Patent foramen ovale is seen in 20% of the population. In normal adults, it may be one of the reasons for right-to-left shunting when the pressure in the right atrium transiently increases more than that in the left atrium. A PFO can be identified by injecting bubbles (i.e. agitated saline) formed in a 10-ml syringe through a central line when Valsalva maneuver (this raises the right atrial pressure transiently more than the left atrial pressure) is released (Fig. 75.11). Presence of several bubbles in the left atrium within three heartbeats signifies the presence of a PFO.

The role of anesthesiologists as primary practitioners and intraoperative echocardiographers

There is continuing debate over the delegation of echocardiographic services intraoperatively: Should the realm of echocardiography be exclusive to cardiologists, or are anesthesiologists equipped to handle the demands of intraoperative treatment and correctly perform and interpret TEEs? In a paper by Mathew et al., the goal was to determine whether diagnostic interpretation of TEE varies widely when the anesthesiologist performing the examination is also providing anesthetic care to the patient. Using continuous quality improvement, an

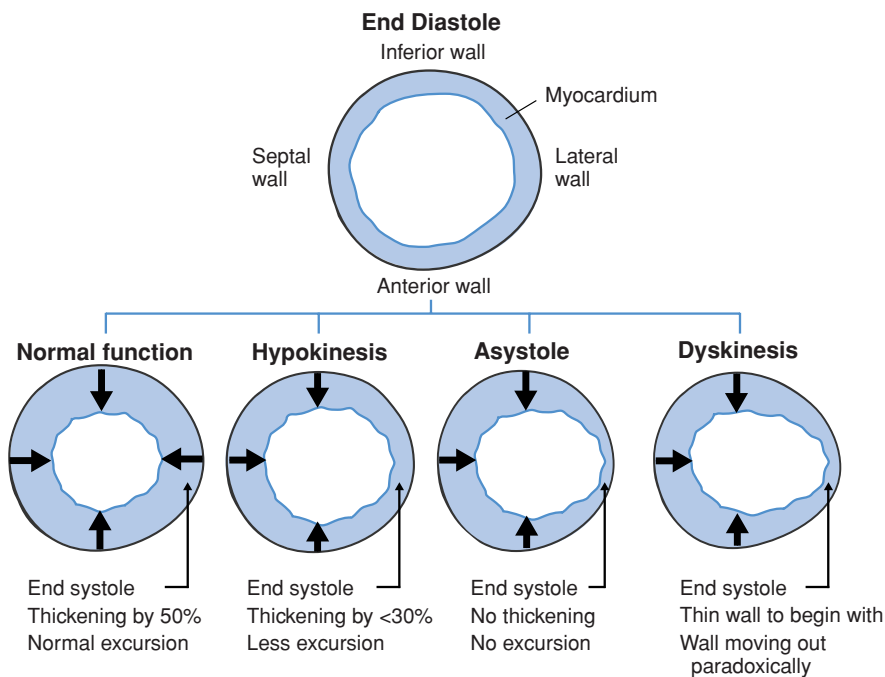

Figure 75.4. Schematic of a transesophageal left ventricle short-axis view showing varying degrees of systolic regional wall motion abnormalities.

educational process to identify problems in health care delivery and to develop solutions to these problems, the authors determined that anesthesiologists responsible for the management of adult cardiac patients and intraoperative TEE were capable of effectively interpreting TEE results. Further results demonstrated that anesthesiologists underestimated the fraction area of change (FAC) compared with radiologist experience in interpretation, but the differences in estimation of the FAC between anesthesiologists and cardiologists and between radiologists and cardiologists were not statistically significant. Finally, as Mathews et al state “during adult cardiac surgery, the roles of anesthesiologists and the intraoperative echocardiographer need not be mutually exclusive.”

Current practice

The literature reports that the use of TEE for cardiac surgery in academic centers averages approximately 91%. ASA practice guidelines consider the use of TEE for coronary artery bypass graft and valve replacement surgery a category II indication, whereas valve repairs, repair of hypertrophic cardiomyopathy, congenital heart surgery, and aortic dissection are category I indications, warranting the use of TEE.

TEE for minimally invasive surgery

The advent of minimally invasive port access during cardiac surgery has enabled patients undergoing cardiac surgery to be placed on cardiopulmonary bypass without the need for median sternotomy for visualization of the heart and great vessels. In the past, placement of catheters was permitted by the use of fluoroscopic guidance, which had limitations. With the increasing proficiency of practitioners using TEE, the use of TEE to aid in the placement of endovascular catheters (coronary sinus

Figure 75.5. Midesophageal four-chamber view.

Figure 75.6. Midesophageal AV short-axis (ME AV SAX) view.

Figure 75.7. Midesophageal AV long-axis view.

catheters, pulmonary artery vent, and venous cannula) has further aided in the progression of minimally invasive surgery. The ability of TEE as an improved, dynamic imaging modality (adequate visualization of cardiac structures) has permitted the placement of catheters without the use of fluoroscopy, with improved success.

TEE in the non–operating room setting

The ASA practice guidelines discuss the use of TEE by anesthesiologists outside the operating room. Common applications include emergent assessment and diagnosis to determine whether surgery is indicated, as well as the postoperative assessment and treatment of patients postoperatively. TEE is useful for recognizing and aiding in the diagnosis of acute hemodynamic instability. Therefore, TEE is critical in nonoperative settings such as the intensive care unit and emergency room. Studies have demonstrated that the impact of TEE on patients with category I indications has been significant, with TEE

Figure 75.10. Transgastric basal short-axis view of the mitral valve.

altering therapy 60% of the time, compared with the alteration of therapy in category II (31%) and category III (21%).

Pericardial effusion

TEE findings vary depending on the progression of the fluid collection in the pericardial space. Chamber collapse occurs when the pericardial pressure becomes greater than the cardiac chambers' pressures. Thus, it will be noted on TEE that there will be atrial collapse prior to ventricular collapse. Collapse occurs in diastole and in later stages will also occur in systole and is seen on the lower pressure (right) prior to the involvement of the higher (left) sided circulation. The most sensitive diagnostic indicator of pericardial tamponade is right ventricular collapse during diastole in a patient with a pericardial effusion.

Pulmonary embolism

In patients with clinical symptoms suspicious for pulmonary embolism, TEE is a modality that may permit rapid diagnosis of pulmonary embolism (Table 75.2). Although the gold standard

for the diagnosis of pulmonary embolism is pulmonary angiography and/or high-resolution spiral CT, it may be difficult to transport a critically ill and hemodynamically unstable patient to the locations for these emergency diagnostic modalities. TEE has 70% sensitivity and 81% specificity for confirmation of pulmonary embolism. Although visualization of thrombus is infrequent by TEE, the main pulmonary and right pulmonary arteries may be visualized. Because of the location of the trachea and difficulty of ultrasound waves to transmit through air-filled spaces, visualization of the left pulmonary artery remains an obstacle.

Table 75.2. TEE findings of pulmonary embolism

Increased size of pulmonary arteries
Right ventricular dysfunction: flattening of the interventricular septum, basal hypokinesis with apical sparing (i.e., McConnell's sign)
Tricuspid regurgitation: severe – due to right-sided pressure overload
Dilated right atrium
Increased size of inferior vena cava

Figure 75.11. A PFO can be identified by injection of agitated saline.

Diagnosis of TEE is often a constellation of findings due to the infrequent visualization of thrombus in the pulmonary arteries. Pulmonary emboli decrease blood flow and result in increased pressures in the right side of the heart. Thus, findings associated with pulmonary emboli would include changes in the vasculature associated with elevated volume or pressure on the right-sided circulation. They include increased size of the pulmonary arteries, right ventricular dysfunction, tricuspid regurgitation, dilated right atrium, and an increase in the size of the inferior vena cava.

Blunt chest trauma

TEE is a safe, reliable, and fast method to diagnosis acute cardiac injury following blunt trauma. Because of its anterior location, the right ventricle is a site of common injury after blunt chest trauma (Table 75.3). Also, because of higher pressures on the left-sided circulation, valve injuries are common. TEE evidence of myocardial injury is an increase in wall thickness of the left ventricle during diastole and impaired systolic function.

Table 75.3. TEE findings of myocardial contusion

Increase in wall thickness of the left ventricle in diastole
Impaired regional wall systolic function
Increased brightness of the ventricular walls

Injuries to the right ventricle typically occur in the right apical wall, whereas injuries to the left ventricle occur along the septal and apical regions.

Massive hypotension

TEE has been used pervasively for the evaluation of hemodynamic instability. Case reports support the usefulness of TEE in diagnosing the etiology of hypotension, with improvements in clinical outcome. The expert opinion of the ASA task-force is that TEE provides more accurate assessment of preload compared with other monitors, such as central venous and pulmonary artery catheters. TEE determines the etiology of disease in a more rapid manner without the addition of increased adverse effects that occur with other monitors (breach in sterility, damage to the cardiovascular or pulmonary systems). In acute, persistent, and life-threatening hemodynamic disturbances unresponsive to treatment, the emergent use of TEE is considered a category I indication.

Patient risk and complications of TEE

No procedure is without risks and benefits; therefore, it is imperative (unless the use of TEE is emergent) that informed consent be obtained. Although a relatively safe intraoperative monitor, TEE is not without risks or side effects. The rate of complications is <1% (0.2%), with the rate of mortality less than one in 10,000 patients. Prior to TEE examination, it is imperative to ascertain a history of esophageal or gastric disease. There is an increased rate of complications in patients with a history of esophageal pathology and dysphagia. Absolute contraindications to TEE include previous esophagectomy, severe esophageal obstruction, esophageal perforation, esophageal hemorrhage, or cervical trauma (Table 75.4). Relative contraindications include esophageal varices, diverticula, fistulas, previous esophageal surgery, previous gastric surgery, and mediastinal irradiation. In addition to obtaining a history of esophageal or gastric disease, a detailed airway examination must be performed to note the presence of oropharyngeal or dental injuries.

Table 75.4. Contraindication to the use of TEE

Absolute contraindications	Relative contraindications
Esophagectomy	Esophageal varices
Severe esophageal obstruction	Esophageal diverticula
Esophageal perforation	Esophageal fistula
Esophageal hemorrhage	Previous esophageal surgery
Cervical trauma	Previous gastric surgery
	Mediastinal irradiation

Table 75.5. Complications of TEE

Oral, pharyngeal, laryngeal trauma
Esophageal injury
Hoarseness/sore throat
Dislodgement of endotracheal tube
Thermal injury
Arrhythmias

The placement of the TEE probe is performed by displacing the mandible gently (with or without the use of a laryngoscope), and advancing the probe midline. To prevent trauma, the TEE probe should not be advanced or withdrawn with the probe in the locked position. The TEE probe should not be forced if resistance is met. During insertion or withdrawal, controls should be in the neutral and unlocked position to allow the natural course of the esophagus to be traversed, thus preventing injury.

Complications of TEE are infrequent but do occur (Table 75.5). They include oral and pharyngeal trauma, hoarseness postoperatively, esophageal injury (a serious but rare complication, with high mortality), arrhythmias, and dislodgement of the endotracheal tube. Bioeffects of TEE placement include thermal effects (e.g., heating and thermal injury), cavitation, and torque forces. There have been case reports of splenic injury secondary to TEE placement, and there is a potential risk of endocarditis after TEE placement. In a retrospective study of 7200 cardiac patients, Kallmeyer et al. demonstrated that TEE-associated morbidity occurred in 14 patients (0.2%), with 86% of the complications attributed to oropharyngeal, esophageal, and gastric trauma. One tenth of 1% of patients had clinically significant odynophagia requiring esophagogastroduodenoscopy, which demonstrated linear abrasions. Dental injuries occurred with a frequency of 0.03%, acute upper gastrointestinal hemorrhage occurred in 0.03%, esophageal perforation occurred in 0.01%, and endotracheal tube advancement occurred in 0.03% of patients.

Future direction of TEE

Throughout the years, TEE has been advancing at an enormous pace. Practice guidelines recommended by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists have recently been updated. (See Suggested

Readings.) TEE has fundamentally enabled two-dimensional imaging of the cardiac structures and great vessels. Continued advancement in TEE with three-dimensional imaging, epicardial echocardiography, and epi-aortic ultrasound imaging has the potential to enhance the role of the anesthesiologist as a perioperative physician and improve the perioperative outcomes of both cardiac and noncardiac surgical patients.

Pacemakers and automated implantable cardioverter–defibrillators

Sugantha Sundar and Eswar Sundar

Introduction

Rhythm disturbances can be treated with drugs, devices, or both. Drugs are useful for the management of rhythm disturbances developing in the structurally normal heart. However, in the heart that has undergone considerable remodeling, because of either ischemia or surgery, rhythm management devices such as pacemakers and automatic implantable cardioverter–defibrillators (AICDs) have been proven superior. Treatment of rhythm disturbances may involve the use of pacemakers, internal defibrillators, and ablation therapy or arrhythmia surgery.

Major indications for pacemakers and AICDs are outlined in Table 76.1.

Pacemaker design and codes

Temporary pacing

Temporary pacing has the advantage of immediate, precise control of an arrhythmia without the side effects produced by drugs. It is indicated as prophylaxis in patients at risk of sudden death from high-degree atrioventricular (AV) block, and should be terminated with the resolution of the underlying condition or changed over to an internal pacemaker if the underlying condition is expected to be chronic. Temporary pacing may be endocardial, epicardial, transesophageal, or transcutaneous. Transvenous pacing, the most popular type, may be used in the awake patient. Pacing can also be performed through specialized pulmonary artery catheters. Transcutaneous pacing is easy and noninvasive; however, the pacemaker-stimulated contraction of the chest muscles in a conscious patient may cause considerable discomfort. Sedating patients and minimizing the current strength can help alleviate this problem.

Permanent pacemakers

Modern implantable pacemakers are extremely compact, physiologically shaped, and capable of responding to complex programming. They have lithium ion batteries that usually last at least 10 years. Almost all current implantable pacemakers use transvenous leads that can be individually programmed.

The North American Society for Pacing and Electrophysiology (NASPE) introduced a coding and shorthand system to describe pacing modes. This coding system enables a complete

description of the pacemaker to be derived from five letters. Every pacemaker is given a five-letter code based on the following five functions (Table 76.2):

- **Chamber paced:** The chamber that can potentially be paced might be the atrium (A) or the ventricle (V), or both (D); rarely, neither is chamber paced (O).
- **Chamber sensed:** The pacemaker monitors for events in the atrium (A) or ventricle (V), or both chambers (D), or does not perform any sensing function at all (O).
- **Response to the sensed event:** Pacemakers function either by inhibiting themselves (I) when there is a sensed event such as a native depolarization within the sensed chamber, or by triggering (T) a stimulus when they sense the absence of a native depolarization within the sensed chamber. It is important to note that the vast majority of patients with pacemakers have a native rhythm capable of producing an adequate cardiac contraction most of the time. Hence, it is important for pacemakers to be able to sense such native depolarizations within the sensed chambers and inhibit itself if required. However, at the same time, the pacemaker must be able to produce a stimulus (not inhibit itself) in case there is a long pause and a native depolarization is not forthcoming within a programmed time interval.
- **Programmability/rate response:** Modern pacemakers have a feature called adaptive rate pacing (ARP). ARP enables the pacemaker to develop a higher or lower pacing speed depending on activity. Activity sensors sense vibration and acceleration of the body and can increase the pacing speed. Some ARP devices change their pacing rate to the QT interval. Some pacemakers sense minute ventilation changes from changes in thoracic impedance and adapt accordingly. Some of the latest adaptive rate pacemakers can sense variables such as blood pH and oxygen saturation and change the pacing rate accordingly. Some versatile pacemakers fitted on athletes and young patients have more than one mode of adaptive rate sensing in which there is an initial increase in heart rate when an activity is begun based on feedback from movement sensors and then long-term adjustment based on blood pH and other metabolic variables.
- **Antitachycardia function:** Electrophysiologic treatment of tachyarrhythmias involves one or more of the following:

Table 76.1. Major clinical indications for pacemaker and AICD placement^a

Indications for pacemaker therapy

- 3rd-Degree and advanced 2nd-degree AV block at any anatomic level
- Type 2 2nd-degree AV block; alternating bundle branch blocks
- Persistent 2nd-degree AV block in the His–Purkinje system with bilateral bundle branch block or 3rd-degree AV block within or below the His–Purkinje system after acute myocardial infarction (AMI); transient advanced (2nd- or 3rd-degree) infranodal AV block and associated bundle branch block after AMI; persistent and symptomatic 2nd- or 3rd-degree AV block after AMI
- Sinus node dysfunction with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms; symptomatic chronotropic incompetence
- Symptomatic recurrent supraventricular tachycardia that is reproducibly terminated by pacing after drugs and catheter ablation fail to control the arrhythmia or produce intolerable side effects; symptomatic recurrent sustained VT as part of an automatic defibrillator system; sustained pause-dependent VT, with or without prolonged QT, in which the efficacy of pacing is thoroughly documented
- Recurrent syncope caused by carotid sinus stimulation; minimal carotid sinus pressure–induced ventricular asystole of more than 3-sec duration in the absence of any medication that depresses the sinus node or AV conduction
- Advanced 2nd- or 3rd-degree AV block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output; sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia; postoperative advanced 2nd- or 3rd-degree AV block that is not expected to resolve or persists at least 7 days after cardiac surgery; congenital 3rd-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction; congenital 3rd-degree AV block in an infant with a ventricular rate < 50–55 bpm or with congenital heart disease and a ventricular rate < 70 bpm; sustained pause-dependent VT, with or without prolonged QT, in which the efficacy of pacing is thoroughly documented
- Medically refractory, symptomatic hypertrophic cardiomyopathy with significant resting or provoked left ventricular outflow obstruction
- Symptomatic bradyarrhythmias/chronotropic incompetence after heart transplantation not expected to resolve and other class I indications for permanent pacing

Major indications for AICD therapy

- Cardiac arrest due to ventricular fibrillation (VF) or VT not due to a transient or reversible cause
- Spontaneous sustained VT in association with structural heart disease
- Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at EP study when drug therapy is ineffective, not tolerated, or not preferred
- Nonsustained VT in patients with coronary disease, prior myocardial infarction, left ventricular dysfunction, and inducible VF or sustained VT at EP study that is not suppressible by a class I antiarrhythmic drug
- Spontaneous sustained VT in patients who do not have structural heart disease that is not amenable to other treatments

^a The reader is referred to the American College of Cardiology/American Heart Association guidelines for other indications for pacemaker and AICD therapy.

antitachycardia pacing (P); shock (S): cardioversion or defibrillation; both pacing and shock (D); or no antitachycardia function (O). Overdrive pacing often may be deployed on short runs of ventricular as well supraventricular tachyarrhythmias. Pacing avoids the need for cardioversion or defibrillation, thereby preserving cardiac muscle as well as the AICD battery life. Devices

with cardioversion or defibrillation capability (S) fall into the category of AICDs.

