pulmonary edema and may impede right ventricular (RV) function and decrease cardiac output. In patients with severe ARDS, it has been shown that inhaled NO may produce selective pulmonary vasodilation, at least transiently. NO-induced pulmonary vasodilation has been associated with improved RV performance, as indicated by improvement of RV ejection fraction and decreased RV end-diastolic and end-systolic volumes. Inhaled NO also effectively decreases the mean pulmonary artery pressure (MPAP) associated with the use of permissive hypercapnic ventilation.

Arterial oxygenation in ARDS

Severe hypoxemia caused by extensive intrapulmonary right-to-left shunting is characteristic of ARDS. Current strategies of management include lung recruitment by high levels of positive end-expiratory pressure, prone positioning, and ventilation with a high FiO_2 . Therapies that permit lower airway pressures and FiO_2 reduce the risk of barotrauma and oxidant injury to the lung. A landmark trial by the National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome Network in 2000 enrolling more than 800 patients concluded that low-tidal volume ventilation (<6 ml/kg) is a key strategy to reduce both mortality and time spent on the ventilator.

When inhaled NO is acutely administered at low concentrations (1–10 ppm), oxygenation improves in most ARDS patients. A recent prospective randomized trial in a small group of patients reported that the acute dose response (e.g., increase of PaO_2) is altered when patients inhale NO (10 ppm) for several days. A leftward shift of the dose–response curve was observed; for example, oxygenation improved at NO concentrations of 1 ppm but deteriorated at higher concentrations (10 or 100 ppm). This effect did not, however, translate into either improved survival or earlier weaning of these patients from ventilatory support.

Outcome in ARDS

Inhaled NO did not reduce the need for ventilatory support or reduce mortality in several single and multicenter trials. Due to the fact that patients with ARDS often suffer from severe multiple organ failure, the beneficial effects of NO inhalation are unlikely to alter overall survival. Several more recent trials in patients with ARDS confirmed the finding that inhaled NO does not improve patient outcome. In pediatric ARDS, there is a more optimistic view of the effect of inhaled NO on outcome and mortality.

Perioperative use

Anesthesia for cardiothoracic surgery

Congenital heart disease

Pulmonary hypertension leading to acute right heart failure may complicate the management of patients during and after cardiac surgery using cardiopulmonary bypass. Before and after the repair of congenital cardiac lesions, transient pulmonary hypertension is frequent. The underlying mechanisms causing pulmonary hypertension are damage to the pulmonary vascular endothelium, a reduced ability to produce NO by endothelial nitric oxide synthase, and possibly a noxious effect of the use of cardiopulmonary bypass. It has been shown that inhaled NO ameliorates the postoperative pulmonary hypertension of congenital heart disease and decreases the need for postoperative ECMO.

Coronary and valvular disease

Several studies have demonstrated that the inhalation of NO effectively decreases the pulmonary artery pressure when coronary artery bypass grafting or surgery for valvular heart disease is complicated by perioperative pulmonary hypertension. Patients with left ventricular valvular disease (primarily mitral stenosis and insufficiency) may have preoperative pulmonary hypertension caused by chronically increased left atrial pressure with retrograde transmission of that pressure into the pulmonary circulation. In these patients, pulmonary vascular remodeling occurs as a result of chronic pulmonary venous hypertension with subsequent chronic pulmonary arterial hypertension. Pulmonary vascular remodeling and vasoconstriction may persist or slowly decrease with time after valve replacement. Intra- or postoperative treatment with inhaled NO after repair of the valvular disease may relieve the vasoconstrictor component. However, no controlled clinical trial has been reported to confirm the effects of inhaled NO on pulmonary hypertension in this patient population.

Lung transplantation

Pulmonary artery hypertension frequently occurs in the immediate postoperative period after lung transplantation. Ischemia–reperfusion (I–R) injury to the graft remains one of the major causes of early graft failure after lung transplantation. Adhesion and sequestration of leukocytes by activated pulmonary endothelium in the graft is believed to be an important contributor to I–R injury. NO possesses anti-inflammatory properties, and inhaled NO can attenuate pulmonary I–R injury in preclinical studies. Inhaled NO may be beneficial for lung graft recipients who develop lung I–R injury, and it has been reported to be effective in the treatment of post–lung transplant pulmonary dysfunction. One study demonstrated that the use of inhaled NO after lung transplantation produced a lower overall mortality rate. Therefore, the immediate visible physiologic benefit (decrease of pulmonary artery pressure) may be followed by a

prolonged benefit (reduction of I–R injury) when inhaled NO is given after lung reperfusion and then continued in the postoperative period. However, further prospective randomized trials are needed to determine whether patient outcome is improved by inhaled NO therapy after lung transplantation.

Heart transplantation

The transplanted heart is particularly prone to develop right heart dysfunction and failure. The newly implanted (right) heart that is not adapted to an elevated PAP must pump blood through the recipient's pulmonary vascular bed, a vascular bed that has been chronically exposed to LV failure and may be restricted. To assess the feasibility of heart transplantation alone without lung transplantation (e.g., right heart adaptation to the pulmonary circulation), a preoperative pulmonary vasodilator response is a significant criterion. If there is preoperative vasodilation in response to inhaled NO, inhaled NO can be used intra- and postoperatively to support RV function via a reduction in right ventricular afterload (e.g., pulmonary vasodilatation).

Left ventricular assist device

RV dysfunction occurs in 10% to 20% of patients after insertion of an LV assist device (LVAD). The ability of the right ventricle to pump sufficient blood to the LVAD is critically dependent on RV contractility and afterload, both of which may be adversely effected by the presence of an elevated PVR due to the primary disease process and/or cardiopulmonary bypass. RV failures after LVAD placement are associated with a poor outcome and often require the addition of an RV assist device (RVAD). Inhaled NO is commonly added to dilate the pulmonary circulation and unload the right ventricle, thereby avoiding RVAD placement (although controlled trials have not been reported).

Diagnostic use

Cardiac catheterization laboratory

In the past, intravenous prostacyclin and calcium channel blockers were the standard drugs for the diagnostic testing of pulmonary vasoreactivity in patients with pulmonary hypertension. Unfortunately, systemic administration of these vasodilating agents may produce severe arterial hypotension and increased intrapulmonary right-to-left shunting, and at times may result in shock and death. In general, demonstration of a vasodilator response to these agents correlates with a more favorable response to oral vasodilators and an improved long-term clinical outcome for patients with pulmonary hypertension. Several studies have demonstrated that inhaled NO can be safely and effectively given to assess the capacity for pulmonary vasodilation in pediatric and adult patients with pulmonary hypertension, without causing systemic hypotension. The ability of inhaled NO to decrease the PVR and PAP in the catheterization laboratory can be used to predict the subsequent response to therapy with oral vasodilators. In adult patients with pulmonary hypertension due to congenital heart disease,

oral vasodilators can significantly improve survival. Therefore, because of its safety, inhaled NO has become the standard agent used to test safely pulmonary vasoreactivity in the catheterization laboratory.

Other uses

Right ventricular ischemia

RV coronary artery occlusion due to a thrombosis or obstruction by air (during and after cardiac surgery) may lead to RV myocardial dysfunction and RV infarction (RVMI), which may be complicated by cardiogenic shock (despite preserved LV function). RVMI is associated with a high mortality rate. A recent study of 13 patients with RVMI and cardiogenic shock demonstrated that when 80-ppm NO was inhaled for 10 minutes, there was a 13% decrease in MPAP and a 24% increase in cardiac index, with a stable systemic arterial pressure. A larger study group has not been reported because of the uncommon nature of this problem.

Liver transplantation

Recent data suggest that inhaled NO may lower hepatocyte apoptosis after orthotopic liver transplantation. Whether these preliminary observations will translate into beneficial effects in terms of graft survival and patient outcome is the subject of ongoing clinical studies.

Other nonpulmonary effects

In addition to the pulmonary effects of inhaled NO, a variety of systemic effects have been reported. NO can form stable, biologically active byproducts that have effects on various vascular beds in the body distant from the lung. Improvement of myocardial ischemia–reperfusion injury has become a major focus of recent research, as several experimental studies have shown beneficial effects of inhaling NO in mice and pig models of myocardial ischemia–reperfusion injury. NO metabolites such as S-nitrosothiols, and NO heme levels in erythrocytes, as well as nitrite and nitrate levels in plasma, increased significantly after NO breathing, and were accompanied by a nearly 50% decrease in experimental myocardial infarct size. Ongoing clinical trials of NO in MI are being conducted in Europe.

Inhaled NO does not reduce the mean SVR; however, it may alter regional blood flow. Significant systemic hypotension has not been observed in clinical studies of NO inhalation. NO breathing provides a convenient and safe technique for loading the NO metabolite stores of the body.

Metabolism

NO is inactivated by interaction with biological target molecules. The half-life of NO in vivo is only a few seconds. The main NO metabolic pathways are its binding to O_2^- and to the ferrous heme ring of hemoglobin, with the subsequent release of NO_3^- . The binding and release of NO to thiols presents another important metabolic pathway. Almost 70% of the inhaled gas appears within 48 hours as NO_3^- in the urine. The remaining

30% of inhaled NO is recovered as NO₃⁻ by secretion from salivary glands. NO₂⁻ is also partly converted to nitrogen gas in the stomach, and some NO₂⁻ in the intestine is reduced to ammonia, reabsorbed, and converted to urea.

Toxicity, administration, and monitoring

The major concerns of severe NO toxicity are methemoglobinemia, NO₂ formation, and cellular damage. A marked overdose of inhaled NO (>500–1000 ppm) leads to rapid gaseous NO₂ formation, severe methemoglobinemia, pulmonary edema and hemorrhage, and hypoxemia, and may cause death within minutes. Therefore, blood methemoglobin concentrations and inspired NO₂ concentrations have been closely monitored in clinical trials of inhaled NO in adults and neonates. In large clinical trials, lower doses of NO were clinically applied (1–80 ppm) and discontinuation of NO inhalation because of methemoglobinemia or NO₂ formation was extremely uncommon. It now is believed that the most important requirements for safe NO inhalation therapy are (1) administration of the lowest NO concentration required to produce the desired physiologic effect (usually pulmonary vasodilation), (2) continuous analysis of gas phase NO and NO₂ concentrations (usually with electrochemical analyzers), and (3) daily analysis of blood methemoglobin levels if administered at higher concentrations for prolonged periods (>20 ppm). If methemoglobinemia (>10%) occurs, it typically responds to a reduction in the inhaled NO concentration or to discontinuation of NO therapy.

NO is a colorless and odorless gas that readily reacts with oxygen to form the pulmonary irritant NO₂; therefore, it must be stored in nitrogen or another inert gas to minimize exposure to oxygen. NO and NO₂ concentrations should be continuously monitored when the gas is administered because the pulmonary vasodilator effects of NO are transient, and rapid pulmonary vasoconstriction may occur if the inhaled NO concentration decreases temporarily. NO delivery systems are commercially available and permit the clinician to provide safe NO inhalation therapy for long periods.

Rapid discontinuation of NO inhalation may result in “rebound” pulmonary vasoconstriction and hypertension with acute right heart failure, leading to a decreased cardiac output and systemic hypotension. After acute NO discontinuation, rebound pulmonary hypertension associated with an increase in intrapulmonary right-to-left shunting and a decreased PaO₂ has been reported. It has been suggested that down-regulation of endogenous NO synthesis by NO inhalation leads to this response. To safely wean the patient from inhaled NO, a slow stepwise reduction in the inhaled NO concentration with immediate control of any adverse effects (e.g., reduced oxygen saturation, arterial blood gas tensions or increased MPAP) is important. Administration of the phosphodiesterase 5 inhibitor sildenafil has been reported to prevent rebound pulmonary hypertension in children receiving NO after cardiac surgery.

Another risk of inhaled NO must be carefully considered when NO is given to patients with markedly impaired LV function (e.g., heart transplant candidates). Inhalation of NO may

vasodilate the pulmonary circulation and increase blood flow to the failing left ventricle, thereby acutely increasing left atrial pressure and PCWP and promoting pulmonary edema formation. Cardiac output and left atrial pressure or PCWP should be carefully monitored when inhaled NO is administered to patients with severe LV dysfunction.

Summary

The effects of NO on the pulmonary vasculature are unique. Selective and potent vasodilation of the pulmonary vasculature without systemic vasodilation and improvement of arterial oxygenation cannot be achieved safely by any other inhaled or systemically administered drug. NO inhalation has evolved into a very useful and safe clinical tool in neonatology, critical care, and perioperative medicine over the past 20 years. The use of inhaled NO has helped in saving many lives. About 30,000 patients receive inhaled NO in the USA each year, and about 36,000 patients have been treated with inhaled NO worldwide. Laboratory studies show that inhaled NO has effects that go beyond the pulmonary vasculature and may benefit an even larger patient population. NO has side effects that must be carefully monitored, but thoughtful practice makes it a safe drug to administer to a wide spectrum of patients.

Skin, the largest organ of the human body, can be divided into three layers: the epidermis, dermis, and subcutaneous tissue. Other components include hairs and follicles, sweat and sebaceous glands, nails, blood vessels, lymphatics, nerves, erector pili muscles, and melanocytes for pigmentation.

Human skin functions involve protection, sensation, body temperature regulation, control of evaporation, storage of lipids and water, vitamin D synthesis, excretion, and absorption. Collagen is the main protein in the skin, ligaments, bone, tendons, cartilage, and connective tissue. More than 20 types of collagen have been discovered; they play a critical role in maintaining the integrity of the tissues and other functions.

Anesthetic management and medication often alter the physiology of the skin. Diseases of the skin and collagen manifest with a variety of clinical signs and symptoms, knowledge of which is important for anesthesiologists because they may have significant impact on clinical management. In this chapter, we discuss the skin and collagen diseases of significant interest to the anesthesiologist.

Hereditary angioedema

Hereditary angioedema (HAE) is an autosomal dominant disorder with acute episodic nonpitting edema of the eyes, lips, larynx, mouth, tongue, face, genitalia, and bowels. It is caused by the leakage of plasma from postcapillary venules into the dermal layers of the skin. Angioedema attacks are often preceded by a “tingling” feeling in the affected areas. Abdominal pain also may accompany the onset and possibly results from peristaltic movement of the swelling bowel with some component of obstruction. Trauma, pressure, and emotional stress appear to cause the acute attack. The swelling is not usually symmetric nor circumscribed. However, airway edema secondary to swelling in the larynx may lead to asphyxiation and death. The attacks may happen at any age.

Pathophysiology of the disorder was thought to be low levels of C1 inhibitor (85%, type 1) or nonfunctioning C1 inhibitor (15%, type 2). Type 3 is designated for patients with HAE symptoms but no clear deficiency in the complement/kinin system. The gene for C1 inhibitor (*C1NH*) has been mapped to 11q12-q13.1. HAE is the result of a mutation within *C1NH* and often coexists with other allergic disorders (Table 170.1).

C1 is a complement system protein consisting of two C1r, two C1s, and six C1q molecules. During an immunologic response, C1 is activated by immune complexes or nonimmune activators. Without its normal inhibitor function, activated C1 will cleave the next two proteins, C2 and C4, triggering the classic complement cascade. The swelling episodes usually progress over a period of 12 to 24 hours. Symptoms may last up to 5 days.

For the treatment of HAE, antihistamines are ineffective. Instead, danazol, stanozolol, and methyltestosterone have been shown to be good long-term prophylactic therapies. However, side effects are somewhat common, and none of these is useful in the acute phase of the disease. Also, ϵ -Aminocaproic acid (EACA) and tranexamic acid have also been shown to be effective. Contraindications include advanced age, thrombosis, and hypercoagulable state.

For short-term prophylaxis, fresh frozen plasma, androgens, and plasmin inhibitors have been used. During the acute attacks, epinephrine and glucocorticoids are commonly required. Narcotics, purified C1 inhibitor, and EACA have been reported to abort the attacks and might be used in the perioperative setting. Newer agents are currently undergoing clinical trials in Europe; these include a kallikrein inhibitor and a bradykinin receptor antagonist.

Ehlers-Danlos syndrome

Ehlers-Danlos syndrome (EDS) is a group of more than 10 different types (type I–X) of inherited disorders. All these disorders involve genetic defects in collagen metabolism and connective tissue synthesis and structure.

Table 170.1. Laboratory study of different types of HAE

Type I	Type II	Type III
Low C1 inhibitor	Normal/elevated C1 inhibitor	Normal C1 inhibitor
	C1 inhibitor dysfunctional	Normal C1 inhibitor function
Low C2, C4 levels	Low C2, C4 levels	C4 level may be normal
Normal C1q level	Normal C1q level	Factor XII mutation may be present

Adapted from Heymann WR, Carolfi A, Hereditary Angioedema. Available at <http://emedicine.medscape.com/article/1048994-overview>, last accessed August 2010.

The prevalence of EDS in the United States is estimated to be one in 400,000 people. A new classification was introduced in 1997 to simplify the categorization of EDS into the classic, hypermobility, vascular, kyphoscoliosis, arthrochalasia, dermatosparaxis, and other types. All types of EDS share common joint hypermobility, skin fragility, bruising, poor wound healing and scarring, joint pain, and arthritis.

Some symptoms may occur with specific forms of EDS – for example, gum disease with type VIII and scoliosis with type VI. Type IV (vascular) is the most severe form of EDS. The pathogenesis of the disease is a result of the decreased or absent type I, III, and/or V collagen synthesis. It is associated with spontaneous rupture of bowel, uterus, or major blood vessels, as well as cervical spine or airway trauma. Preterm labor and excessive bleeding with delivery are common obstetric problems. Cardiac manifestation of EDS includes cardiac conduction abnormalities and valvular defects, such as mitral valve prolapse and regurgitation.

EDS patients are at risk for perioperative endocarditis. Prophylactic antibiotics may be indicated in the presence of cardiac murmur. Careful manipulation during laryngoscopy is necessary to avoid trauma to the airway. Complications of pneumothorax and bleeding from arterial and central venous line placement must be closely monitored and followed. Caution is needed in patients requiring regional anesthesia, because of the bleeding tendency.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a chronic multisystem autoimmune disease. Antinuclear antibodies are present in all patients with active SLE. Antibodies to native double-stranded DNA (anti-dsDNA) are relatively specific for the diagnosis. The clinical presentation of SLE is highly variable. The American College of Rheumatology has published detailed criteria for classification of SLE.

Given the nature of the disease, the need for involvement by multiple specialists is very common. Anesthesiologists should be aware of and familiar with their patients' disease progress and follow closely with the developments within the domain of each specialty, such as rheumatology, neurology, pulmonology, cardiology, gastroenterology, nephrology, dermatology, hematology, and infectious disease.

Management of anesthesia in patients with SLE is based mainly on the disease stage. Patients on chronic steroid therapy will need stress dose treatment perioperatively. Prudent evaluation and manipulation of the airway is necessary to avoid trauma and complications. Parturients with coexisting pulmonary hypertension with pulmonary parenchymal and vascular inflammation secondary to SLE have been reported.

Several rheumatoid and inflammatory conditions and diseases, such as scleroderma, CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome, and antiphospholipid syndrome, are closely related to or associated with SLE. Difficult venous access

is not trivial in these patients. Inhalation induction may be preferable; however, if gastric esophageal reflux is severe, aspiration precaution is necessary. Sellick's maneuver (application of cricoid pressure) may not be effective though, because the esophagus may be fibrosed as well. Stiff temporomandibular joints in these patients may create difficulty with regard to direct laryngoscopic endotracheal intubation. In addition, patients should be kept warm to avoid exacerbation of Raynaud's phenomenon. Arterial line placement is relatively contraindicated in patients with severe Raynaud's phenomenon. Ischemic changes in the distal limb should be monitored when practiced.

Epidermolysis bullosa

Epidermolysis bullosa (EB) consists of three major types: EB simplex, junctional EB, and dystrophic EB. The differences among the three are determined by the location of the lesion. EB simplex involves intraepidermal skin separation, whereas junctional EB is separation in the lamina lucida and basement membrane zone. Dystrophic EB is separation in the sublamina densa basement membrane zone.

EB simplex is caused mostly by genetic mutations in keratins 5 and 14. Several mutations may be responsible for junctional EB, including laminin 5 subunits, collagen XVII, α_6 integrin, and β_4 integrin. Dystrophic EB is associated with the gene for type VII collagen.

For patients with EB, a careful preoperative evaluation should be performed, including a detailed patient history and physical examination. Past history of disease process should be obtained. Intramuscular medication should be avoided. Monitoring devices with skin attachments may potentially damage the skin by adhesive taping or scratching. Artificial tears and ointment may be used to protect the eyes instead of tape or adhesive patches.

Extra caution should be used for intubation, suction, temperature probe placement, and other instrumentation. Epidural and spinal anesthesia reportedly has been successful in patients with EB and no lesions on the back; however, skin infiltration with local anesthetics is contraindicated.

In situations in which intubation is unavoidable, airway manipulation may be difficult in patients who have had recurrent injury and scarring. Fasciculation-induced tissue damage in response to succinylcholine with hyperkalemia has been reported, and sensitivity to nondepolarizing agents may be unpredictable. Although paralysis facilitates atraumatic intubation, tissue scarring and tongue fixation may compromise success; therefore, awake intubation may be preferable. Preparedness for emergent airway is always needed. Ketamine has been used successfully to achieve rapid induction while maintaining laryngeal reflexes.

Patients with severe cases of porphyria cutanea tarda may have signs and symptoms resembling dystrophic EB. Barbiturates and other enzyme-inducing agents should be avoided in these patients.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI), also called “brittle bone disease,” is a rare autosomal dominant disease. Mutations in several genes coded for proteins that contribute to type I collagen are identified with OI. Type I collagen, the most abundant type in humans, is found in bones, artery walls, tendons, fibrocartilage, and scars.

Clinical features of OI include osteomalacia and excess fractures, short stature, scoliosis, basilar skull deformities, blue sclerae, hearing loss, easy bruising, and increased laxity of the ligaments and skin. Increased serum thyroxine levels occur in 50% of the patients with OI and are associated with increased oxygen consumption and body temperature. Reports suggest a relationship between OI and malignant hyperthermia, although a scientific rationale is lacking. However, close monitoring of body temperature perioperatively is necessary.

OI patients are vulnerable to fractures. Cervical spine deformity often makes direct laryngoscopy and intubation a challenge. For cases in which difficult intubation is anticipated, elective awake fiberoptic tracheal intubation is a prudent approach. Laryngeal mask airway is an alternative to airway management in OI patients. Dentition in OI patients often is fragile because of defective mineralization. Fracture may be caused by an inflated blood pressure cuff, as well as fasciculation after succinylcholine. These patients potentially are prone to hypoxemia because of the restriction and decreased compliance from associated kyphoscoliosis and pectus excavatum.

According to reports, regional anesthesia has been administered successfully to avoid tracheal intubation. Laboratory studies of coagulation function generally are appropriate before neuraxial anesthesia, given that OI is associated with a prolonged bleeding time without decreased platelet counts.

Malignant hyperthermia has been reported in patients with OI. However, this has not been confirmed by muscle biopsy. General anesthesia with succinylcholine and halogenated gases has been administered to OI patients safely, although hyperthermia and metabolic acidosis could happen with the nature of the disease process.

Marfan syndrome

Marfan syndrome is an autosomal dominant disorder characterized by cardiovascular, skeletal, and ocular connective tissue abnormalities. It is caused by a mutation in the *FBNI* gene on chromosome 15, which encodes an important extracellular matrix glycoprotein fibrillin 1.

Patients with Marfan syndrome are prone to aortic dilatation and dissection because of weakness of the aortic media, which is the most life-threatening manifestation. However, severe aortic regurgitation is often one of the late findings and is attributed to the stretching of the aortic annulus.

Thickening of the atrioventricular valves makes mitral and/or tricuspid prolapse a common abnormality. Appropriate antibiotic prophylaxis for bacterial endocarditis is a common practice. Cardiac conductivity, especially bundle branch block,

is common. Craniofacial deformities frequently are present. Dislocation of joints, such as the temporomandibular joint, and cervical spine abnormality with atlantoaxial dislocation also are common in Marfan syndrome because of the reduction in connective tissue elasticity. When thoracolumbar scoliosis is severe, pulmonary function may be compromised. Ocular involvement, such as ectopic lentis or retinal detachment, has been shown to occur in around 60% and 10% of the patients, respectively.

For Marfan syndrome patients, hypertension must be tightly controlled to prevent dissecting complications. Close peripartum follow-up with cooperation among obstetrics, cardiology and anesthesiology teams is the key to success in managing such patients.

Periodic echocardiography is performed to measure the size and progress of the aortic root and cardiac function. For parturients, an aortic root diameter of 40 mm is considered the upper limit for vaginal delivery. Regional anesthesia repeatedly has been used successfully in labor and delivery. Epidural and combined spinal epidural anesthesia for cesarean section has been reported in patients with aortic dissection. Cesarean section delivery has been reported in patients who had aortic root replacement.

Lumbosacral dural ectasia, the widening of the lumbosacral dural sac, has been reported in 63% to 92% of patients with Marfan syndrome. Erratic spread of intrathecal local anesthetics has been reported. In the presence of dural ectasia, continuous spinal, epidural, or combined spinal–epidural anesthesia may be a better option than single-shot spinal anesthesia to guarantee an adequate level and titratability for cesarean section. It is not clear whether this population has higher dural puncture rates when epidural is attempted.

In cases of general anesthesia, the focus should be to establish an airway and to maintain hemodynamic stability. Vasodilators may increase the ejection velocity of the left ventricle, which may need to be used together with β -adrenergic blockers to prevent dissection. Transesophageal echocardiography may provide useful real-time cardiac function information intraoperatively.

Anesthesia for aesthetic surgery

Stephen L. Ratcliff and Fred E. Shapiro

More than 10 million surgical and nonsurgical cosmetic procedures were performed in the United States in 2008. Of these, 53% were performed in the office facility, 19% were performed in the hospital, and 26% in a free-standing surgical center. Newer techniques have allowed the total number of cosmetic surgeries to increase more than 162% since 1997. With the increase in environments in which anesthesia is provided, it is imperative that both the anesthesiologist and nonanesthesiologist administering anesthesia adhere to evidence-based standards and safe practices. This is done while continuing to offer patients lower costs, increased efficiency, faster recovery times, fewer infections, and a more streamlined and comfortable experience.

Accompanying the increase in aesthetic procedures being performed in the office and ambulatory surgical centers is an increase in the number of patients with major medical problems and risk factors who are undergoing these procedures. Therefore, there is great concern regarding patient safety, particularly as the number of health care providers who administer sedation in the office-based setting continues to grow.

Procedure selection

Procedures involving significant blood loss, major intra-abdominal, intrathoracic, or intracranial cavities, or significant postoperative pain may not be appropriate for the office setting. Furthermore, the procedure should be of a duration and degree of complexity that will permit the patient to recover and be discharged from the facility within a reasonably short period of time.

The American Society of Plastic Surgeons Task Force on Patient Safety has recommended, for example, that long procedures be scheduled sufficiently early in the day to allow for adequate recovery before discharge. Ideally, the overall procedure(s) should be completed within 6 hours to allow adequate time for recovery and discharge. The procedure to be performed should be agreed upon by the patient, anesthesiologist, and surgeon before the procedure is undertaken and before sedative medication is administered to the patient.

Preoperative patient selection

Each office should establish guidelines that describe criteria for determining patient selection for office procedures. These guidelines will take the following into account:

1. Patient's medical status (specific diagnosis, severity of disease state, and optimization of therapy)
2. Degree of stability of that medical status
3. Patient's psychological status
4. Patient's support system at home (social evaluation)
5. Intensity and duration of postprocedure monitoring (e.g., obstructive sleep apnea)
6. Risk of developing a deep vein thrombosis or pulmonary embolism and the ability to provide thromboembolic prophylaxis

Preoperative preparation

Before undergoing anesthesia for aesthetic surgery, a complete preoperative history and physical examination should be performed and an American Society of Anesthesiologists (ASA) class assigned. Patients who are healthy or have mild systemic disease (ASA 1 and 2) are generally appropriate candidates for a procedure in an office-based setting. If the patient has a higher severity of underlying medical disease (ASA 3 or 4), further direct consultation with an anesthesiologist is necessary, and the decision to undergo the procedure at a hospital or surgical center may be made so that resource risks can be minimized. Preoperative testing such as laboratory tests, electrocardiography, and chest radiography should be guided by preexisting medical conditions and whether the anesthetic plan will be changed by the outcome of such tests.

The choice of anesthesia

There are four broad types of anesthesia used for aesthetic procedures: local anesthesia, monitored anesthesia care, regional anesthesia, and general anesthesia. The technique employed may comprise two or more types of anesthesia and is determined by taking several factors into consideration, namely the type and length of procedure, the level of sedation required, whether the procedure is in a hospital or office-based setting, the patient's physical and psychologic status, and the qualifications of the anesthesia provider.

Anesthesia for office-based surgery can be accomplished using a variety of approaches. Induction and maintenance of

sedation or anesthesia may include intravenous and inhalational techniques. Short-acting agents are most appropriate. Central and peripheral regional anesthetic techniques also may be valuable. More important than the choice of specific agents or techniques, the anesthesiologist should focus on providing an anesthetic that will give the patient a rapid recovery to *normal function*, with minimal postoperative pain, nausea, or other side effects.

Procedures

With increasing numbers of aesthetic procedures being performed annually, it is becoming more paramount to have anesthetic techniques that allow for quick, safe recovery while providing optimal surgical conditions. Aesthetic facial surgery, which previously had been done primarily under general anesthesia, is now possible under local and total intravenous anesthetic techniques.

Liposuction

Liposuction is one of the leading surgical cosmetic procedures in the United States. There are two similar liposuction techniques, superwet and tumescent, both of which involve infiltrating the surgical area with a mixture of normal saline or lactated Ringer's solution with a low concentration of lidocaine. Common lidocaine concentrations range from 0.025% to 0.5% and contain epinephrine, usually in a dilution of 1:200,000 to 1:1,000,000. In the context of aesthetic head and neck surgery, if closed (cervicofacial) liposuction is performed, local anesthesia and monitored sedation may be adequate. Infraorbital, mental, and cervical plexus nerve blocks are often used to supplement this technique. If liposuction is performed with another aesthetic procedure, such as rhytidectomy, general anesthesia with a laryngeal mask or endotracheal tube may be necessary. In all instances, close communication should be maintained among the health care team to avoid local anesthetic toxicity, particularly when more than one provider may be administering local anesthetic through various regional and infiltrative techniques.

Complications that may arise from liposuction include hypervolemia or hypovolemia, pulmonary embolism, hypothermia, and lidocaine toxicity. Although smaller volumes of tumescent injection are used for head and neck procedures, care should be taken because cervicofacial liposuction may be undertaken in the same setting as lower-extremity liposuction, in which larger volumes of tumescent solution are employed. In this setting, complications may have a greater incidence, particularly with lidocaine toxicity. There is evidence to suggest that lidocaine toxicity may occur earlier than expected in head and neck liposuction. Although Ramon et al. used total lidocaine doses in facelift procedures that amounted to 21 mg/kg, without adverse events and with plasma levels 72% below the level considered safe, other studies have shown higher plasma concentrations with liposuction.

Rhytidectomy

Rhytidectomy, or “facelift,” may include removal of excess facial skin and tightening of underlying tissues on the patient's face and neck. Taghnia et al. retrospectively reviewed 142 consecutive rhytidectomies with two different sedation/analgesia techniques. Both techniques included propofol, ketamine, fentanyl, and midazolam. However, one group used the α_2 -agonist dexmedetomidine. This short-acting medication allows the patient to breathe spontaneously on room air while providing sedation and analgesia and decreasing the risk of combustion. In this study, patients encountered lower blood pressure, decreased episodes of oxygen desaturations, a decreased requirement of supplemental oxygen, and reduced opioid, anxiolytic, and antiemetic use. This technique is made possible largely through the use of local infiltration of 0.5% lidocaine with 1:200,000 epinephrine as a background analgesic.

Blepharoplasty

Blepharoplasty involves reshaping of the eyelids by removing or repositioning excess tissue. Blepharoplasty under local anesthesia or with intravenous sedation affords surgeons the ability to perform the procedure in multiple settings, including offices and hospitals. In a recent study, Harley and Collins examined 86 healthy patients who underwent blepharoplasty using oral medication and local anesthetic in an office-based setting. This retrospective review assessed patient satisfaction and determined that the procedure is well accepted by patients. Patients were given oral sedation prior to slow injection of 2 ml of 1% lidocaine with 1:100,000 epinephrine into each eyelid. An 83% response rate was obtained, with 91% reporting an excellent experience. The authors believed the ability to choose local anesthesia and sedation in the office setting was a major factor in determining whether patients would have the procedure done. They concluded that this anesthetic approach to blepharoplasty is safe, convenient, and cost saving.

Rhinoplasty

Rhinoplasty, or surgical reshaping of the nose, can be performed under either general or local anesthesia, depending on the extent of the planned operation. In both settings, local anesthetics can provide analgesia while lowering opioid requirements. In one study, Demiraran et al. compared 60 patients randomly assigned to receive preincisional lidocaine 2% with epinephrine or levobupivacaine 0.25% without epinephrine. Patients receiving levobupivacaine required significantly fewer supplemental analgesics.