Based on NASPE and British Pacing and Electrophysiology Group (NBG) coding there are many varieties of programmable modes. Often, for devices that have only pacing function, the first three letters are used. Thus, a VVI pacemaker will pace the ventricle (V) by not inhibiting itself (I) when it senses a lack of native depolarizations in the ventricle (V). An AAI pacemaker will sense the atrium (A) for depolarizations, and if it does sense a native depolarization, it goes on to pace the atrium (A) by not inhibiting (I) itself. VDD pacemakers pace the ventricle (V) while sensing both the atrium and ventricle (D), and their response could be inhibition or triggering (D) based whether the device senses a native depolarization. The DDD and DDDR (ARP capable) pacemakers are the most widely used mode of pacing, as they are the most versatile and can be used for many indications with only minor programming modifications. The workings of a VVI and DDD pacemaker in various scenarios is illustrated in Figs. 76.1 through 76.4.

Pacemaker programming

Pacemakers are classified as single- or dual-chamber pacemakers depending on whether they pace a single chamber (atrium or ventricle) or both chambers based on programming. The number of leads seen on radiography does not cast any light on whether a pacemaker is single or dual chamber. However, an electrocardiogram (ECG) taken while a dual-chamber pacemaker is functioning usually shows separate atrial and ventricular pacer spikes, unlike a single-chamber pacemaker.

Figure 76.1. This figure shows an atrioventricular node/bundle of His conduction block (AVN unshaded). The sensing unit of the VVI pacer does not sense a depolarization in the ventricle (unshaded arrow). Hence there is no “inhibition” of the pacing unit. This allows the un-inhibited pacing unit to fire and depolarize the ventricle (shaded arrow).

Table 76.2. Pacemaker/AICD codes

I Chamber paced	II Chamber sensed	III Response to sensed event	IV Programmability/rate response	V Antitachycardia function
O = none A = Atrium V = Ventricle D = Dual (A & V) S = Single	O = none A = Atrium V = Ventricle D = Dual (A & V) S = Single	O = none I = Inhibit T = Triggered D = Dual (I & T)	O = none R = Adaptive rate	O = none P = ATP S = Shock D = Dual (P & S)

ATP = Antitachycardia pacing

From Atlee JL, Bernstein AD. Cardiac rhythm management devices (part II): perioperative management. *Anesthesiology* 2001; 95(5):11265–11280.

Single-chamber pacemakers

Single-chamber pacemakers have a single timing interval between successive depolarizations. This interval is called the escape interval – ventricular escape interval (VEI) or atrial escape interval (AEI) depending on the chamber sensed. This escape interval gets reset if a spontaneous depolarization is sensed within the interval. If no spontaneous depolarizations are sensed within the escape interval, the interval then lapses, triggering a paced depolarization and the initiation of a fresh VEI or AEI.

Dual-chamber pacemakers

Dual-chamber devices have two atrial escape intervals and one ventricular escape interval.

Figure 76.2. In this scenario the patient briefly does not have an atrioventricular nodal (AVN)/bundle of His block. This allows a native depolarization to travel to the ventricle. The sensing unit of the VVI pacer detects this depolarization (shaded arrow) and becomes stimulated. The programmed event of this “stimulation” is the inhibition of the pacer unit (unshaded arrow) allowing native depolarizations to travel through the ventricle and initiate a contraction. SA, sinoatrial node.

Pacemaker malfunctions

Most modern pacemakers are robust and have excellent shielding properties. Common pacemaker malfunctions and their descriptions are described in Table 76.3. Diagnosis of individual pacemaker malfunction is beyond the scope of this chapter and should be left to electrophysiologists.

AICD design, function, and programming

AICD design and function

An Automatic Internal Cardiac Defibrillator has a microprocessor driven pulse generator that is capable of a biphasic electrical current delivery to minimize the defibrillation energy requirements as well as to conserve battery life. The powering

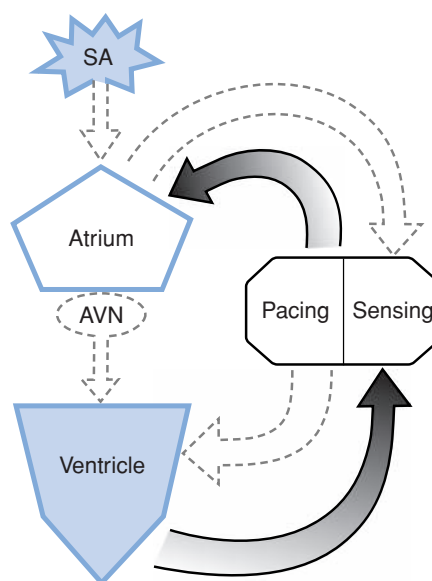

Figure 76.3. In this scenario a DDD pacemaker is functioning normally in a patient with sinoatrial node (SA) block: atria and atrioventricular node [AVN] (all unshaded straight arrows); a ventricular escape rhythm (upward facing shaded arrow). Because of the SA block, the sensing unit does not sense an impulse from its atrial lead (unshaded arrow). This results in an atrial pacing beat (downward facing shaded arrow). A few milliseconds later, because of an escape ventricular depolarization (shaded ventricle), the ventricular lead triggers the sensing unit (upward facing shaded arrow) which inhibits further ventricular pacing (left facing unshaded arrow).

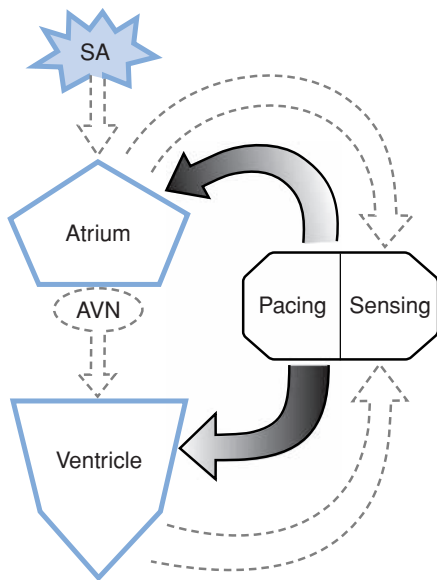

Figure 76.4. Figure 76.4 illustrates a normally functioning DDD pacemaker in a patient with sinoatrial node (SA) and AV node block. However, in this situation, no ventricular escape beat or conduction of the paced atrial beat is forthcoming (unshaded ventricle and unshaded upward and downward facing arrows). Thus, the ventricular lead does not transmit any impulse to the sensing unit (upward facing unshaded arrow). This allows the sensing unit to trigger the pacing unit and the pacing unit induces a paced beat to the ventricle and atria (shaded arrows). In this situation both atria and ventricle are being depolarized by the pacing device. AVN, atrioventricular node.

batteries are often Li-SVO (Lithium Silver vanadium oxide batteries). Batteries are usually changed every 5 to 8 years. The device also has electrolytic storage capacitors to store energy to be used during electrical therapy. The pulse generator attaches to the endocardial surface of the heart by means of transvenous leads that detect and treat arrhythmias.

AICD programming

The first step in the treatment of tachyarrhythmias is the sensing of ventricular depolarizations. The sense amplifier is usually programmed to respond to rates of 50–350 bpm. A band pass filter throws out low and high frequency signals (Electrocautery) and derives an R-R interval. The derived R-R interval is then matched with the set R-R VT/VF detection interval that has been programmed into the device. If the detected R-R interval is less than the programmed R-R detection interval, the device readies itself for electrical therapy. In addition, modern AICDs may take into consideration the morphology of the waveform (chaotic versus regular) and the suddenness of onset (VF is of sudden onset compared to sinus tachycardia) in diagnosing ventricular tachyarrhythmias. Most AICDs have the following electrical treatment capabilities, and the device progresses through the following treatment options:

- **Overdrive pacing** is the process of increasing the heart rate by means of an artificial cardiac pacemaker in order to suppress certain arrhythmias.
- **Cardioversion.** The pacemaker synchronizes to the R or S wave of the surface EKG and then shocks are delivered outside these waves to avoid an R-on-T phenomena that can cause the rhythm to degenerate to fibrillation.
- **Defibrillation.** A process of delivering electrical shocks to a heart in fibrillation or ventricular tachycardia.

The device can be programmed to treat VT with overdrive pacing and if that fails, it progresses on to cardioversion and then defibrillation. The ability to utilize overdrive pacing in the treatment of many tachyarrhythmias helps in the conservation of battery life as well as minimizes the damaging effects of shocks on the myocardium. In tiered therapy, treatment is started with overdrive: atrial tachycardia may be treated with

Table 76.3. Pacemaker malfunctions and descriptions

Malfunction	Description
<i>Failure to sense</i>	Failure to sense is a condition where there may be inadequate cardiac signal strength, and this condition can be diagnosed by the presence of native complexes coexisting with pacing spikes in the same time frame.
<i>Oversensing</i>	In oversensing, the pacemaker becomes exquisitely sensitive to electrical activity outside its zone of surveillance (far-field sensing). Electrocautery, or cross-chamber oversensing can cause the unit to inappropriately trigger or inhibit the pacing unit.
<i>Failure to pace</i>	Failure of a pacemaker to pace maybe the result of battery drain, breakage in the circuit due to lack of contact of the leads at either end, or oversensing.
<i>Failure to capture</i>	In failure to capture, pacing spikes are present appropriately but are not followed by chamber depolarizations. Myocardial ischemia, fibrosis, hyperkalemia, severe acidosis, beta-blockers, hyperglycemia, and some class II and III antiarrhythmics may occasionally cause this type of malfunction.
<i>Pacing at abnormally high rates</i>	Lead disruption, inadequate hysteresis programming, or a dual chamber pacemaker responding to an atrial tachycardia event can lead to pacing at abnormally high rates.
<i>Pacing at abnormally low rates</i>	An abnormally low pacing rate may be caused by excessive hysteresis programming, battery depletion, or an ARP pacemaker responding to deep sleep, or slow respirations.
<i>Pacemaker-mediated tachycardia</i>	Pacemaker-mediated tachycardia is a malfunction unique to dual-chamber pacemakers. Pacemakers can sometimes detect myopotentials from the chest musculature, which may be mistaken for atrial depolarizations and cause the pacemaker to drive ventricular pacing at a high rate.
<i>Crosstalk</i>	Crosstalk occurs when events in the atrial channel are sensed by the ventricular channel, and vice versa, which may lead to inappropriate pacing.

overdrive pacing; ventricular tachycardia (VT) may be preferentially treated initially by cardioversion and ventricular fibrillation (VF) treated by defibrillation.

AICD malfunction

Diagnosing pacemaker malfunction requires a long rhythm strip and a 12-lead ECG, along with a chest radiograph. Information about the pacemaker also can be obtained from the cardiology service that implanted it, or the electrophysiology (EP) service can interrogate the device. If the device appears to be malfunctioning, placement of a magnet over the device usually trips a reed switch; then, if there is a preprogrammed asynchronous pacing mode, the pacer usually reverts to this fixed mode. If a magnet does not seem to fix the problem, then there is a lack of programming of switch behavior, disruption of the leads, or battery failure. In that case, arrangements must be made for urgent transcutaneous or transvenous pacing if there is no time to have the EP interrogate the device.

Failure to deliver effective shocks

Myocardial ischemia and severe acidosis alter the morphology of the rhythm, which may lead to nonrecognition. Recurrent arrhythmias may occur in the context of myocardial ischemia or severe acidosis, leading to repeated shocks; this leads to a degree of “tolerance” by the device, resulting in ineffective therapy. The same conditions may raise the threshold for effective defibrillation, causing the usual current strength to be ineffective. Repeated shocks and depletion of the battery, as well as loss of lead contact, are other causes.

Inappropriate shocks

Electrocautery artifacts, supraventricular tachycardia misdiagnosed as ventricular tachycardia (VT), double counting of R and T waves during pacing, and lead artifacts are some of the reasons for the administration of inappropriate therapy. Sometimes the AICD senses pacer spikes of the pacemaker subunit, leading to miscounting and inappropriate shocks. Conversely, inappropriate AICD shocks may result in the pacemaker failing to sense or capture.

Drug–device interaction

Drugs are often used for rhythm management in patients with an AICD. They may be used for the suppression of nonsustained VT, prophylaxis of atrial fibrillation, or other indications. Such drugs may affect the device function in several ways, including:

- Making the myocardium proarrhythmic
- Increasing defibrillation thresholds (class 1C drugs, phenytoin, amiodarone)
- Altering the ECG morphology, resulting in failure to detect shockable rhythms

Preoperative evaluation of a patient with an AICD or pacemaker

History and physical examination

Patients with rhythm management devices often have coexisting conditions, such as coronary artery disease, cardiomyopathy, valvular heart disease, diabetes, or congenital heart disease. A complete drug history is essential, as some patients may be on antiarrhythmics.

Vitals signs and pulse plethysmography or palpation will confirm that the paced beats do get converted to mechanical contractions of the ventricle. A 12-lead ECG with a rhythm strip may be useful in determining the type of leads and whether the patient is pacemaker dependant. A chest radiograph may be useful in identifying the pacemaker and visualizing any gross malpositioning of the leads. In most cases, a chest radiograph may not shed much light on the status of the pacemakers, and other factors may be taken in account before ordering one. Serum electrolytes may be useful in patients who are extremely ill or on drugs that can alter electrolyte levels, such as diuretics. Electrophysiology or cardiology consults must often be requested before an anesthetic in a patient with a pacemaker or AICD to obtain most of the information listed in [Table 76.4](#).

Evaluating pacemakers

[Table 76.4](#) summarizes the information needed from a pacemaker or AICD before an anesthetic. Some of this information, such as the type of pacemaker and date of the last test, sometimes may be obtained from the patient, EP service consultation and interrogation of the device are necessary to obtain the rest. If needed, the manufacturer may be contacted directly.

Preanesthetic device management

Before the procedure, it is important to answer the following:

- Is the patient pacemaker dependent?
- Is the pacemaker an adaptive rate device?
- How close is the operative site to the device?
- Will monopolar diathermy be used?
- Does the pacemaker need to be reprogrammed?

Patients who are dependent on their pacemakers must have the pacemaker programmed to an asynchronous mode to avoid interference from the electrocautery unit. Adaptive rate pacemakers are known to increase their pacing rate in response to mechanical ventilation; hence, it may be desirable to reprogram the unit to switch off ARP. A patient with an AICD who is pacemaker dependent should have the pacemaker programmed to an asynchronous mode, and the tachycardia sensing mode should be turned off. In such a situation, the anesthesiologist must have the ability to defibrillate externally or internally through an alternate source in case the patient has an episode of unstable tachycardia.

Table 76.4. Preanesthetic pacemaker and AICD evaluation

Determine the indication for and date of placement.
Determine the make and model of the device.
Determine the number of leads and types of leads.
Ascertain the last test date and the status of the battery.
Extract a data log of device events, if any.
Obtain the specifics of the current program residing on the device.
Ensure that pacemaker discharges are converted to peripheral pulses.
Determine the effects of an application of a magnet on the device.
Determine whether the device should be reprogrammed.

Device management during procedures

Place the grounding plate as far as possible from the device. If the cautery is being used less than 6 inches from the device, significant interference may occur. Therefore, consider using bipolar cautery and the lowest-current energy. With simple pacemakers, the use of electric coagulating devices may have serious hemodynamic consequences in pacemaker-dependent patients. Electrocautery may be misinterpreted as native electrical activity and inhibit the pacing function. Placement of the magnet will inhibit device-sensing capabilities and switch the device to automatic pacing at a manufacturer-determined rate. Invariably, this rate is >80 bpm in pacemakers with substantial battery life and cannot be programmed by the electrophysiologist to a lower rate. Limiting the use of monopolar electrocautery to a defined period or use of bipolar electrocautery can minimize periods of elevated heart rates. Also remember that the atrial kick is lost during ventricular pacing and may adversely affect hemodynamic stability.

Modern AICDs are well shielded from electrocautery and have excellent bandpass filters to recognize the high frequencies of the electrocautery unit. However, in some cases failure to use a magnet may result in inappropriate device discharge, because electrocautery may be erroneously interpreted as a malignant rhythm and battery depletion may result from frequent charging. Juxtaposition of a magnet on a combined AICD/pacemaker most likely will disable the defibrillator function but will not affect pacing. The response of the AICD to magnet placement varies and depends on the specific manufacturer. Defibrillation function may be affected by the placement of the magnet, and arrangements for external defibrillation should be at hand.

External electrical therapy

Direct application of defibrillation paddles over a device must be avoided. Paddles should be at least 4 inches from the device, and the lowest possible joule setting with biphasic therapy is recommended. External cardioversion or defibrillation will cause a temporary loss of inhibition of the pacemaker; loss of sensing or failure to capture also may occur, requiring the stimulus strength to be adjusted to a higher setting. All devices must be interrogated after cardioversion or defibrillation.

MRI

Most manufacturers have absolutely contraindicated MRI in patients with an AICD or pacemaker. However, there are published reports of a series of non-pacemaker dependent patients who have safely undergone MRI.

Electroconvulsive therapy

The device (AICD or pacemaker) must be interrogated before the procedure and changed to an asynchronous mode. If a magnet is placed over an AICD during electroconvulsive therapy, then the ability to externally defibrillate must be ensured.