In reviewing all the aforementioned procedures, the common denominator is the liberal use of local anesthetics. Because of the exponential growth in the number of procedures, increasing comorbidities of patients, sedation administered by anesthesia and nonanesthesia personnel, and recent media attention to high-profile mishaps, a discussion of aesthetic surgery should include the topic of local anesthetic toxicity.

Table 171.1. Guidelines for the management of severe local anesthetic toxicity**Signs of severe toxicity:**

- Sudden loss of consciousness, with or without tonic–clonic convulsions
- Cardiovascular collapse: sinus bradycardia, conduction blocks, asystole, and ventricular tachyarrhythmias all may occur
- Local anesthetic (LA) toxicity may occur some time after the initial injection

Immediate management:

- Stop injecting the LA
- Call for help
- Maintain the airway and, if necessary, secure it with a tracheal tube
- Give 100% oxygen and ensure adequate lung ventilation (hyperventilation may help by increasing pH in the presence of metabolic acidosis)
- Confirm or establish intravenous access
- Control seizures: give a benzodiazepine, thiopental, or propofol in small incremental doses
- Assess cardiovascular status throughout

Management of cardiac arrest associated with LA injection:

- Start cardiopulmonary resuscitation (CPR) using standard protocols
- Manage arrhythmias using the same protocols, recognizing that they may be very refractory to treatment
- Prolonged resuscitation may be necessary; it may be appropriate to consider other options:
 - Consider the use of cardiopulmonary bypass if available
 - Consider treatment with lipid emulsion

Treatment of cardiac arrest with lipid emulsion (approximate doses are given for a 70-kg patient)

- Give an intravenous bolus injection of Intralipid 20% 1.5 ml/kg over 1 min
 - Give a bolus of 100 ml
- Continue CPR
- Start an intravenous infusion of Intralipid 20% at 0.25 ml/kg/min
 - Give at a rate of 400 ml over 20 min
- Repeat the bolus injection twice at 5-min intervals if an adequate circulation has not been restored
 - Give 2 further boluses of 100 ml at 5-min intervals
- After another 5 min, increase the rate to 0.5 ml/kg/min if an adequate circulation has not been restored
 - Give at a rate of 400 ml over 10 min
- Continue infusion until a stable and adequate circulation has been restored

Remember:

- Continue CPR throughout treatment with lipid emulsion
- Recovery from LA-induced cardiac arrest may take > 1 h
- Propofol is not a suitable substitute for Intralipid
- Replace the supply of Intralipid 20% after use
- If possible, take blood samples into a plain tube and a heparinized tube before and after lipid emulsion administration and at 1-h intervals afterward. Ask your laboratory to measure LA and triglyceride levels (these have not yet been reported in a human case of LA intoxication treated with lipid).

Reproduced with the permission of the Association of Anaesthetists of Great Britain and Ireland.

Treatment of local anesthetic toxicity

Along with local anesthetics becoming an invaluable part of head and neck aesthetic procedures come the concerns regarding increased risks of local anesthetic toxicity. In addition to understanding the current literature on dosing guidelines and recognizing the signs and symptoms, the health care provider should establish a treatment plan for managing adverse outcomes. Table 171.1 shows sample guidelines for the management of the airway, seizures, cardiopulmonary resuscitation, as well as for the administration of 20% Intralipid emulsion (Baxter Healthcare; Deerfield, IL), if indicated.

Intra-abdominal hypertension and abdominal compartment syndrome

Joaquim M. Havens, James F. Watkins, and Selwyn O. Rogers Jr.

An increase in the volume of any abdominal or retroperitoneal contents causes an increase in intra-abdominal pressure (IAP). Markedly increased IAP leads to intra-abdominal hypertension (IAH), which has profound effects on both local and systemic tissues and organ systems that if untreated, may lead to lethal organ failure. The clinical condition that results from the organ dysfunction that occurs with IAH is termed *abdominal compartment syndrome* (ACS). If untreated, ACS can be rapidly fatal, making early identification imperative.

IAH has been described in a variety of clinical situations, including abdominal trauma, ruptured abdominal aortic aneurysm, intraperitoneal hemorrhage, hemorrhagic pancreatitis, pneumoperitoneum, ovarian tumor, and liver transplantation. Ultimately, any circumstance that leads to an acute expansion of the intra-abdominal or retroperitoneal contents toward a volume greater than the capacity of the abdominal cavity to expand will result in IAH. Local factors that may contribute to IAH are the rapid accumulation of blood and clot, bowel edema or congestion from injury to mesenteric vessels or excessive crystalloid resuscitation, and perihepatic or retroperitoneal packing after damage control laparotomy for diffuse non-surgical bleeding (Fig. 172.1).

Closure of the abdominal wall under tension may further aggravate IAH in these conditions. This was first described by Gross et al. in 1948 when he noted that in the surgical repair of large omphaloceles, it was possible to forcefully close the abdomen only to have the neonate die from respiratory and cardiovascular collapse. Pediatric surgeons began to recognize the consequences of “abdominal overcrowding,” which led to the construction of plastic silos, or chimneys, to avoid tight closure of the abdomen. Rowlands et al. first described the use of a temporary abdominal closure in the adult to prevent the consequences of IAH, which has led to deliberate avoidance of primary closure of the abdominal fascia in patients at risk for IAH.

Different techniques have since been developed for the maintenance of the open abdomen. These include placement of prosthetic mesh; plastic sheets, as in the “Bogotá bag” (Fig. 172.2); and a vacuum pack technique of a large adherent operative drape over closed suction drains. The underlying principle of all temporary abdominal closures is to allow expansion of the abdominal contents without significantly increasing IAP, while conserving heat, reducing fluid loss, and bridging fascial edges

to create a temporarily larger intra-abdominal space. Definitive treatment for ACS involves abdominal decompression.

Because patients who suffer from ACS are generally critically ill to begin with, the organ dysfunction that results from ACS may be mistakenly attributed to their primary illness. Failure to recognize ACS will result in tissue hypoperfusion, multisystem organ failure, and death, with mortality approaching 100% for patients who do not undergo surgical decompression.

Diagnosis

It is important to note that IAH and ACS are not synonymous. IAH is a parameter that can be measured and monitored, whereas ACS is a clinical syndrome of multiple organ dysfunction that results from progressive uncontrolled IAH. The exact level of IAP that causes end-organ dysfunction is not known. The detrimental physiologic effects of IAH likely take place before the manifestations of ACS become clinically evident. In one study recording a random sample of IAP in patients following abdominal surgery, pressures ranged from 3 to 15 mm Hg with no evidence of ACS. Decreases in splanchnic blood flow have been noted with IAPs as low as 10 mm Hg. In a dog model, Richards et al. showed that oliguria occurred when IAP reached 15 to 20 mm Hg and anuria occurred when IAP exceeded 20 mm Hg.

Figure 172.1. Perihepatic packing for damage control laparotomy.

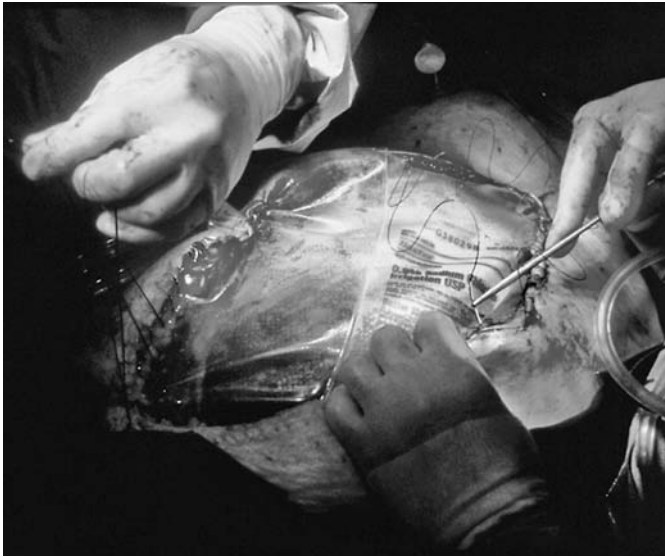

Figure 172.2. Placement of the Bogotá bag as a temporary abdominal closure.

The 2004 International ACS Consensus Definitions Conference defined IAH as an IAP above 12 mm Hg. ACS is defined as an IAP above 20 mm Hg with evidence of organ dysfunction/failure. ACS is further classified as primary, secondary, or recurrent, based on the duration and cause of the IAH-induced organ failure. Primary ACS develops as a result of injury or disease that originates within the abdomen, whereas secondary ACS develops because of conditions outside the abdomen, such as sepsis, capillary leak, major burn, bacteremia, pneumonia, acute respiratory failure, or other conditions that require massive fluid resuscitations. Recurrent ACS is the redevelopment of ACS in a patient with an open abdomen after initial successful surgical or medical treatment of primary or secondary ACS, or it occurs following the closure of a previous decompressive laparotomy.

IAP may be measured by direct and indirect methods. The direct method is measurement of intraperitoneal pressure by transducing the pressure from a catheter placed directly into the peritoneal cavity. The indirect method makes use of transduced pressure measurements from inside accessible abdominal organs, which secondarily reflect IAP. Techniques have been described for intragastric, intracolonic, intravesical, and inferior vena cava catheters. These methods all depend on the IAP being transmitted across the wall of the visceral organ or vascular structure, which may then be transduced.

The most common organ used for transduced pressures is the bladder. Kron and colleagues first described measurement of the bladder pressure in 1984. It is simple, accurate, and minimally invasive, and has become the standard for measurement of IAP. Kron's technique involves instilling 50 ml of saline into the urinary bladder through the Foley catheter. The tubing of the collecting bag is then clamped, and a needle is inserted into the specimen-collecting port of the tubing proximal to the clamp and is attached to a manometer (Fig. 172.3).

The transducer is zeroed at the level of the symphysis pubis. This technique has a high degree of correlation with IAP but may be inaccurate in the setting of intraperitoneal adhesions, pelvic hematomas or fractures, abdominal packs, or neurogenic bladder.

Normal IAP is generally considered to be equivalent to atmospheric pressure, but there is significant patient variability. In a study of bladder pressures in 58 supine hospitalized patients who had not undergone abdominal surgery, pressures varied from 1 to 18 cm H₂O (0.7–13.2 mm Hg), with pressures slightly higher in men than women and increasing as the patients were placed in the upright position. Body mass index is positively correlated with higher IAP, but the relationship between obesity and ACS is unclear. Patients have differing abilities to tolerate IAH, and any pressure measurement must be taken within the clinical context. Shown in Table 172.1, a grading system has been proposed by Burch et al.

Radiography is insensitive in the detection of ACS and should not be considered a diagnostic modality. Nevertheless, several radiographic findings that may be present in ACS

Figure 172.3. Using a patent Foley catheter with clamped drainage tube, 50 ml of sterile water is infused into the bladder via a three-way stopcock system.

Table 172.1. Grading system for ACS

Grade	Pressure, mm Hg	Possible organ dysfunction
I	7–11	Splanchnic hypoperfusion
II	11–18	Elevated airway pressure, reduced cardiac output, oliguria
III	18–25	Hypotension, hypercarbia, hypoxia, anuria, increased intracranial pressure
IV	>25	Multiple organ failure

Adapted from Burch JM, Moore EE, Moore FA, Franciose R. The abdominal compartment syndrome. *Surg Clin North Am* 1996; 76:833 (Table 1).

have been described. Chest radiographs may demonstrate low lung volumes and elevated hemidiaphragms. CT findings that have been described in ACS include tense infiltration of the retroperitoneum out of proportion to peritoneal disease, extrinsic compression of the inferior vena cava, massive abdominal distention, direct renal compression or displacement, bowel wall thickening, and bilateral inguinal hernias. In a recent study of 24 critically ill surgical patients, only bowel wall thickening was significantly associated with the presence of ACS. As ACS is a clinical diagnosis, and radiology is insensitive, intervention should never be delayed for the purpose of imaging.

Clinical manifestations

The acute expansion of intra-abdominal contents toward a volume in excess of the capacity of the abdominal cavity to expand results in pressure-related end-organ dysfunction. Much of the pathology results as a direct effect of pressure on organs, transmitted pressure across flexible structures, and pressure on the venous system. In addition, there is a systemic response, resulting in a delicate interplay between organ systems mediated by catecholamines, hormones, and cytokines.

Characterized by a tense, distended abdomen, elevated IAPs, decreased cardiac output, inadequate ventilation with elevated peak airway pressures, hypoxia and hypercarbia, and renal dysfunction, ACS can affect all organ systems, with most of the literature focusing on the cardiac, pulmonary, and renal effects.

Cardiovascular

IAH causes elevation of the diaphragm, resulting in direct compression of the heart, reducing both ventricular compliance and contractility. IAH also reduces venous return by functionally obstructing inferior vena caval blood flow within the abdomen. As IAP increases, systemic vascular resistance increases proportionally. The combination of increased systemic vascular resistance, decreased venous return, and reduced cardiac compliance and contractility leads to a fall in cardiac output. Barnes et al. demonstrated a 36% reduction in cardiac output and stroke volume after IAP increased from 0 to 40 mm Hg in anesthetized dogs.

Potent inhalation anesthetics and intravascular volume depletion accentuate the deleterious hemodynamic effects of increased IAP. In the setting of IAH, the addition of 1 minimum alveolar concentration of halothane anesthesia in hypovolemic dogs led to a greater decrease in cardiac output than hypovolemia or halothane anesthesia alone. Anesthetic gases have differing effects on specific organ perfusion, which might precipitate further end-organ damage in ACS. Enflurane has been shown to cause a decrease in splanchnic perfusion, whereas isoflurane maintains splanchnic perfusion despite similar decreases in cardiac output. Whether this difference in splanchnic perfusion is relevant in the setting of an increased IAP has not been studied.

Pulmonary capillary wedge pressure and central venous pressure typically increase with rising IAP, despite decreased venous return and cardiac output. These elevated pressures are not reflective of true intravascular volume status and are present despite apparent hypovolemia. Hypovolemic patients have shown a reduction in cardiac output at lower levels of IAH than normovolemic patients. Hypervolemia tends to result in increased venous return in the setting of IAH. However, a retrospective analysis of 156 patients from a prospective database of trauma patients receiving supranormal resuscitation (oxygen delivery index ≥ 600 ml/min/m²) versus normal resuscitation (oxygen delivery index ≥ 500 ml/min/m²) demonstrated increased incidence of IAH, ACS, multiple organ failure, and death in patients receiving supranormal resuscitation. In a small prospective study of burn patients, the volume of fluid required to cause IAH (defined as an IAP > 25 mm Hg) varied from 9 to 35 L, with a mean of 25 L. Excessive fluid resuscitation thus is an important risk factor for the development of ACS.

Pulmonary

IAP is transmitted to the thorax via the elevated hemidiaphragm, resulting in extrinsic compression of the pulmonary parenchyma and progression of pulmonary dysfunction. Extrinsic compression leads to atelectasis, edema, decreased oxygen transport, increased intrapulmonary shunt fraction, and increased alveolar dead space. Pleural pressure increases proportionately to abdominal pressure. This increase in pleural pressure leads to the artificially elevated central venous and pulmonary capillary wedge pressure found in IAH, similar to those found with the use of high levels of positive end-expiratory pressure (PEEP), or the development of auto-PEEP in mechanically ventilated patients.

In addition to the direct effects of increased IAP, oxygenation and ventilation are further compromised as a result of the volume of resuscitation and capillary leakage, worsening pulmonary compliance, systemic inflammatory response, and acute lung injury. In a prospective study of 38 burn patients, IAH was associated with an increase in serum levels of plasma interleukin (IL)-8 and higher lung injury severity score. In addition, an increase in the incidence of pulmonary infections has been described in association with ACS.

The pulmonary dysfunction associated with IAH may present as intractable hypercarbia, hypoxia requiring increasing levels of PEEP, increased peak inspiratory pressures, and progressively greater mean airway pressure requirements to achieve adequate tidal volume. If driving pressures are sufficiently high, significant amounts of set tidal volume may be lost from the distention of the ventilator circuit tubing itself.

Most authors note rapid improvement in pulmonary parameters after abdominal decompression. Burch et al. and Morris et al. documented that peak airway pressures in excess of 80 cm H₂O returned nearly to normal after abdominal decompression. Meldrum et al. noted significant improvement in both static compliance and PaO₂/fraction of inspired oxygen content (FiO₂) following abdominal decompression in patients with ACS. In burn patients with IAH, Oda et al. showed there was improvement in peak inspiratory pressure and PaO₂/FiO₂ ratio immediately after abdominal decompression. However, lung injury severity and sequential organ failure assessment score continued to increase significantly for 48 hours after abdominal decompression when compared with similar burn patients without IAH. This was also associated with a similar rise in IL-8, implicating a systemic inflammatory response to IAH that once initiated, persists beyond abdominal decompression.

Renal

Oliguria has been described with IAP as low as 15 mm Hg. Renal dysfunction in ACS is mediated directly by increased venous resistance, resulting in impaired venous drainage, as well as by arterial vasoconstriction mediated by the sympathetic nervous and renin-angiotensin systems secondary to the fall in cardiac output. This results in decreased renal perfusion as IAP increases. Renal impairment from ACS results in progressive reduction in glomerular perfusion and urine output. Harman et al. infused tritiated para-aminohippuric acid and carbon-14 inulin into anesthetized dogs and showed that IAP of 20 mm Hg leads to a decrease in glomerular filtration rate to 21% of baseline and a decrease in renal blood flow to 23% of baseline. A further increase in IAP to 40 mm Hg reduced glomerular filtration and renal blood flow to 7% of baseline in four of seven dogs and to unmeasurable levels in the remaining three dogs. Placement of ureteral stents did not improve renal function. The authors further demonstrated that correction of cardiac output alone does not reverse the renal dysfunction in ACS.

Renin, aldosterone, and antidiuretic hormone levels rise to more than twice baseline, further exacerbating renal hypoperfusion. As in other instances of hypoperfusion of the kidney, decreased urine sodium and chloride will be evident. The primary mechanism of renal dysfunction is believed to be direct compression of the renal vein, rather than compression of the parenchyma itself. By relieving IAP through abdominal decompression, renal vein compression is reversed and renal function often returns to normal, provided the diagnosis is made and decompression is performed before renal hypoperfusion has led to acute tubular necrosis.

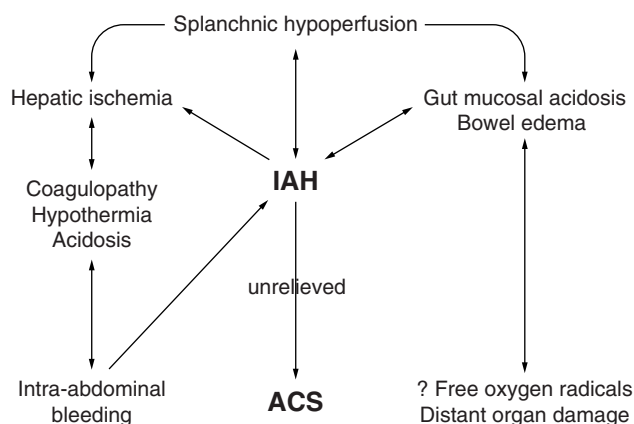

Figure 172.4. The vicious circle of events created by IAH on splanchnic circulation. Unrelieved, IAH will lead to ACS. (Reproduced with permission from Ivatury RR, Diebel L, Porter JM, Simon RJ. Intra-abdominal hypertension and the abdominal compartment syndrome. *Surg Clin North Am* 1997; 77: 783).

Gastrointestinal

Changes in mesenteric blood flow are noted with an IAP as low as 10 mm Hg. Decreased intestinal mucosal perfusion has been demonstrated with an IAP of 20 mm Hg. These changes are independent of the decrease in cardiac output. Hypoperfusion of the intestine as a result of IAH has been proposed as a mechanism for the loss of the mucosal barrier and subsequent bacterial translocation, which may lead to sepsis and multiple system organ failure. This is supported by the findings of Bargiulo et al. that bacterial translocation to mesenteric lymph nodes may occur in the setting of hemorrhage at an IAP of 10 mm Hg. As with other organ systems, the negative effects of IAH on mesenteric perfusion are exacerbated by the presence of hypovolemia or hemorrhage.

The thin-walled mesenteric veins are easily compressed in the setting of IAH, leading to venous hypertension and intestinal edema. As illustrated in Fig. 172.4, visceral swelling further increases IAH, initiating a vicious cycle of worsening hypoperfusion, bowel ischemia, decreased intramucosal pH, and lactic acidosis. Furthermore, the ability of the liver to clear lactic acid is impaired, leading to delayed clearance of lactic acid, even in the setting of otherwise adequate resuscitation. This cycle of increased production of lactic acid and decreased clearance may lead to refractory metabolic acidosis, despite adequate resuscitation. Elevated lactate and increased base deficit are markers for increased mortality in intensive care unit patients, and normalization of serum lactate has been shown to correlate with survival. Attempts to correct the acidosis associated with ACS by aggressive fluid resuscitation alone, however, may lead to supranormal resuscitation, which further worsens the end-organ damage in ACS.

Central nervous system

IAH has been shown to cause elevated intracranial pressure (ICP) and decreased cerebral perfusion pressure (CPP) in

animals. These findings were confirmed by Karakoulas et al., who also showed that bacterial lipopolysaccharide-induced endotoxemia in a swine model with IAH resulted in further reduction of CPP without a change in ICP. Ertel et al. reported two patients with multiple injuries in whom ACS caused a critical increase in ICP, which markedly dropped after abdominal decompression. Further demonstrating the relationship between IAP and ICP, Joseph et al. presented a series of 17 patients with severe brain injury and refractory intracranial hypertension, but no evidence of ACS, and only mildly elevated IAP. The authors noted that ICP significantly decreased in every patient after abdominal decompression.

The precise mechanism of the effect of increased IAP on ICP is not clear; however, it is suggested that the elevated central venous pressure due to IAH interferes with venous drainage from cerebral venous outflow. Decreased cardiac output and rising ICP will result in decreased CPP.

Beyond the individual organ systems, an interrelationship between the different compartments of the body exists. IAH elevates the hemidiaphragms, causing respiratory failure. Ventilatory maneuvers used to treat respiratory failure may increase intrathoracic pressure, limiting venous return and worsening cardiac output. ICP is increased as a result of limited venous return, leading to catecholamine surges that reduce renal blood flow. Fluid therapy used to treat falling cardiac output worsens pulmonary compliance and increases visceral edema, thus increasing IAP. Without definitive treatment, this spiral continues unrelenting toward death. This interaction of increasing pressure within various compartments led Scalea et al. to term the process *multiple compartment syndrome*.

Management

Paramount in the management of ACS is prevention. Intraoperative communication between the surgeon and anesthesiologist is critical. At the time of abdominal closure, the anesthesiologist may identify increasing ventilatory pressures, falling tidal volumes, or changes in oxygenation, indicating IAH. Similarly, any fall in blood pressure, cardiac output, or urine output abruptly after abdominal closure should be communicated to members of the surgical team.

As bleeding increases the risk and consequences of IAH, every attempt should be made to obtain meticulous hemostasis at the time of the original procedure. To avoid IAH and ACS, forceful closure of the abdomen in patients at risk for developing IAH should be avoided. Several methods have been described for the deliberate avoidance of primary closure of the abdominal fascia. The most common and cost-effective is the Bogotá bag, which involves suturing an opened 3-L genitourinary bag to the abdominal fascia. Other materials have been used, including polyglactin (Vicryl; Ethicon, Somerville, NJ) mesh. More recently, temporary abdominal closure with a vacuum pack technique has been described. This consists of a thin plastic sheet, a sterile towel, closed suction drains, and a large adherent operative drape. All

Table 172.2. Relative indications for IAP monitoring

Sepsis/systemic inflammatory response/ischemia reperfusion

- Sepsis and resuscitation with > 6 L of crystalloid/colloid or > 4 U of blood in 8 h
- Pancreatitis
- Peritonitis
- Ileus/bowel obstruction
- Mesenteric ischemia/necrosis

Visceral compression/reduction

Trauma

- Shock requiring resuscitation (ischemia-reperfusion)
- Damage control laparotomy
- Multiple trauma with or without abdominal trauma requiring resuscitation with > 6 L of crystalloid/colloid or > 4 U of blood in 8 h
- Major burns

temporary abdominal closures are designed to allow expansion of the abdominal contents without significantly increasing IAP, while conserving heat, reducing fluid loss, and bridging fascial edges.

Appropriate fluid management in patients with IAH is critical to avoid contributing to IAH and pulmonary dysfunction. As previously noted, supranormal trauma resuscitation is associated with an increased incidence of IAH, ACS, multiple organ failure, and death. Resuscitation to normovolemia should be the goal. Several small studies in burn patients have shown a lower incidence of IAH in patients resuscitated with colloid and hypertonic lactated saline than in those receiving isotonic crystalloid; however, neither study was adequately powered to demonstrate any benefit in survival. A meta-analysis has suggested that giving albumin to critically ill patients for treatment of hypovolemia or hypoalbuminemia increases mortality. The Saline versus Albumin Fluid Evaluation Study (SAFE) found no advantage of colloid over crystalloid resuscitation in critically ill patients.

Patients at risk for IAH must be identified early and monitored frequently. Repeated measurement of bladder pressure at frequent intervals is critical in the management of IAH. The level at which IAH causes ACS is not known. Patients do not respond uniformly to the same levels of IAH. The detrimental effects of IAH occur before the clinical manifestations of ACS are observed. Abdominal decompression is the only treatment that reverses the physiologic derangements of ACS (Table 172.2).

There is no consensus on the appropriate timing of intervention in the patient with significant IAH but without overt signs of ACS. Some authors recommend surgical intervention based on IAH alone. Ivatury et al. recommend intervention for persistent IAP > 20 to 25 cm H₂O (14.7–18.3 mm Hg). Others

favor interpreting the absolute pressure in light of end-organ dysfunction, and using the IAP only as supportive data. Burch et al. found that most patients with IAP > 25 cm H₂O (18.3 mm Hg) and all patients with IAP > 35 cm H₂O (25.7 mm Hg) require surgical intervention.

Chatham et al. demonstrated that abdominal perfusion pressure, defined as mean arterial pressure (MAP) minus IAP, is a useful resuscitation end point in patients with IAH or ACS. In their retrospective study, the inability to maintain an abdominal perfusion pressure > 50 mm Hg predicted mortality with greater sensitivity and specificity than IAP or MAP alone.

Definitive management of IAH and ACS involves operative decompression of the abdomen (decompressive laparotomy) and maintenance of the open abdomen with a temporary abdominal closure, as previously described. Abdominal decompression leads to rapid improvement in cardiac output and pulmonary and renal function.

Suspicion of IAH mandates early surgical consultation, as rapid deterioration is likely and surgical decompression remains the standard of treatment. Paracentesis has been shown to be beneficial in the case of burn patients with IAH. Reed et al. described the benefits in placing of an intra-abdominal catheter in burn patients with elevated bladder pressures to facilitate fluid removal as a first step in the early management of ACS in that population. These techniques have been described only in small trials with specific populations, and are not standard of care.

Recurrent ACS and a progressive increase in IAP in the trauma patient with an open abdomen often signify ongoing bleeding within the abdominal cavity. Bleeding may be the result of coagulopathy, ineffective packing, and/or failure to control all surgical bleeding. Prompt reexploration of any patient with rising IAP despite an open abdomen facilitates removal of blood and clots, allows reassessment of packed areas, identifies surgical bleeding, and allows assessment of the bowel's viability. The temporary abdominal closure simplifies reexploration by allowing entry via cutting through the mesh or plastic closure and suturing the cut ends together at the end of the procedure. The surgeon may choose to perform this procedure in the operating room or the surgical intensive care unit.

Nutritional support in the trauma patient can prevent acute calorie malnutrition, modulate the immune response, and promote gastrointestinal structure and function. The open abdomen presents specific challenges with respect to nutritional support. Patients with an open abdomen suffer an increased loss of nitrogen/protein, leading to increased nutritional requirements. Nutritional studies in critical care have demonstrated that an increase in morbidity and mortality occurs once a deficit of approximately 10,000 calories occurs. Early enteral feedings have been shown to improve outcomes in trauma patients. Although it is possible that those with an open abdomen may not tolerate enteral feeds because of poor hemodynamics or ileus, there is no literature to support withholding enteral feeding. Although there are no prospective studies of the safety or efficacy of enteral feeding in patients with an open abdomen,

several retrospective analyses have shown potential benefit. Recently, Collier et al. reviewed 78 trauma patients with open abdomens who received enteral feeds either within the first 4 days or after more than 4 days of admission and found that the early enteral feeding group had earlier abdominal closure and lower rates of fistulae.

The remaining challenge then becomes definitive closure of the abdomen in the successfully resuscitated patient. Closure should be delayed until conditions are optimal. There should be complete resuscitation, no systemic or tissue acidosis, and no organ dysfunction. The lateral tractive forces of the broad, flat muscles of the abdominal wall preclude primary closure of the fascia in many instances. In patients who cannot undergo a definitive procedure, temporary coverage may involve closure of skin or skin grafting with a planned ventral hernia repair at a later date.

Summary

ACS is a clinical syndrome of multiple organ dysfunction that results from progressive uncontrolled IAH. It is characterized by a tense, distended abdomen; elevated IAP; decreased cardiac output; inadequate ventilation with elevated peak airway pressures; hypoxia and hypercarbia; and renal dysfunction. The deleterious effects of ACS result not only from hydrostatic pressure, but also from the systemic effects of catecholamines, hormones, and cytokines. An interrelationship among the different compartments of the body subjected to increasing pressure results in rapid progressive deterioration. Without definitive treatment, this spiral continues unrelenting toward death.

ACS should be anticipated and prevented whenever possible by meticulous surgical hemostasis, deliberate avoidance of closure of the abdominal fascia, and judicious fluid administration. The patient at risk for IAH requires frequent monitoring of IAP, most commonly performed by measurement of bladder pressures. Bladder pressure > 12 mm Hg signifies IAH; a bladder pressure > 20 mm Hg in the presence of organ dysfunction has been defined as ACS. The standard of treatment for ACS is immediate decompressive laparotomy and placement of a tension-free temporary abdominal closure.

The patient with an open abdomen requires special considerations for increased fluid loss, nutritional support, and prevention of wound complications. Definitive closure of the open abdomen may be performed during the initial admission by primary fascial closure, fascial closure by component separation, or serial abdominal closure. If autologous fascial closure is not possible, closure with prosthetic mesh and skin grafting may be performed. Morbidity from wound complications remains high.

Carbon monoxide and cyanide poisoning

Samuel Park and Hugh L. Flanagan Jr.

Carbon monoxide (CO) poisoning remains the most common cause of death by poisoning in the United States. The Centers for Disease Control and Prevention (CDC) recently sponsored a study that identified approximately 15,000 emergency department visits in the United States annually and 500 deaths from unintentional nonfire-related CO exposures.

Cyanide occurs naturally in wool, nylon, and various seeds and plants. Products such as glue removers and plastics contain cyanide. Poisoning can occur through inhalation of hydrogen cyanide in a dwelling fire involving combustion of synthetic cyanide-containing products. There is also concern that cyanide might be used in a terrorist attack.

Carbon monoxide

CO is a colorless, odorless, poisonous gas. Exogenous sources of CO include incomplete combustion of carbon-based fuels such as oil, natural gas, wood, kerosene, or gasoline. Poisoning can occur with exposure to smoke in a dwelling fire or to automobile exhaust. A 10-year review of unintentional CO poisonings in the United States revealed that automobile exhaust caused 57% of the deaths with 83% of these deaths associated with stationary automobiles. Fuel-burning appliances (gas heaters, generators, furnaces, and motor vehicles) common in homes or work environments can cause CO exposure and poisoning.

During general anesthesia, patients may be exposed to CO when inhalation anesthetics react chemically with certain carbon dioxide (CO₂) absorbents used in the anesthesia machine breathing circuit. Endogenous CO can also be produced by the breakdown of methylene chloride, a halogenated hydrocarbon, which can be inhaled from the vapors of paint thinner, super glues, or spray paint. In humans, methylene chloride is metabolized 25% to 34% to CO and 70% to CO₂. The enzyme hemoxygenase (HO) produces endogenous CO while enzymatically degrading hemoglobin (Hb) to free iron, CO, and biliverdin. An inducible form of HO has been identified. It is felt by some that CO may function as an endogenous mediator and may play a regulatory role in certain pathologic conditions.

Pathophysiology

CO produces tissue hypoxia by impairing oxygen transport and interfering with cytochrome oxidase function, causing cellular

hypoxia. Absorbed rapidly via the lungs, CO binds avidly to Hb, forming carboxyhemoglobin (COHb) with an affinity more than 200 times greater than that of oxygen. The tight binding of CO to Hb decreases the affinity and binding of oxygen to Hb, resulting in a leftward shift of the oxygen–hemoglobin dissociation curve (Fig. 173.1).

There is a reduction of oxygen transport by CO-bound Hb and a subsequent decreased release of oxygen to tissues. CO binds to mitochondrial cytochrome oxidase and interferes with mitochondrial function, uncouples oxidative phosphorylation, decreases adenosine triphosphate (ATP) production, and ultimately reduces cellular respiration. The net effects are profound tissue hypoxia, anaerobic metabolism, and lactic acidosis, even with a normal PaO₂. CO also binds to myoglobin and decreases its oxygen-carrying capacity. Symptoms are nonspecific and often mimic the common cold (Table 173.1).

Evidence of CO exposure may be difficult to recognize perioperatively because the symptoms are difficult to distinguish from those commonly seen in patients recovering from a viral upper respiratory tract or even a general anesthesia. One must maintain a high index of suspicion of CO inhalation in any setting in which there has been a high probability of exposure. Signs of CO exposure are relatively nonspecific and may be confused with other common conditions (Table 173.2).

Figure 173.1. Normal oxyhemoglobin dissociation curve (top: Hb concentration, 14 g/dl) compared with oxyhemoglobin dissociation curve in CO poisoning (50% COHb) and anemia (Hb concentration, 7 g/dl). Note the CO poisoning curve is shifted to the left of the anemia curve. (Reproduced with permission from Ganong, William, Review of Medical Physiology (LANGE Basic Science), section VII, Respiration: chapter 37.)

Table 173.1. Symptoms of CO exposure

Shortness of breath	Headache
Dizziness	Confusion
Clumsiness	Nausea
Vomiting	Diarrhea
Pallor	Chest pain

The detrimental cardiac effects are due to the impairment of oxygen-carrying capacity. In addition, CO is thought to be a direct myocardial toxin. Cardiac manifestations include ischemic chest pain, arrhythmias, heart failure, and hypotension.

Respiratory manifestations include tachypnea in response to systemic (lactic) acidosis. The carotid bodies respond predominantly to fluctuations in oxygen tension (PaO_2) and not overall oxygen content. Recall that arterial oxygen content (ml) is defined by the following equation:

$$\text{Arterial oxygen content} = (1.34 \times \text{Hb} \times \text{arterial oxygen saturation} [\text{SaO}_2]) + (0.003 \times \text{PaO}_2) \quad (1)$$

Oxygen content is predominantly determined by the Hb and SaO_2 components of Eqn. 1. Dissolved oxygen ($0.003 \times \text{PaO}_2$) ordinarily provides only a minor contribution to overall oxygen content. Therefore, despite a low overall blood oxygen content in these patients, PaO_2 may be normal unless there has been a coexisting lung injury or hypoventilation. An erroneously normal SaO_2 on pulse oximetry will occur because COHb is misinterpreted as oxyhemoglobin. The true SaO_2 is in fact lower, however, and is accurately measured on arterial blood gas (ABG) tests by a co-oximeter.

Renal dysfunction may occur due to secondary myonecrosis and attendant elevated creatine phosphokinase/lactate dehydrogenase (CPK/LDH) and myoglobinuria. Skin manifestations can include a characteristic “cherry red” blood color, which occurs when COHb levels exceed 40%. Skin color is more commonly affected by hypoxia and results in pallor/cyanosis. Diagnosis is confirmed by obtaining blood levels of COHb using a co-oximeter. Higher concentrations of CO produce the more severe symptoms listed in Table 173.3.

Table 173.2. Signs and laboratory findings of CO exposure**Signs**

Tachypnea	Syncope
Visual field defects	Blindness
Respiratory depression	Loss of consciousness
Myoglobinuria	Cerebral edema
Renal dysfunction	Arrhythmia/ischemia
Congestive heart failure	Hypotension
Cyanosis/pallor	“Cherry red” blood color

Laboratory findings

Metabolic acidosis	Falsely normal SaO_2 on pulse oximetry
Normal PaO_2	Low SaO_2 on co-oximeter (ABGs)
Variable PCO_2	

Treatment

Tobacco smokers

Patients should be advised to stop smoking for at least 24 to 48 hours preoperatively. The baseline level of COHb in chronic smokers can be as high as 10%. The level decreases rapidly with abstinence (4-hour half-life) and eventually causes a normalization of the oxyhemoglobin dissociation curve, manifested as a shift to the right. Normalization improves oxygen transfer in the short term but does not address other significant respiratory pathologies associated with smoking, such as decreased mucociliary clearance and airway reactivity, which may require at least 6 to 8 weeks to normalize.

Fire/burn/industrial exposure

First, the patient's exposure to CO must be discontinued and 100% oxygen should be administered by nonbreathing face mask at 15 L/min. More serious exposures require intubation to achieve a PO_2 greater than 300 mm Hg. Dissociated CO is excreted through the lungs. Table 173.4 describes the half-lives as related to treatment with various fractions of inspired oxygen content (FiO_2).

Arterial PO_2 of 300 to 400 mm Hg is desired in order to quickly displace CO bound to Hb. Endotracheal intubation may be advisable and indicated in patients with altered mental status and in whom the arterial PO_2 has not increased dramatically with administration of 100% oxygen via nonbreather. This treatment should continue unless CO poisoning is ruled out by co-oximetry.

Hyperbaric oxygen

CO also binds intracellularly to cytochromes and myoglobin interfering with intracellular oxygen transport. Intramitochondrial oxygen tension is on the order of 3 to 20 torr. This low partial pressure is less able to displace intracellular CO. There is some evidence that hyperbaric oxygen treatment may reduce cognitive sequelae following CO poisoning. Thom, based on research by Weaver and colleagues, recommends hyperbaric oxygen to treat victims of CO poisoning who have a base excess greater than -2 mmol/L or a CO level greater than 25%. Raphael and colleagues and Isbister and colleagues dispute the study by Weaver and colleagues on methodologic grounds.

Carbon monoxide exposure from anesthesia gas breakdown

A decade ago there were anecdotal reports of CO being produced by chemical reactions involving inhalation anesthetics in breathing circuits. These reports prompted several investigations. Fang and colleagues found that, for a given minimum alveolar concentration (MAC) multiple, the amount of CO produced in the presence of soda lime or Baralyme (Allied Healthcare/Chemetron, Kinderhook, NY) was greatest in the presence of desflurane followed in decreasing severity by

Table 173.3. Clinical findings in CO poisoning

Estimated CO Concentration, ppm	COHb, % of total Hb	Symptoms
<35 ppm (cigarette smoking)	5	None, or mild headache
0.005% (50 ppm)	10	Slight headache, dyspnea on vigorous exertion
0.01% (100 ppm)	20	Throbbing headache, dyspnea with moderate exertion
0.02% (200 ppm)	30	Severe headache, irritability, fatigue, dimness of vision
0.03%–0.05% (300–500 ppm)	40–50	Headache, tachycardia, confusion, lethargy, collapse
0.08%–0.12% (800–1200 ppm)	60–70	Coma, convulsions
0.19% (1900 ppm)	80	Rapidly fatal

Adapted from Longnecker DE, Brown DL, Newman MF, et al. *Anesthesiology*. New York: McGraw-Hill; 2008.

enflurane > isoflurane > halothane = sevoflurane. Dry soda lime or Baralyme (1.4%) produced more CO than absorbents containing 9.7% or more water – the latter absorbents produced no CO. This finding suggested that CO production might be higher on Monday mornings if the anesthesia circuit was flushed with air or oxygen during the preceding weekend. There was also a report of a fire in a breathing circuit. The Anesthesia Patient Safety Foundation (APSF) studied both of these issues and released a report in 2005.

There is increasing evidence that exposure of volatile anesthetics to desiccated carbon dioxide absorbents may result in exothermic reactions leading to fires in anesthetic breathing circuits and production of toxic products (e.g. carbon monoxide, compound A, methanol, formaldehyde). Although fires have only been reported in association with sevoflurane exposed to desiccated Baralyme (Allied Healthcare/Chemetron, withdrawn from the market), there is significant evidence that potentially toxic products can be produced upon exposure of volatile anesthetics to other desiccated absorbents containing strong bases, particularly potassium and sodium hydroxide. In some cases this may lead to sub-clinical carbon monoxide exposure.

The APSF published the following consensus statement:

The APSF recommends use of carbon dioxide absorbents whose composition is such that exposure to volatile anesthetics does not result in significant degradation of the volatile anesthetic.

The APSF further recommends that there should be an institutional, hospital, and/or departmental policies regarding steps to prevent desiccation of the CO₂ absorbent should they choose conventional CO₂ absorbents that may degrade volatile anesthetics when absorbent desiccation occurs.

Cyanide poisoning

Cyanide occurs in a variety of forms. Hydrogen cyanide (HCN) can occur as a volatile liquid or flammable colorless gas at room temperature. Cyanide can also occur as a crystal, such as sodium

Table 173.4. Half-life of CO with O₂ therapy

Room air = 4–6 h
100% oxygen = 40–80 min
Hyperbaric oxygen = 15–30 min

cyanide (NaCN) or potassium cyanide (KCN). Cyanide gas has a faint bitter almond odor detectable at 2 to 10 ppm. The ability to detect HCN odor is genetically determined (20%–40% of the population cannot detect HCN). Olfactory fatigue can occur rapidly.

In the workplace, cyanide is used in the manufacture of plastics, paper, fabrics, dyes, and pesticides. Inhalation exposure may occur during house or industrial fires where nitrogen-containing materials such as wool, silk, or plastics are burned. Cyanide was used as a weapon of mass destruction in World War II under the name of Zyklon B.

Certain foods, such as cassava, bitter almond, pits of stone fruits, and lima beans contain cyanide. Eating large quantities of these foods may lead to cyanide poisoning. Such poisonings are more common in tropical environments where these foods represent a larger portion of the diet.

Cyanide is a rapidly acting poisonous asphyxiant that has a very high affinity for ferric iron in the mitochondrial cytochrome oxidase. This binding blocks respiration and therefore oxidative phosphorylation resulting in the production of lactic acidosis, high mixed venous oxygen saturation, and cellular death. The oxygen content, SaO₂, and carrying capacity of the blood may be unaffected.

The diagnosis of cyanide poisoning is difficult because there are no pathognomonic signs. Confirmatory laboratory tests may take considerable time. Multiple agent poisoning, for instance, may occur when a victim inhales CO and cyanide in a closed-space fire where nitrogen-containing substances are burned. Signs and symptoms of HCN poisoning develop rapidly. Initially, the victim may complain of shortness of breath and chest tightness. Heart rate and blood pressure may be elevated initially. Other nonspecific symptoms include dizziness, excitement, nausea, vomiting, headache, and weakness. If the poisoning becomes more severe, obtundation, coma, severe acidosis, and hypotension ensue. Cyanide levels greater than 0.5 mg/L are considered toxic.

This rapidly acting poison must be treated quickly and effectively to avoid central nervous system (CNS) damage and death. Cyanide is normally detoxified in the body by the action of the mitochondrial enzyme *rhodanese*:

Rhodanese converts cyanide into less toxic thiocyanate, which is excreted by the kidneys. Treatment includes the administration of 100% oxygen. Although this treatment may not improve cytochrome function, it will antagonize CO toxicity, which may be simultaneously present in victims of closed-space fires. The antidotal strategy for cyanide poisoning involves the administration of nitrites to convert hemoglobin to methemoglobin. Cyanide preferentially binds to methemoglobin, converting methemoglobin into cyanmethemoglobin. Sodium thiosulfate converts cyanmethemoglobin to the less toxic thiocyanate, which is then excreted in the urine. Cyanide is avidly bound by the iron ion moiety in the methemoglobin molecule. As a result, the induced methemoglobin scavenges free cyanide, thus preventing it from complexing with mitochondrial cytochromes. It is important to keep the methemoglobin level less than 20% to avoid impairing oxygen delivery. This limit should be lowered in anemic patients.

Methemoglobin can be induced before intravenous (IV) access is obtained by having the victim inhale vapors from crushed amyl nitrite pearls for 15 to 30 seconds with a 30-second rest between doses. Each pearl lasts approximately 2 to 3 minutes. Inhalation will produce a methemoglobin level of approximately 5%. When IV access is established, 300 mg of sodium nitrite (10 ml of a 3% solution) in adults is given over 5 minutes while monitoring for hypotension, to convert additional Hb to methemoglobin. Sodium nitrite (150 mg) can be administered again in 2 hours (in adults) if the methemoglobin level is less than 20%. Methemoglobin levels must be monitored. Nitrite-induced methemoglobin can be particularly hazardous to young children because Hb kinetics vary with age. Sodium thiosulfate (the usual adult dose is 12.5g; 50 ml of a 25% solution) is also administered IV over 10 to 20 minutes as part of the antidote strategy because thiosulfate acts as a receptor for the cyanide radical, yielding thiocyanate. One half of this dose may be repeated in 2 hours if cyanide toxicity persists. Thiocyanate produced can also be toxic if excretion is limited by renal failure.

In Europe, hydroxocobalamin is used to treat cyanide toxicity because the cobalt moiety binds with intracellular cyanide to form cyanocobalamin (a form of vitamin B12). Recently in the United States, the US Food and Drug Administration (FDA) approved the use of hydroxocobalamin for the treatment of

cyanide toxicity. The most commonly reported adverse reactions were red urine, skin redness, headache, and nausea. This drug is available in the approved Cyanokit manufactured by EMD Pharmaceuticals (Durham, NC).

Chemical and biologic warfare agents: an introduction for anesthesiologists

David J. Baker and Michael Nurok

International events have caused renewed interest in the management of patients exposed to chemical and biologic warfare (CBW) agents, and it is now crucial that all anesthesiologists have a basic understanding of this area of medical practice. Agents with major respiratory effects, including nerve- and lung-damaging agents and cyanides, are of particular importance. Many of these agents cause early, life-threatening respiratory failure, and they interfere with the actions of drugs used in general anesthesia. This chapter provides an introduction to CBW agents for anesthesiologists.

Definitions and classifications

The definition of a chemical warfare agent is a chemical substance that is intended for use in military operations to kill, seriously injure, or otherwise incapacitate humans through pathophysiologic effects. Biologic warfare agents are defined as living organisms that are intended to cause disease or death in humans, animals, or plants. In terms of their pathophysiologic effects, chemical and biologic agents may be considered part of a spectrum of hazards with toxins placed between the two.

CBW agents have four essential properties: toxicity, latency, persistency, and transmissibility. Toxicity and latency are most relevant in determining the danger to the victim, whereas persistency and transmissibility are primary determinants of the danger to rescuers. Different agents have different levels of toxicity, and their toxic effects appear with variable latency. Persistency refers to the ability of an agent to remain in the environment after it has been released, and transmissibility refers to the ability to transfer effects to other individuals by either physical contact or contagion. Chemical agents tend to have a short latency and variable persistency, whereas biologic agents tend to have a longer latency and limited persistency. The profile of these four essential properties for each CBW agent determines the strategy for managing CBW casualties and protecting responders.

Although nuclear agents have the potential to be used in terrorist attacks, nuclear devices cause large-scale loss of life and should be more appropriately grouped with conventional weapons systems that cause mass destruction. The explosive release of a radioisotope to cause injury and contamination (the *dirty bomb*) is managed in a similar way to that of chemical agents.

CBW agents have inappropriately been referred to as *weapons of mass destruction*. Medically, this is an inaccurate characterization because CBW agents cause mass injury rather than physical destruction. Early and effective emergency medical management can break the link between mass injury and mass loss of life.

The United Nations International Hazardous Materials (HAZMAT) system classifies and controls toxic industrial chemicals and provides guidance for the management of accidental chemical releases. The accidental release of HAZMAT material can cause mass injury and may represent a more common clinical scenario than the deliberate release of chemical agents.

Principles of incident management and patient care

Anesthesiologists confronted with potential CBW release must be prepared to adopt an approach that protects both responders and patients. Drills should be conducted regularly with other hospital departments and emergency agencies, and anesthesiologists should be familiar with local disaster planning, including the command structure. Protection of emergency responders is essential to avoid further casualties and the transmission of contamination into the hospital, so responders must enact an *all hazards* approach encompassing the ability to respond to multiple potential agents unless the causative agent is known with absolute certainty. Incident management should involve the following key elements:

- Reliance on preexisting communication and command plans,
- Use of appropriate personal protection by all responders,
- Early notification of all relevant personnel and agencies,
- Identification and isolation of the involved area,
- Positioning the response effort away from contaminants,
- Effective scene control,
- Isolation of casualties,
- Integrated reporting of information, and
- Decontamination and care of victims – initially by removing clothing and washing and rinsing skin with soap and water.

Figure 174.1. An anesthesiologist of the Paris emergency medical service wearing Level C protective equipment with a filtration respirator. Anesthesiologists are trained and equipped to work inside contaminated zones in France. (Photograph courtesy of SAMU de Paris.)

Critically injured patients may require advanced life support from responders in protective gear prior to decontamination. Emergency teams with special training and equipment now operate in a number of countries.

CBW release should be suspected if unusual odors or clouds are observed, if large numbers of casualties present with either similar symptoms or from the same area, or if multiple dead or sick animals are reported near the scene. Other features of CBW release include large numbers of otherwise healthy people suddenly becoming sick or multiple patients presenting with neuromuscular illness, weakness, diarrhea, vomiting, and other unusual symptoms. It is important to recognize that mobile patients may have contaminated large geographic areas and other patients prior to being identified. In such situations it is imperative to trace and isolate previous contacts.

There are different levels of personal protection equipment for responders. Level A is the most rigorous protection and includes a positive-pressure, self-contained breathing apparatus

HAZARD IDENTIFICATION CODES DISPLAYED ON SOME INTERMODAL CONTAINERS

Hazard identification codes, referred to as “hazard identification numbers” (also referred to as the Kemler Code) under European and some South American regulations, may be found in the top half of an orange panel on some intermodal bulk containers. The 4-digit identification number is in the bottom half of the panel.

Evacuation

in an impermeable airtight suit. This level of protection is usually worn by firefighters facing high levels of contamination. Level B equipment provides a similar level of respiratory protection compared to Level A, but less skin protection. Level D equipment usually consists of regular barrier and respiratory protection incorporated into working clothes. Level C equipment is the most appropriate for medical personnel when the substance is known, concentrations are measured, and working conditions are identified. Level C provides a good compromise between dexterity and patient access. It includes an air filtration respirator and a chemical-resistant suit, gloves, and boots (Fig. 174.1).

The first step in managing a CBW event is detection and identification of the hazard. Detection and monitoring devices are not widely available for civilians, although local agencies are increasingly acquiring such equipment. The detection, identification, and monitoring of chemical hazards are usually the responsibility of fire departments. A toxidrome, or list of signs and symptoms of contaminated victims, will provide valuable clues to early agent identification. These clues should be communicated to local toxicologists or poison control centers as part of a flash initial assessment. In accidental releases, the agent is generally more easily identified from the hazard identification numbers displayed on tankers or storage facilities (Fig. 174.2).

Initial management should involve triage and use of the advanced life support for acute toxic injury (TOXALS) system introduced by the International Trauma Anesthesia and Critical Care Society (see Table 174.1). This system includes assessment

Figure 174.2. Hazard identification plate. The form of these plates varies among countries and contains information about the agent in question.

and management of the airway, breathing (ensuring filtration of entrained air), circulation, and disability; administration of drugs; management of exposure of the casualty; and control of the environment. Initial casualty management in the contaminated zone must be done by personnel trained to function in protective gear.

Most principles of basic airway management remain the same, but the skills of the rescuer may be impaired by protective gear. The laryngeal mask airway is frequently used by responders who have a loss of manual dexterity due to protective suits and gloves. After the airway is secured, supplemental oxygen and ventilation should be available as many CBW agents cause respiratory depression and failure. If artificial ventilation is used in a contaminated environment, entrained air must be filtered. To assess and address circulation, noninvasive monitoring should be provided for all casualties in addition to intraosseous access, which may be more easily achieved in a contaminated zone than the conventional intravenous route. Disability should be frequently assessed and recorded using the simple AVPU system (patient Alert or reacts to Vocal or Painful stimuli or is Unreactive). In a contaminated zone, this system is more suitable for use than is the Glasgow Coma Scale, which should be used after decontamination. Drugs administered during the event should be recorded in an easily identifiable location either on or attached to patients. Casualties should be completely exposed so that responders may perform a complete injury assessment and thoroughly remove all contaminating agents.

In large-scale disasters, mass ventilation may be required. A number of simple devices are available (Fig. 174.3); anesthesiologists should be involved in their procurement and should be familiar with their function.

During an event requiring mass ventilation, operating conditions and patient monitoring are likely to be suboptimal; these considerations must be taken into account in selecting strategies for mass ventilation. A simple, standardized approach should be

Figure 174.3. A Pneupac VR1 emergency ventilator with a chemical, biologic, radiologic, and nuclear circuit for use in a contaminated zone. (Photograph courtesy of Smiths Medical International Ltd, United Kingdom.)

selected, ideally using equipment that is familiar, interchangeable, compatible, and widely available in a given region.

Agents, pathophysiology, and treatment

Various agents may be involved in CBW and can be classified as nerve agents, vesicants, lung-damaging agents, mitochondrial agents (cyanides), toxins, bacteria, or viruses. Comprehensive reviews of these agents are available elsewhere. The following sections are intended as a brief overview with a focus on agents for which anesthesiologists will be required to provide early treatment. Treatment recommendations change frequently, and clinicians should consult government regulatory agencies for the most recent recommendations.

Nerve agents

Nerve agents are organophosphate compounds, the same chemical class to which many pesticides belong. The least persistent agents, such as sarin, are usually inhaled, whereas more persistent agents, such as VX, pose a greater risk of transmissibility because they remain on skin and clothing.

Organophosphates produce their primary toxic effect by inhibiting acetylcholinesterase. They also inhibit butyrylcholinesterase, providing a convenient marker of exposure, and they may create a neuropathy through the inhibition of neurotoxic esterase. Cholinesterase inhibition produces a buildup of acetyl and butyryl choline. Muscarinic effects include miosis, ciliary body spasm, glandular hypersecretion, sweating, bradycardia, heart block, bronchoconstriction, vomiting, and diarrhea. Nicotinic peripheral effects include fasciculation, paralysis, and anomalous tachycardia due to ganglionic stimulation in the sympathetic system. Central effects include apprehension, dizziness, amnesia, seizures, coma, and respiratory depression. Nerve agents also have effects on other receptor systems, including γ -aminobutyric acid (GABA) and *N*-methyl-*D*-aspartate (NMDA). The time necessary for irreversible binding of nerve agents to acetylcholinesterase depends on the particular agent.

Primary treatment of organophosphate poisoning should involve the provision of life support and symptomatic management. Specific treatments include atropine, which antagonizes acetylcholine at the muscarinic synapses. Atropine should be given every 5 to 10 minutes until the heart rate rises above 80 bpm and the pupils dilate. Oximes can reverse the action of organophosphates at the nicotinic receptor, but their efficacy depends on the particular organophosphate and duration of exposure. The most appropriate oxime for the civilian setting is pralidoxime mesylate, which should be given simultaneously with atropine and slowly (over 20 minutes) to prevent laryngospasm, rigidity, and hypertension. Cerebral convulsions due to the central actions of organophosphates on M_2 receptors must be treated with benzodiazepines. Atropine, oxime, and lysine diazepam may be combined into a single automatic syringe that can be used to deliver an emergency intramuscular injection of the drugs at the point of exposure.

Pyridostigmine is a dimethyl carbamate compound with a quaternary nitrogen atom that prevents it from crossing the blood–brain barrier. Pyridostigmine has an action similar to that of organophosphates, is reversible, and produces only a mild parasympathetic response. These features make the agent useful for pretreatment by binding approximately 40% of acetylcholinesterase, yielding it resistant to further attack by organophosphate. The complexed enzyme returns to 90% of normal within 12 hours of a dose. Victims of high-level organophosphate exposure may require life support during the window of time that it takes for pyridostigmine-bound acetylcholinesterase levels to return to normal, as large quantities of organophosphate will complex with any acetylcholinesterase not bound to pyridostigmine and thus will cause an acute cholinergic syndrome with depolarizing block.

It is important to note that the metabolism of succinylcholine will be inhibited in patients who have been pretreated with pyridostigmine. Patients may also exhibit resistance to nondepolarizing neuromuscular blocking agents.

Mitochondrial (or blood) agents

Hydrogen cyanide is a chemical agent that inactivates cytochrome oxidase, thereby inhibiting the production of adenosine triphosphate (ATP). Exposed patients report a smell of almonds and a metallic taste that precedes dyspnea and hyperventilation, which further increases the absorbed dose. Loss of consciousness, convulsions, and respiratory arrest ensue.

Antidotes to cyanide poisoning work by removing free cyanide. Sodium and amyl nitrite induce the formation of methemoglobin, which has a high affinity for cyanide. Hydrogen cyanide is naturally broken down by rhodanese into non-toxic thiocyanate, a process that can be accelerated by giving sodium thiosulfate. Finally, hydroxycobalamin, a cobalt-containing precursor of vitamin B12, can be given to chelate free cyanide. In most cases, methemoglobin inducers or hydroxycobalamin should be given before sodium thiosulfate. Glucose should be given with these treatments to address the toxicity caused by cobalt ions. Finally, mechanical ventilation with 100% oxygen should be used because it is now believed to enhance the effect of cyanide antidotes. Given the complexity of cyanide poisoning, the reader is encouraged to consult a toxicologist for a comprehensive treatment strategy.

Only a few of the toxins produced by bacterial organisms are likely to be encountered in disasters or chemical warfare. Botulinum toxin is produced by the bacteria *Clostridium botulinum*. It permanently blocks the release of acetylcholine and is highly potent. Symptoms include a dry mouth, progressive bulbar palsy, and ocular signs followed by descending muscular weakness and respiratory failure. An antitoxin exists, but its efficacy is uncertain. Treatment is based on ventilatory support combined with specific antitoxin administration.

Ricin is produced by the seeds of the castor bean plant, and the ease with which it can be extracted makes it a likely candidate for terrorist use. There is a significant latent

period after exposure, followed by signs and symptoms consistent with the inhibition of protein synthesis. These symptoms include diarrhea, drowsiness, confusion, convulsions, coma, cardiorespiratory collapse, and multiorgan failure. Treatment is supportive.

Saxitoxin is a marine toxin that acts directly on motor neurons. It can be inhaled, and it blocks voltage-gated sodium channels, causing cardiorespiratory failure and neurologic symptoms. Treatment is supportive and includes mechanical ventilation.

Lung-damaging agents

Lung-damaging agents cause irritant effects on upper and lower airways. They interact with various cells in the respiratory system, including type I and II pneumocytes and alveolar macrophages. The inflammatory cascade that they induce results in pulmonary edema after a latent period of 12 to 24 hours and subsequent acute respiratory distress syndrome. Agents include chlorine, phosgene, and isocyanates.

There is no specific treatment for lung-damaging agents, but experience from World War I mandates that all potentially exposed victims be observed for at least 24 hours. The likelihood of acute respiratory distress syndrome makes protective ventilation strategies in intensive care units desirable for persons who have been exposed.

There is controversy about the use of steroids following an exposure to lung-damaging agents. Cyclic adenosine monophosphate (cAMP) diesterase inhibitors and β -adrenergic agents have theoretical value by virtue of the fact that they increase levels of cAMP. In addition, some experts believe that agents that increase intracellular glutathione (namely, *N*-acetylcysteine) may be useful.

Vesicants

The best known vesicant is mustard gas. It has a latency of 2 to 4 hours, and initial symptoms include blurred vision, ocular pain, and lacrimation. These symptoms are followed by erythema and edema of exposed skin that progress to first-degree burns, bullae, and necrosis.

Respiratory effects are initially limited to dry cough and hoarseness but may go on to produce bronchiolitis that is of variable severity, potentially requiring ventilation. Leukopenia is also evident several days following exposure.

There is no specific treatment for mustard gas exposure, and decontamination during the latent period is essential. Early respiratory support and intubation are advised, and there is some evidence to support using a combination of sodium thiosulfate, vitamin E, and dexamethasone to improve survival in cases of respiratory distress.

Biologic agents

Effective biologic agent dispersal requires aerosol release, but only a few organisms have been shown to survive this process,

particularly in strong sunlight. Biologic agents can be difficult to manage because of their long latency, persistency (in the case of spore-forming organisms, such as anthrax), and contagious transmissibility. Victims contaminated with biologic agents should be decontaminated in the same way as persons contaminated with chemical agents.

As noted earlier in text, few biologic agents are capable of withstanding the stress involved in aerosolization. A notable exception is anthrax in its spore form. Following the initial exposure to inhaled spores, victims report malaise, fatigue, fever, and a nonproductive cough for up to 4 days. During this period, anthrax toxin is being released into the blood. This release is followed by necrotizing, hemorrhagic mediastinitis and multiple organ failure. Approximately half of all cases develop hemorrhagic meningitis.

Vaccines are available against anthrax. Prophylaxis and treatment with antibiotics are also effective, and updated recommendations should be consulted regularly. Anesthesiologists and intensivists should use filter protection against cross-contamination where possible.

Cholera is another potential terrorist agent that could be delivered by contamination of a water supply. Treatment consists primarily of rehydration, and antibiotics play a secondary role in therapy.

Glanders is an equine disease caused by *Burkholderia mallei* that can affect humans. Septicemia occurs 1 to 2 weeks after exposure and may progress to septic shock and multiorgan failure. Antibiotics are the mainstay of treatment.

Now that smallpox vaccination programs have ended, the disease presents a potential threat as a terrorist hazard. Treatment consists of isolation and supportive therapy, but antiviral drugs may be effective.

Other agents that could be used include tularemia-contaminated fodder and *Yersinia* in rat-borne fleas.

Conclusions

As physicians skilled in life support, anesthesiologists are the logical choice for caring for victims of contamination by chemical and biologic agents. Required competencies include familiarity with local emergency plans, access to protective gear and training in its use, local mass ventilation capabilities, knowledge of the pathophysiology and treatment of potential agents, and access to necessary treatments. This chapter should be considered an introduction to this complex field; comprehensive reviews are available elsewhere.

Anesthesia for robotic surgery

Ervant Nishanian

The minimally invasive surgical revolution has ultimately evolved into robot-assisted surgery. Robotic devices allow for unprecedented control and precision of surgical instruments in minimally invasive procedures. The anticipated benefits of minimally invasive surgery offer the patient less pain and trauma, shorter hospital stays, quicker recovery, and better cosmetic results. Surgical robots are mechanical helping hands that offer assistance in various fields of surgery. With these robotic technological innovations, however, new patient anesthetic concerns have emerged. As surgery moves into the robotic era, so too does the need for new anesthetic skills.

Abdominal surgery

The most commonly performed robot-assisted procedures include cholecystectomy, Nissen fundoplication, Heller myotomy, bariatric surgery, and colectomy. Robotic surgery overcomes some of the disadvantages of conventional laparoscopic procedures with three-dimensional imaging, elimination of motion reversal (fulcrum effect), motion scaling, and filtration of resting tremors and offers an ergonomically comfortable position. Although outcome data on robotic surgery are sparse, some of the reported advantages include a short learning curve, better quality of repair, and ease of operation in morbidly obese patients.

Anesthetic considerations

In the operating room, the patient is monitored with an electrocardiographic (ECG) device, pulse oximetry, an axillary temperature probe, and blood pressure monitoring devices. Bilateral peripheral intravenous access is valuable because one of the upper extremities may not be available during the surgery. The patient is sedated with a mild sedative and prepared for induction after preoxygenation. The trachea is intubated with a single-lumen endotracheal tube, and its placement is confirmed. Patients with reflux may require rapid-sequence induction. Anesthesia can be maintained with a volatile agent. Muscle relaxation and monitoring are paramount in avoiding any movements by the patient while the surgical instruments are within the abdominal cavity. An orogastric tube, urinary bladder catheter, and convective-air body warmers are applied whenever possible.

With the patient in the supine position, the patient is prepared and draped, and the abdominal cavity is insufflated with carbon dioxide (CO₂) to a pressure not to exceed 20 mm Hg. The trocar for the camera is placed manually. Incision ports for Nissen fundoplication and cholecystectomy are shown in [Fig. 175.1](#). The side cart robot is then brought close to the patient's head to engage the other trocars with visual guidance from the robotic camera. Because of the proximity of the side cart to the patient's head, there is limited access to the patient's airway and neck, and the head must be guarded against inadvertent collision by the movements of the robotic arms. After the robot is engaged, the patient's body position or table height cannot be changed. For example, if the patient requires an increase in cardiac filling pressures, the patient can be placed in the Trendelenburg position only after disengaging the robot from the patient. The surgical team should be capable of rapidly disengaging the robotic device if an airway or anesthesia emergency arises. As with any abdominal laparoscopic procedure that requires a CO₂-pressurized pneumoperitoneum, ventilator adjustments may be required to normalize the exhaled CO₂ while protecting the lungs from barotrauma.

Cardiothoracic surgery

Cardiothoracic applications of robot-assisted surgery have expanded and include atrial septal defect closures, mitral valve repairs, patent ductus arteriosus ligations, totally endoscopic coronary artery bypass (TECAB) grafting, minimally invasive atrial fibrillation (AF) surgery, and left ventricular (LV) pacemaker lead placement.

Although technical advances in minimally invasive surgery have introduced techniques that are done through small ports and may eventually make surgical sternotomy obsolete, surgeons must still be trained and prepared to convert to an open sternotomy if the need arises.