Lithotripsy

Modern lithotripsy units have an ECG input, and the unit fires on the R waves. Lithotripsy units may inhibit the pacemaker or, rarely, damage the circuitry. The following steps minimize the potential for complications:

- Program pacemakers to the VVI or VOO mode.
- Keep the lithotripter focal point at least 15 cm (6 inches) away from the pacemaker, especially in ARP devices.
- If possible, the shockwave delivery should be timed synchronously with the patient's R wave.
- Interrogate the device after the procedure.

Radiofrequency ablation

There have been no reports of electromagnetic interference between a cardiac rhythm management device and radiofrequency ablation. Generally, it is recommended that the cluster electrode be at least 5 cm from the device.

Postprocedure device management

All patients with a pacemaker or AICD who have been exposed to one of the procedures listed previously must have their device interrogated by the EP service in the recovery room. If a magnet was placed over the device, it is reasonable to leave it there until the device has been checked and it is determined that all previously programmed functions are not affected. It is important to have facilities to pace and defibrillate if a situation arises in the recovery room prior to the interrogation of the device.

Ventricular assist devices

Amanda A. Fox and John A. Fox

In the United States alone, approximately 5 million people suffer from heart failure, with 300,000 to 800,000 of these patients having advanced heart failure (New York Heart Association class III and IV) despite maximal medical therapy. Although heart transplantation is a very effective treatment for end-stage heart failure, there is an increasing shortage of suitable donor hearts available for patients who need them. In the mid-1970s, the National Institutes of Health established a research initiative to develop mechanical circulatory support devices that could serve as effective alternatives to heart transplantation. Today, there are a variety of mechanical ventricular assist devices (VADs) that can be used to:

1. Provide short-term ventricular support in patients who have suffered acute but potentially reversible myocardial insults
2. Support heart transplant candidates until a donor heart becomes available
3. Provide definitive or “destination” therapy for patients with refractory heart failure who are not heart transplant candidates

What is a VAD?

VADs are mechanical devices that take over all or part of the work of a damaged ventricle to improve patient hemodynamics and end-organ perfusion. VADs have been designed that can provide left, right, or biventricular support. Although there are many types of VADs, they all function according to the same general principles: Blood is removed from a left- or right-sided cardiac chamber via an inflow cannula that then delivers blood to the VAD pumping chamber. Blood is then pumped out of the VAD chamber into an outflow cannula that delivers blood to either the aorta (in the case of a left ventricular assist device [LVAD]) or the pulmonary arteries (in the case of a right ventricular assist device [RVAD]). The VAD therefore decompresses a failing ventricle and simultaneously augments systemic (LVAD) or pulmonary arterial (RVAD) perfusion. Desirable potential outcomes of VAD therapy include improved end-organ function; neurohumoral down-regulation of circulating catecholamines, renin, angiotensin, and other cytokines that are upregulated during end-stage heart failure;

and potential myocyte recovery with related ventricular reverse remodeling. Although improved end-organ function and neurohumoral down-regulation appear to occur relatively consistently with VAD therapy, the propensity for reverse ventricular remodeling has been fairly disappointing. A schematic of a HeartMate vented electric pulsatile LVAD (Thoratec Corp., Pleasanton, CA) is shown in Fig. 77.1.

All VADs currently require some intracorporeal to extracorporeal connection or breach to provide the VAD with power. This need for an extracorporeal power supply makes infection a serious potential complication of VAD therapy. Depending on the type of VAD, external power is supplied by a relatively large electric or pneumatic console. However, some of the newer VAD designs allow for increased patient mobility by allowing power to be supplied from a small battery pack that can be worn in a shoulder holster. VADs may be implanted with the aid of cardiopulmonary bypass (CPB) in a cardiac operative suite, or

they may be placed percutaneously in the cardiac catheterization laboratory. Examples of available VADs are listed in [Table 77.1](#). Available VADs may be considered and classified according to whether the VAD:

1. Is intended to be implanted inside or outside the body
2. Generates pulsatile or continuous (axial) flow
3. Is intended for left ventricular support only (LVAD) or is also used for right or biventricular support (BiVAD)
4. Is intended to provide shorter- versus longer-term support

Indications and contraindications for VAD placement

Assuming correction of hypovolemia, acid–base abnormalities, and electrolyte disturbances, VADs are indicated in patients who are in refractory cardiogenic shock despite inotropic or intra-aortic balloon pump support (or both). Although the definition of cardiogenic shock may vary somewhat among institutions, typical criteria include a cardiac index < 2 L/min/m², a systolic blood pressure < 80 mm Hg, a pulmonary capillary wedge pressure > 20 mm Hg, and a urine output < 20 to 30 ml/h. When VAD insertion is considered, the goal is to implant the VAD before irreversible multisystem organ failure occurs. Typical contraindications to VAD insertion include patients with renal failure (serum creatinine > 5 mg/dl), severe

hepatic dysfunction (an international normalized ratio that is not correctable to < 1.5), severe lung disease (pulmonary function tests showing forced expiratory volume in the first second of expiration [FEV₁], forced vital capacity, or diffusing capacity of lung for carbon monoxide [DLCO] $< 50\%$ of predicted), or significant irreversible or progressive neurologic deficits. Because hepatic dysfunction in heart failure patients often reflects right ventricular dysfunction and related hepatic congestion, elevated liver function tests suggest that insertion of a BiVAD might be more successful than an isolated LVAD. Most cancers are also considered contraindications to VAD insertion. Because infection is a significant morbidity after VAD insertion, patient infections should be successfully treated prior to VAD insertion. Some advocate that blood cultures should be negative in such patients for at least a week prior to VAD insertion.

Preoperative assessment of the VAD candidate

When assessing a patient preoperatively before VAD insertion, it is important to recognize that many patients with long-standing heart failure develop concurrent dysfunction of other organs secondary to poor perfusion or vascular congestion. Therefore, it is important to conduct a thorough preanesthetic evaluation of a VAD candidate, paying particular attention to the status of the patient's cardiovascular, renal, hepatic, pulmonary, and neurologic systems. This evaluation will allow the anesthesiologist to identify preoperative organ dysfunction and to discuss with the primary medical team ways in which the patient might be further optimized prior to surgery. Detailed awareness of patient comorbidities also allows anesthesiologists to better anticipate and prepare for related perioperative difficulties.

With regard to the patient's cardiopulmonary and vascular status, it is helpful to know what inotropes and vasopressors the patient is receiving, and at what dosages. It is useful to know whether the patient has been on a stable dosage of a certain inotrope for many months or whether he or she has been requiring rapidly escalating inotrope dosages. This knowledge gives the anesthesiologist a sense of whether VAD surgery is urgent or emergent, thereby dictating how much time (if any) is available for further evaluation or optimization of the patient. Furthermore, if a patient has been reasonably stable on an infusion of a specific inotrope at home and is presenting with gradual deterioration warranting VAD placement, the anesthesiologist would then know that administration of that inotrope may be helpful at preoperatively administered or slightly higher doses during induction of anesthesia as well as during other perioperative phases. In patients undergoing isolated LVAD implantation, knowledge of potentially effective inotropes may be useful for supporting right ventricular function after VAD implantation.

It also is helpful for the anesthesiologist to review the patient's preoperative echocardiogram, as right ventricular dysfunction often occurs in conjunction with left ventricular

dysfunction. If the patient has moderate or severe right ventricular dysfunction, it may be useful to discuss with the surgeon the possibility that the patient may require an RVAD as well as an LVAD. Many patients may have significant tricuspid regurgitation that the surgeon may elect to repair as well. This is important for the anesthesiologist to know, as some surgeons may request that the patient's pulmonary artery catheter be withdrawn from the right ventricle before the tricuspid valve is repaired.

Left heart catheterization data are particularly important in LVAD patients who have significant obstructive disease of the right coronary artery, as they indicate that the patient may require a right coronary artery bypass graft as well as LVAD placement. Right heart catheterization data are useful in identifying patients with moderate or severe pulmonary hypertension. Some institutions initiate trials of intravenous inodilators (e.g., milrinone) or vasodilators (e.g., prostaglandins) as well as inhaled pulmonary vasodilators (e.g., nitric oxide) with a pulmonary arterial catheter in place to determine whether a potential VAD candidate has pulmonary hypertension that is "fixed" versus reduced with pharmacotherapy. If such a preoperative evaluation is conducted, it is useful to know which drugs reduce pulmonary hypertension, as those drugs may be useful in the post-CPB period for reducing right ventricular afterload and related right ventricular dysfunction.

It is important to evaluate whether a patient has pulmonary edema, particularly to the degree that it is impairing oxygenation. If a patient has substantial preoperative pulmonary edema, it is worth determining whether he or she might be responsive to further preoperative diuresis. Most VAD candidates are on daily diuretics. It is important to know what diuretics they are on and at what dosages, as, particularly for intraoperative diuresis with loop diuretics, it will be most effective to administer at least, if not more than, the intravenous equivalent of the normal daily dose.

Preoperative renal insufficiency is often associated with diminished renal perfusion secondary to low cardiac output. Many patients experience improved renal function in the weeks and months after VAD insertion. However, patients with preoperative renal insufficiency may develop acute on chronic renal failure in the immediate perioperative period secondary to the insults of surgery and CPB. For patients with moderate to severe preoperative renal insufficiency, it may be useful to consult a renal specialist preoperatively, as such patients may require venovenous hemodialysis during the days after surgery. If this is anticipated, access for such dialysis can be placed sterilely prior to leaving the operating room after VAD placement. It is also important to recognize the potential for uremic platelet dysfunction and to be prepared to transfuse platelets after separating from CPB.

Patients who have elevated liver function tests are more likely to experience significant perioperative coagulopathy. Many VAD candidates have also undergone prior cardiac surgeries. Both of these scenarios increase the patient's risk for substantial bleeding after CPB (one or more patient blood

volumes). The anesthesiologist should recognize this and plan for adequate intravenous access for rapid volume resuscitation. It is also useful to communicate with the institution's blood bank preoperatively to ensure rapid access to sufficient packed red blood cells, fresh frozen plasma, cryoprecipitate, and, possibly, recombinant factor VII. Autologous blood scavenging can also be arranged for the intraoperative period. Many VAD candidates have also undergone at least one prior cardiac surgery and therefore also have increased risk for perioperative bleeding secondary to mediastinal scarring and adhesions.

Induction of anesthesia

To maintain hemodynamic stability during induction of anesthesia for VAD surgery, the anesthesiologist must understand the unique physiology of patients with severe left, right, and biventricular failure. A frequent scenario is a patient with severe left ventricular dysfunction (left ventricular ejection fraction of approximately 10%), moderate right ventricular dysfunction, and moderate pulmonary hypertension. Such patients have high levels of circulating endogenous catecholamines as part of the body's attempt to compensate for the failing left ventricle's small, fixed stroke volumes and correspondingly low cardiac output. Increased circulating catecholamines help compensate for this by engendering higher heart rates as well as increased systemic vascular resistance, both of which will improve systemic perfusion. Therefore, it is important for the anesthesiologist to attempt to minimize the sympatholysis that often occurs in response to induction of anesthesia. This can be done in a number of ways. An arterial line should be placed prior to induction to allow blood pressure monitoring with each beat of the heart. If a patient has pulmonary arterial pressures that are approaching systemic pressures, it may be useful to place a pulmonary arterial catheter preoperatively to titrate inodilators and vasodilators during induction. It is also important to minimize hypoxia and hypercarbia by adequately ventilating such patients during induction so as not to exacerbate pulmonary hypertension. Induction drugs such as midazolam and etomidate tend to minimize sympatholysis, but it is important to remember that all drugs administered to VAD candidates prior to VAD insertion will have a slow circulating time before taking effect. Therefore, initial doses of induction agents should be given slowly and patiently before any supplemental doses are given. Higher heart rates are generally desirable for sustaining adequate cardiac outputs in end-stage heart failure patients. Because most end-stage heart failure patients have severe diastolic dysfunction as well as severe systolic dysfunction, these patients generally do not tolerate sudden changes in preload or afterload. Consequently, preoperative inotropes are often continued or increased during induction and maintenance of anesthesia prior to initiating CPB.

Given the potential for hemodynamic collapse with induction of anesthesia, the anesthesiologist inducing the patient should also be ready for urgent initiation of CPB. This means having an adequate heparin dose ready to administer, as well as

a primed CPB circuit and an immediately available cardiac surgeon and perfusionist. The Jarvik FlowMaker axial flow VAD (Jarvik Heart, Inc., New York, NY) has been designed so it can be implanted through a left thoracotomy incision with the outflow cannula implantable into the descending thoracic aorta. An advantage of this potential is the ability to avoid scarring and adhesions in patients who have had multiple prior sternotomy incisions. However, the anesthesiologist should be aware of when such a device's implantation and approach are planned, as this situation will require double-lumen endotracheal tube placement or other provisions for lung isolation during VAD implantation.

Anesthetic considerations for the pre-CPB period

The hemodynamic principles discussed earlier with regard to induction of anesthesia also apply to maintenance of anesthesia in the pre-CPB period. Patients are generally continued on inotropes and vasopressors in doses that are equivalent to or higher than those they were receiving preoperatively. Maintenance of anesthesia is usually achieved with low but amnestic doses of volatile agent, as well as slowly administered doses of intravenous narcotics such as fentanyl. If a pulmonary arterial catheter is not placed prior to induction, it should be placed soon thereafter. In patients who have undergone previous heart surgeries, it may be safer to cannulate a femoral artery and vein prior to sternotomy. Some surgeons actually elect to initiate CPB prior to sternotomy, as adhesions and scarring increase the risk of massive bleeding from injury to the right ventricle or other cardiovascular structures that may be adherent to the sternal table. The anesthesiologist should be certain that enough peripheral or central venous access is established to allow for large-volume administration of crystalloids, colloids, and blood products. As discussed in the preoperative assessment section, VAD patients often have hepatic congestion and associated preoperative coagulopathy. Some patients have preoperative uremia and associated platelet dysfunction. When these factors are coupled with the iatrogenic insults to the coagulation system introduced by the overall increased systemic inflammatory response to surgery, as well as by blood exposure to the extracorporeal surfaces of the CPB circuit and the VAD, substantial post-CPB blood loss should be anticipated.

Many institutions also initiate a prophylactic perioperative antibiotic regimen in an attempt to minimize patient risk for serious perioperative infection or sepsis. Intravenous antibiotics such as vancomycin, levofloxacin, rifampin, or fluconazole often are given before skin incision and are regularly redosed throughout the immediate perioperative period. Parts of the VAD are also frequently soaked in antibiotic solution before implantation.

Various aspects of the standard perioperative transesophageal echocardiographic (TEE) examination have particular relevance for identifying cardiac and aortic abnormalities that might contribute to adverse patient outcomes

or VAD failure after implantation. When well communicated to the responsible cardiac surgeon, knowledge of such TEE findings can guide additional surgical interventions prior to VAD implantation that might contribute to success. There are several particularly important diagnoses that should be considered by the physician performing the intraoperative TEE prior to VAD implantation:

1. VAD surgeons typically consider correcting greater than mild aortic (in the case of LVAD implantation) or greater than mild pulmonic insufficiency (in the case of RVAD implantation). Such valvular insufficiency is typically addressed surgically by oversewing or replacing the patient's native, incompetent valve. This procedure is necessary with LVAD surgery because the VAD outflow cannula delivers blood to the patient's aorta. Significant aortic insufficiency will result in a substantial percentage of LVAD blood output repeatedly recycling retrograde across the incompetent aortic valve and back through the LVAD pump rather than progressing antegrade to provide systemic perfusion. A parallel concept applies to RVAD placement in the setting of pulmonic insufficiency with regard to retrograde recycling of VAD outflow delivered to the pulmonary artery.
2. Particularly with isolated LVAD surgery, cardiac septal defects such as a patent foramen ovale, atrial septal defects, or ventricular septal defects should be surgically closed to avoid significant right-to-left shunt after VAD support is initiated.
3. Although mitral regurgitation typically improves and becomes insignificant with adequate LVAD function, moderate or severe mitral stenosis may significantly impair VAD filling and should be surgically evaluated and addressed.
4. Because many VAD candidates have severely enlarged cardiac atria and ventricles accompanied by slow or static passage of blood flow through these chambers, TEE examination should assess carefully for intracardiac thrombus to prevent potential embolic events as well as thrombotic complications within the VAD itself. The cardiac surgeon is particularly likely to perform a thrombectomy for left ventricular apical thrombi, as the VAD inflow cannula is often placed directly into the left ventricular apex.
5. As mentioned earlier in this chapter, depending on the type of LVAD inserted, the VAD outflow cannula can be implanted into the ascending or descending thoracic aorta. TEE can be used to assess whether there is significant atheroma in the descending aorta. If descending aortic atheroma is moderate or severe, the surgical approach might be changed to allow for implantation of the VAD outflow cannula in the ascending aorta instead. Because many VAD implantations occur in patients who are undergoing repeat sternotomies that might warrant femoral venous to femoral arterial CPB, knowledge of a

significant descending aortic atheroma might alter the surgical arterial cannulation approach to favor axillary arterial or ascending aortic cannulation. This shift in plan for CPB cannulation might be made out of concern that femoral arterial cannulation might result in significant retrograde embolization of a descending aortic atheroma. With most VAD types, the LVAD outflow cannula is implanted into the ascending aorta, with surgery performed through a midline sternotomy incision. In this case TEE, as well as epiaortic ultrasound, can be used to detect a significant ascending aortic atheroma, which can be addressed surgically by atherectomy or ascending aortic replacement prior to insertion of the LVAD inflow cannula.

6. The VAD candidate should be carefully assessed for severity of right ventricular dysfunction and tricuspid regurgitation. Particularly in the situation of isolated LVAD surgery, cardiac surgeons may conduct tricuspid valve repair for the indication of tricuspid regurgitation. The idea behind such repair is to promote forward flow from the right ventricle to help ensure adequate blood return to the LVAD. Furthermore, knowledge that a patient has moderate or severe right ventricular dysfunction prior to isolated LVAD implantation will allow better planning for right ventricular support with inotropes as well as right ventricular afterload reduction with pulmonary vasodilators. Such knowledge of right ventricular dysfunction also allows preparation for potential additional RVAD implantation.