Knowledge of and expertise in cardiac and thoracic anesthesia are imperative because both organ systems need to be managed safely. The ability to perform and maintain single-lung ventilation is mandatory, as is management of the physiologic consequences ([Table 175.1](#)). Preoperative assessment of lung function is indicated if a patient has significant lung disease. An abnormal result of a pulmonary function test may be a contraindication to robot-assisted cardiac surgery because

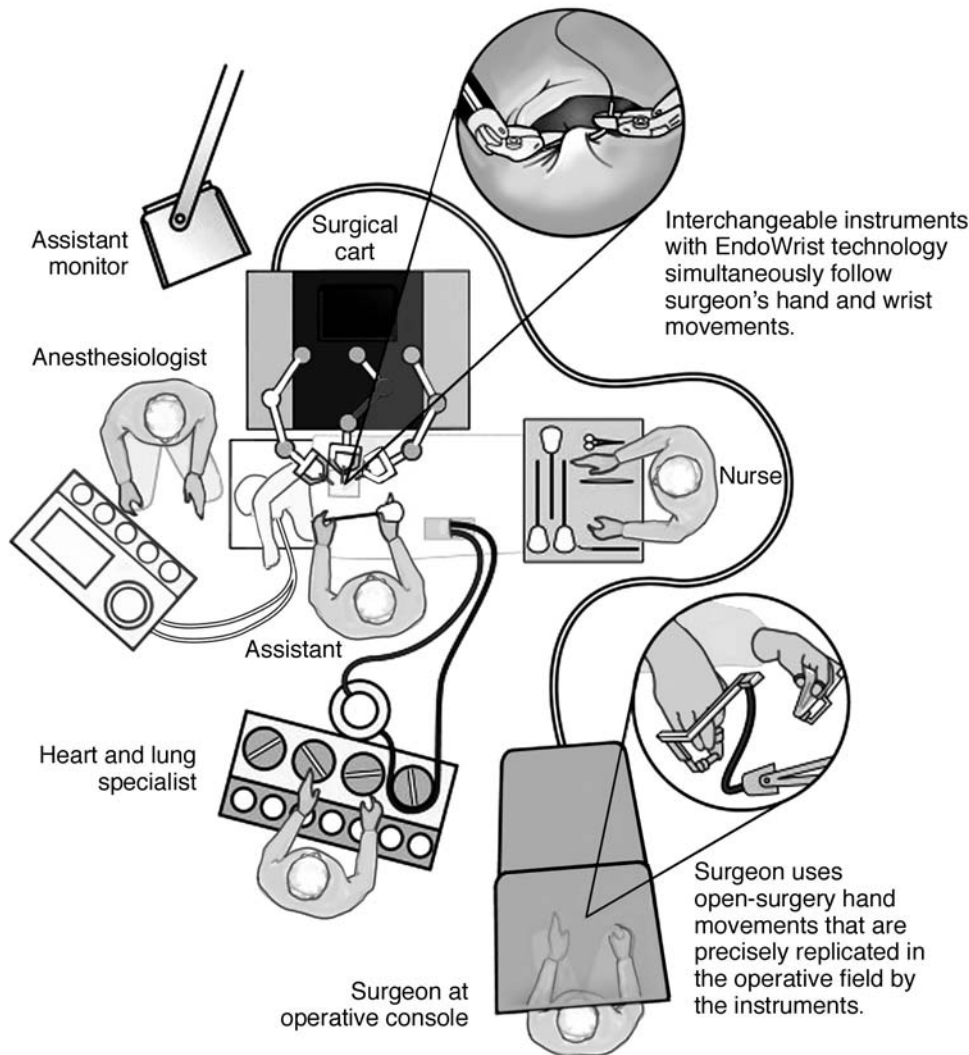

Figure 175.1. Operating room schematic of the use of a robotic surgical system in fundoplication surgery. (Courtesy of Intuitive Surgical, Inc., Sunnyvale, CA.)

single-lung ventilation may be poorly tolerated. Severe pulmonary hypertension renders a patient unsuitable for robotic surgery due to the potential for hypercarbia with single-lung ventilation. Robotic surgery may require unprecedented, prolonged single-lung ventilation with nonpulsatile flow, which may challenge the extent of our knowledge about respiratory physiology. Continuous monitoring of cardiac function with transesophageal echocardiography (TEE) has become a standard of care. All patients undergoing robotic cardiothoracic

surgery are evaluated preoperatively by TEE to exclude the possibility of persistent left-sided superior vena cava (SVC) or patent foramen ovale.

In 2002, the US Food and Drug Administration (FDA) approved the use of robot-assisted surgery in performing mitral valve repairs. Mitral valve repair, initially done through mini-thoracotomy incisions, could be done completely with a closed chest. Mitral valve replacements, however, may still require a small thoracotomy to introduce the new prosthetic valve.

Table 175.1. Single-lung ventilation strategy

1. Use $FiO_2 = 1.0$.
2. Begin single-lung ventilation with pressure control ventilation, maintaining a plateau pressure < 30 cm H_2O .
3. Adjust respiratory rate so that $PaCO_2$ approaches 40 mm Hg.
4. Check arterial blood gases periodically.
5. Apply continuous positive airway pressure to nonventilated lung.
6. Apply positive end-expiratory pressure to ventilated lung.

FiO_2 , fraction of inspired oxygen content.

Anesthetic implications for mitral valve surgery

Mitral valve surgery employing robotic devices is performed at a few cardiac centers in the United States and Europe. Patients are initially evaluated by using cardiac catheterization to estimate the degree of coronary artery stenosis and to assess valve function. Most hypertensive patients with significant mitral regurgitation are treated with afterload reducers. A concomitant enlarged left atrium is often susceptible to AF, which may

Figure 175.2. Operating room schematic of the use of a robotic surgical system in cholecystectomy surgery. (Courtesy of Intuitive Surgical, Inc., Sunnyvale, CA.)

mean additional medication for anticoagulation and rate control. Chronically elevated left atrial pressure may manifest with pulmonary hypertension, which may be further exacerbated by obstructive lung disease.

Patients are provided with a large peripheral intravenous line and routinely monitored with ECG leads II and V5, pulse oximetry, and a noninvasive blood pressure cuff prior to placement of arterial lines. Light sedation with midazolam is offered before the placement of bilateral radial arterial lines. Occlusion of the innominate artery by an endovascular aortic occlusion balloon can be monitored with the right radial arterial line.

After ample oxygenation, the patient is anesthetized with a combination of midazolam, fentanyl, and an inhalational agent. Upon muscle relaxation, the trachea is intubated with a double-lumen endotracheal tube. Proper tube position is confirmed by bronchoscopy. A TEE probe is inserted to assess heart and valve function and to guide central line placement. A left internal jugular 9-French introducer catheter is inserted, and an 8-French pulmonary artery catheter is floated into the pulmonary artery. Secondarily, the right neck is prepared for insertion of a percutaneous, 17-French armored Bio-Medicus cannula, which

is inserted directly into the internal jugular vein; its proper position in the SVC is confirmed by TEE. At the time of insertion, the SVC cannula is flushed with 5000 units of heparin to ensure its patency. The cannula is anchored and secured with a purse-string suture at the skin. The pelvis is also prepared for cardiopulmonary bypass cannulation.

After the patient is positioned (Fig. 175.2), transcutaneous defibrillation and pacing pads are applied. The surgeon can then determine proper location for port access, which may vary according to a patient's body habitus.

Anesthesia is continued with opioids, muscle relaxants and volatile agents delivered through a double-lumen tube with the right lung deflated. A right-sided mini-thoracotomy incision is made. The heart is exposed after a pericardial opening is made. After the patient is heparinized based on an activated coagulation time (ACT)-guided protocol, the femoral vein and artery are cannulated in anticipation of femoral-femoral cardiopulmonary bypass. The positions of the arterial and venous cannulas are confirmed with TEE. Anterograde and retrograde cardioplegia cannulas are placed. After initiating cardiopulmonary bypass, a transthoracic aortic cross-clamp is passed

percutaneously through the right axilla and applied to the ascending aorta, and the heart is arrested with cardioplegia. Alternatively, an endovascular balloon occlusion device can be used instead of an aortic cross-clamp.

The robotic arms are engaged through their respective trocars lateral to the mini-thoracotomy incision while the camera arm passes directly through the thoracotomy incision. The left atrium can be entered for mitral valve repair or replacement.

Before terminating cardiopulmonary bypass, TEE is used to evaluate the function of the mitral valve and residual valvular regurgitation and to confirm the disappearance of intracardiac air. The anterior leaflet of the mitral valve is further inspected for systolic anterior motion.

Patients may be excluded from robot-assisted mitral surgery if they have significant mitral annular calcification, ischemic heart disease, a requirement for multiple valve repairs, previous surgery in the right hemithorax, or significant pulmonary hypertension.

Atrial septal defect repair

Dogan and coworkers reported the first successful closed-chest closure of an atrial septal defect. Operations for atrial septal defects are similar to those for mitral valve repairs, except that a mini-thoracotomy is not required. Like all robotic procedures that demand entrance into the thoracic cavity, single-lung ventilation must be instituted during surgery. Atrial septal defect repairs also require opening the heart and preventing any blood from flowing into the heart. The interruption of blood flow into the heart is facilitated by jugular and femoral vein cannulation and snaring the inferior vena cava (IVC) and SVC. Cardiopulmonary bypass with cardioplegia administration into the aortic root is used to arrest the heart.

Internal mammary artery harvest

Patients are monitored in the usual way for cardiac surgery. A central venous line and a radial artery cannula are placed on the same side as the harvested internal mammary artery. There is a mandate for single-lung ventilation with tube placement confirmed by bronchoscopy. The patient is positioned supine, with the thorax rotated 20° by placing a roll under the left scapula. External defibrillation and pacing pads are applied to the left posterior chest and anterolateral right chest. Raising the left arm provides more exposure and thins the skin overlying the left anterolateral chest. The opposite can be done to the right chest when harvesting only the right internal mammary artery. CO₂ insufflation is needed to provide exposure and counter traction. CO₂ insufflation (5–10 mm Hg) into the left hemithorax pushes the mediastinal fat pad medially and enlarges the space between the sternum and heart to a small extent to provide a better view. When harvesting both internal mammary arteries, insufflation of the left hemithorax is sufficient to expose the right internal mammary artery because of the leftward position of the heart and the improved angle of sight. Insufflation is begun in increments of 2 to 4 mm Hg. The insufflation flow

rate is adjusted automatically to achieve a preset intrathoracic pressure limit. Caution should be exercised when insufflating the thorax in patients who have poor LV function or who are hypovolemic (central venous pressure < 5 mm Hg). Patients should have their volume status augmented before proceeding to full insufflation. CO₂ insufflation and single-lung ventilation increase central venous pressure and pulmonary artery pressure by a small amount. Bilateral pneumothoraces are deliberately produced when doing bilateral internal mammary artery harvest. Most patients studied tolerate small bilateral pneumothoraces well for periods less than 1 hour.

Coronary artery bypass grafting

Patients are prepared and monitored for anesthesia in a manner similar to that for mitral valve surgery. Monitoring of the right radial artery pressure tracing is imperative when using an endovascular balloon-occlusion catheter. After the patient is asleep, inspired oxygen tension and expired CO₂ are monitored. TEE is used to monitor cardiac function and confirm catheter placement. Pulmonary artery catheters may be redundant and are judiciously used in the appropriate patient population. The patient is positioned the same as for internal mammary artery takedown, and trocars are placed as depicted in Fig. 175.3.

When cardiopulmonary bypass is anticipated, the left femoral artery is cannulated with a 17- or 21-French remote access perfusion (RAP) catheter with an aortic occlusion balloon. This catheter allows antegrade flow of 4 or 5 L/min, respectively. The cannula has a separate lumen for delivering cardioplegia to the aortic root beyond the occlusion of the balloon. The aortic cannula is positioned in the ascending aorta, 2 cm above the aortic valve. The endovascular balloon is inflated with a volume equal to the diameter (in milliliters) of the sinotubular junction of the aorta. A balloon pressure greater than 300 mm Hg usually provides complete occlusion of the aorta. Residual flow around the balloon can be seen and monitored with color flow on TEE. The use of bilateral radial artery lines is useful in detecting the migration of the occlusion balloon toward the innominate artery. Proximal migration of the balloon can be monitored with TEE to prevent balloon herniation through the aortic valve.

After left lung ventilation is begun, the ventilator is adjusted to provide an end-tidal CO₂ pressure of 35 to 40 mm Hg. Ports can be placed safely after the right-sided pneumothorax has formed. CO₂ is insufflated into the right hemithorax and continued at a pressure of 5 to 10 mm Hg, allowing the affected lung to collapse further and providing a larger visual field. It may also prevent mediastinal shifts during single-lung ventilation when large tidal volumes are used, such as in a patient with emphysematous lungs. Sternal lift retractors can increase the retrosternal space by raising the sternum above the anterior surface of the heart and provide better exposure.

Robot-assisted, beating-heart coronary artery bypass grafting can be accomplished with appropriate patient selection. Articulating stabilizers passed through a subxiphoid port can

Figure 175.3. Operating room schematic of the use of a robotic surgical system in cardiac surgery. (Courtesy of Intuitive Surgical, Inc., Sunnyvale, CA)

stabilize the anterior surface of the heart to facilitate grafting. Bilateral internal mammary artery grafting has also been accomplished.

Atrial fibrillation surgery

AF is one of the most common rhythm disturbances encountered in clinical practice. The Cox maze procedure is the treatment of choice in medically resistant AF. Excellent long-term results have been reported with this procedure, in which right and left atrial atriotomies are combined with cryoablation to interrupt reentrant rhythms and restore sinus rhythm.

Many approaches have been used for minimally invasive AF ablation surgery. The most commonly used approach uses the da Vinci system via right mini-thoracotomy using peripheral cannulation and cardiopulmonary bypass, but a total endoscopic approach on the beating heart has also been described.

The patient is placed in a supine position. In addition to the standard monitors, invasive arterial and central venous pressures are also monitored. Pulmonary artery catheters can be

used in appropriate patients. After induction of anesthesia and tracheal intubation, the position of the double-lumen endotracheal tube is confirmed by fiber-optic bronchoscopy. A TEE probe is inserted for intraoperative cardiac monitoring and to rule out a clot in the left atrial appendage. External defibrillator pads are applied to the chest. Single-lung (left) ventilation is instituted, and CO₂ is insufflated to produce a right pneumothorax. Three 1-cm port access incisions are made at the level of the third, fourth, and fifth intercostal space on the anterior axillary line for the robotic arms and the endoscope. The beating heart is exposed after dissecting the pericardium. By using a microwave probe (Flex10; Boston Scientific, Natick, MA), a continuous circular lesion is produced encircling the pulmonary veins. Arrhythmias in the early postoperative period are treated with amiodarone and β -blocker therapy.

Left ventricular lead placement

A large number of patients with heart failure exhibit cardiac dyssynchrony secondary to delay in activation of LV free

wall. These patients can have a further decrease in ventricular function, which later might worsen mitral regurgitation and increase the risk of death. Ventricular resynchronization has been shown to improve ventricular function, exercise capacity, and quality of life. Standard biventricular pacing is performed by inserting transvenous right atrial and ventricular endocardial leads. An epicardial LV lead is inserted by cannulating the coronary sinus in the right atrium and advancing the lead via venous tributaries of the coronary sinus to the ventricular surface. This approach suffers from a failure rate of 15% to 20% due to inability to cannulate the coronary sinus. Late LV lead dislodgement occurrence is 5% to 10%.

Some surgical groups have developed a total endoscopic robotic approach to lead placement. A total endoscopic approach requires isolated right lung ventilation. Left lung is excluded and left hemithorax is insufflated with CO₂ at a pressure of 8 to 10 mm Hg. Robotic arms are inserted by incisions in the left fifth and ninth intercostal spaces, respectively, in the posterior axillary line, and the camera is inserted into the seventh intercostal space. The pacing lead is introduced through a working port and attached between the first and second obtuse marginals between the base and the apex. A second pacing lead is attached near the second obtuse marginal, and the pericardium is closed over the leads. Both the leads are tunneled to an incision in axilla, and retested for threshold. The lead with the best threshold is connected to the pacemaker; the other lead is capped and secured to the fascia for future use. If a right-sided pacing lead is needed, it is inserted transvenously at this time and connected to the biventricular pacemaker.

This approach allows for reliable entry into the chest for LV lead insertion, while also allowing complete cardiac access for mapping.

Thoracic surgery

Thoracic procedures being performed include multiple esophageal procedures including Heller's myotomy, resection of esophageal and mediastinal masses, esophagectomy, thymectomy, and pulmonary lobectomy.

Although video-assisted thoracoscopic surgery (VATS) is well established, its use is limited to simple procedures. Robotic thoracic surgery presents with a different set of challenges. The surgical challenges include rigidity of the chest wall and movement of heart, lungs, and mediastinum. The anesthesia-related challenges are similar to the cardiac issues and include prolonged single-lung ventilation and hemodynamic instability associated with CO₂ insufflation of the hemithorax.

Patient positioning plays a major role in exposing otherwise inaccessible areas, as mediastinal structures are heavy and mobile and change position in response to gravity. The supine or slight lateral decubitus (raising one side 15–30°) position is ideal for anterior mediastinum pathology. A 90° lateral position may be optimal for hilar masses and lobectomies, whereas a nearly prone position may create better exposure for posterior mediastinal masses. CO₂ insufflation also plays a big role

in achieving adequate exposure by pushing mediastinum to the opposite site while compressing the lung away from the operative site. It also reduces fogging and removes cautery smoke. Steep head-down position (>30°) will decrease FRC (functional residual capacity) by the accumulation and pooling of intrathoracic blood.

Neurosurgery

From the late 1980s through 1993, neurosurgeons investigated the use of robots to precisely position resection probes and devices within neural parenchyma to provide minimally invasive surgery and to protect normal tissue. Stereotactic navigation during neurosurgery has provided an image-guided system for real-time tracking of surgical instrument tips. CyberKnife (Accuray, Inc., Sunnyvale, CA) is an image-guided, frameless, stereotactic radiosurgery system for treatment of spinal tumors. The major potential benefit of radiosurgical treatment of spinal lesions is that it can be performed in an outpatient setting, with rapid recovery. The Neuromate stereotactic robot (Integrated Surgical Systems, Davis, CA) is a frameless system and uses MRI data for treatment of movement-based disorders. MRI-compatible robotic systems have also been developed for neurosurgery. Patients may be placed in sitting or beach chair positions, which present to the patient a number of anesthetic concerns that are mentioned elsewhere.

Urologic surgery

The first use of robotics in urology was in the late 1980s when a robotic frame was developed for transurethral resection of prostate (TURP). The frame was constructed to support the six-axis Unimation Programmable Universal Machine for Assembly (PUMA) robot. The safety of this device is derived from the circular steel frame that restricts and confines the robot to a precise arc of resection. Such procedures can be done more quickly with a robotic instrument, and because hemostasis is done only once at the end of the procedure, there is less time for absorption of irrigation fluid. The PUMA robot has been used to resect prostate tissue safely.

The percutaneous access robot (PAKY-RCM; URobotics, Baltimore, MD) is used with fluoroscopy or CT guidance to improve accuracy of needle placement in percutaneous nephrolithotomy and tissue biopsies. The most advanced system currently being used in urology is the da Vinci robotic system. The procedures performed using the da Vinci system include radical prostatectomy, radical cystectomy, radical and simple nephrectomy, live donor nephrectomy, pyeloplasty, and adrenalectomy.

Radical prostatectomy

Guillonneau and Vallancien were the first to show the feasibility and efficacy of laparoscopic radical prostatectomy. Since then, robot-assisted radical prostatectomy (RAPR) has become the most common procedure performed with robotic assistance.

In 2005, more than 8000 procedures were performed. Outcome data, such as transfusion rate, positive surgical margin rate, urinary continence recovery, and erectile function with RAPR, seem to compare favorably with laparoscopic or traditional retropubic approach.

Anesthetic considerations

After induction of anesthesia, an arterial line may be placed for frequent phlebotomy and as dictated by the patient's comorbidities. An additional, large-bore intravenous line may be considered when the potential for excessive blood losses is anticipated. Muscle relaxation is imperative to the safety of the patient because any movements by the patient while the surgical instruments are within the abdominal cavity could be catastrophic. The patient is placed in a supine lithotomy position with 30° Trendelenburg incline (Fig. 175.3). The thighs are spread apart far enough to allow the approach of the robotic system between them. Patients shorter than 6 feet have their legs in a frog-leg position. The prolonged Trendelenburg position may be relatively contraindicated in patients with a history of stroke or cerebral aneurysm. Because of the long procedure, silicone gel pads are placed at every pressure point. Some surgeons advocate tucking the patient's arms while the patient is awake to maintain optimal comfort and avoidance of neurapraxia. After a 14-French Foley catheter is inserted, the body is prepared and draped. A pneumoperitoneum is created through an umbilical puncture needle, and the maximum pressure is set to 15 mm Hg. The trocar is inserted according to the standardized Heilbronn approach using a semilunar five-trocar arrangement, with a sixth trocar in the suprapubic area.

Radical cystectomy

Radical cystectomy remains the gold standard for treatment of bladder cancer. The first case series of robotic radical cystectomy was described in 2003; since then, other case reports and small case series have been published.

Anesthetic considerations

Patients are monitored and anesthetized in a similar manner to that in radical prostatectomy procedures. An arterial line may be placed depending on the patient's comorbidities. After tracheal intubation, an additional, large-bore intravenous line may be considered. Anesthesia can be maintained with a volatile agent. Muscle relaxation must be continued to prevent injury with the stationary robot. The patient is positioned in an extended lithotomy position with 45° of Trendelenburg incline, and silicone gel pads are placed at every pressure point. Convective-air body warmers are applied whenever possible. Using the da Vinci system, a six-port approach is used to perform pelvic lymphadenectomy and cystoprostatectomy. The specimen is removed in a bag through a 5- to 6-cm suprapubic incision. Through this incision the bowel is exteriorized and a

neobladder is created extracorporeally. Subsequently urethero-neovesical anastomosis is performed with robotic assistance. When compared to open radical cystectomy, the advantages of the robotic approach seem to be decreased blood loss and shorter hospital length of stay.

Orthopedic surgery

Total hip arthroplasty

In 1992, a veterinarian who worked in collaboration with IBM developed a robotic system that could be used for hip replacement in dogs. The research collaboration resulted in the first surgical robot – ROBODOC (CUREXO Technology Corp., Fremont, CA).

In the operating room, the surgeon removes the native femoral head and places the acetabular cup into its place according to the routine manual procedure. The femur is then rigidly clamped and secured by the robot fixator. The robot is allowed to recognize the three titanium registration pins and compares their location relative to the data obtained from CT. In this manner, the robot has a perfect sense of where the femur lies in three-dimensional space and can perform precise milling of the femoral canal. The remainder of the surgery proceeds manually.

Knee replacement

Most total-knee replacements depend on a system to guide bone sawing. The placement of the jig is based on the surgeon's visual cues from the exposed bone surfaces. Inaccuracies can produce patellofemoral pain and limited flexion in 40% of patients when conventional approaches are used. Inaccuracy of 2.5 mm can produce a 20° change in the range of motion of a joint.

Robotic surgical assistants have been developed to increase the accuracy of prosthetic joint alignment. For the robot to recognize specific landmarks, the pelvis and the ankle must be fixed to the surgical table. Osseous material is less likely to deform under pressure and can keep its shape. Small trials have demonstrated increased accuracy of robotic systems in knee surgery.

Although robots are used in orthopedic surgery to perform repetitive tasks with high precision, their use has minimal impact on the type of anesthesia and monitoring offered to the patient. Orthopedic patients are treated in the same safe manner regardless of the type of robot used.

Ophthalmologic surgery

The challenge of creating a robot that is accurate and has an extremely high level of dexterity and precision was mandated for laser retinal surgery. Because blood vessels in the retina are only 25 μm apart, high precision is necessary. Collaboration between Stephen Charles and the NASA Jet Propulsion Laboratory developed the Robot-Assisted Microsurgery System (RAMS). It is capable of performing laser microsurgery with 10- μm accuracy. The unaided human eye can discern an increment of only 200 μm . RAMS provides a 200-Hz gating system

for eye tracking, and it eliminates the saccades of the eye, allowing the eye to appear perfectly still to the observer. The system also provides a 100:1 scaling that allows for 10- μm incremental movements. Tremor is filtered out between 8 and 14 Hz to eliminate inaccuracy. The ability to work at such small scales is the robot's strength. Newer robotic devices intended for microsurgical application have an accuracy of 5 μm . Such precision would not be conceivable without the dexterity of robotic technology. The type of anesthesia offered is the same as any other offered to patients undergoing ophthalmic surgery.

Summary

The use of robots in surgery is likely to increase because of their enhanced precision and control. Their minimally invasive nature is better tolerated in terms of reducing the stress response, overall pain, tissue trauma, and length of hospital stay, as well as hastening recovery from surgery and improving cosmetic results.

Anesthesiologists need to be aware of this fast-changing field and how it affects anesthetic techniques and their delivery. Initially, robot-assisted surgical thoracic procedures increased the length of time that patients were under general anesthesia. Concomitantly, the duration of single-lung ventilation has been taken to new time extremes, which has given us insight into the respiratory physiology of prolonged single-lung ventilation. As surgeons gain expertise with robot-assisted surgery, operative times will shorten dramatically to the point of traditional open surgery. The inability to move the patient while the robot is attached to the patient will be a challenge when attempting to alter cardiac filling pressures by gravity. As a result, clinicians will be more likely to use pharmacologic agents instead. Anesthesiologists have experience working in locations that are remote from the patient's airway. It should come as no surprise that robot-assisted surgery of the upper body will also provide that challenge. Improved monitoring methods will be needed to make remote anesthesia safe and practical. Perhaps the minimally invasive revolution will advocate earlier patient recovery and the increased implementation of regional anesthetic techniques. The extent of the surgical stress response may be attenuated, ultimately minimizing the inflammatory response.

Preoperative diagnostic imaging in combination with virtual reality simulators will allow the surgeon to rehearse the complex procedures in advance and program the robot to avoid any vital structures during the surgery. Visualization systems

are being developed that will improve surgery on mobile structures, such as the beating heart. Advances in motion-gating technology will allow the heart to appear as if it is standing still. Another area in which development in medical robotics might take place is nanotechnology. The world's smallest untethered robot was recently shown to measure $250 \times 100 \mu\text{m}$. In the future, nanoscale robots will be used to deliver targeted gene therapy or chemotherapy to remote locations in the body. As with all innovations, we must progress with robotic surgery, but with optimistic caution.

Human immunodeficiency virus, methicillin-resistant *Staphylococcus aureus*, and vancomycin-resistant enterococcus

Karan Madan

Since the advent of chemotherapeutic agents, the prevalence of infectious diseases in the Western world has been reduced tremendously. Indiscriminate use and overuse of antibiotics, however, has led to increasingly resistant strains of bacteria. Furthermore, we are also facing the challenge of new diseases, such as human immunodeficiency virus (HIV). Therefore, anesthesiologists encounter patients with infectious comorbidities in the operating room and in intensive care units (ICUs). Anesthesiologists have the responsibility to protect the patient, the operating room staff, and themselves from infections while providing high standards of care to the patient. In this chapter we will discuss HIV, methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococcus (VRE) and their affects on anesthesia and vice versa.

HIV

AIDS was first recognized in 1981 among homosexual young men with Kaposi's sarcoma and *Pneumocystis carinii* pneumonia. Cases were later reported among intravenous drug users and patients with hemophilia. In 1984, it was determined that the causative agent for the disease was what is now called the human immunodeficiency virus type 1 (HIV-1). HIV-2 was identified in 1985 in healthy prostitutes from Senegal. HIV-2 seems to have a slower transmission and progression than HIV-1. End-stage disease for both strains appears to be similar, however.

HIV is transmitted through sexual contact or parenteral exposure to contaminated blood and blood products and perinatally from mother to infant during gestation, delivery, and breast-feeding. Occupational transmission by percutaneous, mucous membrane, and cutaneous exposure is well known. Postexposure prophylaxis has reduced considerably the risk of occupational transmission.

Although the global percentage of people living with HIV has stabilized since 2000, the overall number of people living with HIV has increased as a result of the ongoing number of new infections each year and the beneficial effects of more widely available antiretroviral therapy (ART). Sub-Saharan Africa remains most heavily affected by HIV, accounting for 67% of all people living with HIV and for 72% of AIDS deaths. Globally, there were an estimated 33.8 million people living with HIV in 2008. The rate of new HIV infections has

decreased in several countries, although globally these favorable trends are at least partially offset by increases in new infections in other countries. In sub-Saharan Africa, most national epidemics have stabilized or begun to decline. Outside of Africa, infections are on the rise in a number of countries. As these numbers suggest, the worldwide burden of the disease is significant (see Fig. 176.1).

More than 64% of the world's HIV population live in sub-Saharan Africa, where transmission is primarily through heterosexual contact, with more infected females than males. In the United States, 44% of HIV transmission is among male homosexuals, and 17% is among intravenous drug users. Despite increased funding and a combined international effort, only 20% of patients in need of ART worldwide are receiving it.

For the anesthesiologist in the operating room and intensive care environment, a patient with HIV may present the following challenges:

1. HIV-related end-organ dysfunction,
2. Drug interactions between anesthetic agents and medications, and
3. Occupational exposure of anesthesiologist and other health care providers to the infection.

Various studies have shown that 28% to 73% of patients with HIV have cardiac problems, resulting in 1% to 6% of deaths. These problems include pericarditis, myocarditis, and endocarditis. Pericarditis is the most common cardiac condition, and myocarditis can be caused by opportunistic infections, such as herpes simplex virus (HSV), cytomegalovirus (CMV), *Toxoplasma gondii*, *Candida*, and *Aspergillus*. Zidovudine can cause a decrease in cardiac ejection fraction, pentamidine may cause torsades de pointes, and amphotericin B and doxorubicin can cause cardiac toxicity. Patients may also have decreased levels of protein C and protein S, causing them to be hypercoagulable.

Pulmonary comorbidities in HIV patients may be due to opportunistic infections causing spontaneous pneumothorax, frequent pneumonias, and destruction of lung parenchyma. Patients frequently have decreased diffusion capacity and alveolitis and, hence may require high inspired oxygen concentrations. HIV patients have a higher incidence of malignant tumors, such as Kaposi's sarcoma and lymphoma, which can manifest as hemoptysis or obstruction. Thrombocytopenia is seen in approximately 40% of HIV patients and may exist in

Figure 176.1. Prevalence of HIV infection. Reprinted from Joint United Nations Programme on HIV/AIDS (UNAIDS). 2008 report on the global AIDS epidemic.

otherwise asymptomatic individuals. Anemia is found in 60% of patients and is due to decreased erythropoiesis.

Primary HIV encephalopathy can result in AIDS dementia. HIV can also cause aseptic meningitis and vacuolar myelopathy and can make patients more susceptible to the herpes simplex and varicella zoster viruses. HIV itself, other related opportunistic infections, and antiretroviral medications can cause significant peripheral neuropathy as has been described earlier in the text. Autonomic dysfunction may cause postural hypotension, dizziness, and cardiovascular lability during induction of anesthesia.

Oral lesions such as candidiasis, Kaposi's sarcoma, and herpes simplex can limit mouth opening and/or cause obstruction of the airway. Esophagitis frequently seen in HIV patients can cause persistent bleeding, obstruction, and even perforation requiring surgery. In the ICU, HIV-related diarrhea can cause severe dehydration electrolyte imbalances, malnutrition, and muscle wasting.

Hepatocellular injury due to HIV or coexisting hepatitis B or C is commonly seen. Liver function also can be affected by coexisting Hodgkin's lymphoma, *Mycobacterium*, CMV, or fungal infections, as well as hepatotoxicity associated with drugs such as sulfonamides.

Ten percent of AIDS patients have progressive renal insufficiency. The syndrome of inappropriate antidiuretic hormone (SIADH) secretion also is seen and is due to malignancies, toxoplasmosis, and tuberculosis. Pentamidine, which is used to

treat pneumocystis pneumonia, can cause hyperkalemia and metabolic acidosis.

Adverse affects of antiretroviral drugs include anemia, leukopenia, thrombocytopenia, lactic acidosis, hepatotoxicity, pancreatitis, confusion, and seizures (among others). These adverse affects have to be considered during the formulation of the anesthetic plan for the patient.

In patients with HIV/AIDS, there is no contraindication for administering regional anesthesia wherever indicated (including spinal and epidural anesthesia). There are no clear data, however, supporting that regional anesthesia is either safer or more dangerous in patients with HIV infection. The CNS is a favored site for HIV and is usually infected early in the disease process. The epidural blood patch has also been performed in HIV-positive patients with postdural puncture headache with no untoward consequences. Studies have shown that there is no higher incidence of complications or neuropsychiatric abnormalities 48 months following blood patch administration.

Chronic pain and HIV

Patients with HIV/AIDS experience pain either directly from the disease process and related tumors and infections or as an adverse affect from their antiviral medications. They may also have pre- or coexistent chronic pain. In the past, pain in HIV patients was grossly unrecognized and undertreated. Recently, however, treatment of pain in HIV patients has improved with

increased willingness on the part of the physicians to use opiates.

Approximately 50% of HIV patients have pain that interferes with quality of life. This statistic has been confirmed by numerous studies, such as those by Hewitt et al. and Breitbart et al. The incidence of pain was found to increase with the progression of disease symptoms and the decrease in CD4 T lymphocyte count. Despite pain symptoms caused by antiviral medications, patients who were not being treated by antiretroviral medications reported more pain. Ninety-three percent of patients in an end-of-life hospice reported pain in a study done by Kimball and McCormick. Of these patients, 88% received opioid medication and 62% experienced relief from the same. Overall, studies show that inpatients with HIV have a higher rate of pain than do ambulatory patients. Furthermore, the studies show that pain is poorly recognized and patients are undertreated by the physicians, leading to deterioration of quality of life and worsening of psychosocial well-being.