Anesthetic considerations after VAD insertion

With any open heart surgery, but particularly with VAD placement, complete de-airing of the heart and the VAD takes time. Intraoperative TEE examination is helpful for determining when most of the air has been removed from the left heart and the VAD. TEE is also used to assess proper VAD inflow cannula placement in the left atrium or the more typical apical left ventricular location. If the supported ventricle appears distended rather than decompressed when weaning from CPB to VAD support, inflow cannula malposition should be high on the differential and should be readjusted by the surgeon. If a single VAD is placed, intraoperative TEE may be useful for evaluating function of the non-VAD-supported ventricle. TEE will often guide the care team in deciding when isolated LVAD support has failed and biventricular assistance needs to be implemented through additional implantation of an RVAD.

Before weaning from CPB, a platelet count and fibrinogen level are often sent to help the anesthesiologist anticipate the post-CPB need for fresh frozen plasma, cryoprecipitate, and platelets. This allows such blood products to be readily available in the operating room for early treatment of coagulopathy. When an LVAD has been initiated alone, inotropes are frequently administered to aid right ventricular contractility that is sufficient to tolerate post-CPB blood transfusions and to provide adequate blood return to the left heart and

associated VAD. In patients in whom there is particular concern regarding potential volume overload of the right ventricle after LVAD implantation, various modes of ultrafiltration can be implemented while they are on CPB to hemoconcentrate the blood and reduce the overall blood volume to be returned to the patients after being separated from CPB. Also in keeping with the concept of promoting right ventricular output, patients in whom significant pulmonary hypertension is anticipated should be placed on vasodilator therapy such as inhaled nitric oxide. In a patient who receives a large-volume transfusion, has persistent nonsurgical bleeding, or has marginal right ventricular function, the cardiac surgeon may elect to leave the chest open after surgery and allow the patient to recover for several days in the intensive care unit before attempting chest closure again in the operating room. Although many VAD patients hemodynamically tolerate atrial fibrillation and other supraventricular arrhythmias, ventricular tachycardia typically is poorly tolerated, particularly in those receiving an LVAD, and is treated aggressively with cardioversion and pharmacotherapy.

All VADs have an essentially fixed filling capacity. If a pulsatile VAD receives increased blood return, VAD output is increased by increasing the pump ejection rate. If an axial flow or centrifugal VAD receives increased blood return, VAD output is increased by increasing the VAD rotation speed. Unlike with native heart tissue, neither pulsatile nor axial flow-type VADs have the compensatory capacity to increase contractility to improve output. Therefore, VADs are extremely preload dependent. If VAD output decreases, TEE and other hemodynamic monitors should be used to assess whether the patient is hypovolemic, the VAD inflow cannula is malpositioned, or the patient is experiencing significant right ventricular dysfunction that is compromising blood passage to the left heart. The anesthesiologist and surgeon then need to address these causative issues. If the patient has significant right ventricular dysfunction, diuretics can be administered to help mitigate volume overload. Inotropes can be increased or initiated to improve contractility, and pulmonary vasodilators such as nitric oxide can be given to decrease pulmonary hypertension and therefore the afterload against which the right ventricle is contracting. One should not increase the VAD rate or rotation in the setting of low outputs, as this will cause the VAD to exert negative pressure on the supported ventricle as well as the inflow cannula suture line. This scenario may result in air embolization from along the inflow cannula suture line. Increasing the LVAD rate or rotation in the setting of poor filling also may result in a leftward shift of the interventricular septum, which may further perpetuate severe right ventricular dysfunction.

The inflow cannula is inserted into the apex of the left ventricle, and the outflow cannula is anastomosed to the ascending aorta. Blood returns from the lungs to the left side of the heart and exits through the left ventricular apex and across an inflow valve into the prosthetic pumping chamber. Blood is then actively pumped through an outflow valve into the ascending aorta. The pumping chamber is placed within the abdominal

wall or peritoneal cavity. A percutaneous drive line carries the electrical cable and air vent to the battery packs (only the pack on the right side is shown in Fig. 77.1) and the electronic controls, which are worn on a shoulder holster and belt, respectively.

Anesthetic considerations for surgical repair of the thoracic aorta

Brian J. Gelfand and Amanda A. Fox

Introduction

Aortic aneurysms and dissections may involve the ascending, arch, or descending segments of the thoracic aorta. Surgical repair of the thoracic aorta involves a variety of perioperative approaches and considerations related to the type, location, and extent of thoracic aortic pathology. Anesthesiologists must understand the full scope of these issues to provide optimal care for patients undergoing thoracic aortic surgeries.

Preparing for urgent or emergent thoracic aortic surgery

In the clinical presentation of thoracic aortic dissection, leaking aneurysm, or contained traumatic transection, a minimum of two large-bore intravenous (IV) catheters must be placed to provide massive volume resuscitation as needed. Placing an arterial line for continuous blood pressure monitoring should be done as soon as possible to allow optimal hemodynamic management. Tight pharmacologic control of a patient's blood pressure and left ventricular ejection velocity should be initiated to help prevent propagation of aortic dissection or aortic rupture. In transporting patients with known or potential acute aortic syndromes to the operating room (OR), it is essential to be prepared for potential acute clinical deterioration and to have appropriate personnel, equipment, drugs, and monitoring available to be able to rapidly intubate the patient (if the patient is not already intubated) and to initiate needed cardiac and volume resuscitation. This is particularly important to remember if the patient is being transported for further diagnostic tests, such as CT imaging, before coming to the OR. Additional venous access or monitoring lines, such as central venous catheters or pulmonary arterial catheters, can be placed in the OR or the intensive care unit when time permits.

In patients with aortic dissections, administering sedatives and pain medication not only will improve patient comfort but should result in better control of high blood pressure and heart rate. However, care must be taken not to oversedate such patients, particularly if they are being monitored for further diagnostic tests prior to going to the OR. The patient needs to be alert enough to respond to serial examinations that would indicate expansion of aortic dissection and the need to go immediately to surgery. Such patients require frequent

neurologic assessments for new mental status changes or spinal cord ischemia, as well as abdominal examinations to assess for mesenteric ischemia. A Foley catheter may be placed in the bladder to aid in detecting oliguria related to renal ischemia.

Pharmacologic hemodynamic management

Drugs used for hemodynamic management of patients with suspected or known critical aortic pathology ideally should have few side effects and short half-lives that allow for rapid onset and offset. To prevent extension of aortic dissection or aortic rupture, systolic and diastolic blood pressure should be tightly controlled, with target systolic and mean systemic arterial blood pressures in most patients approximating 100 to 120 mm Hg and 60 to 80 mm Hg, respectively. Vasodilator drugs commonly used to control preoperative hypertension are shown in [Table 78.1](#).

Reducing left ventricular ejection velocity also may be helpful for minimizing expansion of aortic dissections. This can be accomplished by using β -adrenergic receptor antagonists (β -blockers), as this group of drugs will decrease the patient's heart rate (and therefore the number of blood flow pulsations directed toward an intimal tear) and left ventricular contractility (decreasing the force of blood flow pulsations toward an intimal tear). When vasodilators are administered, particularly those that markedly reduce systemic afterload, patients may experience both increased forcefulness of left ventricular ejection and pronounced reflex tachycardia. Therefore, β -blockers are useful alone or as adjuncts to vasodilator therapy in patients with thoracic aortic aneurysms or dissections. Target heart rate for most patients is between 60 and 80 bpm. Commonly used perioperative β -blockers are shown in [Table 78.2](#).

Anticipating bleeding and transfusion requirements

Particularly for patients presenting with acute aortic emergencies, in addition to establishing adequate large-bore intravenous access, the blood bank should be notified regarding the potential for substantial blood loss. Initially, 8 to 10 U of packed red blood cells (PRBCs) should be crossmatched for repair of acute aortic dissections, other potential aortic leak or rupture, or descending thoracic aortic aneurysms. Crossmatching 2 to 4 U of PRBCs may be adequate initially for elective aneurysm

Table 78.1. Common IV vasodilators used to control hypertension

Drug	Common dosages	Comments
Sodium nitroprusside	Start infusion at 0.5–1.0 $\mu\text{g}/\text{kg}/\text{min}$ and titrate to effect Cyanide toxicity has occurred with doses of 8–10 $\mu\text{g}/\text{kg}/\text{min}$	Rapid onset and offset. Vasodilates both arterial and venous smooth muscle. Central administration is ideal, but can be administered through a large peripheral IV line.
Nitroglycerin	Typical infusion range is 1.0–4.0 $\mu\text{g}/\text{kg}/\text{min}$	Rapid onset and offset. Less potent than sodium nitroprusside. May be particularly helpful in settings in which aortic dissection affects coronary arterial flow, as blood flow may be somewhat improved with coronary vasodilation.
Fenoldopam	Start infusion at 0.05–0.1 $\mu\text{g}/\text{kg}/\text{min}$ and titrate to effect to a maximum dose of 0.8 $\mu\text{g}/\text{kg}/\text{min}$	Selective D_1 dopamine receptor agonist with little affinity for D_2 dopamine or other adrenoceptors. Although fenoldopam results in dilation of many vascular beds, it may have some renal-protective benefits related to increasing renal blood flow.
Nicardipine	Typical infusion range is 5.0–15.0 mg/h and can be titrated to effect; also may be administered as an IV bolus (usually 0.5–2.0 mg)	A dihydropyridine calcium channel blocker that inhibits calcium influx into vascular smooth muscle, thereby causing vasorelaxation. It is marketed as having more selectivity for cerebral and coronary arteries than the other dihydropyridines.

repair of the arch or ascending aorta. Blood warmers and rapid transfusion setups should be ready to use in the OR. Arrangements for intraoperative autologous blood salvaging, such as a Cell Saver (Haemonetics Corp., Braintree, MA), should be coordinated if possible.

Risk of significant bleeding with thoracic aortic surgeries appears to result from multiple factors. In a series of 20 patients with unruptured abdominal aortic aneurysms reported by Balduini et al., platelets were activated in all patients and signs of platelet consumption were present in most patients preoperatively. In another series reported by Fisher et al. in 32 patients scheduled for elective thoracoabdominal aneurysm repair, 9% of the patients had frank disseminated intravascular coagulation, whereas 14% had elevated fibrin degradation products without evidence of consumptive coagulopathy. These findings suggest that patients with thoracic aortic disease may have

subtle preoperative coagulopathy. Coagulopathy is thought to worsen in thoracic aortic surgeries requiring extracorporeal circulation, such as cardiopulmonary bypass (CPB) or left heart bypass. Although these bypass circulation techniques can improve systemic perfusion during aortic repair, they often require anticoagulation (generally with heparin) and also may stimulate inflammatory responses, consumptive coagulopathy, and increased fibrinolysis. Bleeding may also be exacerbated by deep hypothermic circulatory arrest (DHCA), which is conducted in patients requiring aortic arch surgery and may require blood temperatures as low as 16°C to 18°C. Such profound hypothermia may be associated with significant platelet dysfunction. In patients undergoing surgical repair of thoracoabdominal aneurysms, massive blood loss may occur, particularly from back-bleeding through intercostal vessels. Liver ischemia related to aortic cross-clamping above the celiac axis may also

Table 78.2. Commonly used β -adrenergic receptor antagonists (β -blockers)

Drug	Common dosages	Comments
Propranolol	Start with IV bolus of 1 mg, but total doses as high as 8 mg may be required to achieve adequate heart rate control	Nonselective β -adrenergic receptor antagonist (β_1 and β_2) that has been used for many years in the setting of aortic dissection to slow heart rate. However, propranolol use is now often supplanted by β_1 -selective adrenergic receptor antagonists (see below). The half-life of the main metabolite of propranolol is 5–7 h, so shorter-acting agents should be considered in patients who are hemodynamically labile.
Labetalol	Loading doses can be administered IV, with initial doses of 5–10 mg. Loading doses should subsequently be doubled approximately every 10 min (up to a maximum total dose of 300 mg) until target heart rate and blood pressure are achieved. Once target heart rate and blood pressure are achieved by IV loading doses, a continuous infusion may be initiated at 0.5–2 mg/min, or the patient may be redosed with small IV boluses approximately every 30 min.	Provides a combination of α_1 -, β_1 -, and β_2 -adrenergic receptor antagonism, and thus can be administered as an alternative to a combination of sodium nitroprusside and β -blocker. The disadvantage of the labetalol approach to blood pressure and heart rate control for aortic dissections is a longer time to onset of desired blood pressure effect and less ease of rapid titration than seen with strict vasodilators.
Esmolol	Bolus IV loading dose of 500 $\mu\text{g}/\text{kg}$ over 1 min, then initiate IV infusion at 50 $\mu\text{g}/\text{kg}/\text{min}$ titrated to effect up to a maximum infusion of 300 $\mu\text{g}/\text{kg}/\text{min}$	β_1 -Selective adrenergic receptor blocker with rapid onset and short duration of action. Its β_1 selectivity makes it favorable for patients who are prone to bronchospasm. Its short half-life makes it easy to titrate and to terminate if a patient develops bronchospasm or becomes hemodynamically unstable.
Metoprolol	Typical initial IV bolus dose of 2.5–5.0 mg; may be repeated every 5–15 min up to a maximum total dose of 20 mg to achieve target heart rate	β_1 -Selective adrenergic receptor blocker with longer duration of action than esmolol, so it can be administered effectively without continuous infusion

worsen bleeding. In addition to red blood cells, the need for potential clotting factor and platelet replacement should be anticipated.

Overview of the surgical objectives for repairing the thoracic aorta

The primary surgical objective for managing acute aortic injury (dissection, ruptured aneurysm, or transection) is to occlude blood flow just proximal and distal to the aortic injury to prevent fatal hemorrhage. The next objective is to restore arterial blood flow to major end organs that are perfused by aortic arterial branches and to repair or replace the region of diseased aorta so that normal antegrade blood flow can resume through the aorta with the ability to provide adequate perfusion to the brain, spinal cord, gut, kidneys, and other tissues.

Aortic aneurysms generally are repaired surgically by replacing the entire length of diseased aorta with synthetic tube graft. Major arterial branches off the replaced aortic segment are individually reimplemented into the synthetic replacement graft, although with aortic arch replacements, an “island” of native aortic tissue containing the ostia for the innominate and the left carotid and subclavian arteries may be reanastomosed to the replacement graft to reduce surgical time. Surgical repairs of thoracic aortic dissections have a somewhat different approach, because often only the region of dissected aorta that actually contains the dissection entry point or intimal tear is replaced with a synthetic interposition graft. The entire length of dissected aorta is generally not replaced; rather, with entry into the false lumen of the dissected aorta now surgically closed, further entry of aortic blood flow into the false lumen should not be possible. The idea is that once continuity of flow is reestablished into only the true aortic lumen, the false lumen will eventually compress and thrombose. In cases of acute aortic transection, the disrupted aortic region is resected, then the aorta is reapproximated to itself. If it is not possible to reanastomose the native aorta to itself, a short interposition graft may be placed.

General anesthetic objectives for repairing the thoracic aorta

In concert with primary surgical objectives to control or prevent aortic hemorrhage and to maintain adequate end-organ perfusion, the anesthesiologist must adequately volume resuscitate patients and monitor and manage the hemodynamics so as to avoid triggering aortic rupture or dissection extension (if they have not already occurred). Anesthesiologists also must take additional measures to monitor and protect the function of organs such as the spinal cord and kidneys that receive blood supply from affected aortic regions. In some emergency situations, massive volume resuscitation may already be underway as the patient enters the OR. To formulate the best overall anesthetic plan for the patient undergoing thoracic aortic surgery, the anesthesiologist should be as aware of significant patient comorbidities as the urgency of surgical

presentation will allow. Patients commonly have significant cardiovascular and pulmonary comorbidities, as well as diabetes and renal insufficiency. It is also extremely important for the anesthesiologist to clearly communicate with the surgical team to understand (1) exactly which regions of the aorta are presumed to be involved and (2) how the surgeons plan to approach aortic repair with regard to both the incision site and extracorporeal circulation. As is discussed in detail in the remaining sections of this chapter, these factors have many important implications for anesthetic planning, including where to place arterial lines, what choices to make for other invasive and non-invasive monitoring, the need for lung isolation, and anticipation of blood loss.

Before inducing anesthesia, the anesthesiologist must follow the basic tenets of airway assessment and consideration of a plan to reduce the risk of aspiration. Many patients present as emergencies with a presumed full stomach. In these situations the risk of using rapid-sequence induction, with its associated swings in hemodynamics, must be balanced against the aspiration risk with a “modified” rapid-sequence induction, in which a slower IV induction is conducted in conjunction with gentle manual ventilations done while cricoid pressure is held. Because hemodynamic swings are common with laryngoscopy, drugs such as nitroglycerin and esmolol should be readily available during intubation. Ideally, an arterial line is placed and monitored prior to induction of anesthesia. In conscious patients, administration of a nonparticulate antacid should also be considered before induction.

Prior to placing an arterial line for direct blood pressure monitoring, thought should be given to the location of the aortic pathology. Central venous access is useful in all thoracic aortic surgeries to effectively administer inotropes, vasopressors, and vasodilators as needed. Pulmonary artery catheters, particularly those that can monitor continuous cardiac output and mixed venous oxygen saturation, may provide useful perioperative guidance in the setting of hemodynamic lability and volume shifts, particularly in patients with substantial concurrent cardiopulmonary or renal disease. Transesophageal echocardiography (TEE) also can offer significant direction for intraoperative management. Complementing its preoperative diagnostic capability, TEE is helpful for determining aortic valve involvement, assessing left ventricular function and filling during periods of aortic cross-clamping and unclamping, locating intimal tears and fenestrations within dissection flaps, and discerning whether aortic flow appears to have ceased in the false lumen after dissection repair.

Specific considerations for ascending aortic or aortic arch surgery

Arterial blood pressure monitoring and cannulation for cardiopulmonary bypass

Aneurysms involving the aortic root, proximal aorta, or aortic arch, as well as Stanford type A aortic dissections, are typically

repaired through a midline sternotomy incision with use of full CPB. If aortic pathology involves the innominate artery, a left radial or femoral arterial line should be placed. This is also true if right axillary cannulation is anticipated, because in this setting, right radial arterial line blood pressure readings will be inaccurate during CPB. In situations in which the aortic arch needs to be repaired and prolonged DHCA is anticipated, the surgeon may wish to administer antegrade cerebral perfusion through a right axillary arterial cannula and may wish to monitor pressure during administration of antegrade cerebral perfusion through a right radial arterial line. In this situation, a right radial arterial line, as well as a left radial or femoral arterial line, should be placed to allow accurate blood pressure monitoring while on CPB. It is important to make the OR team aware of which arterial line tracing is displaying accurate systemic blood pressure during CPB and which one should be used to monitor antegrade cerebral perfusion during DHCA. Stanford type A dissections may extend into the iliac and femoral arteries, and the possibility of inadvertently monitoring false lumen blood pressures with a femoral arterial line should be considered in this scenario.

Repairs isolated to the aortic root or proximal ascending aorta may permit both cannulation and cross-clamping of an area of nondiseased aorta proximal to the aortic arch. This approach allows the aorta to be repaired on CPB with a bloodless surgical field and concurrent perfusion of the brain and other organs. Arterial cannulation for CPB also may occur in the axillary or femoral arteries, possibly improving surgical exposure for ascending aortic repair.

For surgical repairs involving the aortic arch, a bloodless surgical field cannot be established for portions of the repair with the patient on CPB. Therefore, CPB is initiated by cannulating aneurysmal or normal portions of the ascending aorta, or the axillary or femoral arteries, but patients must undergo periods of cessation of CPB after the heart is arrested for the arch to be repaired. In this scenario, the patient is placed on CPB and is typically aggressively cooled prior to conducting repair of the arch with DHCA. Venous cannulation for CPB is often in the right atrium for both ascending aortic and arch surgeries; however, if the surgeon is concerned that view of the aneurysm will be obstructed or that the aneurysm is too large to allow easy access to the right atrium, a femoral vein can be cannulated.

Cerebral protection strategies

Hypothermia is an important cerebral protection strategy, as it markedly reduces the cerebral metabolic rate of oxygen consumption. Mild to moderate hypothermia on CPB is typically desirable for ascending aortic aneurysm repairs. However, deliberate intraoperative hypothermia is particularly valuable for surgeries involving the aortic arch, as these operations require transient interruption of cerebral blood flow, increasing a patient's risk for postoperative stroke and neurocognitive dysfunction. For aortic arch repairs, profound hypothermia is established on CPB (core temperature of

15°C–20°C) prior to circulatory arrest (DHCA). In this temperature range, a DHCA period of < 40 minutes is generally considered “safe” for the brain. The degree of cooling depends on the anticipated duration of DHCA. During the CPB cooling period prior to DHCA, the heart is arrested and ice is often placed around the patient's head in an effort to more uniformly cool the brain. To avoid thermal injury, care should be taken to avoid direct contact between ice and the ears and nose. Once the target patient temperature for DHCA is reached for the venous return to the CPB circuit, CPB at this temperature should continue until the patient's nasopharyngeal temperature (reflective of brain temperature) is equally cool. Either raw or processed electroencephalogram (EEG) monitoring is often used to verify an isoelectric cerebral state before initiating DHCA. In addition to using hypothermia to establish an isoelectric EEG, a barbiturate such as thiopental is sometimes also administered a few minutes prior to initiating DHCA to further decrease the cerebral metabolic rate. To promote cerebral protection, other pharmacologic measures, including administration of steroids or mannitol (to reduce perioperative cerebral swelling) or magnesium, are sometimes taken prior to initiating DHCA, but there are no strong data to support the efficacy of these measures. Following DHCA, slow rewarming is essential to evenly rewarm the patient's core and periphery; this will better allow the patient to remain warm once separated from CPB, reducing the risk of postoperative bleeding. Slow rewarming also avoids cerebral hyperthermia, which may exacerbate cerebral injury.

To enhance the cerebral protection provided by hypothermia alone during blood flow cessation for aortic arch repair (particularly for complex repairs for which the DHCA period is anticipated to be longer than 40 minutes), selective antegrade or retrograde cerebral perfusion techniques may be employed. Both strategies involve infusion of cold oxygenated blood to the brain. Selective antegrade cerebral perfusion is often administered through a right axillary arterial cannula, with infusion pressure monitored via a right radial arterial line. However, antegrade cerebral perfusate can also be administered directly into the innominate or carotid arteries. Assuming an intact circle of Willis, administering antegrade cerebral perfusate through one arch vessel should provide perfusion to both the ipsilateral and contralateral cerebral hemispheres. Retrograde cerebral perfusion is easily conducted immediately after DHCA is initiated by infusing perfusate through the superior vena cava while the patient is in slight Trendelenburg position.

Specific considerations for descending thoracic or thoracoabdominal aortic surgeries

One-lung ventilation

Repair of descending thoracic or thoracoabdominal aneurysms typically is conducted through a left thoracotomy incision with the patient positioned in full right lateral decubitus position. To optimize surgical exposure, the anesthesiologist usually is asked to ventilate only the right lung during the thoracic portion of the

repair. The trachea and left main bronchus may be anatomically distorted in patients with large ascending aortic aneurysms. Placement of a double-lumen endotracheal tube should be done gently to minimize risk of rupturing the aneurysm. Additionally, left-sided double-lumen tubes may be difficult to seat effectively in the left main bronchus. Therefore, some anesthesiologists prefer to place right-sided double-lumen tubes for these operations. For patients potentially difficult to intubate, placing an endobronchial blocker may be preferable to a double-lumen tube, as this avoids the need to change the double-lumen tube to a single-lumen tube at the end of the surgery. This is important, as descending thoracic surgeries may be lengthy and require massive volume resuscitation, factors that both may cause significant airway edema that may make endotracheal tube changes difficult.

Surgical approaches to distal aortic perfusion

One approach to descending thoracic aneurysm repair is to cross-clamp the aorta proximal and sometimes distal to the affected aorta and to conduct subsequent aortic repair as quickly as possible without taking additional measures to provide distal aortic perfusion. This approach has the advantage of not requiring heparin for extracorporeal circulation, which may increase surgical bleeding, but has the disadvantage of increased incidence of hypertension proximal to the aortic cross-clamp, as well as hypotension in the distal aorta and its branches. With this simple cross-clamp technique, the anesthesiologist must prepare to treat proximal hypertension with short-acting vasodilators such as nitroglycerin or sodium nitroprusside to prevent acute congestive heart failure instigated by high left ventricular afterload. Perioperative physicians also should be aware that any prolonged period of distal aortic hypotension presents an increased potential for gastrointestinal, renal, or spinal cord ischemia.

To mitigate the proximal aortic hypertension and distal hypoperfusion that occur with the simple aortic cross-clamp technique, some surgeons use shunts whereas others use extracorporeal circulation to divert aortic blood flow from proximal to the aortic cross-clamp to more distal aortic regions. The Gott shunt is heparin bonded, so generally it does not require additional systemic heparinization. However, these shunts have very small internal diameters (5–6 mm), limiting the degree of decompression and augmentation that can occur for the proximal and distal aorta, respectively. Furthermore, these shunts sometimes can kink. Traditional CPB can be employed with full systemic heparinization and typically is used for descending thoracic aneurysm repairs that will require DHCA because of involvement of the proximal descending aorta or the aortic arch. Full heparinization increases bleeding complications, particularly within the left lung, as this lung is often subjected to surgical manipulation and incidental trauma during repair of the descending thoracic aorta. Traditional full CPB also involves a heat exchanger, which decreases the risk of perioperative hypothermia. Left heart bypass is often used during repairs

of the descending thoracic or thoracoabdominal aorta that are distal to the take-off of the left subclavian artery. Left heart bypass does not require an oxygenator, so required heparinization is typically less than that for full CPB. A heat exchanger may be added to the left heart bypass circuit for cases anticipated to be lengthy and thus at higher risk for hypothermia and related bleeding. Left heart bypass diverts blood from the left atrium, left ventricular apex, or left axillary artery to the distal aorta or femoral artery. The rate of blood flow through the left heart bypass circuit should be titrated according to arterial blood pressure monitoring above and below the aortic cross-clamp, and should be slowed as needed to preferentially provide adequate perfusion of the proximal aorta.

Spinal cord protection

Anterior spinal cord ischemia with resultant paraplegia is a major complication of open repairs of descending thoracic and thoracoabdominal aneurysms. In this scenario, motor function typically is lost but the patient may have some sensation. This complication is caused by compromised blood flow through the anterior spinal artery (the major blood supply to the anterior spinal cord) during aneurysm repair, particularly if this occurs for more than 30 minutes. Significant spinal cord ischemia is more likely to occur if collateral blood flow through vessels such as the intercostal arteries also is compromised during aortic repair. The vertebral arteries fuse to become the anterior spinal artery, and as the anterior spinal artery travels down the spinal cord, it collateralizes with the radicular branches of the intercostal arteries. In many patients, one of these radicular branches, often called the great radicular artery of Adamkiewicz, arises at the T8–L4 spinal cord levels and supplies blood to a major portion of the anterior spinal cord (Fig. 78.1). Unfortunately, this vessel is difficult to locate preoperatively with angiography or during surgical inspection.

Several methods have been tried to prevent hypoperfusion of the spinal cord and resulting paraplegia during repair of the descending thoracic aorta. As mentioned previously, some groups use a passive shunt or extracorporeal bypass to provide some distal aortic blood flow to the mid and lower spinal cord or other end organs. However, although logical, the efficacy of this approach is controversial, as a study conducted by Coselli et al. at a center performing a large volume of descending aortic repairs found that left heart bypass did not reduce that center's incidence of perioperative paraplegia. However, a randomized controlled trial conducted by Coselli et al. at the same center supports the efficacy of perioperative cerebral spinal fluid (CSF) drainage through a lumbar spinal drain in preventing paralysis. At many centers, the lumbar spinal drain is placed preoperatively by anesthesiologists. Commercially available spinal drain catheter kits are available. The technique for placement is similar to lumbar epidural catheter placement at the L3–4 or L4–5 interspaces, but larger-diameter hollow needles are typically used to thread the catheter (12 gauge), and the needle is advanced through the epidural space and into the subarachnoid

Figure 78.1. Blood supply of the spinal cord. **(A)** Vertical distribution and **(B)** horizontal distribution of the blood supply. Branches of the vertebral, deep cervical, intercostal, and lumbar arteries contribute to three arteries that run the length of the spinal cord: the anterior spinal and the two posterior spinal arteries. The anterior spinal artery arises at the level of the foramen magnum by the junction of two branches, one from each vertebral artery. Each posterior spinal artery arises from the posterior inferior cerebellar artery at the same level. Twenty-one pairs of segmental radicular arteries supply the nerve roots and about half of them contribute to the spinal arteries. Of these larger branches, the largest is the great anterior radicular artery of Adamkiewicz (radicularis magna), which supplies the lower thoracic and upper lumbar parts of the cord. It usually arises from a lower intercostal or a high lumbar artery but may arise as low as L4 or as high as T8. Because it makes a major contribution to the spinal cord blood supply, spinal injury or aortic surgery may compromise the blood supply of the lower part of the spinal cord. Although the other segmental radicular arteries are small, their contributions to the anterior and posterior spinal arteries are important.

space before the lumbar drain catheter is threaded. The lumbar spinal drain is then connected to a manometer and collection bag (Fig. 78.2). The rationale for CSF drainage is that decreasing the external pressure applied to the spinal cord by surrounding CSF will permit increased arterial perfusion of the spinal cord. Spinal cord perfusion pressure (SCPP) can be monitored by using the lumbar spinal drain to transduce CSF pressure around the spinal cord. The equation for SCPP is mean systemic arterial pressure (MAP) minus CSF pressure or central venous pressure (whichever is higher). Some experts suggest maintaining the intraoperative CSF above 10 mm Hg to prevent intracranial hypotension and potential related complications, such as subdural hematoma formation. Additionally, one must monitor for potential lumbar epidural hematoma formation and resultant spinal cord compression at the spinal drain insertion site, particularly in cases that require full systemic

heparinization or otherwise involve extended periods of perioperative coagulopathy. There is no clear evidence-based timing for when spinal drains should be removed postoperatively, but Coselli et al. have reported removing the drains approximately 48 hours after surgery and replacing the drains if delayed paraplegia occurs. Care should be taken to normalize the patient's coagulation profile prior to placing or removing spinal drains.

If paraplegia is noted in the postoperative period, attempts to reverse it by improving SCPP involve increasing MAP pharmacologically or with volume resuscitation in conjunction with increasing CSF drainage. During the surgery itself, such strategies may also be used if spinal cord hypoperfusion is suspected. Some centers try to detect anterior spinal cord function indirectly or directly during periods of potential hypoperfusion by monitoring somatosensory evoked potentials (SEPs) or motor

Figure 78.2. Intraoperative CSF drainage during thoracoabdominal aortic repair.

evoked potentials (MEPs), respectively. SEPs monitor the brainstem and cerebral cortex response to peripheral nerve stimulation and therefore directly reflect performance of the posterior sensory columns in the spinal cord. However, the assumption is that if the posterior spinal cord is affected, the anterior spinal cord very likely is underperfused as well. Various anesthetic agents, such as volatile anesthetics, may affect the latency and amplitude of SEPs, so the anesthetic plan must be designed with careful communication with the neuromonitoring team. Several centers have successfully monitored MEPs to gauge anterior spinal cord compromise more directly. Although MEPs can reflect the integrity of the anterior motor horns, transcranial stimulation of the motor cortex is required during thoracic aortic surgery and therefore is an approach that is cumbersome and requires considerable expertise. This approach also may trigger seizure activity.

Conclusions and future directions

Anesthesiologists must have a full appreciation for the wide spectrum of issues associated with urgent or emergent surgical repair of the thoracic aorta to provide optimal perioperative management for these surgeries. The past several decades have seen significant developments in both surgical and anesthetic practice that have improved patient morbidity and mortality from surgical repair of the thoracic aorta. Progression in the arena of less invasive endovascular stent repairs of the thoracic aorta has shown great promise. In addition, continued research efforts directed at understanding the acute physiologic changes encountered with interruption of aortic blood flow should aid in development of measures to reduce end-organ damage from associated ischemia or reperfusion.

Cardiac transplantation in the adult

Martina Nowak, Prem S. Shekar, and Michael N. D'Ambra

Cardiac transplantation is the therapeutic procedure of choice for end-stage heart failure patients. Since South African Christiaan Barnard performed the first allogenic orthotopic (human-to-human) heart transplant in 1967, advances in immunosuppression, early diagnosis, and treatment of rejection and infection have transformed a once experimental intervention into routine treatment.

Nevertheless, heart transplantation in the United States has declined over the past 10 years, leveling at approximately 2200 per year in 2007, mainly because of limited donor organ availability.

The vast majority of patients referred for cardiac transplantation suffer from New York Heart Association class III or IV symptoms and carry a diagnosis of ischemic heart disease or idiopathic dilated cardiomyopathy.

After heart transplantation, 30-day mortality ranges from 5% to 10%, with primary graft failure being the most frequent cause of early death. The 1-year survival rate approximates 80%, with an annual mortality rate of 4% for subsequent years. The most common causes of death in the first 6 months are infection and/or rejection. Accelerated coronary artery disease, allograft vasculopathy, chronic rejection, and posttransplant lymphoproliferative disease are causes of late mortality.

Donor selection and matching

A potential donor is declared brain dead by a medical team that had not been involved in the donor's or recipient's care. Donors are screened and evaluated by the local organ procurement agencies, and donor organs are made available to potential recipients via the United Network of Organ Sharing (UNOS). The accepting transplant center may then evaluate the suitability of the allograft. (See [Table 79.1](#) for complete donor selection criteria.) The donor is matched to the prospective recipient for ABO blood type compatibility and heart size (HLA matching has not shown to improve survival but is still done in some centers). A donor heart size within 20% of the recipient's is preferable. If the recipient has elevated pulmonary vascular resistance (PVR), the increased right ventricular (RV) afterload will require a larger RV muscle mass, which will necessitate a larger donor heart. Care must be taken not to oversize the heart for recipients with acute myocardial infarction or a ventricular assist device (VAD).

Anesthesia management issues for heart transplant donors

Donors normally exhibit major hemodynamic and metabolic disturbances, the main causes of which are hypovolemia (secondary to diuretics or central diabetes insipidus), myocardial impairment (as a result of major catecholamine release during periods of increased intracranial pressure), and insufficient sympathetic tone secondary to absence of brainstem function. Neurogenic ST-T-wave changes, as well as neurogenic arrhythmias, are possible. Volume administration and inotropic support should be guided by invasive monitoring and transesophageal echocardiography if available. Hemodynamic goals are a mean arterial pressure of 80 to 90 mm Hg, central venous pressure (CVP) of 5 to 12 mm Hg, urine output > 100 ml/h,

Table 79.1. Donor selection for cardiac transplantation

Suggested criteria for cardiac donor
Age < 55 y
Absence of the following:
Prolonged cardiac arrest
Prolonged severe hypotension
Preexisting cardiac disease
Preexisting pulmonary hypertension (unresponsive to pharmacologic intervention) with PVR > 5 Wood units and transpulmonary gradient > 15 mm Hg
Intracardiac drug injection
Severe chest trauma with evidence of cardiac injury

and normal serum electrolyte levels and arterial blood gas values. Vasopressin administration (0.8–1.0 U/h) might become necessary to limit volume loss from diabetes insipidus. Administration of anesthetic agents to the donor is controversial but recommended to blunt systemic stress responses mediated by functional components of the brainstem, spinal cord, and sympathetic and parasympathetic nervous systems.

Myocardial protection of the donor heart

The donor heart is usually protected with University of Wisconsin (UW) cold crystalloid hyperkalemic cardioplegia during the cardiectomy. The organ is then transported in two sterile plastic bags filled with ice-cold UW solution and carried in an ice chest. The present limit for ex vivo ischemia time is approximately 4 to 6 hours, but new technology to prolong this limit beyond 24 hours is in clinical trials. Prolonged cold ischemia time in conjunction with acute reperfusion injury may lead to tissue necrosis with a fatal outcome, most commonly manifested by RV failure.