HIV/AIDS patients differ from other chronic pain patients in that they are usually younger and more active. Their pain syndrome is complicated by feelings of isolation, frustration, and social withdrawal. Being infected with an incurable disease adds significantly to this psychological state. The combination of feelings leads to hopelessness, pain, despair, and anger.

Current recommendations for pharmacologic management of pain in HIV/AIDS are based on expert opinion as a result of randomized, controlled trials. Unfortunately, the population-based outcomes are not yet available. Therefore these recommendations may reflect the bias of specialists who primarily treat inpatients in the terminal phase of disease.

There is no validated protocol to treat HIV-related pain. There are many similarities between cancer and HIV patients suffering from chronic pain. These similarities include the following:

1. The potential to enter a phase, after failure of curative therapy, in which palliation becomes a goal;
2. Phases in which acute, episodic, procedure-related, or chronic stable patterns may predominate;
3. Comorbidities, such as herpes zoster, or altered pharmacokinetics that are caused by concurrent disease or medications;
4. Worsening of suffering because of pain; and
5. Psychosocial issues, including isolation and depression.

There is consistent evidence validating the World Health Organization (WHO) pain ladder (see Fig. 176.2) as a tool for cancer pain management, and it serves as a good starting point for managing HIV/AIDS-related pain.

Methicillin-resistant *Staphylococcus aureus*

MRSA has been a major cause of bloodstream infections in the hospital and intensive care unit. In 2003, it was reported that 64.4% of infections in US intensive care units were due to MRSA causing higher mortality and increased cost. In a 2007 epidemiologic study published by the Centers for Disease Control and

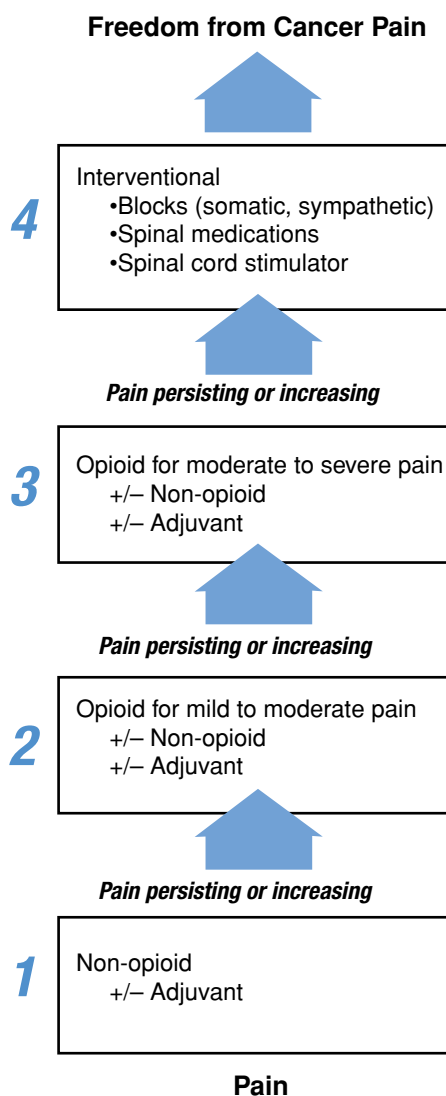

Figure 176.2. The WHO analgesic ladder.

Prevention (CDC), the reported incidence of invasive MRSA ranged from 20 to 50 per 100,000 and approximately one-fourth (26.6%) of these MRSA infections were hospital-onset infections.

Risk factors for hospital-onset infections were history of hospitalization, history of surgery, residence in a long-term care facility, and MRSA infection or colonization. Clinically, the invasive MRSA infections presented as bacteremia (75.2%), pneumonia (13.3%), cellulitis (9.7%), osteomyelitis (7.5%), endocarditis (6.3%), and septic shock (4.3%). Mortality was noted to be approximately 18%, the highest being for patients with septic shock and/or pneumonia. Recurrent infections were seen in approximately 13% of cases.

Vancomycin-resistant enterococcus (VRE)

VRE first emerged in the eastern United States in the early 1990s, and then a few years later was found in the western

United States. According to the National Nosocomial Infection Surveillance system, in 2003 VRE was responsible for approximately 28% of *Enterococci* infections in the intensive care unit.

The risk of a patient in the intensive care unit becoming infected increases with the number of days the patient is exposed to VRE and with the increase in the number of other patients in the unit who are infected. In 2006, the CDC published *Management of Multidrug-Resistant Organisms in Healthcare Settings*. Representative studies quoted in this report suggested that transmission rates of VRE, MRSA, and other drug-resistant organisms can be decreased with aggressive and sustained infection control interventions.

Protect self, patients, and staff from spreading infection

In 2007, the CDC published updated guidelines for isolation precautions and transmission prevention of infectious agents in health care settings. This publication reaffirms the success of standard precautions taken to prevent infectious disease transmission. The report directs all caregivers to “assume that every person is potentially infected or colonized with an organism that could be transmitted in the healthcare setting and apply the following infection control practices during the delivery of health care.”

These guidelines emphasize the importance of hand hygiene and personal protective equipment such as gloves, gowns, and mouth, nose, and eye protection. Respiratory hygiene and cough etiquette in health care settings is also detailed.

Alternative medicines and anesthesia

Mary Ann Vann

Introduction

Herbs, vitamins, and supplements may potentially interact with anesthetic drugs or cause unexpected responses to the stresses of surgery or anesthesia. Typically patients do not volunteer information on their use of these over-the-counter (OTC), often mail order supplements or enhanced foods or drinks, which may cause harm in the perioperative period. It is helpful to understand the risks that these supplements pose, identify which patients are likely users, anticipate problems, and respond promptly to adverse events in the perioperative period.

Alternative medicine

What is it?

A common type of alternative medicine uses nonprescription herbs or supplements to replace traditional medications. Herbs (also referred to as *nutraceuticals*) are “naturally bioactive compounds” extracted from plants and usually ingested by patients as dietary supplements (see [Table 177.1](#)). They are not manufactured or patented. Often these treatments arise from traditional knowledge, such as Chinese medicine or ayurveda from India. The World Health Organization has taken the position that these medications have stood the test of time, and thereby should be considered safe and effective. These compounds often have unproven benefits, however, because many alternative medicine proponents reject basic scientific methodology, and few products have been scientifically studied. Patients may choose herbs or supplements under false belief that, because they are natural, they are safe and result in fewer side effects than traditional medications. In homeopathy, another form of alternative medicine, preparations contain only minuscule amounts of active compounds, which are intended to stimulate the body’s defense mechanisms. These compounds rarely cause drug interactions due to these extremely small amounts of active ingredients.

How pervasive is it?

The use of alternative medicines varies among population groups, geographic areas, ages, and medical conditions. In 1997, patients spent \$27 billion for all alternative therapies and \$5.1 billion for herbal products. It is believed that use peaked in the

early 21st century and has plateaued. Overall, 14% to 20% of adults in the United States admit to use of nonvitamin dietary supplements. Twenty-one percent of patients on prescription medications, as many as 27 million patients, are at increased risk of drug interactions due to combinations with herbs and supplements. Even more disconcerting is the fact that 40% to 69% of these patients mixing prescription medications with nonvitamin dietary supplements do not report this use to their physicians. The patients most likely to be using dietary supplements are middle-aged women who are well educated and living on the West Coast of the United States. The use of any other drug, prescription or OTC, makes one more likely to use herbal supplements. The medical conditions most frequently associated with supplement use are menopause, gastrointestinal disorders, and severe headaches or migraines. Patients least likely to combine prescription medications with supplements include elderly persons (older than 65 years), persons with serious cardiac conditions, such as coronary artery disease, a history of congestive heart failure, or myocardial infarction, and persons living in the Midwest or Southern portions of the United States. Among surgical patients, the prevalence of use of herbal medicines or supplements is higher than that of the general population for plastic surgery patients and for women undergoing gynecologic surgery. Some children are given nonvitamin dietary supplements by caregivers who are also users, especially if they consider the child to be chronically ill. Interestingly, patients continue to take supplements even after they recognize that they have not received any benefit from them.

Herbs, vitamins, and supplements are frequently marketed on the Internet. Family members and the media usually serve as the patient’s primary sources of information on herbs and

supplements. Supplements are available to the consumer in many forms. Diet and weight loss products and alternative therapies for common medical conditions, such as menopause, high blood pressure, arthritis, colds and flu, and diabetes, are often sold in local drug stores (see [Table 177.2](#)). More recently these products have moved into the supermarket in the forms of energy drinks, teas, juices, soups, and even toothpaste. Stimulants and hallucinogens have been marketed on the Internet with names such as *herbal ecstasy*.

What are the risks?

Regulations

The US Food and Drug Administration (FDA) and the Center for Food Safety and Applied Nutrition (CFSAN) regulate dietary supplements. Because these products are usually extracts, they are not patented and thus not considered to be drugs in the United States, but are regulated as such in many European countries. The Dietary Supplement Health and Education Act (DSHEA) of 1994 stipulated “good manufacturing practices” to “assure potency, purity and consistency in the product.” It also required the packaging to include a list of ingredients and disclaimers that the product has “not been evaluated by the FDA” and is “not intended to diagnose, treat, cure or prevent any disease.” CFSAN, however, bears the burden of proof that a particular product is unsafe or mislabeled. Also, they perform only minimal marketplace surveillance and monitoring. In June 2007, CFSAN announced improved quality standards for supplements in the Interim Final Rule on Dietary Supplement Current Good Practices. A study of the Internet, a frequent source for supplement buyers, reported that 81% of retail sites made health claims and half omitted the FDA disclaimer. Reporting of adverse effects from supplement use is voluntary via the FDA MedWatch site. It has been suggested, however, that this only captures approximately 1% of adverse events associated with these products. The FDA process to ban retail sales of ephedra in 2004 took many years and followed 16,000 reports of adverse effects and 150 deaths of ephedra users.

Quality issues

The FDA’s efforts to enforce better quality standards for supplements are in response to the multiple reports of poor quality and consistency of supplements as they relate to amounts of active compounds and contamination. While inferior quality supplements are sometimes manufactured in the United States

Table 177.3. Serious side effects of common supplements

1. Bleeding
Feverfew, ginkgo, ginseng, garlic, ginger, vitamin E
2. Hypotension/hypertension
Weight loss supplements, licorice
3. Arrhythmias/electrolyte disturbances/volume depletion
Licorice, goldenseal, milk thistle
4. Hepatotoxicity
Kava kava, echinacea, black cohosh
5. Possible potentiation of anesthetic action
Valerian, Kava kava, St. John’s wort
6. Hypoglycemia
Ginseng, glucosamine

those made abroad are especially suspect. ConsumerLab, a subscription Internet site, as well as other reliable investigators, routinely test supplements sold in the United States for the quantity and quality of active ingredients. Often supplements are discovered to have fewer or no active ingredients, but occasionally there is an excess, possible toxic amount of certain compounds. On many occasions, supplements have been found to contain ingredients not listed on the label, including significant amounts of prescription drugs or other herbal preparations. A study of ayurvedic herbal medicine products produced in South Asia and purchased in the Boston area showed that 20% of these products contained potentially harmful amounts of lead, mercury, and/or arsenic. Other contaminants reportedly found in supplements include bacteria, pesticides, and glass.

Harmful reactions to supplements

Direct adverse effects (such as hepatotoxicity) may be caused by certain nonvitamin supplements. Other products have had documented interactions with certain medications. Adverse events, such as increased bleeding, are more likely to be revealed during surgical procedures than during daily living (see [Table 177.3](#)). The potential for drug interactions is higher in anesthesia than in other areas of medicine because the risk of adverse events increases exponentially with the number of drugs a patient receives.

Hypertension is a common response to weight loss supplements. Despite the removal of ephedra from the market, these products remain a source for concern because the alternative ingredients in these preparations often have harmful effects. Frequently these products combine several substances with similar stimulant effects such as methylxanthines (e.g., caffeine) and synephrine. Other compounds in these supplements with potential hypertensive effects include green tea extract (caffeine), bitter orange extract (synephrine and methyltyramine), and DMAE (dimethylaminoethanol). Some of these stimulants can lead to depletion of endogenous catecholamine stores, which may result in a downregulation of receptors. This scenario (often seen with ephedra use) causes refractory hypotension under anesthesia that requires treatment with large doses of direct acting sympathomimetics.

Interference with platelet function is seen with several herbs, leading to a potential for bleeding in the perioperative period.

Therefore, the American Society of Anesthesiologists (ASA) statement that all herbs and supplements should be discontinued 2 weeks before surgery is similar to that for potent antiplatelet drugs, such as ticlopidine. The combination of supplements and prescriptions or OTC drugs with antiplatelet effects, such as aspirin, is even more reason for concern for bleeding events.

Drug interactions may occur between supplements and prescription medications or anesthetics. St. John's wort induces the metabolism by the P450 cytochrome system, which leads to decreased levels of certain prescription drugs. If this supplement is discontinued in the perioperative period, one must be watchful for potentially elevated levels of other drugs such as digoxin. Also, increased metabolism of isoflurane was found in patients taking St. John's wort, leading to a concern for potential toxicity due to elevated levels of metabolites.

Potential of anesthetic action is another concern, especially with supplements taken for sedation, which may alter neurotransmission. These supplements include valerian or kava kava. No evidence for this interaction has been discovered in the few studies of these substances, but case reports of interactions with anesthetics exist.

Hepatotoxicity of certain supplements may be a concern if these potentially toxic effects are not recognized before surgery. Kava kava has been banned in Europe and Canada due to multiple reports of liver failure, but is still available in the United States. Echinacea and black cohosh have been associated with liver damage in some case reports.

Electrolyte disturbances and resultant arrhythmias have been noted with licorice, milk thistle, and goldenseal.

Common supplements in the perioperative period

Although the ASA recommends that all herbs and supplements be discontinued at least 2 weeks preoperatively, often patients are not informed of these risks in time. A more measured approach is described below, and when there is conflicting information as to the best time to discontinue a supplement, a range is listed. The recommendations by AngLee and others to discontinue supplements or herbs with antiplatelet effects 1 week prior to surgery will allow production of adequate numbers of normal platelets to prevent abnormal bleeding.

Ginkgo (*Ginkgo biloba*)

Often taken by patients for memory enhancement, ginkgo may decrease symptoms for patients suffering from peripheral vascular disease. It has been proven to be beneficial for patients with cognitive disorders, such as Alzheimer's disease. Ginkgo has antiplatelet effects and has been associated with spontaneous bleeding when combined with other anticoagulants and aspirin.

Recommendation: Discontinue (D/C) 1 week prior to surgery

Ginseng (*Panax ginseng*)

This Asian root is used as a stimulant, to protect the body against stress, to restore homeostasis, and to treat some menopausal symptoms. It has steroid-like effects and may cause hypoglycemia, Stevens–Johnson syndrome, and decreased blood concentrations of warfarin and ethanol. It inhibits platelet aggregation.

Recommendation: D/C 1 week prior to surgery

Garlic (*Allium sativum*)

Extracts of garlic are often used to stave off symptoms of heart disease due to its lipid-lowering and vasodilatory effects. Garlic causes a dose-related inhibition of platelet aggregation.

Recommendation: D/C 1 week prior to surgery

St. John's wort (*Hypericum perforatum*)

This supplement has been proven effective for the short-term treatment of mild to moderate depression. It inhibits the reuptake of serotonin, norepinephrine, and dopamine. Serotonin syndrome has been reported in patients combining St. John's wort with certain selective serotonin reuptake inhibitors. It induces the metabolism by the P450 cytochrome system. Case reports describe subtherapeutic levels of benzodiazepines, theophylline, amitriptyline, cyclosporine, warfarin, protease inhibitors, estrogens, chemotherapy agents, and digoxin in patients using St. John's wort. If this supplement is discontinued in the perioperative period, one must be watchful for elevated levels of these other drugs.

Recommendation: D/C 5 days prior to surgery

Kava kava (*Piper methysticum*)

This supplement is often taken for antianxiety and muscle relaxant purposes. It has led to hepatic failure in some users, however. It potentiates γ -aminobutyric acid inhibitory neurotransmission and could potentiate anesthetic actions. It inhibits thromboxane synthetase.

Recommendation: D/C 24 hours to 2 weeks prior to surgery

Saw palmetto (*Serenoa repens*)

In studies this supplement has been found to be beneficial for the symptoms of early benign prostatic hypertrophy. There is one case in the literature of intraoperative hemorrhage in a patient taking this supplement.

Recommendation: D/C 24 hours to 2 weeks prior to surgery

Echinacea (*Echinacea purpura*)

Thought to be immunostimulating, this supplement has not been found to be effective for prevention or treatment of colds. It should be avoided in patients requiring perioperative immunosuppression, such as transplant patients. It has been found to potentiate the hepatotoxic effects of other drugs, and it inhibits the P450 cytochrome system.

Recommendation: D/C 24 hours to 2 weeks prior to surgery

Feverfew (*Tanacetum parthenium*)

Useful for prevention and treatment of migraine headaches, this supplement has antiplatelet activity that may lead to bleeding in the perioperative period. Also, when feverfew is discontinued, some patients may experience withdrawal symptoms, which may be treated with benzodiazepines.

Recommendation: D/C > 2 weeks prior to surgery to allow for weaning period

Ginger (*Zingiber officinale*)

In studies ginger has been found ineffective for prevention or treatment of postoperative nausea and vomiting despite its purported success for treatment of motion sickness and nausea. This supplement inhibits thromboxane synthetase and may lead to perioperative bleeding.

Recommendation: D/C 1 week prior to surgery

Glucosamine

Often found in supplements with chondroitin, glucosamine is used to relieve symptoms of osteoarthritis. In diabetic patients, it may increase insulin resistance, but in nondiabetic persons its structural similarity to human insulin may lead to hypoglycemia.

Recommendation: D/C 24 hours prior to surgery

Valerian (*Valeriana officinalis*)

Patients suffering from insomnia may take valerian. It increases activity at γ -aminobutyric acid receptors. There are case reports of interaction with barbiturates, and there could be possible potentiation of anesthetic action.

Recommendation: D/C 1 to 2 weeks prior to surgery

Goldenseal (*Hydrastis canadensis*)

This supplement has been used to improve digestion, treat ulcers, and act as a natural antibiotic. It causes sodium depletion and potentiates diuretic effects of other drugs, however. It also inhibits the P450 cytochrome system.

Recommendation: D/C 2 weeks prior to surgery

What you can do

Education about these herbs is vital to preventing adverse effects from supplements in the perioperative period. Knowl-

edge of herbs and supplements and their effects has been shown to be poor, however, in both anesthesiologists and plastic surgeons. Identification of patients likely to be users of these products is important because the information will not be volunteered. Personal and specific questions about supplement use need to be asked by health care workers in the preoperative areas. Some of these products should be discontinued, and thus patients need to be questioned prior to arrival. Patients should also be instructed to bring bottles or boxes from the products to the physician for proper identification of the ingredients. Because not every case in which patients are taking herbs and supplements will be recognized or cancelled, Table 177.3 covers some of the adverse effects that may result from these products. When necessary, act with appropriate treatments, based on knowledge about the supplements. Remember that patients as well as health care workers often may not know what is in the bottle, due to poor regulations and quality control of these supplements.

Anesthesia at high altitudes

Pankaj K. Sikka

Anesthesia administration at high altitudes is challenging and poses several risks to patients, compared to anesthesia administered at sea level. Approximately 10 million people live at an altitude of greater than 13,000 feet, the majority in South America and the Himalayan region of Asia. In addition to people living at high altitudes, who may require anesthesia for various illnesses, high altitude anesthesia administration may be required for aviation or mountaineering accidents or for troops moved from the plains to high altitudes. The latter is even more challenging as often the patients are not physiologically acclimatized to the high altitude.

Physiologic changes at high altitudes

Respiratory system

The atmosphere contains approximately 21% oxygen at sea level. At higher altitudes, although the atmosphere still contains 21% oxygen, the number of molecules decreases, leading to a lower partial pressure of oxygen in ambient air (PO_2 at 760 mm Hg/sea level = 160 mm Hg, at 540 mm Hg (e.g., Denver), PO_2 = 113 mm Hg). To compensate for the lower PO_2 at high altitudes, three main mechanisms become operative. These compensatory mechanisms are (1) decreased tissue metabolism due to the decreased availability of oxygen, (2) adjustment of oxygen transport characteristics (Table 178.1), and (3) hyperventilation, which usually increases the alveolar oxygen tension by 25% to 30%. Therefore, the final PO_2 in mixed venous blood of a person at a high altitude is similar to that of a person at sea level.

Lower alveolar PO_2 at high altitudes causes the stimulation of peripheral chemoreceptors, which causes an increase in ventilation. Increased ventilation is the primary mechanism for increasing the oxygen availability to the tissues. Oxygen delivery to tissues is facilitated by an increase in red blood cell 2,3-diphosphoglycerate. This increase shifts the oxygen-hemoglobin dissociation curve to the right, allowing red cells to more easily unload oxygen in tissues. At high altitudes, however, respiratory alkalosis occurs, which shifts the oxygen-hemoglobin dissociation curve to the left, allowing oxygen to be more easily taken up by red blood cells in the pulmonary circulation.

The PO_2 gradient decreases from the ambient air (inspired) to the mitochondria. This is known as the oxygen cascade. The

gradient is much steeper in a person at sea level than in a person at a high altitude (Fig. 178.1). The final PO_2 in mitochondria is approximately 1 to 2 mm Hg, below which there is a shift from aerobic to anaerobic metabolism.

Persons ascending to high altitudes exhibit (normal) symptoms, which include hyperventilation, dyspnea on exertion, and periodic breathing. Periodic breathing (Cheyne–Stokes breathing) is characterized by periods of hyperpnea followed by apnea (alternating cycles), and most often occurs during sleep. Apnea may last anywhere from 3 to 15 seconds. Periodic breathing is thought to occur due to a decrease in cortical influence on respiration during sleep. Periodic breathing may decrease with acclimatization, but usually resolves on descent to a lower altitude. Acetazolamide, a respiratory stimulant, may be effective in decreasing periodic breathing.

Cardiovascular system

Acclimatization (physiologic adaptation) changes at high altitudes begin to take place in approximately 2 to 3 weeks and take months to complete. The decreased PO_2 in ambient air at high altitudes leads to an increase in red blood cell production. The hematocrit increases from approximately 45% to 65% (hemoglobin increases from approximately 15 g/dl to 22 g/dl), and the bone marrow becomes hyperplastic. In addition, there is an increase in the production of erythropoietin by the kidney, which stimulates the production of red blood cells. Cardiovascular changes at high altitudes are summarized in Table 178.2.

The plasma volume decreases by approximately 10% to 20% because of movement of fluid out of the vascular compartment into the interstitial compartment. The resulting hemoconcentration results in an increased oxygen carrying capacity of the blood. Cardiac output initially increases due to hypoxia-driven stimulation of the sympathetic nervous system. The increase in cardiac output is mainly due to an increase in the heart rate, as

Table 178.1. Oxygen transport changes at high altitude

Increase in pulmonary oxygen diffusion capacity by three- to fourfold ^a
Increase in pulmonary capillary blood flow
Increase in lung volume and surface area of alveolar membrane
Increase in blood supply to upper lobes of lung

^aNormal oxygen diffusion capacity is 21 ml/mm Hg/min.

Figure 178.1. Oxygen cascade at sea level.

stroke volume decreases due to a decrease in the plasma volume. The increased sympathetic nervous system activity also increases systemic blood pressure, peripheral vasoconstriction, and metabolic rate. Within a few weeks of exposure to high altitudes, cardiac output tends to normalize as a result of decreased sympathetic nervous system activity (decrease in relative heart rate, increase in plasma and stroke volume).

High altitude may cause the following pulmonary changes. First, pulmonary arterial pressure increases because of the lower barometric pressure and decreased partial pressure of oxygen, causing constriction of the pulmonary vasculature. Second, this pulmonary vasoconstriction is patchy with some areas in the lung receiving overperfusion, thereby causing leakage of fluid. Also, due to the increased pulmonary arterial pressure and blood viscosity, there is capillary endothelium damage, again causing leakage of fluid. Third, there is an increased incidence of fibrin thrombi formation in the lungs due to an increase in plasma fibrinogen levels. And fourth, there is an increased production of oxygen free radicals causing oxidation of alveolar intracellular lipids and mitochondrial cell membranes.

All of these changes at high altitudes make a person prone to developing a noncardiogenic pulmonary edema, or in other words, high altitude pulmonary edema (HAPE), which is characterized by the presence of an elevated pulmonary artery pressure and normal ventricular function. HAPE usually occurs on rapid ascent to altitudes of 8000 feet and manifests during the first 2 to 4 days. The mechanisms of HAPE are summarized in Fig. 178.2.

Diagnosis of HAPE can be made by the presence of any two of the symptoms and signs shown in Table 178.3. Oxygen saturation will be significantly lower than normal, the value being altitude dependent. Healthy individuals may have oxygen saturation values of 80% to 85% at high altitudes, and with HAPE the values may drop to 50% to 60%. Arterial blood gas measurements will show hypoxemia, hypocapnia, and a slight increase in pH. Multiple patchy infiltrates on a chest radiograph, the

presence of fever, and leukocytosis common with HAPE may be misdiagnosed as pneumonia.

Definite treatment of HAPE is urgent descent to a lower altitude. Treatment includes oxygen, bed rest, morphine, diuretics (furosemide), calcium-channel blocker (e.g., nifedipine)-induced pulmonary vasodilation, and hyperbaric oxygen, if available. It is important to remember that morphine can depress respiration and that diuretics can aggravate dehydration, if present.

Dehydration is common at high altitudes due to increased insensible water loss from the respiratory tract and skin, low humidity in cold weather, and a decreased thirst sensation. It should be remembered that dehydration could aggravate symptoms and signs of coexisting diseases. High altitude-related peripheral edema is a benign condition thought to occur as result of hypoxia-induced sodium and water retention. This condition can be treated with descent to a lower altitude, diuretics or acetazolamide, and salt restriction. Hypoxia-induced polycythemia and clotting abnormalities can lead to thromboembolic events at high altitudes, such as thrombophlebitis, deep vein thrombosis, or transient ischemic attack (TIA). Cold, dehydration, venous stasis, and inactivity can aggravate these events. Treatment includes adequate hydration, descent to a lower altitude, and subcutaneous heparin.

Central nervous system

Cerebral blood flow at high altitudes is a balance between hypoxia-induced vasodilation and hypocapnia-induced vasoconstriction (hypocapnia from hypoxia-induced hyperventilation). Persons ascending to a higher altitude may exhibit acute mountain sickness (AMS), a spectrum of illness, which is self-limiting and usually resolves in 3 to 7 days. AMS is thought to occur due to hypoxia-induced subclinical cerebral edema, with rapid ascent to altitudes of 6000 feet. AMS is characterized by the presence of a symmetric, global, and throbbing headache plus one of the following symptoms: loss of appetite, nausea, fatigue, dizziness, or insomnia.

Table 178.2. Cardiovascular changes at high altitude

Increase in hematocrit
Decrease in plasma volume
Increase in cardiac output (initial)
Increase in pulmonary artery pressure
Increased incidence of CHF

Table 178.3. High altitude pulmonary edema (HAPE)

Symptoms	Signs
Dyspnea at rest	Lung crackles
Decreased exercise performance	Tachycardia
Chest congestion	Tachypnea
Cough (pink frothy sputum)	Cyanosis

Figure 178.2. Mechanisms of HAPE.

Treatment of AMS includes descent to a lower altitude, rest, supplemental oxygen, analgesics (headache), prochlorperazine (nausea), dexamethasone, and acetazolamide (which has been shown to accelerate acclimatization). Acetazolamide is a carbonic anhydrase inhibitor, which produces metabolic acidosis by causing renal excretion of bicarbonate. It also alters the pH of the cerebrospinal fluid, thereby stimulating the respiratory centers in the brain. It should be remembered that acetazolamide is a sulfa-based drug.

A severe form of AMS may lead to high altitude cerebral edema (HACE). The decreased availability of oxygen at high altitudes causes cerebral vasodilation and may lead to cerebral edema. Hypoxia increases the permeability of the blood–brain barrier (vasogenic cerebral edema) and also an alteration in intracellular fluid distribution (cytotoxic edema). Patients will have symptoms of AMS, gait ataxia, and mental function changes, leading to altered behavior; depression; speech, visual, and/or sleep disturbances; hemiparesis; or coma. HACE is a medical emergency and can lead to death.

The definitive treatment is urgent descent to a lower altitude, which should be carried out as soon as possible. If descent is prevented due to bad weather or terrain, temporary measures include treatment with dexamethasone, acetazolamide, diuretics (caution with volume status), a high-carbohydrate diet (increase CO₂ production), supplemental oxygen, and simulated descent in portable hyperbaric chamber, if available.

Other nervous system disturbances at high altitudes include hypothermia (core body temperature less than 35°C), which can lead to cardiac arrhythmias, platelet dysfunction, and cold injuries. In addition, immune suppression may lead to poor wound healing and persistence of skin and tissue bacterial infections. A sudden and massive central nervous system sympathetic discharge can lead to neurogenic pulmonary edema, as a result of blood being shifted from the high-resistance systemic circulation to the low-resistance pulmonary circulation. Blood pressure surges within distended retinal vessels can cause high-altitude retinal hemorrhages. These hemorrhages are usually self-limiting and resolve by descent to a lower altitude.

Anesthetic concerns at high altitudes

Perioperative hypoxia is more common at high altitudes due to the low atmospheric PO₂, especially in newcomers more so than in acclimatized individuals. Major operations tend to be less numerous at high altitudes because of the scarcity of surgical personnel and the number of major hospitals. Fluid resuscitation (warmed to body temperature) should be done carefully in patients because of the increased risk of developing HAPE, as discussed earlier in this chapter. Patients' increased tendency to bleed is attributed to a high venous pressure, vasodilation, and increased capillary density. Facilities for blood transfusion should be available, as far as possible. Anemia should be corrected before performing elective operations. Infections, frostbite, wound healing, and hypothermia are more common at high altitudes (Table 178.4).

Acute trauma is a major hazard at high altitudes. Falls are common as hypoxia and cold can impair judgment and physical and mental performance. Coexisting diseases, such as chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), valvular heart disease, and coronary artery disease, may get aggravated on exposure to high altitudes. High-risk pregnancies, sickle cell trait, or presence of a respiratory tract infection may be aggravated on exposure to high altitudes.

Any drug that interferes with oxygen delivery at high altitudes will increase the risk of hypoxia-induced effects and injuries. Such substances include caffeine, tobacco, and alcoholic beverages. Tobacco smoke increases carboxyhemoglobin levels (which interferes with oxygen delivery to

Table 178.4. Anesthetic concerns at high altitude

Prone to hypoxia
Scarcity of surgical teams
Elective surgeries in acclimatized patients
Risk of developing pulmonary edema with fluid resuscitation
Increased tendency to bleed
Increased risk of hypothermia
Increased risk of infection

tissues) and causes peripheral vasoconstriction, thereby increasing the risk of cold injuries. Alcoholic beverages, caffeine, and diuretic medications induce diuresis and can aggravate the effects of dehydration at high altitudes. Alcohol can also alter mental status (leading to errors in judgment and injuries), hypoglycemia, heat loss, and depression of respiration. In addition, the use of sedatives and tranquilizers will aggravate the effects of hypoxia by depressing respiration.

Premedication, induction agents, and muscle relaxants

Patients at high altitudes may be more sensitive to the depressive effects of opioids and benzodiazepines. Therefore, these drugs should be used more cautiously. Supplemental oxygen should be provided and readily available. It is important to remember that patients at high altitudes may be more anxious due to loneliness and isolation.

Induction agents at high altitudes should also be used cautiously. Because of hypothermia and a slow metabolism, their effects may be prolonged and recovery may be delayed. Ketamine may be a more useful drug at high altitudes, not only due to its analgesic effects but also because of its lower tendency (than that of other agents) to depress respiration. Muscle relaxants can be safely used for intubation and maintenance of anesthesia. It should be remembered, however, that hypothermia could slow their metabolism and, therefore, prolong their effects.

Inhalational agents

Nitrous oxide loses potency at high altitudes. Therefore, its anesthetic and analgesic effects are reduced at high altitudes. It is important to remember that potency of inhalational agents is proportional to their partial pressure and not their percentage of mixture in oxygen.

Except for the Tec 6 Plus desflurane vaporizer (GE Healthcare), in all other vaporizers the output of the anesthetic agent (in mm Hg) at high altitude remains close to the output at sea level because of two physical principles.

Principle 1

The depth of clinical anesthesia is determined by the partial pressure of the anesthetic agent in the brain, which in turn is determined by the inspiratory partial pressure. At sea level, where the atmospheric pressure is 760 mm Hg, the inspiratory partial pressure of isoflurane at 1% dial setting is 7.6 mm Hg ($1\% \times 760$). At higher altitudes, where atmospheric pressure is lower (e.g., 540 mm Hg in Denver, CO), the vaporizer output as inspiratory partial pressure (in mm Hg) will be 5.4 mm Hg for the same dial setting. This is not enough to maintain

similar clinical anesthesia depth at sea level. The second principle, however, overcomes this effect.