Selection and preanesthesia assessment of the recipient

The basic objective of the selection process is to identify patients with end-stage cardiac disease refractory to medical therapies who possess the potential to resume a normal active life and maintain compliance with a rigorous medical regimen after cardiac transplantation.

Each candidate awaiting cardiac transplantation is assigned a *status code* based on UNOS criteria that corresponds to how medically urgent the transplant is:

IA: A patient who has *at least one* of the following in place:

- Total artificial heart
- Left and/or right ventricular assist device (LVAD/RVAD; Elective 1A time for 30 days)
- Intra-aortic balloon pump
- Extracorporeal membrane oxygenator
- Mechanical circulatory support for more than 30 days with significant device-related complications
- Mechanical ventilation
- Continuous infusion of two high-dose inotropes in addition to continuous hemodynamic monitoring of left ventricular filling pressures
- Life expectancy without transplant of < 7 days

IB: A patient who has *at least one* of the following devices or therapies in place:

- LVAD and/or RVAD
- Continuous infusion of intravenous (IV) inotropes not meeting the preceding criteria

II: All other waiting patients who do not meet Status Code IA or IB criteria.

Because the preoperative period is often marked by critical time constraints, a focused history including last oral intake,

allergies, recent anticoagulant use, recent change in ventricular function, and/or anginal symptoms should be obtained. Physical examination should focus on cardiopulmonary signs of congestive heart failure, airway and access issues, and volume status. A preoperative chest radiograph, as well as a laboratory review, should be examined by the anesthesiologist. Many patients will be admitted on warfarin with therapeutic international normalized ratio levels, and the anesthetic plan will need to address anticoagulation reversal.

Once the organ procurement team has confirmed the acceptability of the donor allograft, the recipient induction may begin. Timing (which is routinely controlled by the harvesting team) is crucial to minimize allograft ischemic time and recipient bypass time. Ideally, the recipient cardiectomy is completed concurrent with the arrival of the cardiac allograft. Catheter placements may be difficult and prolonged because of previous surgery, catheterizations, interventions, and medical care. Be sure to communicate anticipated line placement difficulties.

Anesthesia management of the recipient

The heart transplant recipient is usually very anxious and requires reassurance. If an extended wait is required in the operating room (OR) before induction, consider allowing the patient to use a phone in the OR to speak with close family and significant others. In addition to standard noninvasive monitors, placement of an arterial catheter is required to facilitate a rapid response to hemodynamic events during induction. Symptomatic ventricular tachycardia or fibrillation is the most common cause of sudden cardiac death in patients awaiting heart transplantation and is most common within the first 3 months after referral for transplantation. Therefore, many patients will have an automatic implantable cardioverter-defibrillator (AICD) in place and/or a history of amiodarone use. For that reason, external defibrillation patches are placed before induction. It is important to know what the device setting is for external magnet placement (usually turns off arrhythmic therapy and maintains pacing at a default setting).

Most patients should be considered “full stomach.” Therefore, a rapid-sequence induction technique using agents with minimal myocardial depression (etomidate 0.3 mg/kg) and a moderate dose of opioids (fentanyl 10 µg/kg) as well as succinylcholine (1.5 mg/kg) have been used successfully. Inotropic and vasoactive agents should be readily available for the rapid management of induction-induced hypotension and/or arrhythmias. Pre- or postinduction central venous access is obtained (preferably avoiding right internal jugular vein cannulation, which will be used for frequent endomyocardial biopsies postoperatively). A pulmonary artery (PA) catheter can be placed into an introducer, but floating the PA catheter into correct position may be difficult because of cardiac chamber dilation, severe tricuspid regurgitation, VAD cannulae, and AICD hardware. Because the PA catheter will be withdrawn to implant the new heart, it is not a major problem to leave the catheter in the CVP position before cardiopulmonary bypass (CPB). Large-bore IV access is mandatory. Meticulous attention should

be paid to sterile technique during all invasive procedures, as these patients are at high risk for postoperative infection, which remains a serious cause of postoperative mortality. A first-generation cephalosporin or vancomycin is administered prior to skin incision.

Anesthesia is maintained with high-dose narcotics and volatile anesthetics. Cross-matched blood (irradiated) should immediately be available once surgery commences. Prior to CPB, the PA catheter should be withdrawn from the right heart and secured in its sterile sheath. It will be refloated after completion of the venacaval anastomoses prior to coming off CPB. Arterial and venous CPB cannulation is performed depending on the surgical technique (see [Chapter 73](#)). Aminocaproic acid currently is the antifibrinolytic of choice.

Weaning from CPB may be difficult and prolonged because of acute RV failure, bleeding, and/or hemodynamic instability. The initial bradycardia encountered post bypass should be treated with an infusion of a positive chronotropic agent (isoproterenol or dopamine) or atrial pacing to achieve a heart rate between 90 and 110 bpm. Patients with elevated PVR are at risk for acute RV failure and may benefit from the preemptive use of a low-dose pulmonary vasodilator such as prostaglandin E₁ (0.125–1.0 nanograms/kg/min) during the period of CPB or inhaled nitric oxide. Transesophageal echocardiography (TEE) can provide immediate information about right and left heart function and filling volumes and also assess for restricted anastomotic flow.

Frequently, hemostasis is problematic, and appears related to suppression of clotting factors often exacerbated by preoperative warfarin therapy. Preprotamine warfarin reversal with fresh frozen plasma (FFP) in the CPB circuit may be helpful if the patient is fully anticoagulated upon arrival to the OR. Commonly, FFP, cryoprecipitate, platelets, and, in severe post-CPB hemorrhage, recombinant factor VIIa are administered to normalize coagulation.

Orthotopic heart transplantation

Operative techniques in the recipient are shown in [Fig. 79.1](#).

The surgery begins with a median sternotomy. Frequently, patients will have undergone prior cardiac surgeries. In this case, the groin is prepared and draped to provide rapid access for cannulation to initiate CPB if necessary. The aorta is cannulated as distally as possible, and the superior vena cava and inferior vena cava are cannulated separately. After aortic cross-clamping, the aorta and PA are separated and divided just above the level of their respective valves, and the atria are transected at their grooves.

A complete excision of the right atrium with bicaval anastomoses is the practiced variant of the classic technique described previously and is reported to reduce the incidence of atrial dysrhythmias, better preserve cardiac function by avoiding tricuspid regurgitation, and enhance cardiac output by enhancing right atrial function.

The donor graft is then implanted beginning with the left atrial anastomosis, followed by the aorta. The aortic

cross-clamp can be removed while the right-sided anastomoses are carried out. The heart is meticulously de-aired using TEE guidance and then weaned from CPB.

Transesophageal echocardiography

A complete TEE examination may be performed post induction and often reveals useful information not immediately available from other sources, such as the presence of cardiac thrombi, ventricular volume and contractility, and atherosclerosis of the descending aorta. To assess the ascending aorta and the aortic arch for appropriate cross-clamp and cannulation sites, epicardial echocardiography is performed.

Posttransplant management and complications

In the past, a total reverse-isolation environment was maintained in the intensive care unit, but this practice has been replaced by universal precautions. Postoperative monitoring is the same as for all open heart patients. Mechanical ventilation is generally required for up to 24 hours, but extubation is accomplished as soon as possible to minimize infection. Meticulous sterility of all intravascular catheters, suction catheters, and equipment connected to the respirator is maintained. Immunosuppressive therapy is continued. Inhaled nitric oxide can be used to decrease PVR in the face of RV compromise. Severe RV dysfunction refractory to medical therapies may require placement of a mechanical assist device (e.g., RVAD).

The primary etiology for posttransplant RV failure is an increased PVR from preexisting left heart failure. These changes in the pulmonary vasculature are not totally fixed and may normalize with time.

Mediastinal reexploration for bleeding may be required in the immediate postoperative period. Most patients exhibit a mild deterioration in renal and hepatic function, as determined by blood chemistries.

Rejection and antirejection strategies

Hyperacute rejection results from preformed donor-specific antibodies in the recipient. Because of preoperative ABO blood group matching and panel-reactive antibody screening, hyperacute rejection has become a rare but nonetheless catastrophic complication that occurs within minutes to hours.

Immunosuppression following transplantation consists of an early induction phase followed by a long-term maintenance phase. The immunosuppressive regimen at our institution begins with methylprednisolone, 1000 mg IV preoperatively and methylprednisolone/prednisone, cyclosporine, and mycophenolate postoperatively. Because the nephrotoxic effects of cyclosporine place the recipient at increased risk for renal insufficiency, doses should be adjusted in preexisting renal insufficiency.

The gold standard for the diagnosis of acute rejection remains an RV endomyocardial biopsy through the right internal jugular vein. Early signs of impending graft rejection

Figure 79.1. Mediastinum after excision of the heart but prior to allograft placement. (A) Classic orthotopic technique. (B) Bicaval anastomotic technique.

include a drop in voltage in leads I, II, III, V₁, and V₆ in serial electrocardiograms; abnormal gallop rhythms; urinary output and weight changes; and fever.

Corticosteroids are the cornerstone of acute antirejection therapy. Rescue protocols for recurring or refractory rejection include methylprednisolone plus OKT3 polyclonal antibody therapy, or methotrexate.

Anesthetic management of the patient with a denervated heart

Cardiac denervation is an unavoidable consequence of heart transplantation. A transplanted heart responds atypically to exercise and to certain cardioactive drugs, effects of which are

thought to primarily be a result of the lack of direct neuronal control of the allograft.

Denervation substantially alters the response to demands for increased cardiac output. Normally, an increased heart rate can rapidly increase cardiac output. This mechanism is not available in the denervated heart. Heart rate increases only gradually with exercise, an effect mediated mainly by circulating adrenal catecholamines. Increases in cardiac output in response to increased demands are mediated mainly via increased stroke volume. Therefore, maintaining an adequate preload in cardiac transplant recipients is crucial. In certain cases, both donor and recipient sinoatrial nodes are intact and functioning. P waves originating from both sources may be recorded with the recipient's neurally mediated responses intact.

Denervation has important implications for pharmacologic therapy. Drugs that act indirectly through the autonomous nervous system, such as ephedrine, atropine, pancuronium, and edrophonium, generally will be ineffective. Anticholinergic drugs should not be used to treat bradycardia in the setting of hypotension. Hypotensive patients with denervated hearts will respond to anticholinergics, with vasodilation lacking a compensatory tachycardic response and leading to worsening hypotension. Drugs with a mixture of direct and indirect actions will exhibit only their direct heart rate effects (e.g., tachycardia with norepinephrine). The hemodynamic drugs of choice in the transplanted heart are those with direct cardiac effects, such as epinephrine and isoproterenol, dopamine, and dobutamine.

The resting bradycardia in the immediate posttransplant period is probably secondary to sinus node dysfunction and graft-based parasympathetic ganglia and should be treated with a dopamine or isoproterenol infusion or atrial pacing. This bradycardia may persist for up to 7 days postoperatively. Eventually, the resting heart rate of the transplanted heart in the absence of vagal tone is between 90 and 110 bpm. The normal sympathetic responses to laryngoscopy and intubation are absent.

Summary

The anesthetic management of heart transplant patients calls into play all the skill sets of the perioperative physician, ranging from careful attention to managing the psychological stress of the waiting time before induction, to the invasive pharmacology

associated with treating life-threatening pulmonary hyper-resistance and right heart failure.

Persistent postoperative bleeding in cardiac surgical patients

Walter Bethune, Michael G. Fitzsimons, and Edwin G. Avery IV

Excessive bleeding after cardiopulmonary bypass (CPB) is associated with cardiac surgical morbidity and mortality. The overall incidence of excessive bleeding after cardiac surgery, commonly defined as the need to transfuse more than 10 U of allogeneic blood in the perioperative period, is commonly reported to be 3% to 5%. Approximately 2% to 4% of patients after CPB require surgical exploration, primarily because of excessive bleeding. Bleeding and surgical reexploration are both established independent predictors of adverse outcomes. Administration of blood products, in the absence of reexploration, may place the patient at risk for transfusion-related complications. Anesthesiologists caring for cardiac surgical patients must understand the risk factors, clinical presentation, diagnosis, and treatment of bleeding after cardiac surgery.

Definition

There is no uniformly accepted definition for excessive bleeding after cardiac surgery. Most patients will demonstrate some bleeding (0.5–1.0 ml/kg/h) within the first 6 hours after surgery. Bleeding in excess of 8 to 10 ml/kg/h generally prompts immediate surgical intervention if there is no response to blood products. Our institutional guideline, based on experience, is that bleeding should not be > 500 ml in the first hour, 400 ml/h for the first 2 hours, 300 ml/h for 3 hours, or 200 ml/h for the first 4 hours. Bleeding in excess of these numbers should prompt strong consideration of surgical reexploration in a normothermic patient, especially if the patient is hemodynamically unstable or if bleeding persists after correction of any coagulopathy.

Risk factors

Risk factors for excessive or persistent bleeding after cardiac surgery may be considered patient specific or surgery specific (Table 80.1). Patient-specific factors include female sex, preoperative cardiogenic shock, renal failure, small body mass, renal insufficiency, and certain preoperative anticoagulants or antiplatelet therapies. Surgery-specific factors include emergency procedures and more complicated heart operations, such as “redo” procedures; combined operations, such as coronary

artery bypass graft (CABG) surgery with valve replacement; and notably, the duration of CPB.

Clinical presentation

Some degree of bleeding after cardiac surgery is expected. Surgeons place chest tubes and mediastinal drains to allow close monitoring of this bleeding and to prevent the complications of concealed blood collection (i.e., cardiac tamponade).

External or free bleeding is evident in the patent, graduated drainage collection system. Blood and fluid that accumulate in the mediastinum from disrupted tissues and suture lines are drained via tubes placed during surgery. Mild bleeding should respond readily to volume replacement. Therefore, it is imperative that the patency of the drainage system be maintained to prevent tamponade and allow an ongoing assessment of blood loss. The color of the drained blood may shed light on the etiology. Blood that is bright red may indicate arterial bleeding from the bed of the internal mammary artery, intercostal arteries or suture lines on the aorta, left atrium, pulmonary veins, or left heart. Darker blood may indicate venous oozing from the chest wall or suture lines on right-sided structures such as the atrial appendage or vena cava. Dilute drainage results from third spacing of fluid in the thoracic cavity.

Concealed bleeding does not appear in the drains. It may result in the accumulation of blood in the pleural or mediastinal space that can simultaneously compromise ventilation or

Table 80.1. Risk factors associated with postoperative bleeding

Patient-specific	Surgery-specific
Female sex	Emergency surgery
Renal insufficiency	“Redo” procedures
Increased age	Combined procedures
Poor nutrition	Long duration of cardiopulmonary bypass
History of excessive bleeding	Excessive operative bleeding
Smaller body mass index	
Preoperative cardiogenic shock

hemodynamics, ultimately leading to tamponade. This clinical scenario does not respond as readily to volume replacement and may require surgical reexploration. Chest radiography may demonstrate a widened mediastinum. Transesophageal echocardiography (TEE) may demonstrate classic tamponade or, more commonly, focal compression by hematoma.

A sudden increase in the rate of bleeding, especially in a patient with relatively normal coagulation test parameters who was not bleeding initially, suggests a surgical etiology, as does the presence of clotted blood in the patient's chest tubes. Diffuse, widespread oozing from the skin incision and intravenous catheter sites, however, suggests a platelet abnormality or disseminated intravascular coagulation. Failure of blood within the mediastinal tubes to clot suggests either a platelet or significant coagulation factor abnormality, or both.

Differential diagnosis and pathophysiology

In caring for the patient suffering from excessive bleeding early after cardiac surgery, high priority is given to determining whether the bleeding is attributable to a surgical cause (i.e., tissue injury with inadequate surgical hemostasis or leaking suture lines) or to coagulopathy (i.e., microvascular bleeding). Coagulopathies that may contribute to excessive bleeding may be divided into those related to platelet abnormalities (dilution, depletion, or dysfunction) or clotting factor abnormalities related to inadequate heparin administration during CPB, heparin rebound, or fibrinolysis.

Complicating the diagnosis is the fact that prolonged “surgical” bleeding will inevitably lead to platelet and clotting factor depletion and an associated secondary coagulopathy. Significant causes of postoperative blood loss are listed in Fig. 80.1. Additionally, hypothermia may exacerbate coagulopathy related to either platelet or clotting factor abnormalities.

Figure 80.1. Causes of bleeding after CPB.

Preoperative anticoagulation

Platelet abnormalities, either quantitative or qualitative, are the most common causes of postoperative bleeding after surgical procedures using CPB. Patients often receive antiplatelet and antithrombotic agents in the setting of an acute coronary syndrome. These agents may include aspirin, glycoprotein (GP) IIb/IIIa receptor antagonists (tirofiban, abciximab, and eptifibatide), inhibitors of platelet adenosine diphosphate (clopidogrel and ticlopidine), low molecular weight heparins (LMWHs), ultra-pure LMWH (fondaparinux), and warfarin (Table 80.2). Not all have been implicated in increasing the risk of bleeding after cardiac surgery.

Despite numerous retrospective and prospective analyses, it is still controversial as to whether aspirin alone before CABG surgery is associated with an increased risk of postoperative bleeding. The consensus regarding aspirin therapy is that by itself it does not put cardiac surgical patients at increased risk for excessive hemorrhage.

The contribution of newer, more potent antiplatelet agents such as adenosine diphosphate (ADP) receptor antagonists and GP IIb/IIIa inhibitors may increase the risk of postoperative bleeding after cardiac surgery. The consensus is to delay surgery for at least 5 days after cessation of clopidogrel therapy to decrease the risk of excessive hemorrhage after cardiac surgery, if such a delay is clinically feasible.

Abciximab, a GP IIb/IIIa receptor antagonist, is often used to reduce ischemic complications in patients undergoing percutaneous coronary revascularization. Although there is concern regarding increased bleeding risk among the subset of these patients who later require urgent CABG, delaying surgery for at least 24 hours in abciximab-treated patients and for at least 6 hours in tirofiban-treated patients, if clinically feasible, presently is recommended. Enoxaparin used alone is associated with greater overall blood loss and a higher incidence of mediastinal reexploration compared with clopidogrel. The current consensus is to delay cardiac surgery for at least 12 hours in patients who have received LMWH, if clinically feasible.