Principle 2

The output of the anesthetic agent from a vaporizer depends on the ratio of vapor pressure of the agent to the atmospheric pressure. For isoflurane, this ratio is approximately 1:3 (isoflurane vapor pressure is 240 mm Hg relative to 760 mm Hg atmospheric pressure) at sea level. At higher altitudes (e.g., Denver, CO), this ratio decreases to approximately 1:2 (isoflurane vapor pressure is 240 mm Hg relative to 525 mm Hg atmospheric pressure). Because of this, the carrier gases passing through the bypass vaporizer will pick up relatively more anesthetic agent at higher altitudes than at sea level. Therefore, the actual output (as a percentage) will be higher than the set dial percentage and will result in a higher inspiratory partial pressure. This mechanism will compensate for the effect of principle 1. Because the anesthetic depth is dictated by partial pressure, contemporary vaporizers function equally well despite the altitude changes.

In other words, except for the Tec 6 desflurane vaporizer, all contemporary variable bypass vaporizers are temperature and pressure (altitude) compensated. The Tec 6 vaporizer will still deliver the dialed volume percentage at higher altitudes, but as soon as desflurane is exposed to the ambient pressure at high altitude, its partial pressure will decrease. Therefore, the Tec 6 vaporizer has to be dialed up (please see Eqn. 1) to deliver the same partial pressure of desflurane at high altitude.

$$\begin{aligned} &\text{Final dial setting (Tec 6)} \\ &= \text{dial setting required} \\ &\quad \times 760 \text{ mm Hg/ambient pressure mm Hg} \end{aligned} \quad (1)$$

Emergence from anesthesia

Emergence from anesthesia may be delayed because of the presence of coexisting diseases, hypothermia, and/or hypoxia. Adequate postoperative facilities should be available for surgeries performed at high altitudes.

Practical considerations for the anesthesiologist in flight

Christopher W. Connor and Massimo Ferrigno

Approximately 2 billion passengers fly on commercial aircraft each year, and a significant in-flight incident will befall up to 1 in 10,000. Passenger deaths are fortunately uncommon, with an incidence of up to 1 in 3 million passengers. As the average age and number of passengers carried on a single flight increase, however, it is likely that physicians will be called on more frequently to provide assistance to fellow travelers in medical distress.

This chapter describes two scenarios: providing medical assistance to an unknown passenger on a commercial flight and taking care of a patient in an air ambulance. In common are the environmental and physiologic stresses of flight itself:

1. **Decreased oxygen pressure:** The decrease in atmospheric pressure with altitude is accompanied by a decrease in partial pressure of oxygen and, consequently, in arterial oxygen saturation. Modern commercial aircraft cruise at altitudes between 28,000 and 45,000 feet; Federal Aviation Administration (FAA) rules require pilots flying above 35,000 feet in a pressurized craft to have oxygen masks that can be placed on the face with one hand in 5 seconds, before becoming incapacitated from hypoxia if pressurization is lost. Pressurization on commercial flights is not to sea level, but rather to an altitude commonly ranging from 5000 to 8000 feet (1524–2438 meters) above sea level; at 8000 feet, arterial oxygen saturation will be approximately 90%. The decrease in partial pressure of oxygen during flight may provoke distress in patients with compromised cardiovascular and/or respiratory function (Fig. 179.1); it can also trigger a sickling crisis in susceptible patients.
2. **Changes in barometric pressure:** During ascent, gas expands, whereas its volume decreases during descent. Therefore, during ascent, expanding gas, unable to escape from body cavities, may exert pressure on surrounding structures. The volume of trapped gas can increase by 30%, which is of particular concern for patients who may have pneumothorax, pneumocephalus, or ileus. The Aerospace Medicine Association suggests that patients “should delay commercial air travel for 2 to 3 weeks after radiographic resolution of pneumothorax,” because of the danger of developing a tension pneumothorax (Fig. 179.1). In the case of medical air evacuation, the US Air Force recommends waiting for at least 24 hours to fly after chest tube removal, preferably with chest radiographs documenting absence of extra-alveolar air. All of these guidelines are arbitrary, lacking any scientific or clinical evidence. In fact, there is a wide variety of physicians’ recommendations for air travel in patients with postoperative extra-alveolar air (pneumothorax and/or pneumomediastinum), with a more permissive attitude in the case of pneumomediastinum.
3. **Decreased humidity:** The higher the altitude, the cooler and, consequently, the drier the air (particularly on a small aircraft in which, after 4 hours of flight, relative humidity is less than 1%, whereas on a commercial aircraft it typically ranges between 10% and 20%). This dry air may dry secretions and worsen a patient’s respiratory status.
4. **Confined spaces:** The dimensions and crowding of a commercial aircraft pose a particular challenge. Prolonged immobilization may predispose to deep vein thrombosis (DVT). Also, it is often difficult to obtain a suitable level of privacy for a physician to perform a thorough history and physical examination, and it may be difficult to lay the patient flat.
5. **Noise:** Particularly in small aircrafts, noise may not only prevent a patient’s examination (e.g., blood pressure cannot always be determined by auscultation with a stethoscope and it may have to be palpated), but it can also interfere with effective communication with patient and/or crew.
6. **Fatigue:** All the stresses of flight, including jet lag, contribute to fatigue and can worsen a patient’s clinical condition.
7. **Thermal changes:** These changes are more likely to occur in small aircraft, especially during en route stops when the aircraft door is opened. In these cases, the patient needs to be protected appropriately.

Figure 179.1. A clinical scenario of in-flight hypoxia and tension pneumothorax developing during ascent and responding to a decrease in altitude. Cabin pressure can be maintained at sea level up to 22,500 feet (Modified from Cheatham ML, Safcsak K. Air travel following traumatic pneumothorax: when is it safe? *Am Surg* 1999; 65(12):1160–1164.)

8. **Vibration** (particularly in older and smaller aircraft): It may increase metabolic rate in a patient equivalent to the level of gentle exercise.
9. **Inertial forces:** Acceleration and deceleration along longitudinal axis during takeoff and landing have the potential to be detrimental to a patient with head and/or spinal cord trauma. Having the patient’s head facing aft during flight, when possible, may help in this regard. Furthermore, a patient needs to be secured with extra padding on vulnerable areas (like the abdomen in case of side-facing or rear seats during medical evacuation flights).

Because of the stresses associated with flying, the Aerospace Medical Association has published a list of contraindications to commercial air travel (Table 179.1) and of indications for medical oxygen in flight (Table 179.2). As a general rule, unstable patients should not fly. With so many patients flying nowadays, however, a medical event may happen independently of the stresses imposed by flight.

In-flight emergencies

The cabin crew handles approximately 70% of in-flight requests for medical assistance, with the commonest problems being diarrhea and nausea. In the remaining 30% of cases, the cabin crew seeks consultation from passengers with some medical training, with physicians being available in 85% of in-flight medical emergencies as reported in a 1991 FAA study. The anesthesiologist’s unique knowledge and skills are particularly

Table 179.1. Contraindications to commercial air travel

Category	Contraindication
General	Low probability of surviving Any contagious disease Unstabilized behavioral problem
Cardiovascular	Myocardial infarction within the previous 3 wk Unstable angina Coronary artery bypass graft within previous 2 wk Decompensated heart failure Uncontrolled arrhythmias
Pulmonary	Contagious pulmonary infection Baseline partial pressure of arterial oxygen < 70 mm Hg at sea level without supplemental oxygen Exacerbation of obstructive or restrictive lung disease Large pleural effusion Pneumothorax within previous 3 wk
Neurologic	Cerebrovascular accident within previous 2 wk Uncontrolled seizures
Surgical	Gastrointestinal, thoracic, otorhinolaryngologic, or neurologic surgery within previous 2 wk
Pregnancy	35 weeks’ gestation Complicated pregnancy
Pediatric	First week after birth
Other	Severe anemia (hemoglobin level < 8.5 g/dl) Sickle cell crisis Decompression sickness

valuable during in-flight emergencies when a physician may be faced with many uncertainties, including:

- the conditions and medical history of the patient,
- the type and paucity of medical equipment and medications available on board,
- the real possibility of being unable to establish a diagnosis in the absence of diagnostic tools,
- the patient's response to the physiologic stresses associated with flying,
- the type of training and background of persons offering assistance,
- the legal aspects of providing medical care in-flight and of possibly having to divert a flight, and
- the security aspects of managing a violent patient.

In an even more dramatic situation, the anesthesiologist may be called to help simultaneously with more than one medical emergency, as in the case of food poisoning. As for the diagnostic equipment available on commercial flights, it may well be limited to a sphygmomanometer and stethoscope. US airlines have been mandated to carry automatic external defibrillator devices (AEDs) since April 2004, and some models of AEDs may display a rudimentary electrocardiogram.

With regard to the types of medical problems affecting passengers, Fig. 179.2 shows their distribution according to two recent studies: the FAA data for US carriers and the British Airways data. As there is no consensus on the definition of a “medical incident,” the FAA data may underestimate the frequency of the more common minor gastrointestinal complaints.

Overall, the commonest incidents are gastrointestinal problems, followed by vasovagal syncope events, cardiac, neurologic, and respiratory symptoms and trauma; with some minor frequency variation across various studies. Trauma commonly consists of injuries caused by luggage items falling from overhead storage bins, but it also includes burns from spillage of hot liquids. In some cases, the patient is a member of the cabin crew suffering from workplace injuries (e.g., those caused by lifting or maneuvering heavy equipment within cramped conditions). With regard to in-flight deaths, the commonest causes appear to be cardiac disorders and stroke.

Figure 179.2. Distribution of the causes of medical incidents aboard commercial aircraft.

As for medications, medical equipment, and supplies available on commercial flights, US airlines have been required since 1998 to carry both basic first aid kits and an expanded in-flight medical kit for use by medical professionals. The contents of these kits are shown in Table 179.3.

Similar requirements have been placed on European airlines, and Table 179.4 shows minimum medical equipment mandated by the European Joint Aviation Authorities (JAA).

In practice, these requirements serve only as a minimum, and airlines may well carry far more extensive medical supplies to satisfy the legal operating requirements of their many destinations. As an example, the contents of the Virgin Airlines emergency medical kit are shown in Table 179.5.

Supplemental oxygen is almost always available for use, although the devices by which it can be administered may be limited to a simple face mask or nasal cannulae. The cabin pressure can often be brought to sea level by reducing the flight altitude to 22,500 feet or less; the cabin pressurization system can usually correct the internal pressure to sea level up to this flight altitude but not from the more common cruising altitudes above 30,000 feet.

Of concern to anesthesiologists may be the lack of intubating equipment to establish a definitive airway in the above equipment lists, with the consequent possible need to maintain an unprotected airway for a protracted period of time in an unconscious or unresponsive patient. The airline Qantas provides intubating equipment on long-haul flights, and British Airways carries a small amount of equipment to manage uncomplicated births, although the incidence of in-flight childbirth is extremely low. The kits are tailored for use by the general practitioner without training in emergency airway management, and there is a concern that using medications and equipment that require specialized training may end up harming the patient. Hence only subtoxic doses of local anesthetics are

Table 179.3. Mandated minimum medical equipment^a for US airlines**FIRST AID KITS**

According to the new rule for aircraft registered in the United States, there must be one to four onboard first aid kits, depending on the number of passenger seats. In general, each first aid kit must contain the following:

Contents	Quantity
Adhesive bandage compresses, 1-in	16
Antiseptic swabs	20
Ammonia inhalants	10
Bandage compresses, 4-in	8
Triangular bandage compresses, 40-in	5
Arm splint, noninflatable	1
Leg splint, noninflatable	1
Roller bandage, 4-in	4
Adhesive tape, 1-in standard roll	2
Bandage scissors	1 pair

EMERGENCY MEDICAL KIT

Sphygmomanometer	1
Stethoscope	1
Airways, oropharyngeal (3 sizes): 1 pediatric, 1 small adult, 1 large adult or equivalent	3
Self-inflating manual resuscitation device with 3 masks: 1 pediatric, 1 small adult, 1 large adult or equivalent	3
CPR mask (3 sizes): 1 pediatric, 1 small adult, 1 large adult or equivalent	3
IV administration set: tubing w/2 Y connectors	1
Alcohol sponges	2
Adhesive tape, 1-in standard roll adhesive	1
Tape scissors	1 pair
Tourniquet	1
Saline solution, 500 cc	1
Protective nonpermeable gloves or equivalent	1 pair
Needles: two 18-gauge, two 20-gauge, two 22-gauge, or sizes necessary to administer required medications	6
Syringes: one 5-cc, two 10-cc, or sizes necessary to administer required medications	4
Analgesic, non-narcotic tablets, 325 mg	4
Antihistamine tablets, 25 mg	4

provided, and the partial agonist nalbuphine is the only opioid. In an emergency situation, additional medications may be provided by other passengers, and the anesthesiologist should carefully double-check the type of medication and its concentration.

When the diagnosis and management of the patient are in doubt, it is helpful to be able to receive a second opinion from another physician. Most airlines provide the capability to contact a ground-based support physician. Whereas some airline companies maintain their own medical support, a large number

Table 179.4. European JAA requirements for emergency medical equipment^a**European JAA Regulation: JAR-OPS 1.755****Emergency Medical Kit**

All aircraft with more than 30 seats must carry an emergency medical kit, if any point on the planned route is more than 60 minutes flying time from an aerodrome where qualified medical assistance could be expected to be available. The commander shall ensure that drugs are not administered other than by qualified doctors, nurses, or similarly qualified personnel.

Sphygmomanometer

A list of contents in at least two languages (English and one other)

Drugs: Adrenocortical steroid, antiemetic, antihistamine, antispasmodic, atropine, bronchial dilator (inhalation and injectable forms), coronary vasodilator, digoxin, diuretic, adrenaline (epinephrine) 1:1000, major analgesic, medication for hypoglycemia, sedative/anticonvulsant, uterine contractant.

^aNo requirement for an IV kit.

contract with an independent medical services provider. The largest of these is a for-profit company called MedAire, based in Arizona. It offers a service called MedLink, which provides global radio access to consultation with attending emergency physicians based at Good Samaritan Regional Medical Center in Phoenix, Arizona. MedAire also maintains a database of medical facilities around the world that can assist with planning a diversion if necessary or with arranging the hand-off of continuing patient care to local medical services on arrival. We recommend having a low threshold for using radio consultation services, unless the diagnosis and management are straightforward and unlikely to require further care.

The type of in-flight treatment can fall into one of three categories, depending on the acuity of the patient. The first category is that of an acutely life-threatening event requiring immediate treatment, such as an acute coronary syndrome or asthma attack. The last category is that of the straightforward, non-threatening presentation, such as diarrhea or the symptoms of hyperventilation secondary to situational anxiety. In this category, only minimal intervention or reassurance is required. The middle category presents the greatest dilemma in management, as the presentation is more uncertain. The patient may appear acutely unwell and in some distress (e.g., the onset of acute abdominal pain in a woman of child-bearing age). Here it may not be possible to provide a definitive diagnosis, and indeed the differential diagnosis may include conditions that would need urgent intervention in a hospital. In these cases, it is best to try and determine whether symptomatic treatment can be used safely until definitive care is available. The decision to divert a flight for medical reasons does not lie with the responding physician but rather with the captain of the aircraft; the physician acts solely in an advisory capacity.

 Needles 18 gauge × 2
 Needles 20 gauge × 2
 Needles 25 gauge × 2
 IV cannula 14 gauge × 1
 A sphygmomanometer and stethoscope are located in the defibrillator bag.

Of the 1132 medical incidents presented in the 1996–1997 FAA study, 239 were available for follow-up. Table 179.6 compares the diagnosis rendered in flight to the diagnosis ultimately determined during postflight medical care. Summing the numbers on the diagonal, it can be seen that the in-flight diagnosis was accurate at least to physical system involved in 79% of the cases.

Legal aspects

Physicians who respond to in-flight medical events within the United States are broadly protected against claims of malpractice by Good Samaritan legislation, provided that the actions they take are the ones that other competent persons with similar training would take under similar circumstances. There is no legal duty under US law to provide medical care to a person with whom no preexisting patient–doctor relationship exists. Judges in the UK have held a similar position. Other countries, however, including France and Australia, impose a legal obligation to assist even when no prior relationship exists. The issue of jurisdiction is unfortunately complex and dependent on the nationality of the carrier, the nation in which the incident occurs if the aircraft is on the ground, and potentially the nationalities of the people involved. Regardless of legal obligations, a strong ethical imperative exists to assist a person *in extremis*. DeLaune and colleagues found that when a physician was involved in the decision to divert a flight for medical reasons, the patient was ultimately admitted to hospital 49% of the time; without physician assistance, admission resulted only 15% of the time. The cost of diverting an aircraft is significant, with estimates of approximately \$100,000 common. Logistic issues involved in diversion include accommodating passengers, possible inability to continue the flight to its destination due to crew work-hour limitations, knock-on effects on flight scheduling and, environmentally, the potential need to dump fuel to obtain a safe landing weight earlier than anticipated.

Airlines do not typically reimburse physicians monetarily for their assistance, although they frequently offer tokens of gratitude, such as wine, flowers, air miles, or complimentary upgrades. They assume that the aircraft is merely the location in which the incident occurs and that any bill for professional services should be the responsibility of the patient. A significant factor for physicians to consider before charging for emergency in-flight care is that the protection of Good Samaritan statutes covers only those persons volunteering their assistance.

In summary, Table 179.7 provides some recommendations for physicians responding to in-flight medical events. Case reports of in-flight assistance include feats of medical ingenuity. A remarkable example is the decompression of a tension pneumothorax that occurred during a flight from Hong Kong to London using a Foley catheter as a chest tube, a coat hanger as a trocar, a bottle of Evian as a water-seal drain, and some brandy as a skin disinfectant. Unfortunately, tragic outcomes are also known, such as the asphyxiation of an agitated passenger who was sedated by a physician and then restrained. Accidents like this one in particular, should provide a reminder to anesthesiologists that sedation of a nonfasted patient with an unknown medical history should be carefully considered.

Medical air evacuation

Air transfer of patients can be carried out with helicopters (mostly in case of traumas where critically ill patients are

Table 179.7. Recommendations for responding to an in-flight medical event

Medicolegal recommendations for physicians volunteering assistance during an in-flight medical event

1. Properly identify yourself and state your medical qualifications. Some airlines require proof of your medical qualifications.
2. Obtain as complete a history as possible, inform the passenger and family members (if present) of your impression, and obtain consent before initiating any form of examination or treatment. Assume implied consent in the case of an incapacitated passenger.
3. If consent has been given, carry out an appropriate physical examination.
4. Request an interpreter if the passenger you are assisting does not speak your language.
5. Inform the flight crew of your clinical impression.
6. If the passenger's condition is serious, request that the aircraft be diverted to the nearest appropriate airport. On-ground medical support staff, if available, will help determine the best location for diversion.
7. Establish communication with on-ground medical support staff, if available.
8. Respect the ground-based physician's expertise and experience in managing in-flight medical events.
9. Document in writing your findings, impression, treatment, and communication with the flight crew and on-ground medical support.
10. Do not use any treatment that you do not feel confident administering. Keep in mind that Good Samaritan statutes protect you only from liability for actions that other competent persons with similar training would take under similar circumstances.

Modified from Newson-Smith MS. Passenger doctors in civil airliners—obligations, duties and standards of care. *Aviat Space Environ Med* 1997; 68(12):1134–1138.

quickly transported to local hospitals), commercial airline flights (when a patient is able to sit during takeoff and landing and has limited need for oxygen or other intensive forms of care), or air ambulances (fixed-wing aircraft, frequently a Learjet or Gulfstream jet, in which the cabin can be pressurized). An anesthesiologist may take care of a patient on either a commercial flight (where an FAA-approved stretcher can be used, an area can be curtained to provide privacy, and an attendant can accompany the patient) or a fully equipped air ambulance. The Commission on Accreditation of Medical Transport Systems (CAMTS) provides voluntary accreditation for air transport of patients on either rotorwing or fixed-wing aircrafts, based on quality of care, safety aspects, equipment, and personnel (for a list of companies with CAMTS certification for basic life support, advance life support, and critical care, see www.camts.org).

Preflight assessment of a patient and his or her therapeutic requirements is particularly important so that appropriate protection from the physiologic stresses of flight can be planned. Patient conditions may vary widely, with some requiring mechanical ventilation and intensive care. In these cases, an intensive care unit (ICU) physician should be helped by at least an ICU nurse and a respiratory therapist. An adequate supply of medications, equipment, and supplies should be available and sufficient for not only the expected flight time but also any unanticipated flight diversions that might occur. The following are some important aspects, related to the in-flight environment, which should be considered when transporting a patient aboard an aircraft.

Respiratory care

Ensure the availability of an adequate supply of O₂ and equipment to maintain or control the airway, including suction, equipment for intubation and bag-mask ventilation, and, when indicated, a ventilator that is approved by the aircraft operator. Use pulse oximetry to guide administration of supplemental, humidified oxygen to maintain an oxygen saturation of at least 90%. Because of the decreased pressure in the aircraft cabin, a fraction of inspired oxygen (FiO₂) higher than at sea level will be required to obtain the same oxygen saturation. In the case of an intubated patient, the pressure in the endotracheal cuff should be monitored during flight to avoid volume changes. An end-tidal monitor is also recommended to monitor adequacy of ventilation. Changes in ventilator settings, in particular tidal volume and FiO₂, are required at altitude.

Chest tubes may be left in place, and drainage units, preferably without glass components, can be used with the following precautions:

1. Ensure tubing is not kinked and not hanging below drainage system.
2. Be aware that water from the seal chamber will be pulled into the collection chamber after each descent.
3. A Heimlich valve should be in place and two large clamps should be available for each chest tube.
4. Do not clamp the chest tube when moving patient.
5. Frequently check the suction control to maintain minimal bubbling (the level of suction may change during flight).

Patients with respiratory problems, particularly with a history of recent pneumothorax, should be closely monitored in flight for the possibility of developing a tension pneumothorax, particularly during ascent when cabin pressure decreases and expanding air in the pleural space cannot escape. Expanding pneumothorax can lead to lung collapse with respiratory distress (Fig. 179.1), mediastinal shift, and even depressed cardiac output from impeded venous return. If possible, cabin altitude should be decreased, and chest tubes should be checked for patency. In particular, the absence of clots in the tube or in the Heimlich valve should be verified. If the patient does not already have a chest tube, a needle thoracostomy should be performed to relieve pressure.

Cardiovascular care

Ensure an adequate supply of intravenous (IV) fluids and, if appropriate, blood products. Minimize heat loss and maintain euolemia, especially because of the low cabin humidity. Pressure changes in flight may change IV rates and affect the volume of air bubbles in the IV bags and tubing; therefore, drip rates and IV tubing should be reassessed often during flight. Plastic IV containers are preferred to glass containers for in-flight use as they are less fragile and are able to expand and contract with changes in barometric pressure without the need for venting. Arterial or other hemodynamic lines should contain no air, which could expand during ascent. If the patient has a

pulmonary artery catheter, its balloon should be deflated prior to takeoff. Finally, most infusion pumps should work in flight but, again, there should be no air in the tubing. Patients with implantable cardiac pacemakers or cardioverter-defibrillators must not be exposed to security screening equipment, such as metal detectors, due to the possibility of malfunction due to electromagnetic interference. Patients with low hemoglobin levels will require supplemental oxygen to compensate for the decreased oxygen pressure at altitude. Finally, a cramped position for prolonged periods of time together with in-flight dehydration may lead to DVT.

Neurologic care

Takeoff may increase intracranial pressure (ICP) due to forces of acceleration; this problem can be minimized with the patient's head facing aft. The use of Valsalva maneuvers for ear-clearing purposes (which also increase ICP) can be avoided by preflight administration of nasal decongestant. Intracranial air from head trauma or surgery may expand during ascent, also increasing ICP. Altitude restriction can improve this situation and also improve brain oxygenation. Protecting a seizing patient from injury in the confined environment of an aircraft cabin is particularly challenging.

Psychiatric care

The physiologic stresses of flight may exacerbate psychiatric or behavioral disorders and may place the aircraft, its crew, and the patient at risk. Restraints should be available and used during the flight only when ordered by the physician; the need for their use should be reevaluated frequently. Benzodiazepines or other sedating medications may also be used to control these patients.

Eye and ENT care

The reduced oxygen pressure at altitude may increase intraocular pressure (IOP) and retinal hemorrhage due to hypoxia-induced vasodilation. Expanding intraocular air (from either trauma or surgery) during ascent may irreversibly damage the eye. Air is normally absorbed in 3 days, whereas certain gases used in surgery may persist for up to 9 weeks. In these cases, a maximal altitude of 2000 feet should be maintained, if feasible. Also, prophylactic antiemetic therapy should be considered to prevent vomiting from motion sickness, and, as in neurologic care noted earlier in text, preflight administration of oral (e.g., pseudoephedrine) or nasal (e.g., oxymetazoline) decongestant can be used to avoid Valsalva maneuvers during descent. Alternative maneuvers for ear clearing include swallowing, yawning, moving the jaw, and/or chewing gum. Inability to equalize pressure in the middle ears may result in a sensation of fullness, mild to severe pain, vertigo, and tinnitus. When feasible, a slower descent may improve the symptoms. Severe pain followed by sudden relief may indicate rupture of the eardrum. Similarly, gas trapped in paranasal sinuses or in a decayed tooth may cause pain due to changes in cabin pressure. The patient's ears should

Table 179.8a. Insulin adjustment when travelling east across multiple time zones

Usual Regimen	Day of departure/travel (east bound)		First day at destination	
Multiple injection regimen with pre-meal soluble insulin and overnight intermediate insulin.	Usual premeal soluble insulin. If less than 4 hours between meals this requires a slightly reduced dose of the third soluble injection (by 1/3) and additional carbohydrate (ie. extra large evening snack if one meal missed) and a reduction (1/3) in overnight intermediate insulin to avoid nocturnal hypoglycemia.		Return to usual insulin regimen. If you have overcompensated with the reduction of the evening intermediate insulin. Additional soluble insulin (1/3 of usual morning dose) should be considered if fasting blood glucose > 14 mmol · L ⁻¹ (250 mg · dl ⁻¹)	
	Day of departure	First morning at destination	10 hr after morning dose	Second day at destination
Two-dose schedule	Usual morning and evening doses	2/3 usual morning dose	Usual evening dose plus remaining 1/3 of morning dose if blood sugar over 14 mmol · L ⁻¹ (250 mg · dl ⁻¹)	Usual two doses
Single-dose schedule	Usual dose	2/3 usual dose	Remaining 1/3 of morning dose if blood sugar over 14 mmol · L ⁻¹	Usual dose

Table 179.8b. Insulin adjustment when traveling west across multiple time zones

Usual regimen	Day of departure/travel (west bound)		First day at destination
Multiple injection regimen with pre-meal soluble insulin and overnight intermediate insulin.	Usual premeal soluble insulin. Additional soluble insulin injection with additional meal/snack. Modest reduction (1/3) in overnight intermediate insulin to avoid nocturnal hypoglycemia.		Return to usual insulin regimen. Additional soluble insulin (1/3 of usual morning dose) should be considered if fasting blood glucose > 14 mmol · L ⁻¹ (250 mg · dl ⁻¹)
	Day of departure	18 hour after morning dose	First morning at destination
Two-dose schedule	Usual morning and evening doses	1/3 usual dose followed by meal or snack if blood glucose > 14 mmol · L ⁻¹	Usual two doses
Single-dose schedule	Usual dose	1/3 usual dose followed by meal or snack if blood glucose > 14 mmol · L ⁻¹	Usual dose

be protected from high noise levels by either position (when possible) and/or appropriate ear protection. Decreased humidity in the aircraft cabin causes dryness of the nasal mucosa, thickening its secretions and increasing risk of epistaxis.

Gastrointestinal care

Gas expansion during ascent may cause abdominal discomfort, nausea, and vomiting and may interfere with diaphragmatic excursions, requiring decompression with a nasogastric tube. Antiemetics (e.g., dimenhydrinate) can be administered 30 to 60 minutes before a flight to prevent motion sickness. If a patient has a feeding tube and/or an ostomy bag, venting should be allowed. An increase in flatus and stool emptying into the vented bag during ascent can be expected, with consequential odor emanating into the cabin. If abdominal distention occurs, it may be necessary to insert a 2-inch catheter into the stoma to relieve gas distention.

Endocrine care

Patients receiving total parenteral nutrition (TPN) require glucose monitoring and close observation for signs of hypo- or

hyperglycemia. Glucose monitoring in flight may not be accurate, however, because of changes in barometric pressure. Tables detailing adjustments of insulin therapy for diabetic patients traveling across multiple time zones have been published by the Aerospace Medical Association (see [Table 179.8a](#) and [179.8b](#)).

Obstetric care

The decreased partial pressure of oxygen at altitude may worsen fetal hypoxia, and abdominal gas expansion may further impede diaphragmatic excursions.

Overall, the physiologic stresses of flight may induce or complicate preterm labor. Usually, patients who are beyond the 34th week of pregnancy are not allowed aeromedical evacuation. If the pregnant patient can sit, place a small pillow between the seatbelt and her lower abdomen. If air transfer of a high-risk obstetric patient is necessary, appropriate medical personnel and equipment (including an incubator) should be on board.

Pediatric care

Infants and children may be more susceptible to hypoxia due to the decreased partial pressure of oxygen at altitude. They

are also more at risk for dehydration and for hypothermia during flight, and fatigue frequently makes them uncooperative. To help them equalize pressure in their middle ears, they can be given a pacifier or a bottle during descent. Phenylephrine nasal drops may also be used if problems with ear clearing are expected. If gastric distention appears to restrict diaphragmatic movement, the patient's head should be elevated and an oral or nasogastric tube may be inserted. If the pediatric patient is intubated, particular care should be paid to avoid tube dislodgement during moving and positioning. If a cuffed endotracheal tube has been placed, the cuff pressure should be monitored frequently, particularly during ascent.

Care of patient with decompression sickness

The decrease in both barometric pressure and partial pressure of oxygen at altitude can dramatically worsen symptoms due to nitrogen bubbles. Therefore, maximal altitude should be restricted as much as feasible when transferring a patient who has been SCUBA diving within the last 24 hours.

Infection control

Water, soap, and/or antiseptics should be available on board for medical personnel to wash their skin, or normal saline to rinse their mucosa, when accidentally exposed to patient's blood and/or body fluids. Guidelines for infection control can be found in the US Air Force's Aeromedical Evacuation Patient Considerations and Standards of Care.

Clinical innovation and engineered vigilance

Stephen B. Corn

In a landmark article titled “To Err is Human: Building a Safer Health System,” the Institute of Medicine (IOM) outlined methods for improving the safety of medical care in the United States. This report says that most medical errors are more likely to occur as a result of faulty systems, processes, and conditions than they are from reckless activity by clinicians. To correct the underlying cause of these errors, the IOM calls for the implementation of a “systems approach” methodology in health care. This approach accepts the fact that clinicians are human and cannot be expected to perform perfectly despite the best of intentions. It follows that we should use technology to develop systems that decrease the likelihood of errors.

Such systems employ what I call *engineered vigilance*, denoting any process using technology to improve the delivery of medical care by either enhancing health care provider vigilance or making it more difficult for the clinician to err. The process can take many forms, and the technology does not have to be elaborate. Recently, both the business and medical communities have become increasingly aware of the need for such clinical innovations. This awareness has resulted in the introduction of a number of new systems that are designed to minimize the chances of clinician error, and the support for such systems continues to increase.

Some of the best ideas for improvement come from persons who are involved in patient care on a daily basis. Individual clinicians frequently find gaps in the technology, or areas in which state-of-the-art care seems to fall short in some way. Many clinicians think of clever, innovative solutions to fill such gaps, but few of them know how to proceed to develop their ideas into licensed products for clinical care. It is regrettable that many good ideas never get translated into finished products that can be used at the bedside. This chapter attempts to address that problem by providing an abbreviated framework for the development of medical technology and including a list of patent and technology resources.

It is important to secure intellectual property rights (such as patents, trademarks, or copyright), which protect the economic value of a new idea. Securing property rights not only helps in personal gain, but also assures that the inventor can maximize his or her chances of attracting the investment capital necessary to develop the idea. Because corporations have a fiduciary duty to their shareholders, the likelihood of

commercial development is dependent on how investor companies view the risk/benefit ratio of investing in each potential product. If they do not view the investment opportunity favorably, the necessary investment capital will not be forthcoming and a good idea might stay on the drawing board. Protecting the idea by securing intellectual property rights enhances the likelihood of success and the inventor’s chances of having a positive impact on patient care.

The following section is an organized framework for taking an idea and developing it into an invention in a manner that will maximize the likelihood of securing patent protection. This list is meant to give the reader a general idea of how to proceed, but the author is not an attorney, and this outline does not constitute legal advice, so the reader is strongly advised to retain an experienced intellectual property attorney early in the process. There are many related issues that are beyond the scope of this text, including ethical and logistic issues of academic–industrial relationships, regulatory processes, clinical trials, and the patenting of drugs, processes, and genetic code. Included are references that provide an excellent sampling of recently written articles addressing these compelling issues.