Patients presenting for cardiac surgery commonly are taking antithrombotic medications in the setting of having in situ artificial valves, atrial fibrillation, or a pulmonary embolism. There is no standard protocol for the cessation of these agents that is guaranteed not to increase the risk of bleeding. The use of warfarin and aspirin has been shown to increase bleeding and the duration of chest drainage. Warfarin generally is stopped 4 to 5 days prior to scheduled surgery.

Bridging agents such as unfractionated heparin (UFH) or LMWH are commonly initiated to prevent thrombosis. Enoxaparin, an LMWH, has been shown to increase mediastinal blood loss and the need for exploration after bypass. Conversion of longer-acting antithrombotic agents (e.g., warfarin or LMWH) to parenteral UFH or direct thrombin inhibitor therapy may provide adequate perioperative anticoagulation if dosing is timed appropriately to the conduct of surgery.

Table 80.2. Drugs that increase perioperative bleeding

Drug	Inhibits	Half-life	Duration of effects	Reversible effects?	Methods to restore function
Aspirin	COX	15–20 min	7 d	No	Platelet transfusion
Abciximab (ReoPro ^a)	GP IIb/IIIa receptor	30 min	48 h	Yes	Platelet (partial) transfusion
Eptifibatid (Integrilin ^b)	GP IIb/IIIa receptor	2.5 h	4–8 h	Yes	Delay surgery 2 h after stopping drug
Tirofiban (Aggrastat ^c)	GP IIb/IIIa receptor	1.5–3 h	4–8 h	Yes	Discontinue drug ASAP before surgery
Clopidogrel (Plavix ^d)	ADP receptor	8 h	7 d	No	Blood product transfusion as needed
Ticlopidine (Ticlid ^e)	ADP receptor	12 h to 5 d with repeat dosing	7 d	No	Blood product transfusion as needed
Dipyridamole (Persantine ^f)	Adenosine uptake; PDE	9–13 h	4–10 h	Yes	Platelet transfusion
Cilostazol (Pletal ^g)	PDE III	11–13 h	48 h	Yes	Blood product transfusion as needed
Herbal therapies	Platelet aggregation	Variable	Variable	Variable	Limited data available

Effects of cardiopulmonary bypass on coagulation

CPB affects all elements of the coagulation system, although platelet number and function appear to be the most severely affected. Three factors contribute to a decrease in platelet count while on CPB: dilution, sequestration within the spleen, and destruction. Initiation of bypass results in a dilutional thrombocytopenia related to the volume of pump-priming solution. Hypothermia, commonly utilized for myocardial and vital organ protection, results in a sequestration of platelets within the spleen.

Platelets are also vulnerable to shear stress injury from field suction, roller pumps, balloon bumps, and simple contact with elements of the bypass circuit. Furthermore, regardless of the platelet count, platelet dysfunction in cardiac surgical patients historically has been attributed to CPB-induced platelet activation with subsequent loss of receptors for von Willebrand factor and fibrinogen. Consequently, platelet transfusion has become the primary therapy for nonsurgical (microvascular) bleeding after operations involving CPB.

Prolonged blood contact with the artificial surface of the CPB circuit is known to activate the contact activation and intrinsic coagulation pathways, eventually leading to thrombin formation and consumption of soluble coagulation proteins. CPB requires anticoagulation to prevent blood from clotting within the bypass circuit. UFH is administered to amplify antithrombin III action and prevent thrombin formation. In our

center, 350 U/kg of heparin is administered prior to CPB. Additional bolus doses are administered as required to achieve and subsequently maintain the activated clotting time (ACT) values at or above 480 seconds, although this varies among centers. The effects of UFH may persist into the postoperative period, and the activated partial thromboplastin time (aPTT) assay is useful to detect residual heparin effects in cardiac surgical patients.

Protamine sulfate is administered after completion of CPB to reverse heparin-induced anticoagulation. Protamine forms a stable 1:1 complex with heparin, rapidly (<10 minutes) neutralizing its anticoagulant activity. Protamine has a short half-life (~5 minutes), and the effects of UFH may often recur, which is commonly referred to as “heparin rebound.” A protamine administration protocol based on plasma heparin concentration measured at the end of CPB has been shown to reduce bleeding into the postoperative period. Commonly, UFH is neutralized empirically with anywhere from 0.5 to 1.3 mg of protamine for every 100 U of UFH administered. Practice patterns vary according to institution, and recently published blood therapy guidelines suggest that lower doses of protamine may help reduce hemorrhage following cardiac surgery.

Blood contact with the foreign CPB surface results in direct extrinsic activation of fibrinolysis. This is caused primarily by the release of tissue plasminogen activator from the vascular endothelium throughout CPB. Thrombin formation, hypothermia, and traumatized endothelial cells also may contribute to fibrinolysis. Unrestricted CPB-mediated thrombin activity and

fibrinolysis ultimately lead to consumption of coagulation factors and platelets, further contributing to bleeding.

Finally, CPB induces an intensive activation of the inflammatory system, leading to leukocyte activation. Activated leukocytes release inflammatory mediators that, in turn, activate monocytes, ultimately bringing about tissue factor (TF) expression, thrombin generation, and paradoxical activation and impairment of the coagulation system in many patients.

Surgical factors

The type of surgery and conductance of bypass itself contributes to bleeding after surgery. The combination of a valve repair/replacement with bypass grafting or aortic surgery increases bleeding, as do repeat procedures. Surgeons are vigilant of the common sites of bleeding after cardiac surgery. Cannulation sites such as the right atrial appendage, pulmonary veins, ascending aorta, and vena cava commonly exhibit some minor bleeding after surgery. Other sites, such as the bed of the internal mammary artery, sternum, and anastomosis sites, may exhibit oozing immediately after surgery.

Most surgeons are diligent in examining the mediastinum and thoracic cavity prior to chest closure, but hypertension after surgery may disrupt formed clot. Although the advent of minimally invasive procedures is felt to decrease these risks, this may not be the case, as such patients may exhibit more postoperative blood loss. The duration of CPB has been shown to be strongly associated with transfusion requirements and bleeding after surgery.

Workup

Clinical examination

The evaluation of a bleeding patient in the postoperative setting begins with a detailed clinical history and targeted examination. The rate of bleeding must be determined, and all drains and wound sites should be assessed for the presence of clot. Hemodynamic variables must be considered; hypotension combined with tachycardia, low central venous pressure (CVP), low filling pressures, and a low cardiac index indicates hypovolemia, whereas hypotension combined with an elevated CVP, decreased cardiac index, and equalization of pulmonary artery pressures may indicate concealed bleeding, potentially resulting in cardiac tamponade. The differential diagnosis of tamponade also includes right, left, and biventricular heart failure.

Chest radiography is commonly employed to evaluate for blood collection in the mediastinum; however, its diagnostic value is poor. Only 20% of chest radiographs met the criteria for an enlarged cardiac silhouette, whereas 86% demonstrated an effusion with echocardiography.

TEE is gaining widespread acceptance among physicians in determining the cause of hemodynamic instability in the postoperative setting. In a study of 301 patients requiring TEE in the intensive care unit (ICU), TEE had a direct therapeutic impact in 73% of the cases. Tamponade was diagnosed in 11% and excluded in 12%.

Laboratory and point-of-care testing

Essential elements of the initial laboratory evaluation of the patient bleeding after surgery include the hemoglobin/hematocrit, platelet count, prothrombin time–international normalized ratio (PT-INR), aPTT, and fibrinogen also may be useful. The ACT is widely used to monitor heparin therapy during CPB but is less sensitive than the aPTT to residual heparin concentration post-CPB, limiting its utility in the postoperative setting.

Transient platelet dysfunction is considered the most common and important defect in hemostasis in the early postoperative period. The platelet count from the complete blood count does not necessarily reflect platelet function. Point-of-care (POC) assays are tests performed at the patient's bedside that evaluate coagulation abnormalities without the time delay associated with central laboratory analysis.

Thromboelastography (TEG) is a viscoelastic measure of clot formation and clot dissolution that measures coagulation, platelet function, platelet–fibrinogen interactions, and fibrinolysis. The TEG maximum amplitude parameter has been shown to be more predictive of bleeding after cardiac surgery than other isolated POC tests of platelet function, such as the platelet-activated clotting test or routine coagulation tests such as the platelet, PT, and aPTT. In a randomized, blinded, prospective trial, Shore-Lesserson et al. randomly assigned cardiac surgical patients to either a TEG-guided transfusion algorithm (n = 53) or routine transfusion therapy (n = 52) for intervention after CPB and showed that the algorithm using TEG was effective in reducing transfusion requirements over the first 2 days postoperatively.

Multiple POC assays that evaluate platelet function have been developed. Most preliminary investigations of their potential role in the postoperative management of cardiac surgical patients have shown favorable results, although the full utility of POC testing for patient management in this setting remains to be demonstrated by large randomized controlled trials.

Management

Persistent postoperative bleeding must be managed by providing the appropriate therapy based on the etiology of the blood loss. A bleeding diathesis must be differentiated from a surgical cause requiring urgent reoperation. Instability not responding immediately to volume expansion should prompt immediate reexploration. Management consists of two goals, return of hemodynamic stability and correction of underlying coagulopathy.

Fluids

In the setting of excessive postoperative bleeding, colloids and/or crystalloids should be administered as needed to maintain intravascular volume and hemodynamic stability without worsening coagulopathy. All fluids should be delivered through a warmer to avoid worsening hypothermia. No clear data exist to justify the use of normal saline over Ringer's lactate for

volume expansion. Likewise, the benefits of colloid administration for volume expansion are unclear. Hetastarch has been implicated in postoperative bleeding when administered during bypass. A meta-analysis of studies investigating the link between synthetic starch administration and bleeding in cardiac surgery patients has confirmed that use of these solutions significantly increases bleeding.

Blood products

Blood products are the primary means of treatment for postoperative bleeding after cardiac surgery. Red blood cells, platelets, fresh frozen plasma, prothrombin complex concentrates, and/or cryoprecipitate may be necessary, depending on the specific coagulation defect. In practice, the decision regarding when to transfuse must take into account not only numbers but also individual patient characteristics and the anticipated physiologic effects of continued blood loss, including ongoing consumption of coagulation factors and inadequate circulating blood volume.

There is no universally accepted hemoglobin level that demands transfusion. The Society of Thoracic Surgeons and Society of Cardiovascular Anesthesiologists note that red blood cell transfusion for hemoglobin levels < 6 g/dl is reasonable and may be lifesaving. Transfusion for hemoglobin levels < 7 g/dl may also be reasonable, although the data are less clear.

Surgical patients with microvascular bleeding generally do not need platelet transfusion if the platelet count is $> 100,000/\mu\text{l}$ but usually do need transfusion for a count $< 50,000/\mu\text{l}$. Current and anticipated bleeding should dictate transfusion when the count is between 50,000 and $100,000/\mu\text{l}$. These recommendations are based largely on expert opinion, with little available evidence to guide platelet transfusion in any setting, including the perioperative state.

Fresh frozen plasma should be transfused only as needed to correct specific coagulation factor deficiencies. In cardiac surgical patients, these deficiencies are caused most commonly by dilution secondary to large-volume transfusion. Other causes include warfarin therapy, liver dysfunction, and consumptive coagulopathy. Whenever possible, purified specific factors (instead of plasma) should be administered to patients with single-factor inherited deficiencies who undergo CPB.

Cryoprecipitate, which contains predominantly fibrinogen, factor VIII, von Willebrand factor, factor XIII, and fibronectin, should be used only to treat specific deficiencies of these factors.

Pharmacologic agents to decrease postsurgical bleeding

Several pharmacologic agents are available to treat persistent postoperative bleeding. Tranexamic acid and ϵ -aminocaproic acid are synthetic lysine analogues that exert their antifibrinolytic effect by displacing plasminogen from fibrin. Desmopressin, an analogue of arginine vasopressin, reduces bleeding by increasing plasma concentrations of factor VIII and von Willebrand factor, thus promoting platelet function.

Recombinant activated factor VII (rVIIa) forms a complex with available tissue factor to activate factor X directly and induce thrombin generation. Recently published guidelines suggest that rVIIa may be considered if administration of blood component therapy fails to reduce bleeding.

Both ϵ -aminocaproic and tranexamic acids have been shown to reduce bleeding and the need for allogeneic transfusion in heart surgery patients. Although there are potential benefits from the administration of ϵ -aminocaproic acid and tranexamic acid during surgery, these conclusions cannot be immediately applied when these drugs are started after surgery. No randomized, controlled, blinded studies are available to support the initiation of antifibrinolytic therapy in the postoperative period.

Desmopressin acetate has not been shown to be of benefit if administered in a prophylactic fashion during cardiac surgery, but it is not unreasonable in patients with excessive bleeding after bypass, especially in those with conditions known to respond (uremia, bypass-induced platelet dysfunction, or von Willebrand's disease).

Recombinant activated factor VII (rVIIa) may be effective in the treatment of patients with uncontrolled postoperative hemorrhage after thoracic surgery. Potential drawbacks include a risk of thrombosis and the agent's expense (approximately \$4500 for a single dose). Appropriately designed studies to establish the safety of this biologic in cardiac surgical patients do not presently exist.

Resternotomy

Excessive postoperative bleeding or profound hypotension unresponsive to volume and pharmacologic resuscitation – suggesting a significant concealed hemorrhage causing hypovolemia and/or cardiac tamponade – is an indication for immediate surgical reexploration of the chest either in the ICU or in the operating room. In patients undergoing cardiac surgery, rates of reoperation for bleeding vary between 3% and 14%, with approximately 5% of all patients requiring reoperation in the early postoperative period; a surgically correctable source of bleeding is found in 50% to 67% of these patients.

The rates of reexploration, however, are substantially declining. In addition to its association with an adverse effect on patients' morbidity and mortality, bleeding requiring reexploration consumes considerable resources as a result of increased operative time, blood product use, and prolonged ICU and total hospital stays. Reoperation in the ICU, as opposed to the operating room, has been shown to be associated with decreased total hospital charges, quicker time to intervention, and no increase in the wound infection rate compared with no reoperation.

Important points

Important points are as follows:

1. Excessive bleeding is associated with increased morbidity and mortality after heart surgery.

2. Risk factors for excessive bleeding after cardiac surgery include female sex, reoperation, combined procedures, longer duration of CPB, hypothermia, preoperative administration of anticoagulants, renal insufficiency, excessive bleeding during surgery, emergency surgery, and smaller body index.
3. No uniform accepted definition for excessive bleeding after cardiac surgery exists, but bleeding that exceeds 10 ml/kg in the first postoperative hour or an average of >5 ml/kg in the first 3 postoperative hours is abnormal and has been suggested as an indication for reexploration.
4. Bleeding after cardiac surgery can be externally manifested as hypovolemia and continued fluid requirements, or concealed bleeding presenting as tamponade.
5. Preoperative medications such as aspirin, GP IIb/IIIa inhibitors, platelet ADP antagonists, LMWHs, and warfarin may be associated with excessive bleeding after cardiac surgery.
6. CPB may contribute to dysfunction of the hemostatic system through platelet activation, depletion, and hemodilution. CPB may also initiate consumption of coagulation factors, activation of fibrinolysis, and stimulation of the inflammatory system, resulting in a cascade of coagulation and fibrinolysis.
7. Evaluation of bleeding after CPB surgery primarily involves the determination of whether bleeding is surgical or microvascular.
8. Prolonged “surgical” bleeding inevitably leads to platelet and clotting factor depletion and an associated secondary coagulopathy.
9. Chest radiograph analysis is inadequate to evaluate for evidence of concealed bleeding or tamponade. TEE is an increasingly used technique to determine the presence or absence of tamponade after cardiac surgery.
10. Essential elements of initial laboratory analysis of the bleeding patient include PT-INR, aPTT, platelet count, fibrinogen, hemoglobin, and hematocrit.
11. Point of care tests (studies performed at a patient’s bedside) avoid the delay associated with central laboratory studies. POC tests are increasingly being used to determine the etiology of bleeding after surgery and employed as part of transfusion algorithms to reduce the administration of allogeneic blood products.
12. The decision regarding when to transfuse must take into account not only numbers and formulaic thresholds but also individual patient characteristics and the anticipated physiologic effects of continued blood loss and inadequate circulating blood volume.
13. No randomized, controlled, blinded studies are available to support the initiation of antifibrinolytic therapy in the

postoperative period, but the literature provides support for the pre-CPB administration of antifibrinolytics to reduce blood loss and for the administration of blood products.

Vascular Anesthesia

Simon Gelman and Stanley Leeson, editors

Carotid endarterectomy

Brian J. Gelfand and Stanley Leeson

Since the introduction of carotid endarterectomy (CEA) for the management of carotid occlusive disease (Fig. 81.1) in the 1950s, the procedure has waxed and waned in popularity, progressively refining its role with the emergence of objective evidence-based support. Operative management of carotid artery stenosis by CEA demands the anesthesiologist's full appreciation of the pathophysiology involved as well as diligent attention to the associated comorbidities of this challenging patient population. CEA can reduce the risk of a fatal or disabling stroke in a selected patient group, but the surgical risk must not outweigh the potential benefits.

Surgical approach

The proper positioning of the patient prior to surgical incision cannot be understated. The patient should be supine with the head comfortably turned toward the nonoperative side, with the patient's neck slightly extended by placement of a roll underneath the shoulders. The anesthesiologist should be aware that hemodynamic instability might result from stimulation of the carotid sinus, presenting as sudden onset of marked bradycardia and severe hypotension. The carotid sinus is located at the carotid artery bifurcation by the initial dilatation of the internal carotid artery. This region contains abundant baroreceptors, which are innervated by the sinus nerve of Hering (Fig. 81.2). This branch of the glossopharyngeal nerve (cranial nerve [CN] IX) synapses in the nucleus tractus solitarius in the brainstem medulla, and its vagal efferents modulate autonomic control of the heart and vasculature.