A simplified approach for developing intellectual property

1. Memorialize the intellectual property (IP) in writing, personally date and have a trusted witness sign and date the documents including drawings, and consider having all signatures witnessed by a notary public.
2. Put original signed documents in a secure location such as a bank vault BEFORE sharing any information about the technology with non-inventors.
3. Clearly identify who is a contributor to the IP and who is not. Strongly consider retaining legal counsel by this time. Sorting out these issues at the earliest stage can help avoid significant legal issues at a later date.
4. Determine if any or all of the inventors have a duty to assign the technology to a hospital, university, institution or other employer. Determine if any claims of Conflict of Interest or Conflict of Commitment are likely. Again, seek the opinion of legal counsel. Consider having a “file memo” written providing the attorney’s opinion on the matter.

5. Determine if similar solutions have been proposed in public settings, or prior art, such as patents or scientific literature, as this will impact your likelihood of being granted IP rights. Clearly identify what is and what is not the invention. The appropriate test in determining whether your invention is patentable is to consider whether the invention is new, useful, and non-obvious in light of the prior art. Since these determinations involve legal definitions, you should consult with a patent attorney on these issues. You should conduct a preliminary patent search at <http://www.USPTO.gov>, Google patents, or some other free search Web site, to determine whether your invention is indeed patentable over the relevant prior art. Familiarize yourself with the website and do some reading about patents and other forms of IP.
6. Consider formally filing a Provisional or regular Utility Patent Application. At a minimum, create an invention summary which:
 - a. Describes the problem.
 - b. Describes the present state of the art to address the problem.
 - c. Describes the shortcomings of the present state of the art.
 - d. Introduces your solution.
 - e. When filing a Provisional Patent Application, the described solution must provide adequate information such that one of ordinary skill in the art can make and use the invention without undue experimentation, based upon your description. Also, the patent application must describe the best mode known to you for using the invention.
7. Consider protecting other related aspects of the IP, such as copyright protection for ideas, and trademarks to protect product or service names that identify the origin of the goods or services. Also consider filing multiple patent applications to protect different aspects of the invention.
8. Disclose to industry and others only *after* confidentiality agreements are in place, even if a patent application has been filed. If you disclose your invention to someone who is not obligated to keep the invention confidential prior to filing your patent application, you may be jeopardizing your IP rights. Please consult with your patent attorney before disclosing your invention. Avoid a bidirectional confidentiality agreement when possible –you do not need the responsibility of protecting the secrets of a large corporate entity.

Definitions from the US Patent and Trademark Office (USPTO) Web site

Copyright protects original works of authorship.

Letters Patent or Patent protects inventions or discoveries. The US Patent and Trademark Office (USPTO) defines a patent as

“a property right granted by the Government of the United States of America to an inventor ‘to exclude others from making, using, offering for sale, or selling the invention throughout the United States or importing the invention into the United States’ for a limited time in exchange for public disclosure of the invention when the patent is granted.”

A *Provisional Patent* is distinguished from a Letters Patent in that the former allows filing without a formal patent claim, oath, declaration, or any information disclosure (prior art) statement. The provisional filing provides the means to establish an early effective filing date for use in a subsequent letters patent application. It allows the term “Patent Pending” to be applied. The provisional filing automatically becomes abandoned after 1 year, if not converted to a letter patent application. The USPTO filing fee in 2011 is \$220.00.

Patent Pending means that someone has applied for a patent on an invention.

Trademark protects words, names, symbols, sounds, or colors that distinguish goods and services from those manufactured or sold by others and to indicate the source of the goods. Trademarks, unlike patents, can be renewed forever as long as they are being used in commerce. The term “trademark” is often used to refer to any of the four types of marks that can be registered with the USPTO. The two primary types of marks that can be registered with the USPTO are trademarks that identify physical commodities and service marks that identify services. Certification marks and collective marks occur infrequently.

Residency program: a guide for the perplexed

Daniel F. Dedrick

Federal government

Non-citizens will need to obtain a visa to travel to the United States. Since the September 11, 2001 attacks on the World Trade Center, the Department of Homeland Security often requires background checks prior to granting travel visas, which frequently takes some time. Sponsorship for these visas may come from a variety of sources.

J-1 visas

The Educational Commission for Foreign Medical Graduates (ECFMG), for example, may sponsor nonimmigrant medical J-1 visas for international medical graduates when their home country certifies to a need for the training sought. More details on the process can be obtained through the Exchange Visitor Program of the State Department. Additionally, the ECFMG may require that U.S. citizens or permanent residents who graduate from foreign medical schools certify medical credentials. This also includes Fifth Pathway candidates as well as international graduates, and applies when applying for travel visas into the US other than J-1 visas.

To qualify for ECFMG certification, thus allowing one initial clearance for medical practice in the United States, one's medical school must be included on the list of approved institutions, which closely corresponds to the list compiled by the World Health Organization. Also, the candidate must pass a series of examinations, including the Test of English as a Foreign Language (TOEFL) or pre-approved equivalent, Step 1 and Step 2 United States Medical Licensing Examinations (USMLE), also known as the Clinical Knowledge [CK] and Clinical Skills [CS] tests.

For a medical professional practicing under a J-1 visa to be certified by the American Board of Medical Specialties (ABMS), a certain number of training years is required. In anesthesiology, the minimum time for certification is 4 years, made up of a Clinical Base Year, followed by CA-1, CA-2, and CA-3 designated years, and also, a requirement that they return to their home country for 2 years. Subsequent to these years, the ECFMG *may*, but is not required to sponsor a foreign medical school graduate for purposes of fellowship training, up to a maximum of 7 years. Also, as described later, there *may* be opportunities for the professional to circumvent the rule that

requires they return to their home country for 2 years prior to certification as well.

It is possible that one may receive a waiver of the J-1 visa requirement that one return to one's home country for 2 years. The related laws and regulations are currently in flux, however, so consultation with a licensed immigration attorney is advised. In the past, the Department of Agriculture sponsored physicians willing to work in rural, medically underserved areas. The program focused on bringing in primary care doctors, but this program was recently discontinued.

H-1B visas

Nonprofit institutions are permitted to sponsor nonimmigrant medical H-1B visas. The H-1B visa applies to an occupation vetted by those who completed a specialized university course in the area, and requires the practical application of the knowledge and theory gained in the field as well. The H-1B visa sponsors are limited to nonprofits; hospitals, medical centers and all for-profit entities are excluded. Further, the nonprofit entity must provide an attestation from the Secretary of Labor stating that there is a need for workers in that specialty, and prove that the sponsoring institution has placed advertisements for filling the position by a US citizen. J-1 visa requirements apply and applicants must also pass the Step 3 examination offered by the USMLE, which in some states requires a medical degree from a US graduate school prior to taking it. The H-1B visa is more expensive than the J-1 visa, leading some nonprofits to avoid H-1B sponsorship. Someone may be trained under this visa for a maximum of 6 years.

O-1 visas

An employer may also sponsor nonimmigrant visas under the O-1 classification, which applies to people with extraordinary ability in the sciences, education, among other specific fields. To be eligible, the potential trainee must have numerous publications, patents or similar work products requiring a high level of knowledge and skill, thus, this categorization is more often appropriate for a faculty recruit.

Under limited circumstances, some individuals may qualify for employment authorization via other types of visas, such as spousal visas.

State Department Programs

There are two options under the State Department: (1) the Conrad program, recruiting 30 professionals per year, per state and specifically targeted to medically underserved areas, with a maximum set at 5 posts for specialists, and (2) the “Interested Federal Agency” program. Both options require 3 years of service, with recommendations from an individual state’s Department of Public Health agency for the first option and by the relevant federal agency for the second option. The US Department of Veterans Affairs (VA) hospital system provides the majority of federal opportunities. Serving in a VA medical center or other federal facility requires a permanent and unrestricted medical license from any state, and not necessarily from the state where the facility is located.

Other Considerations

If a medical professional has financed any part of his or her medical education with a military scholarship or attended the Uniformed Services University of the Health Sciences, one must request a delay of active duty for civilian residency. The military may also require participation in a military PGY-1 program and/or serve 2 to 3 years as a general medical officer (GMO) prior to allowing civilian training. Special training, as required for a flight surgeon, for example, may entail additional active duty obligations. Anesthesiology is typically an understaffed specialty for the military, so obtaining a military residency in anesthesiology or a delay for civilian residency has been readily granted in the past.

Those who have not completed their military obligations may qualify for benefits under the GI Bill during training if one’s program is directly affiliated with a university medical school that categorizes trainees to be “postgraduate students in the school of medicine.” One should contact the university’s VA office for details.

Although the needs of the military vary from year to year, one may secure funds in exchange for Reserve commissions during residency. Recently, the federal government has established a new requirement for *all* practitioners, trainees included.

A National Provider Identifier (NPI) number is to be given to medical professionals to assist with billing for medical services. The NPI is necessary not only for federal Medicare billing, but also for all Medicaid and commercial insurers as well. One may apply for an NPI online with or without the assistance of your institution.

Anesthesiologists, like all medical practitioners, must have authorization from the Drug Enforcement Administration (DEA) and possibly from an analogous state agency to prescribe and administer controlled substances.

Trainees in many states are allowed to prescribe using their teaching hospital federal registration number within the bounds of their residency. Note that if a trainee practices outside of the teaching program (“moonlighting”), that person must have an independent, site-specific DEA registration.

Is research part of your training or subsequent career? Researchers must be aware of federal, as well as any state or local regulations. Human studies must have institutional review by a formally established institutional review board (IRB), and animal care must meet standards set by the Department of Agriculture. Research fraud may be grounds for dismissal from federal funding mechanisms, as is earning an unsatisfactory evaluation from the American Board of Anesthesiology (ABA).

State and local government

Under the supremacy clause of the US Constitution, powers not specifically given to the federal government will go to the states and territories (e.g. Washington D.C.). The states, for example, determine requirements for medical licensure.

Because each jurisdiction has its own rules, one should work closely with the institution where they will work to assure compliance with the relevant licensing regulations. For instance, some states may require no license for the PGY-1 year, whereas others have some form of limited registration for training. Still others use a single type of license for all levels of physician’s training. More information about specific medical licensure requirements can be found at the annual Green Book, the American Medical Association’s (AMA) Graduate Medical Education Directory, as well as its online equivalent, AMA-FRIEDA (Fellowship and Residency Electronic Interactive Database), at www.ama-assn.org/go/freida.

Information in matters of professional liability and disciplinary action can be found at the National Practitioner Data Bank. It is worth noting that sequence matters, and some institutions may require, for example, that a fully trained individual have a full and unrestricted medical license before applying for DEA registration, which must be obtained before hospital credentialing. This is particularly relevant when pursuing job opportunities. Also, some states may require their own unique application, a personal interview, proof of education and training, from the primary source, or directly from the degree-granting or certifying institution. Some states have reciprocity agreements with other states, allowing licenses in one state to permit practice in another, with the permission of the second state. The first state will normally endorse the practitioner’s license, usually with an added fee.

The Federation of State Licensing Boards (FSLB) assumes the responsibility of compiling much of the requisite data and deals with the primary source verification for that documentation. The program is especially helpful to an individual doing *locum tenens* jobs, or substituting in the place of another on a temporary basis. Some localities also require registration with the town clerk for all physicians practicing within the city limits. Likewise, some counties (in Louisiana, parishes) may also add their own layer of registration. One is advised to work closely with the training or practice institution, as its personnel should be familiar with the local rules and regulations. You may also wish to examine the web sites of the state,

county, and municipal governments for any additional requirements.

Professional liability insurance is regulated by local governments. Generally, the cost of such insurance is higher in urban settings. Normally, the hiring institution will pay for the practitioners insurance, but if one works on one's own, additional malpractice insurance may be required under law. Professional liability insurance is usually one of two types: *occurrence* or *claims made*.

An occurrence policy will apply to events during the period of coverage, whereas a *claims made* policy applies only to professional liability *claims made* during the covered interval. Because most allegations of malpractice are filed long after the provoking event, insurers offer “tail” coverage for the *claims made* policies, extending coverage for some defined number of years, ideally for the full length allowed by the local jurisdiction for “discovery” and filing of the complaint in a lawsuit.

Note that if the patient is a minor, depending on state law, this time period (I.e. the statute of limitations) may extend to the legal age of majority plus the jurisdiction's applicable discovery period – potentially age 21 plus 3 or more years! For your own protection, know what type of policy is held in your name by your training institution or your group or employer and demand tail coverage if the coverage is *claims made*.

In some settings, liability coverage may come from another source. For example, should you work for the federal government in any capacity, including the military, coverage is provided by the government under the terms of the Federal Tort Claims Act. Similar protection may be available through similar provisions of state or municipal hospitals, depending on local statutes and regulations.

Nongovernmental bodies

A medical residency is also subject to the rules and regulations of the Accreditation Council for Graduate Medical Education (ACGME), the ABA, as well as the sponsoring institution. Note that the sponsor must also abide by ACGME Institutional Guidelines; federal, state, and local laws and regulations; and the rules of the Joint Commission (JC). Specifically as it relates to its teaching programs, the sponsoring institution must demonstrate appropriate support and ongoing oversight, including periodic internal reviews of each such program. Support includes not only trainee or resident benefits and salaries, but also maintenance of facilities, such as libraries and call rooms, and compliance with a number of defined policies and procedures enumerated in the institutional guidelines.

What are the different roles of the ACGME and the ABA? In many other countries, a single entity may control both training programs and the credentials of graduates of those programs. In the United Kingdom, for example, training and licensure for anesthesiology are managed by the Faculty of Anaesthetists.

The primary difference in the United States is that the ACGME accredits the training programs and sponsoring institutions and the ABA grants licensure. Although many of

the rules of the two bodies are congruent, the main roles they play are different, and program directors and trainees must always be cognizant of both sets of demands.

Under the ACGME, trainees in residency and fellowship programs are required to attend certain accredited training programs, which range from instructional courses on policies and contracts to the rules regarding due process and faculty training. Further, the individual specialty Review Committee (RC), previously known as the Residency Review Committee (RRC), offers additional guidance as to the common requirements. The language contained in these ACGME documents follows several conventions, including: bold type for required elements; carefully parsed words, with “must” and “shall” as *imperatives* for accreditation, while the words “will” and “should” indicate something is highly encouraged but not absolutely demanded for accreditation. An example is provided below. The RC for Anesthesiology expands on the ACGME core competencies in a specialty specific manner:

ACGME core competencies

The program must integrate the following six ACGME Core Competencies into the curriculum:

Patient care

Residents must be able to provide patient care that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health. Residents: must have a wide spectrum of disease processes and surgical procedures available within the program to provide each resident with a broad exposure to different types of anesthetic management within the anesthesiology residency program. The following list represents the minimum clinical experience that should be obtained by each resident in the program (see actual ACGME document).

Medical knowledge

Residents must demonstrate knowledge of established and evolving biomedical, clinical, epidemiological and social behavioral sciences, as well as the application of this knowledge to patient care. Residents should have didactic instruction that encompasses clinical anesthesiology and related areas of basic science, as well as pertinent topics from other medical and surgical disciplines. Didactic presentations related to the specific issues noted in section IV.A.5.b (Medical Knowledge) are required. Practice management should be included in the curriculum, and should address issues such as operating room management, types of practice, job acquisition, financial planning, contract negotiations, billing arrangements, professional liability, and legislative and regulatory issues. The material covered in the didactic program should demonstrate appropriate continuity and sequencing to ensure that residents are ultimately exposed to all subjects at regularly held teaching conferences.

The number and types of such conferences may vary among programs, but there must be evidence of regular faculty participation. The program director should also seek to enrich the program by providing lectures and contact with faculty from other disciplines and other institutions; must have appropriate didactic instruction and sufficient clinical experience in managing problems of the geriatric population; and must have appropriate didactic instruction and sufficient clinical experience in managing the specific needs of the ambulatory surgical patient.

Practice-based learning and improvement

Residents must demonstrate the ability to investigate and evaluate their care of patients, to appraise and assimilate scientific evidence, and to continuously improve patient care based on constant self-evaluation and life-long learning. Residents are expected to develop skills and habits to be able to meet the following goals:

1. identify strengths, deficiencies, and limits in one's knowledge and expertise;
2. set learning and improvement goals;
3. identify and perform appropriate learning activities;
4. systematically analyze practice using quality improvement methods, and implement changes with the goal of practice improvement;
5. incorporate formative evaluation feedback into daily practice;
6. locate, appraise, and assimilate evidence from scientific studies related to their patients' health problems;
7. use information technology to optimize learning; and
8. participate in the education of patients, families, students, residents and other health professionals.

Interpersonal and communication skills

Residents must demonstrate interpersonal and communication skills that result in the effective exchange of information and collaboration with patients, their families, and health professionals. Residents are expected to:

1. communicate effectively with patients, families, and the public, as appropriate, across a broad range of socioeconomic and cultural backgrounds;
2. communicate effectively with physicians, other health professionals, and health-related agencies;
3. work effectively as a member or leader of a health care team or other professional group;
4. act in a consultative role to other physicians and health professionals; and
5. maintain comprehensive, timely, and legible medical records, if applicable.

Professionalism

Residents must demonstrate a commitment to carrying out professional responsibilities and an adherence to ethical principles. Residents are expected to demonstrate:

1. compassion, integrity, and respect for others;
2. responsiveness to patient needs that supersedes self-interest;
3. respect for patient privacy and autonomy;
4. sensitivity and responsiveness to a diverse patient population, including but not limited to diversity in gender, age, culture, race, religion, disabilities, and sexual orientation.

Systems-based practice

Residents must demonstrate an awareness of and responsiveness to the larger context and system of health care, as well as the ability to call effectively on other resources in the system to provide optimal health care. Residents are expected to:

1. work effectively in various health care delivery settings and systems relevant to their clinical specialty;
2. coordinate patient care within the health care system relevant to their clinical specialty;
3. incorporate considerations of cost awareness and risk-benefit analysis in patient- and/or population-based care as appropriate;
4. advocate for quality patient care and optimal patient care systems;
5. work in interprofessional teams to enhance patient safety and improve patient care quality; and,
6. participate in identifying system errors and implementing potential systems solutions.

How does a trainee know what specific details are mandated by the ACGME? Each recognized specialty has an RC, and any subspecialties within that area will have their own subsidiary RCs as well.

The RCs are charged with setting the program requirements, including the minimum specialty curriculum, and assuring that individual programs are in compliance with those requirements. The ACGME asks that the RCs periodically review and update the specialty program requirements as practice changes and as the common requirements evolve. For the most current anesthesiology program requirements, go the ACGME Web site (www.acgme.org), click on the button in the left column for RCs, and then select "Anesthesiology" from the pop-up list. Note that you will find pdfs of the program requirements not only for the primary residency, but also for the subspecialties recognized by the ACGME: Pain Medicine, Critical Care Medicine, Pediatric Anesthesiology, Hyperbaric and Undersea Medicine (a joint program with other specialties), and the newest addition, Adult Cardiothoracic Anesthesiology.

The existence of an RC for an anesthetic subspecialty may not be associated with a corresponding certification mechanism

for graduates in that subspecialty. The ABA does not offer an examination and certification mechanism in every area.

What if a trainee, having completed the basic anesthesiology program, wishes to enter a non-ACGME subspecialty? Nonstandard education in obstetric, neurosurgical, ambulatory, regional, thoracic, transplant, and other key areas of anesthesiology is widely available. Absence of a matching RC means that the ACGME-supported program requirements have not been established. The sponsoring institution may elect to require all of its programs (not only the ACGME fellowships) to conform to the common requirements. National subspecialty organizations may have drafted “suggested curricula” but have no mechanism for direct oversight of individual programs.

International graduates on any type of visa may have additional hurdles to overcome. Obtaining an extension for a non-ACGME subspecialty program may require assembling a number of additional documents: a statement from the parent specialty board (in our case, the ABA) that the given area is indeed a recognized subspecialty, acceptance of the subspecialty program by the sponsoring institution through its Graduate Medical Education Committee (GMEC), and a statement from the Program Director of the ACGME core anesthesiology residency that the subspecialty program is directly associated with the residency. Even with these documents, the State Department and the ECFMG may deny the necessary visa extension for a nonstandard subspecialty program.

What kind of responsibilities should a trainee have for certification by the ACGME? The organization asks that there be resident representation on the institutional GMEC and on any GMEC subcommittee or other internal review group conducting the mandated institutional oversight of individual residencies. During the periodic site visits by ACGME field staff or specialist staff, residents will be asked to review details of the training program privately, with no faculty present, to encourage candid discussion. Note that the purpose of the site visit is to confirm information provided to the ACGME on its program information form, with a view to establishing whether substantial compliance with program requirements truly exists.

Trainees shall maintain a log of work hours and should consult with the Program Director if any rotation or division is not in compliance, as well as for resolution of other problems seen in the training scheme. The ACGME offers its own Web-based System for these case logs. If issues are not addressed even at that level, the ACGME has a web based complaint system available that maintains the anonymity of the trainee. Each trainee must also maintain a separate log of cases, consultations, and procedures performed. The ACGME requires specific minimum clinical experiences across the range of the specialty and expects the department to provide an electronic method for the case log. While the ACGME offers its own system, many departments use commercial or proprietary products, often web-based, for the case logs, with a periodic upload (at least annually) to the ACGME system. The ACGME shares case data with the ABA.

What is the role of the ABA? As mentioned previously, the ABA offers certification for individuals who complete ACGME-approved training programs. Due to recent added requirements of the ABMS, the non-governmental entity that manages standards for all member boards, the ABA now also provides periodic recertification for those previously certified. The ABA maintains a comprehensive compilation at www.theABA.org containing all of its publications, rules, examination dates, content outlines for examinations, and other essential information. The web site also includes a portal to private areas for each enrolled individual, geared toward helping those who are preparing for recertification. **Note that ABA policy is that each trainee is responsible for knowing the content of its “Booklet of Information,”** available for download on the web site. It is your responsibility to learn the information contained therein!

At the beginning of training, individual candidates enroll as ABA candidates with the Program Director (PD). Twice per year, the department shall report the performance of the enrolled individuals as Satisfactory or Unsatisfactory. For the residency, the departmental Clinical Competency Committee is responsible for this evaluation, with endorsement by the PD. While the primary purpose of the semiannual assessment is clinical progress toward full consultant status, the Board mandates that all elements of professionalism and “Essential Character Attributes” be included in the overall report. Should any Essential Character Attribute be unsatisfactory, then that six-month report **must** be Unsatisfactory. The following text is from the ABA document *Defining the First Step Toward Board Certification and Maintenance of Certification in Anesthesiology*

ESSENTIAL ATTRIBUTES: The physician who lacks one or more of the following attributes is not considered qualified to practice anesthesiology safely.

1. Demonstrates high standards of ethical and moral behavior.
2. Demonstrates honesty, integrity, reliability, and responsibility.
3. Learns from experience; knows limits.
4. Reacts to stressful situations in an appropriate manner.
5. Has no documented current abuse of alcohol or illegal use of drugs.
6. Has no cognitive, physical, sensory, or motor impairment that precludes acquiring and processing information in an independent and timely manner or independent responsibility for any aspect of anesthesia care.
7. Demonstrates respect for the dignity of patients and colleagues and sensitivity to a diverse patient population.
8. Has no restriction, limitation, or revocation of license to practice medicine.

Board policy is that a six-month period ending in an “unsatisfactory” must be immediately followed in the same program by a “satisfactory” or the Board will mandate training. Also note that history of substance abuse may delay a candidate’s ability to receive certification. The Board looks towards three major elements for its certification process: satisfactory marks

from the PD for the clinical training program, professionalism, and essential character attributes. The ABA Step 1 Examination, previously known as the Written Examination, evaluates the knowledge base of the candidate. The ABA Step 2 Examination, previously known as the Oral Examination, tests the ability of the candidate to respond to issues of clinical care in changing conditions and the ability of the candidate to communicate concisely and effectively his or her specific medical concerns, balance of risks, judgments, and also manage at the level of a true consultant in the specialty.

Do all international graduates have to complete an ACGME-approved residency in order to enter the ABA examination sequence? The ABA is currently trying out alternative paths of entry for only international graduates who are fully certified in anesthesia in their home country and have planned an academic career in the United States. The Chair of each residency program may sponsor no more than two individuals at the same time. The Alternate Pathway is no shorter than the residency pathway, both requiring a minimum of four years. The Alternate Pathway may include subspecialty fellowship training, research, or service as academic faculty, or some combination of those elements. The ABA reserves to itself the right to approve or disapprove individual petitions by the Chairs. Parallel to the required semiannual resident candidate assessment by the Clinical Competency Committee, the ABA also mandates semiannual evaluation of Alternate Pathway candidates by the Chair, who decides whether to allow continued sponsorship. Other requirements for entry into the examination sequence of the ABA are generally identical to the requirements for an ACGME-approved residency.

How do I best prepare for the examinations? The ABA and the American Society of Anesthesiologists, through their Joint In-Training Council, offer an opportunity to practice for the Step 1 Examination through an annual In-Training Examination (ITE). In addition, on its Web site, the ABA provides a Content Outline that lists subject areas that may be included. As of 2008, the Step 1 Examination is a computer-based test. Even though the contents will no longer be the same, the general format and range of material will still make the ITE a good review of important skills. The In-Training Council provides the candidates and the Program Directors with a listing of subject key word areas with wrong answers. The PD will usually share the global listing with the departmental education committee to improve teaching in areas that many trainees err.

Some PDs also employ other tests, either designed in-house or from resources such as the Society for Education in Anesthesia or the Inter Hospital Study Group for Anesthesia Education. The latter group publishes an examination series known as the Anesthesia Knowledge Tests, as well as examinations in between annual ITEs, and after six and eighteen months of experience. Similar to the ITE, the AKT series provides key word information to the individuals and the PD. All of these tools give opportunities to see where one needs to focus preparation for the ABA Step 1 examination, which is given after one completes residency. Note that if one does not hold a full, unrestricted license

in any state or Canadian province, one must pass the full set of USMLE examinations, including Step 3, prior to the registration deadline for the ABA Step 1, which is in mid-December of the year before graduation, and no later than end of September of the examination year, according to ABA policy. This USMLE certification allows one to receive a permanent and unrestricted license. The Board will not validate or release the results of Step 1 and will not allow resitration for Step 2 if one fails to secure said license by the end of November of the examination year. Preparation for the Step 2 (formerly Oral) Examination is usually available through a residency or training program. Nearly all residencies will have one or more individuals who are current or former examiners or faculty specifically trained by the Board to administer mock oral exams. In many programs, case conferences or morbidity/mortality conferences are modeled after the oral examination format. The actual test is two separate 35-minute sessions. Each may have different times allocated to preoperative assessment, intra-operative management, and postoperative care, including pain management. In addition to the primary case, there will also be other topics, typically based on three short vignettes. The Board itself provides model “stem questions” on its web site. An example follows below.

ABA Sample part 2 examination – session 1

Session 1 – 35 minutes

A 56-year-old, 70 Kg, 5'8" tall man is brought to the operating room for a left upper lobectomy.

- HPI:** Patient noted the onset of a productive cough 6 weeks ago and an episode of hemoptysis 10 days ago. He was seen by a pulmonary specialist who noted a 2 cm mass in his left upper lobe on chest x-ray. Fiber-optic bronchoscopy revealed irregularity of the left upper lobe bronchus, and biopsy revealed carcinoma. Metastatic workup was negative.
- PMH:** Uncomplicated myocardial infarction 4 months ago. He notes angina with exercise over past month. A stress test 7 days ago showed minimal ST segment depression at a heart rate of 120 beats per min. without angina. An echocardiogram revealed an ejection fraction of 55%. Medications include diltiazem and nitroglycerin PRN. He has no allergies. He smoked 2 packs of cigarettes per day for 25 years until 10 days ago. He drinks an occasional beer.
- PHYS EXAM:** P 72, BP 140/80, R 20, T 37.1°C. His airway appears normal. Chest auscultation reveals expiratory wheezes over left posterior upper lung field. Cardiac exam is normal. He has no organomegaly or peripheral edema.
- X-RAY:** 2 cm mass and small infiltrate left upper lobe

- EKG: Q waves in II, III, aVf with T wave inversion in the same leads.
- LABS: Hgb 14.5 gm/dl, normal electrolytes and normal coagulation studies.

He arrives in operating room at 10:00 A.M. with 1st nitropaste, having taken his diltiazem at 7:00 A.M.

Intra-operative management – 10 Minutes

1. Induction: Would you induce with thiopental? Why/Why not? Propofol? Your choice? Why? The surgeon requests double-lumen tube. You respond? How do you confirm position? Is a right-sided tube appropriate? Why/why not?
2. Anesthetic Selection: Is nitrous oxide-opioid anesthesia appropriate? Why/why not? Your choice? Why? Would halothane be preferable if patient has reactive airway disease? Prefer another inhalation agent in this patient? Why?
3. Intra-operative Hypoxia: After 20 minutes of one-lung ventilation, SpO₂ decreased from 99% to 90%. Your interpretation and response? Rationale for therapeutic choices. What if SpO₂ is 80%?
4. Massive Blood Loss: The surgeon loses control of the pulmonary vein and the patient loses 1200 ml blood in two minutes. Two units of packed cells are available. How do you manage blood loss? Why? Blood pressure not responding to volume replacement. Your plan? Rationale. Ischemia on ECG. How does it influence your management? Your plan? Why?

Post-operative care – 15 Minutes

1. Extubation Criteria: How will you decide suitability for extubation? Rationale. How does criteria for this patient differ from ASA-1 cholecystectomy patient? Explain.
2. Post-operative Ventilatory Support: Assume ABG at end of surgery with double-lumen ET tube and bilateral ventilation shows PaO₂ = 65 mm Hg, PaCO₂ = 58 mm Hg, pH = 7.29 with FIO₂ = 0.5 and spontaneous ventilation. Interpret. How will you proceed? Why? If decide to ventilate in ICU will you change ET tube? Why/Why not? Discuss ventilator settings. Discuss IMV vs. PCV. Discuss PEEP.
3. Pain Management: Would PCA be a good choice? Why/Why not? Is thoracic epidural a better choice? Why/Why not? If epidural in place, what medications would you administer? Why?
4. Myocardial Ischemia: 8 hours after surgery patient complains of anterior chest pain and you note new S-T segment elevation on bedside monitor. How will you proceed? Why? 30 minutes later, his blood pressure is 80/30 and you note tachypnea and diffuse rales. Discuss evaluation and management.
5. Nerve Injury: Following extubation and at time of discharge from ICU, the patient complains of numbness

over ulnar distribution of right forearm and hand. What might be the causes? How will you evaluate? Is there any treatment for this? What will you tell patient?

6. Jaundice: 4 days after surgery, the patient's bilirubin is 6.5 mg/dl. Surgeon questions if anesthesia might be the cause. You respond? Discuss further evaluation.

Additional topics – 10 Minutes

1. Obstetrical Anesthesia – Pre-eclampsia: Urgent C/S for fetal distress is scheduled for 19-year-old parturient who is pre-eclamptic and in active labor. She is receiving MgSO₄ and intermittent hydralazine. Blood pressure is 150/110. What would be your choice of anesthesia? Why? Discuss advantages/disadvantages of epidural. How would you control blood pressure? Why? What are your goals? Explain.
2. Post-CABG tamponade: A 65-year-old man underwent an uncomplicated CABG 16 hours earlier and was extubated 4 hours ago. In the past hour his BP fell from 110/70 to 70/50 and the CVP rose from 8 to 22 mmHg. What are the possible etiologies? How would you evaluate? Manage? If tamponade is suspected and mediastinal exploration is required, how would you provide anesthesia? Explain.
3. Temperature: A 48-year-old man is undergoing a radical prostatectomy during general anesthesia. Two hours into the operation, his esophageal temperature is 34.5°C. Would you treat? Why/Why not? If so, how? Thirty minutes later it has decreased to 33.5°C. Your management? Surgeon attributes a problem with bleeding to the hypothermia. Agree? Why/Why not? What might be the mechanism? Explain. How will decreased temperature influence your plans for extubation? Describe.

Typically, there are two examiners for each of the thirty-five minute sessions. Sometimes a third individual may be present, most commonly either a new junior examiner being introduced to the system or a senior examiner performing quality assurance. As you may gather from the above example, you will be challenged to describe and defend your thought processes, and respond to changing situations. At present, the ABA uses an equivalent of the Step 1 Examination for each of its subspecialties after completion of the specific fellowship. For hospice and palliative care certification, individuals who have been practicing in the subspecialties may document their clinical experience and sit for the examination. The reason for this “grandfathering” provision is that fellowship opportunities have just started to become widely available. Many practitioners interested in this additional certification are also actively involved in pain medicine.

Per ABA rules, recertification is required after ten years have passed since taking the examination. ABMS guidelines are the same, and state that this applies to any individual certificate, whether the primary anesthesiology or the ABA subspecialties of critical care medicine or pain medicine.

From the Booklet of Information: “The ABMS approved the concept of maintenance of certification (“MOC”) in 2000. The twenty-four ABMS Member Boards subsequently endorsed the concept. MOC is a program of continual self-assessment and lifelong learning, along with periodic assessment of professional standing, cognitive expertise and practice performance and improvement. The ABA is committed to evolving its recertification programs to MOC programs. The ABA presented a proposal for the Maintenance of Certification in Anesthesiology Program (“MOCA”) to ABMS in 2002. The transition from the current recertification program to MOCA began in 2004. This allows adequate time for diplomates issued a time-limited certificate to satisfy all MOCA requirements. The maximum interval between initial certification that is time-limited and successful completion of the requirements to maintain certification for the first time, as well as each time MOCA is required thereafter, is ten years. Details of the MOCA program are available on the ABA web site, as well as a personal private web page for each enrollee to document the requirements for the program. Continuing medical education, holding current and unrestricted full medical licensure, having an original certificate from the ABA, an evaluation of one’s practice, and a minimum of one day per week devoted to the specialty are among the primary items mandated for entrance to the required secure examination. Note that for all enrolled trainees and certified practitioners alike, the ABA requires that it be informed of any change in address or of any restrictions imposed on medical licensure. Substance abuse, “loss of or severe restriction imposed on the medical license, fraud in application materials, and a few other failures of professionalism may lead to deferral of issuance of a certificate or possible revocation of a current certificate.”

The world of practice

Once one is trained, certified, licensed, and has obtained NPI and DEA numbers, it’s time to take stock and determine one’s personal values in order to find a good fit in practice. What are your personal goals? Do you enjoy the academic setting? Working in a major teaching institution provides the opportunity to teach and conduct research. Do you not wish to deal with the academic “publish or perish” schema, but still enjoy teaching? Working in an affiliated institution to which trainees rotate offers that option. Do you prefer the private practice setting? Then you must consider a wide range of different practice models. You may even find blended situations. Some choose to see many institutions by doing *locum tenens* jobs.

In the private practice environment, there is significant regional variation. There may be an individual personal service contract (with others working for that individual) or exclusive group contracts. Other parts of the country are dominated by groups of anesthesiologists, under a variety of business arrangements, including partnerships, limited liability corporations, tax-exempt foundations, hospital employees, and others. Some regions work as physician-only practices, whereas the

more common pattern is the “care team model”, with physicians supervising anesthesia assistants or certified registered nurse anesthetists and sometimes teaching student anesthesia assistants or student registered nurse anesthetists. In some areas, there are multi-specialty group practices.

No matter the nature of the practice you prefer, you will need to negotiate a contract. While many new graduates have substantial educational debt, spending a bit more to have a labor attorney review any proposed contract may be well worth the expense. Do not be blinded by salary alone. Consider the entire employment package, such as professional liability insurance, disability income insurance, life insurance, health insurance, dental and vision coverage, parking, support for direct professional expenses (membership in professional societies, CME, license renewal, DEA renewal), time off for CME, vacation time, use of an automobile (particularly if you will be expected to work at more than one location), retirement, and call obligations. Any of these items left to you diminishes your effective salary, so always look at the entire package! Should you be involved in the governance of the group, you may also need “officers and directors” liability coverage. How are the business expenses dealt with, including office staff salaries and benefits, Worker’s Compensation insurance, and billing, coding, and collection services? I can understand a probationary period to see if I mesh well with the group and perform clinically to its satisfaction. But why do they want money from me to join the group, either as an explicit buy-in or as a reduced salary for one or more years? While some groups may allocate some of this to corporate “goodwill” and an established referral base, the biggest factor is the lag between providing a service and collections. If the bill is not correctly coded, there will be a delay. Even with a “clean” bill and electronic rather than paper submission, payment may take literally months. In the meantime, the group is supporting you in full!

Will you be working at more than one site? If so, in most jurisdictions, each entity may be required to perform credentialing on its practitioners, although some state medical societies offer a credentialing service to hospitals and ambulatory surgery centers within the state. Your DEA registration is site-dependent. You may wish to confirm that your professional liability coverage extends to all of your practice environments. Be familiar with each institution’s staff bylaws and practice rules, including public health or occupational health requirements such as rubella immunization or periodic tuberculin skin testing.

Making a difference

Now that I am in the real world, how do I contribute? Political activism begins at home. Volunteer for hospital committees. Be an active member of your medical staff, physician organization or hospital-physician organization. Join your local and state medical associations and participate! Consider membership with the American Medical Association or the National Medical Association. The governance of the AMA has been recently

changed to reflect the developing power of the specialties. Maintain membership in your state's anesthesiology society and the American Society of Anesthesiologists (only military doctors may join ASA without being members of a state organization). Seek office, join panels, and attend the annual ASA Legislative Meetings (where you may obtain formal media relations training). Speak with your state legislators and your Congressional Representatives and Senators. Donate to the appropriate political action committee and work directly to support legislators who care about patients and the profession.

Volunteer your skills and knowledge. Time is precious, but donated professional skill is precious time given to a higher purpose. The ASA maintains a teaching program in less developed countries, as does Health Volunteers Overseas (HVO). Many charitable organizations offer medical care to the poor and underserved, particularly in the less developed areas of our world. If there is any element of surgery in that care, such as with Operation Smile, ProjectHope, Interplast, and many more, it is particularly important to have volunteers. Physicians should be advocates for patients!

Medical informatics and anesthesia information management systems

Jesse M. Ehrenfeld

Medical informatics

Medical informatics is the application of information science to health care. It is a burgeoning field, brought on by the widespread availability of electronic medical records, high-speed computers, and networkable patient monitors. The field of medical informatics focuses on using information technology to optimize the storage and retrieval of health information. Information technology can include individual patient level data for use in routine clinical care (such as the reporting of laboratory results) or large data sets including thousands of patients to facilitate the performance of health outcomes research.

Today, medical informatics encompasses many of the electronic tools that anesthesiologists use to interpret and act on clinical data. These tools include advanced clinical decision support systems, which have the ability to evaluate real-time data while incorporating practice guidelines, to help providers and end users make better decisions. Other tools facilitate the reporting of both patient- and provider-level data for quality assurance, billing, and other administrative purposes.

The field of medical informatics began in the 1950s with the advent of computers and the microchip. The earliest use of computers in medicine took place at the U.S. National Bureau of Standards. The National Library of Medicine started MEDLINE in 1965, and, at approximately the same time, the Massachusetts General Hospital Utility Multi-Programming System (MUMPS) was developed in Boston. For decades, MUMPS was the single most commonly used computer programming language for medical applications.

Anesthesia information management systems

Anesthesia information management systems (AIMS) are a specialized form of electronic health records that allow the automatic and reliable collection, storage, and presentation of patient data during the perioperative period. In addition to providing basic record-keeping functions, most AIMS also allow end users to access information for management, quality assurance, and research purposes. AIMS typically consist of a combination of hardware and software that interface with intraoperative monitors and, in many cases, hospital electronic

health records. Although the primary role of an AIMS is to capture data during the intraoperative phase, most systems also can incorporate pre- and postoperative patient information. Typically, all of this information is stored in a robust relational database that can be accessed simultaneously by multiple users either via a vendor's commercial application or standard database tools, such as structured query language.

Widespread adoption of AIMS, which have been in existence since the 1970s, has been hindered primarily by the financial barriers associated with implementation of these systems. As a result of these hurdles, only an estimated 5% of US operating rooms in 2006 had an AIMS. Adoption has accelerated recently, driven primarily by a need to address increased regulatory reporting requirements and a desire to improve routine clinical documentation. The areas in which AIMS have proved beneficial to both patients as well as anesthesia departments are summarized in [Table 182.1](#).

The specific benefits of a particular AIMS installation ([Table 182.2](#)) depend on a number of factors, including the system

Table 182.1. Areas impacted by anesthesia information management systems

Impact on patients
<ul style="list-style-type: none"> • More accurately records patient responses to anesthesia • Improves availability of historic records • Allows an anesthesiologist to focus on the patient, rather than charting
Impact on the practice of anesthesia
<ul style="list-style-type: none"> • Improves quality assurance functionality due to more accurate and complete records • Allows quick searches for specific occurrences or rare events across multiple cases • Provides a means to track individual provider performance over time • Assesses patient outcomes through integration with other hospital databases • Makes available accurate, high-resolution charts for educational purposes • Provides legal protection through more accurate, unbiased information
Impact on departmental management
<ul style="list-style-type: none"> • Facilitates accurate and timely billing • Allows analysis of supply costs by patient, provider, or type of surgery • Can assist with concurrency and other regulatory compliance issues • Satisfies the Joint Commission requirements for comprehensive, legible records • Provides ready verification of ACGME case requirements for residents in training programs

ACGME, Accreditation Council for Graduate Medical Education.

Table 182.2. Specific benefits of AIMS in peer-reviewed literature

Cost and billing improvements

- Controlling and reducing anesthesia drug costs
- Improving capture of anesthesia-related charges
- Impact on hospital reimbursement

Decision support and provider education

- Clinical decision support
- Training and provider education

Patient safety and quality assurance

- Increased patient care and safety
- Enhancement of clinical quality improvement programs
- Support of clinical risk management
- Monitoring for diversion of controlled substances

Data quality and clinical research

- Enhancement of clinical studies
- Improved intraoperative record quality

purchased, the overall implementation scheme, and the departmental work flow. One mistake that institutions often make when installing an AIMS is to simply replace paper with an electronic system – without changing processes to obtain the full benefit of these systems. For example, after installing an AIMS, one institution continued to send copies of incomplete anesthesia records to physicians via interoffice mail with a handwritten note asking for correction of the documentation error. The rate of unbillable charts was unchanged until the institution began using electronic tools that interfaced with the new AIMS installation to facilitate error correction.

Many departments choose to install AIMS because, fundamentally, anesthesia relies on the provision and timely documentation of accurate information. These data are the basis for how we make decisions; given the ever-growing amount and complexity of the information, electronic systems can facilitate the capture and interpretation of data.

In addition to assisting providers with the specific task of record keeping, AIMS have been shown to improve patient safety in a variety of settings by facilitating appropriate clinical care and providing accurate documentation for retrospective review. Most systems can generate point-of-care alerts for patient allergies or drug–drug interactions. In fact, the Anesthesia Patient Safety Foundation has both endorsed and advocated the use of AIMS because of the ability of the technology to provide high-quality data.

In fact, many departments are using AIMS to facilitate reporting of the increasing number of quality measures (such as on-time administration of prophylactic antibiotics and maintenance of normothermia) as a condition of participation in various pay-for-performance contracts. In the absence of an AIMS, reporting on these types of quality metrics typically requires a laborious – and often expensive – manual chart review. Electronic systems also offer the advantage of providing a means for changing provider behavior, through clinical decision support, to meet quality metrics, as opposed to merely reporting on them.

Decision support, or the provision of tools that allow end users to more effectively accomplish a particular task, is a fast-

growing area within AIMS product development. Although this advanced feature is not universally available, decision support can facilitate both improvements in the quality and reductions in the cost of providing care. The most basic decision support tools – such as systems that provide drug-dosing guidance based on a patient's weight – offer passive guidance. More complex tools are designed to actively manage provider behavior; they may use on-screen pop-up displays or link to a hospital's paging or e-mail system to alert clinicians about changes in a patient's clinical condition.

The potential for addiction in anesthesia providers

Ethan O. Bryson and Jeffrey H. Silverstein

Introduction

The potential for addiction among anesthesia providers is a major issue in the anesthesia workplace. The incidence of alcoholism and other forms of impairment (such as mental illness) in all health care providers is similar to that in other professions, but anesthesia providers have a higher rate of substance use disorders.

The drug of choice for anesthesia personnel entering treatment for substance abuse is usually an opioid, most commonly fentanyl and sufentanil, although anesthesia providers have reported abuse of propofol, ketamine, sodium thiopental, lidocaine, nitrous oxide, and the potent volatile anesthetics as well.

Etiology

Many theories have been proposed to explain the high incidence of drug abuse among anesthesia providers. The proximity to large quantities of highly addictive drugs may contribute to the development of addiction in persons at risk. Despite strict controls and accounting measures, it remains relatively easy to divert small quantities for personal use. Some health care professionals have cited the high-stress environment in which anesthesia personnel work as a contributing factor, and others have suggested that exposure to trace quantities of these agents in the workplace sensitizes the reward pathways in the brain and promotes substance abuse. It is important to note that none of the proposed theories have been able to identify a specific cause; they merely suggest factors that may increase the risk of developing addiction among anesthesia personnel.

An association between chemical dependence and other psychopathology may contribute to the development of addiction in susceptible individuals. It has been suggested that one source of motivation for the self-administration of drugs of abuse is the self-medication of symptoms associated with comorbid psychiatric disorders. The observation that individuals with the same personality traits tend to self-administer drugs from the same class (i.e., opioids for anxiety and depression; amphetamines for attention deficit and hyperactivity states) lends credence to this theory. Intensive work on the underlying genetics of addictive behavior may prove enlightening in the next decade.

Behavior patterns

The chemically dependent anesthesia provider generally seeks to maintain a job in close proximity to the source of drugs. The addict may volunteer for additional evening and weekend assignments or for long cases in which large opioid requirements would be expected. These behaviors, however, are also exhibited by anesthesiologists seeking to increase personal income or establish a reputation in major cases. Thus the behaviors are not unique to addicts. Rather, changes in behavior are frequently noted with periods of irritability, anger, euphoria, and depression.

Some of the changes typically observed in the addicted anesthesia provider include, but are not limited to, the following:

- Withdrawal from family, friends, and leisure activities as more time is spent at work where the drug can be used;
- Mood swings, with periods of depression or bad moods alternating with periods of euphoria or gregariousness, depending on whether the addicted provider is high or in withdrawal;
- Increasing episodes of anger, irritability, and hostility;
- Spending more time at the hospital, even when off duty, often with odd intentions (coming in on a Saturday afternoon to set up a room for a case scheduled for late on Monday) in order to obtain and use drugs;
- Volunteering for extra call as an excuse to remain at work;
- Refusing relief for lunch or coffee breaks, so that the diversion of drugs for personal use is not discovered;
- Requesting frequent bathroom breaks, during which the addicted provider frequently self-administers drugs;
- Signing out increasing amounts of narcotics or quantities inappropriate for the given case, so that more is available for self-administration; and
- Weight loss and pale skin, as less time and energy are spent taking care of him- or herself.

Whereas addiction to alcohol may take years to become apparent, addiction to the short-acting opioids, fentanyl and especially sufentanil, becomes apparent over the course of a few months of use. Depending on the half-life of the abused agent, tolerance can develop rapidly. Self-administration of 1000 μg (20 ml) of fentanyl in a single injection has been reported by addicts and described as simply relieving the symptoms of

withdrawal. An addicted anesthesia provider will often request increased quantities of opioids on Fridays in preparation for an extended period of time away from work.

Early identification of the addicted anesthesia provider can prevent harm to both the impaired provider and his or her patients. Unfortunately, the entire picture of the addicted provider is seldom appreciated by any one person. Friends and family may observe behavioral changes at home that may pass unnoticed by colleagues at work and are attributed to stress on the job. Hanging around work may be interpreted as stress at home. The individual who suffers from addiction is almost always the last to recognize that a problem exists. It is therefore important that those people most likely to observe the signs and symptoms of addiction gain a clear understanding of the disease and what to do if they suspect that someone may have a problem. Education of both professional staff and the significant others of anesthesia staff is important.

Diversion

Addicted anesthesia providers have reported charting the use of their drug of choice when in fact either an alternate agent or none at all was administered, allowing for the diversion of the drug for personal use. To facilitate this diversion, β -blockers may be administered and charted as opioids. Addicts have been known to substitute a syringe containing a β -blocker or saline for one containing an opioid while providing a relief break for a coworker. Some addicted anesthesia providers have admitted to rummaging through sharps containers looking for residual drug in discarded syringes. Addicted anesthesia providers are extremely ingenious and quickly become proficient at removing controlled substances from secure places and defeating the security features of automated dispensing machines. Drugs have been removed from glass ampules and replaced with another liquid without apparent evidence of tampering.

Intervention

Unfortunately, many addicted anesthesia providers are first identified by a crisis, particularly an overdose. Anesthesia groups should have a designated individual (or group) responsible for health and welfare with sufficient information and expertise to assist in interventions for colleagues whose behavior raises concerns. This position is extremely sensitive and must be handled with care to avoid ruining the career of a colleague. Erratic behavior may have many causes, and professionals learn to avoid using the term *addiction* without clear support of such a diagnosis.

Diagnosis and treatment

An addictionologist and an additional psychiatrist, who focuses on evaluation and treatment of individuals with alcohol, drug, or other substance-related disorders and of individuals with a dual diagnosis of substance-related disorders, should direct the diagnosis and treatment of the addicted

anesthesia provider. A referral may be obtained from drug treatment centers, the American Society of Addiction Medicine, or state impaired-physician programs. Because of the association between chemical dependence and other psychopathology, successful treatment for addiction is less likely when comorbid psychopathology is not treated. Any individual under evaluation or treatment for substance abuse should have an evaluation with subsequent management of comorbid psychiatric conditions.

Anesthesia providers who are abusing opioids or other anesthetic agents are commonly sent for residential treatment that may last anywhere from 2 months to a year or more. Inpatient treatment in a facility that specializes in the treatment of addicted medical professionals is important because the affected individual may develop the support of other similarly affected colleagues. There are currently no programs in the United States that admit only medical professionals, but several treatment centers offer programs for medical personnel as a group within the larger inpatient population. Typically in these programs group therapy sessions are structured so that the members of the medical professional population are separated from the general population. Treatment in such a facility (where some of the other patients are health care professionals) is perceived to be beneficial.

Treatment typically involves detoxification, monitored abstinence, education, exposure to self-help groups, and psychotherapy. Inpatient therapy is typically intensive, with staff contact extending up to 12 hours per day, 7 days per week. In this setting, the addicted anesthesia provider is removed from the stresses of daily life as well as from access to alcohol and drugs. Participation in self-help groups is considered a vital component in the therapy of the impaired anesthesia provider. Following successful completion of the inpatient treatment program, the individual is discharged either to a halfway house or directly to the community.

Returning to work

Most states allow an anesthesia provider to return to work after inpatient treatment as long as they remain under the supervision of a health and well-being organization, such as those sponsored by the state medical or nursing society. Anesthesia providers in recovery are typically required to sign a monitoring contract that includes regular contact with a caseworker at the monitoring organization, worksite observation, and random urine drug and alcohol screens for a minimum of 5 years. These contracts mandate complete abstinence from all mood-altering drugs, participation in facilitated group psychotherapy with other recovering medical professionals, and regular attendance and participation in self-help fellowships such as Alcoholics Anonymous or Narcotics Anonymous.

The Americans with Disabilities Act (ADA) offers some protections to the addicted anesthesia provider, placing the onus of responsibility on the employer to prove that the employee is unable to perform the responsibilities of his occupation. These

protections are limited in scope and have been applied differently to individuals who are dependent on alcohol versus illegal drugs. No protection is afforded to the user of substances other than alcohol unless he or she is currently in a treatment or monitoring program. Diversion of controlled substances is a felony. If charges are brought, the ADA does not offer any protection.

Whether anesthesia personnel should be allowed to return to the operating room after successful treatment remains highly controversial. Redirection of anesthesia providers who have successfully completed treatment into other medical specialties may allow a greater percentage to achieve successful careers. A graded reintroduction into the clinical practice of anesthesia may reduce the incidence of death as the initial presenting sign of relapse as compared to reintroduction after only a short period of treatment. The current thought is that the decision to allow an individual to return to the practice of clinical anesthesia should be made on a case-by-case basis.

Risk factors for relapse

The disease of addiction is conceptualized as chronic and incurable. As such, individuals who have successfully undergone treatment and are currently in recovery are still at risk for relapse. Factors that are associated with an increased risk of relapse include a family history of substance use disorder, the use of a major opioid, and the presence of a coexisting psychiatric disorder. The use of a major opioid increases the risk of relapse only in patients with a coexisting psychiatric disorder.

Prevention

Control of drug supply and education are the mainstays of prevention. Random drug screening for all anesthesia personnel remains a contentious issue; few training programs or hospitals employ such a policy.

Because a major contributing factor of addiction in anesthesia providers may be easy access to opioids and other psychoactive substances, a number of methods for control of these agents in the operating room have been developed. Careful record keeping and evaluation of use of narcotic patterns allows for tighter control and earlier detection in suspected cases of abuse. Anesthesia information management systems have been successfully used to identify patterns suspicious for diversion among anesthesia personnel. Computerized records may be examined to identify high use of opiates, high wastage of controlled substances, transactions that occur on cancelled cases or after case completion, and automated dispenser transactions that occur in a location away from that of the scheduled case.

Education of the anesthesia community regarding the potential for substance abuse among anesthesia providers is also important. Widespread education of the anesthesia community

may aid in the early detection of afflicted colleagues. Unfortunately, despite the increased number of hours devoted to such education, the rate of known substance abuse by anesthesia providers remains constant at approximately 1.5%. There are a number of educational videos that directly address the issue of substance abuse and anesthesia personnel and may be used as part of an educational program for individuals in training in anesthesiology. Some programs have specifically organized sessions for the spouses of the trainees to view one or more of these films together.

Conclusion

Addiction is still considered by many to be an occupational hazard for persons involved in the practice of anesthesiology. It has been suggested that the presence of readily available, highly addictive agents in our work environment contributes to the potential for abuse in a subset of the population at risk. Because it is not possible to identify these people before they become addicted, it is essential that each of us learns to recognize the signs and symptoms of addiction when they are manifested so that we may preserve the safety both of our colleagues and of their patients. Although some highly motivated individuals have been able to successfully reenter the clinical practice of anesthesia and avoid relapse, this is not always the case. Successful completion of a treatment program does not guarantee freedom from future relapse, even several years into recovery. Each case must be carefully evaluated before the decision is made to allow an addicted physician to attempt a return to the practice of anesthesiology.

Hypertrophic cardiomyopathy and prolonged QT interval

Michael Decker and John D. Mitchell

Introduction

Hypertrophic cardiomyopathy (HCM) is now known to be an autosomal dominant genetic disorder involving mutation of 1 of 12 possible genes. It has an incidence of approximately 1:500. The disease is often unrecognized and remains one of the most common causes of sudden cardiac death in young persons. The diagnosis of HCM can be made by echocardiography and involves left ventricular (LV) hypertrophy in the absence of other diseases capable of producing such hypertrophy. The pattern of hypertrophy is typically asymmetric, and the hypertrophy is associated with a nondilated chamber. Although an LV wall thickness of 15 mm is part of the usual criteria, there are cases of HCM mutations with normal wall thickness. The anterior ventricular septum is the most common region affected, with the basal posterior LV wall typically spared.

Patients with HCM present numerous challenges for the anesthesiologist. The hypertrophied heart in HCM is associated with a disorganized myocardial architecture leaving patients susceptible to *ventricular arrhythmias*. The mitral valve apparatus can be malformed (increased valve area and anomalous papillary muscle insertion) and can be responsible for *outflow tract obstruction* associated with a majority of HCM cases. Patients also show evidence of impaired myocardial relaxation with prolonged isovolumic relaxation time, deceleration times, and increased filling pressures. Finally, patients have abnormal microvasculature and are susceptible to *myocardial ischemia* (see Figure 184.1).

The LV outflow tract obstruction that occurs associated with HCM is a dynamic one. It is exacerbated by a reduction in preload, an increase in contractility, or a decrease in afterload. It will typically occur in mid to late systole with apposition of the anterior leaflet of the mitral valve against the hypertrophied septal wall. The goals in management often involve minimizing the possibility of this dynamic obstruction.

The medical management of these patients typically involves β -blockers or calcium channel blockers – specifically, verapamil. These drugs tend to improve the symptoms of exertional dyspnea and atypical angina associated with HCM. When symptoms are refractory to first-line medications, other agents with negative inotropic effects have been used, including disopyramide. For those patients with obstructive disease and refractory symptoms, septal myomectomy is a surgical option.

More recently, catheter-based alcohol ablation has been used. There has, however, been an increased incidence of arrhythmia post ablation, possibly related to the large scar after the technique. Concern about sudden death has in the past warranted prophylaxis in asymptomatic patients with β -blockers, verapamil, and Class I antiarrhythmic agents. There is little evidence of risk reduction with these therapies, so patients deemed at high risk of sudden death are now often having implantable cardioverter-defibrillator (ICD) placements. In persons with previous arrest or sustained ventricular tachycardia (VT), ICD implantation is strongly recommended.

As anesthesiologists, we can encounter either the patient with diagnosed and managed or undiagnosed HCM. These patients are susceptible to various complications, including congestive heart failure, myocardial ischemia, systemic hypotension, and arrhythmias. In untreated patients diagnosed with HCM in the perioperative period, the use of β -blockers might seem counterintuitive for management of hypotension

Figure 184.1. Mechanism of HCM.

Table 184.1. Medications that may trigger torsades de pointes

Antibiotic	Antiarrhythmic
Chloroquine	Amiodarone
Clarithromycin	Bepidil
Erythromycin	Disopyramide
Halofantrine	Dofetilide
Pentamidine	Ibutilide
Sparfloxacin	Procainamide
	Quinidine
Pain	Sotalol
Levomethadyl	
Methadone	Antipsychotic
	Chlorpromazine
Miscellaneous	Haloperidol
Cisapride	Mesoridazine
Droperidol	Pimozide
	Thioridazine

Adapted from ArizonaCERT list of drugs that are generally accepted to have a risk of causing torsades de pointes. Visit www.torsades.org for complete list.

with tachycardia but certainly may prove useful in easing the obstructive pattern in well-resuscitated patients. Phenylephrine and fluid resuscitation would also be more than appropriate for management of acute hypotension with tachycardia if obstructive physiology is the suspected cause.

Prolonged QT syndrome

The prolonged QT syndrome is the result of a defect in cardiac ion channels. The syndrome can be inherited in an autosomal recessive pattern (part of Jervell and Lange-Nielsen syndrome), can be autosomal dominant (Romano and Ward syndrome), or can arise out of spontaneous mutations. The congenital syndrome has an incidence estimated at 1 in 5000.

Patients with long QT syndrome display prolongation of the QT interval on electrocardiogram (ECG) defined as $QT_c > 440$ ms (QT/\sqrt{RR} interval). The clinical symptoms can include syncope, cardiac arrest, and pseudoseizures. These symptoms are likely triggered by the ventricular arrhythmia known as torsades de pointes. The arrhythmia causes a decreased cerebral perfusion and manifestation of the symptoms just mentioned. A small percentage of patients with the long QT syndrome will have these symptoms, despite a normal QT_c interval. In addition to a prolonged QT interval, other ECG changes may be present, including T wave alternans (beat-to-beat T wave amplitude variation), which is considered pathognomonic. There are published criteria for the diagnosis which take into account family history, clinical history, and ECG findings.

The feared arrhythmia of torsades de pointes and its relationship to QT prolongation is not entirely clear. It is believed that the abnormal repolarization (specifically, increased transmural dispersion of repolarization) can lead to the formation of reentry circuits. The trigger may be increased sympathetic activity or any of a number of medications (Table 184.1).

When patients with long QT syndrome have been identified, it is essential that they are treated. Mortality approaches 50% over 10 years in untreated symptomatic patients, but it can be reduced to less than 5% with treatment. The mainstay of therapy is β -blockade, which has been shown to reduce mortality in long QT syndrome patients. In those patients who are symptomatic despite adequate β -blockade, ICDs have been used. Finally, left cardiac sympathetic denervation also has been used in refractory cases.

Patients presenting for surgery with the long QT syndrome may be asymptomatic, may have a normal QT interval on ECG, or may be diagnosed and treated. For the anesthesiologist, identification of persons at risk, avoidance of triggers, and management of torsades de pointes are essential.

Patients presenting for surgery with any personal or family history of symptoms suspicious for the syndrome should have, at the least, an ECG. Sympathetic stimulation, including loud noises, can be triggers, so ensuring a quiet, calm environment is important, and premedicating these patients is reasonable.

If a patient is on β -blockade, it should be continued throughout the perioperative period. Serum electrolytes should be normal. Hypokalemia, hypocalcemia, and hypomagnesemia can all delay repolarization. Avoid medications that are known to prolong the QT interval or precipitate torsades de pointes.

Blunt the stimulation of laryngoscopy with potent short-acting opioids, or manage the sympathetic response with β -blockers. Opioids can be helpful in blunting sympathetic stimulation from intubation. Avoid hypothermia. Halothane should also be avoided, but enflurane, isoflurane, and sevoflurane all increase the QT interval. Propofol may be beneficial as an induction agent with respect to QT duration, and thiopental and midazolam appear safe. Succinylcholine and pancuronium should be avoided if possible. Avoid anticholinergic drugs (used with reversal agents), if possible.

Regarding postoperative nausea and vomiting, haloperidol and droperidol both prolong the QT interval and should be avoided. Evidence also suggests that ondansetron has a possible risk for torsades de pointes but may be preferable to the butyrophenones. Regional anesthesia appears to be safe, but avoid epinephrine-containing solutions.

If, despite all your efforts, a patient develops torsades de pointes, it is important to treat the arrhythmia aggressively before it degenerates into ventricular fibrillation and requires defibrillation. Magnesium sulfate is the treatment of choice to treat and prevent short bursts of torsades, even if the magnesium level is normal. The dose is 30 mg/kg as a bolus, followed by a 2 mg/min infusion. Transvenous pacing can be effective in patients not responding to magnesium. In patients with sustained torsades, cardioversion is required.

 right-sided lesions
 pulmonary stenosis, 36
 pulmonic regurgitation, 36
 tricuspid regurgitation, 36
 tricuspid stenosis, 36
 transesophageal echocardiography assessment, 467, 469f, 470f
- Vancomycin, nosocomial infections, 994
- Vancomycin-resistant enterococci (VRE), 1083, 1085–1086
- Vaporizers, 134–136
- Vascular anesthesia. *See* Abdominal aortic aneurysm (AAA); Carotid endarterectomy (CEA); Endovascular abdominal aortic aneurysm repair (EVAR); Peripheral vascular disease (PVD)
- Vascular complications. *See also* Venous thromboembolic disease
 epidural injections, 926–927, 927t
 ganglion blocks, 929
- Vasoconstrictors, 440–443, 442t
- Vasodilators, 444t, 968–969
- Vasopressin. *See also* Antidiuretic hormone (ADH)
- Vasopressors, septic shock/sepsis, 998–999
- Vecuronium, 193, 204–205, 254, 779t
- Vena cava filters, 1012, 1014f, 1014
- Venlafaxine, 84–85, 85t
- Venous air embolism (VAE), 595, 729
- Venous thromboembolic disease, 1010–1015
 deep venous thrombosis, 1010–1015
 overview, 1010
 pulmonary embolism, 1013–1015
- Ventilary depression, 245, 269–270, 299–302
- Ventilator dependence, 977
- Ventilator-associated pneumonia (VAP), 991–993
 clinical manifestations, 991–992
 diagnosis, 992t, 991–992
 incidence, 991
 microbiology, 991t, 992
 pathogenesis, 991
 treatment, 992, 993t
- Ventilator-induced lung injury (VILI), 553t, 553
- Ventilators. *See* Anesthesia ventilators
- Ventricular assist devices (VADs), 479–484, 970t, 971. *See also* Cardiac transplantation; Cardiopulmonary bypass (CPB); Transesophageal echocardiography (TEE)
 anesthesia induction, 481–482
 anesthesia maintenance, pre-CPB period, 482–483
 anesthesia postinsertion, 483–484
 components, 479f
 definition and principles of, 479–480
 indications and contraindications, 480
 nitric oxide, 1049
 overview, 479
 preoperative assessment, 480–481
 types of, 480t
- Ventricular fibrillation (VF), CPR, 947–949
- Ventricular septal defect (VSD), 816f, 815–816
- Ventriculostomy, intracranial pressure, 1020
- Verapamil, 445t, 961t
- Versed, burn injuries, 1027
- Vertebral arch and body, 335, 336f
- Vertebral body augmentation therapy, 920, 921f
- Vertebroplasty, 920, 921f
- Vesicants. *See also* Chemical and biological warfare (CBW) agents
- Victoria, Queen, 2t, 3–4
- Video Macintosh intubating laryngoscope system (VMS), 116f, 115–116
- Virchow, Rudolf Ludwig Karl, 1010
- Visceral pain, 941
- Vision. *See* Ophthalmic procedures; Perioperative visual loss (POVL)
- Vital capacity, 217, 978
- Vitamin K deficiency, 67
- Vocal cord polyps and cysts, 709

- Vocational rehabilitation, pain management and, 905–906
- Voltage, 150f, 150, 151
- Volume-controlled ventilation (VCV), 138, 139f
- Vomiting. *See* Postoperative nausea and vomiting (PONV)
- von Willebrand disease (vWD), 66t, 66, 770–771, 793
- Waiver of consent, 1034
- Wake-up test, 204–205
- Warfarin, 498
 postoperative care, 1011
 pulmonary embolism, 1014–1015
- Warren, John Collins, 3f, 3
- Washed red blood cells, 407–408
- Waste anesthetic gases, 127f, 127, 142, 868–869, 869t
- Waters, Ralph, 2t, 5–6
- Waterton, Charles, 5
- Weaning protocols
 mechanical ventilation, 977–981
 sedation, 976
 steroid therapy, 999
- Wells, Horace, 2t, 2–3
- Whitacre and Sprotte needles, 342, 342f
- Wolff-Parkinson-White (WPW) syndrome, 177f, 176–177, 178f, 964
- Wood, Alexander, 4
- Work of breathing, 978, 980
- World Health Organization (WHO), analgesic ladder, 942–943, 943f
- Xenon
 mechanisms, 234–235
 minimum alveolar concentration, 224t
 properties, 214–215, 219t
- “Zeus” anesthesia machine, 129
- Ziconotide, pain management, 945
- Zonisamide, pain management, 897t
- Zygapophyseal joints. *See* Facet joints