The surgeon may inject lidocaine 1% into the tissue at the carotid bifurcation to attenuate the afferent limb of this reflex, and the anesthesiologist may administer atropine or glycopyrrolate to diminish the effect of the vagal parasympathetic efferent effects associated with manipulation of this region. The carotid sinus must be differentiated from the carotid body, which also lies within the area of the carotid artery bifurcation. In contrast to the carotid sinus, the carotid body contains a cluster of chemoreceptors, which are sensitive to changes in the composition of arterial blood. Unlike the central brainstem chemoreceptors that are primarily sensitive to changes in CO₂, the type I glomus cells of the carotid body are principally sensitive to changes in the partial pressure of oxygen and increase their output at partial pressures below 100 mm Hg. To a lesser

degree, increases in partial pressure of CO₂ and decreases in pH may elicit an increase in glomus activity. These changes are transmitted to the medullary respiratory centers via glossopharyngeal (CN IX) and vagal (CN X) afferents.

Shunting

The decision to use a shunt during CEA still is a focal point of considerable debate. The primary advantage of using a shunt is that during the endarterectomy, ipsilateral cerebral blood flow is continued. Studies have demonstrated that 10% to 15% of patients will have inadequate perfusion crossover to prevent evidence of cerebral ischemia. Without adequate ipsilateral perfusion pressure, cerebral infarction would result. Shunt placement is not without its risks and potential complications; errant placement may result in occlusion or carotid dissection, embolization may occur through the shunt, or thrombus may form because of the shunt, with resultant emboli. In all circumstances, the blood pressure must be sufficient to provide flow through the shunt.

Determination of the need for carotid shunting can be made by several commonly used techniques to assess the adequacy of cerebral perfusion. The first is direct communication with the patient who is awake and anesthetized via regional technique. Communication is usually via a signaling device, such as a "clicker," or by squeezing a ball in the contralateral hand. Voice responses are discouraged to prevent neck movement and disturbing the operative field. The second technique is to determine stump or back pressure by placing a transduced needle or catheter into the carotid artery while the proximal common carotid artery and the external carotid arteries are clamped. In this way, the transduced pressure reflects the internal carotid artery pressure and correspondingly the ipsilateral hemispheric perfusion pressure by means of the contralateral carotid artery pressure across the circle of Willis. This technique has been critically debated in the literature, referencing "safe" stump pressures varying from 25 to 90 mm Hg as indicators of adequate cerebral perfusion. Finally, the gold standard of electroencephalographic (EEG) monitoring by an experienced technician directly compares the ipsilateral and contralateral waveforms and can note any changes at the time of clamping that would indicate inadequate hemispheric perfusion.

Anesthetic technique

CEA may be performed under either general or regional anesthesia, with either technique having similar morbidity and mortality rates. The choice of anesthetic must be an appropriate balance among patient selection, the desires of the surgeon, and the expertise of the anesthesiologist. The primary objective in the anesthetic management of the patient undergoing CEA is the prevention of cardiac and cerebral ischemic events. This intention can present as a delicate balance between augmentation of cerebral perfusion pressure and reduction of myocardial oxygen demand. Preparation for and anticipation of hemodynamic fluctuations is essential toward this end. Individual

syringes of low-dose ephedrine (5 mg/ml), phenylephrine (40 μ g/ml), and nitroglycerin (40 μ g/ml) should be readily available. Additionally, infusions of phenylephrine and nitroglycerin on a preset pump should be in line. Likewise, in treatment, prevention of therapeutic overcorrection by the judicious titration of these short-acting pharmacologic agents is key.

General anesthesia

Proponents of a general anesthetic approach to CEA espouse the ability to control ventilation, maintain a secure airway, and more easily manage the potential intraoperative complications as the major advantages of this technique. Within the

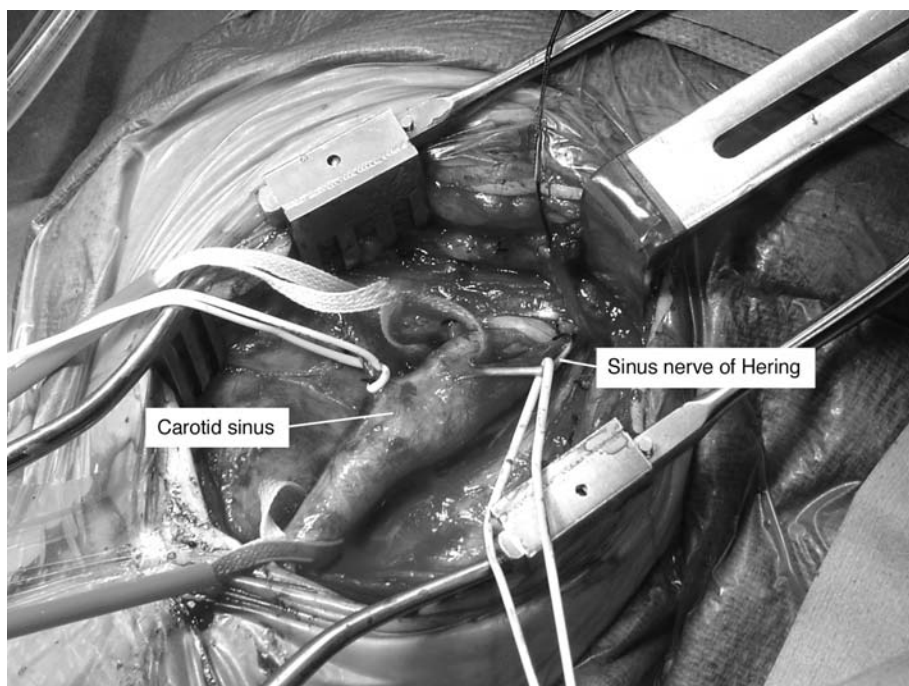

Figure 81.2. Vessel loop denotes the sinus nerve of Hering (branch CN IX) at the carotid artery bifurcation.

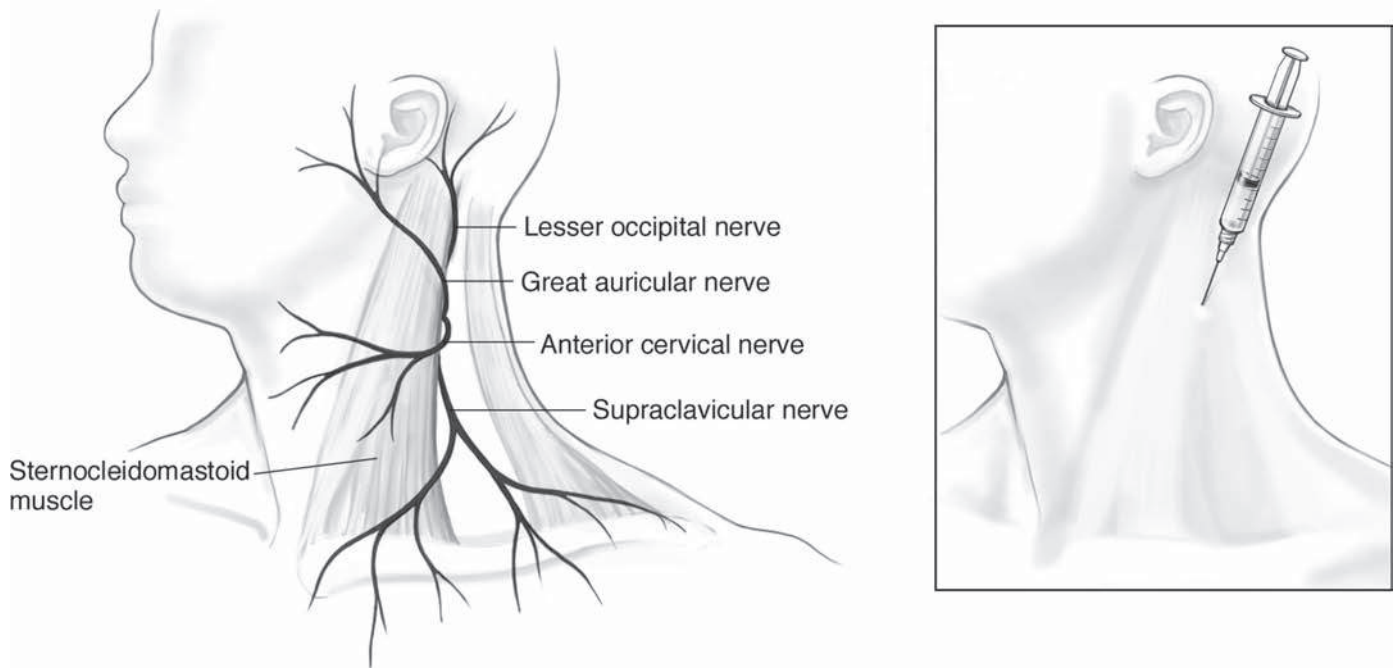

Figure 81.3. Superficial cervical block. Local anesthetic is injected along the middle third of the posterior border of the sternocleidomastoid muscle.

broad spectrum of various anesthetic induction and maintenance options, there are no data to absolutely delineate a particular combination of agents.

Ideally, the induction should be designed to maintain hemodynamic stability and avoid the shifts associated with the depressant effects of certain medications or the stimulation of tracheal intubation. It is worth noting that the use of succinylcholine is contraindicated in patients who have had a recent parietic cerebral infarction.

Maintenance anesthesia is usually achieved with the combination of a volatile anesthetic with the addition of an opioid such as fentanyl (2–5 $\mu\text{g}/\text{kg}$), sufentanil (0.5–1.0 $\mu\text{g}/\text{kg}$), or nitrous oxide. The use of nitrous oxide supplementation, although popular, remains controversial because of reports of increases in cerebral metabolic rate and cerebral blood flow (CBF). More recently, there also are reports that the use of nitrous oxide increases serum homocysteine levels during CEA. This association may possibly be correlated with perioperative myocardial ischemic events. Alternatively, a propofol and remifentanyl (0.1–1 $\mu\text{g}/\text{kg}/\text{min}$) anesthetic may be used. Remifentanyl's short half-life permits simple titration during varying levels of stimulation during CEA. The use of easily titratable, short-acting pharmacologic agents also permits a smooth, rapid emergence to facilitate early neurologic assessment.

Regional anesthesia

CEA is commonly performed under regional anesthesia using superficial and deep cervical plexus blocks (Fig. 81.3 and Fig. 81.4). Anesthesiologists may prefer one block to another, although no consensus exists within the literature as to a

comparison of efficacy. The necessary region of anesthetic blockade is in the C2–4 dermatomes and may be achieved via either of these blocks, or by subcutaneous infiltration of the peripheral nerves infiltrating the incision site.

Advocates of a regional technique for CEA claim that this approach provides for direct cerebral monitoring, improved hemodynamic stability, and avoidance of endotracheal intubation, as well as its attendant complications in patients with chronic obstructive pulmonary disease or limited cardiac reserves. It should be recognized that this anesthetic approach should be attempted only in a patient likely to remain calm and cooperative throughout the operative procedure with a minimal amount of sedation. These limitations illustrate the disadvantages of a regional anesthetic in this patient group. The onset of seizures, loss of consciousness, or need to control the airway emergently, although uncommon, may present significant difficulty during surgical management.

Monitoring

Intraoperative patient monitoring during CEA should recognize the goals of protection from cerebral and cardiac ischemia. As such, diligent observation of electrocardiographic leads II and V₅, along with ST-segment analysis, provides increased sensitivity in detecting early cardiac ischemic changes. Likewise, direct and continual hemodynamic monitoring by placement of a transduced intra-arterial catheter is recommended. Additional invasive procedures, such as placement of a central venous line to record central venous pressures, or a pulmonary artery catheter, should be dictated by individual patient comorbidities and not used on a routine basis.

Figure 81.4. Deep cervical block. The needle is inserted on the vertical line at the C2, C3, and C4 level and directed medially and slightly caudad to contact the groove of the transverse processes.

The literature indicates that neurophysiologic monitoring is not associated with a stroke risk reduction or an improvement in outcome. Most perioperative strokes are thromboembolic in origin and not the result of hypoperfusion. The use of various cerebral perfusion monitors, such as the electroencephalogram (EEG), transcranial Doppler (TCD), or cerebral oximetry, may offer guidance in determining the appropriateness of shunt use and more cautious and precise utilization of pharmacologic vasopressors.

The EEG is a graphic representation of the spontaneous electrical activity of the superficial cerebral cortex (Fig. 81.5). Compared with the hemispheres, such as during carotid artery cross-clamping, relative ischemia will demonstrate a decrease in electrical activity and change in regional patterns. This usually will occur below a CBF rate of approximately 15 ml/100 g/min. It should be recognized that EEG monitoring during CEA is not without its limitations. EEG does not monitor deeper structures in the brain, and patients with certain preexisting neurologic deficits may incur a perioperative ischemic event without evidence of EEG changes. In addition, interpretation of the EEG waveforms may be made more difficult by decreases in body temperature, blood pressure, or an increase in anesthetic level, as each of these may mimic an ischemic change in EEG pattern. Therefore, it is absolutely essential to maintain communication between the anesthesiologist and EEG technician when any change is made to the maintenance anesthetic regimen.

TCD presents another modality for assessing the adequacy of CBF. TCD applies the concepts of Doppler ultrasound to determine middle cerebral artery blood flow velocities and embolic events. TCD's utility in the intraoperative evaluation of

the patient undergoing CEA may be somewhat limited in terms of its positive predictive value and may be more useful postoperatively for stroke surveillance or in predicting which individuals may be at risk for cerebral hypoperfusion syndrome following CEA or carotid artery angioplasty and stenting. Likewise, the application of cerebral oximetry during CEA provides a visual measurement of frontal lobe saturation. Limited work has been

Figure 81.5. Representative EEG patterns. *Line 1:* Beta waves seen in the awake patient. *Line 2:* Alpha waves seen in a relaxed patient. *Line 3:* Theta waves seen in the somnolent patient. *Line 4:* Sleep spindles seen in the sleeping patient. *Line 5:* Delta waves in the relatively deeply anesthetized patient.

done to accurately define a cutoff threshold to indicate when employing a shunt is appropriate.

Postoperative care

The most common postoperative complications following CEA include delayed emergence, hemodynamic instability, respiratory insufficiency, local hematoma, and new evidence of neurologic dysfunction. Although most wound hematomas are relatively small, emergent operative intervention is required for large and rapidly expanding hematomas. The anesthesiologist must be particularly attuned to any evidence of airway compromise that will demand immediate attention. The most common cause of mortality is myocardial infarction, whereas the most common cause of morbidity is stroke. Although seemingly similar to many other procedures and their potentials for postoperative difficulties, the patient undergoing CEA is unique.

In the postoperative setting, approximately 60% of these patients may present with either hypotension or hypertension, with the latter being more common. The etiology of post-CEA hypertension is not exactly clear. It is possible that it could be related to surgical denervation of carotid baroreceptors, and it may be exaggerated in patients with poorly controlled preoperative hypertension. The pattern of postoperative hypertension appears to peak approximately 2 to 3 hours after completion of the procedure, but may persist up to 24 hours. The goal of hemodynamic management in the postoperative period should be directed toward maintaining patients within their usual preoperative range of blood pressures. Postoperative hypertension may be managed with a variety of short-acting agents, such as esmolol, labetalol, and hydralazine, to avoid unnecessary periods of hypotension. In refractory situations, titration of nitroglycerin or nitroprusside may be employed.

In evaluating the postoperative CEA patient for hypotension, it is essential to remember the high correlation with coronary artery disease in this patient population and to exclude myocardial ischemia and infarction as reasons for a decrease in blood pressure in the postanesthesia care unit.

Following CEA, patients may present with varying degrees of neurologic dysfunction, ranging from focal neurologic signs from cranial nerve injury to full-blown cerebral hemispheric insults from carotid artery occlusion, embolic phenomenon, or graft thrombosis. Unilateral recurrent laryngeal nerve injury will appear as transient hoarseness, but preoperative assessment of vocal cord function should be made in any patient who previously underwent contralateral endarterectomy or operative thyroid intervention if the possibility of bilateral recurrent laryngeal nerve injury exists, and as such, an acute airway emergency. Injury to the hypoglossal nerve will result in paresis of the ipsilateral tongue musculature and deviation of the tongue to the side of injury. More commonly, traction injury to the marginal mandibular branch of the facial nerve will manifest as drooping of the corner of the mouth on the ipsilateral side.

Another, less common cause of post-CEA neurologic dysfunction is cerebral hyperperfusion syndrome (CHS) resulting

from the rapid restoration of a normal perfusion pressure to areas of brain tissue with impaired autoregulation secondary to chronic ischemic states. The literature reports an incidence of 0.5% to 2.2% and defines CHS as a major increase in ipsilateral CBF, well above the metabolic demands of the brain tissue, following repair of carotid artery stenosis. Occurring between postoperative days 3 and 8, the clinical presentation of CHS may consist of severe unremitting ipsilateral head, facial, or eye pain, with increasing signs of cerebral irritability progressing to seizure activity. Prompt recognition and hemodynamic control are essential for management. The compounding involvement of intracerebral hemorrhage bodes a poor prognosis.

Future trends

The validation studies of the 1990s (North American Symptomatic Carotid Endarterectomy Trial [NASCET], European Carotid Surgery Trial [ECST]) demonstrated absolute risk reduction for the surgical versus medical management of carotid artery stenosis and defined acceptable morbidity and mortality rates. In 2004, the US Food and Drug Administration approved the clinical application of carotid artery angioplasty and stenting systems in the revascularization of symptomatic patients with stenosis $\geq 50\%$ and asymptomatic patients with $\geq 80\%$ stenosis. Early carotid artery stenting literature reported unacceptably high complication rates. The elevated stroke rate in these studies most likely was related to the absence of distal embolic protection filters in the deployment systems. With technologic improvements, further studies such as the SAPPHERE (Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy) and CaRESS (Carotid Revascularization Using Endarterectomy or Stenting Systems) trials demonstrated lower morbidity and mortality rates. Defined complication rates for carotid artery angioplasty and stenting have not been determined yet, pending publication of larger series evaluating longer follow-up and stent durability.

Abdominal aortic aneurysm

Fred Cobey, Simon Gelman, and Jonathan D. Gates

An arterial aneurysm is a dilation of the artery at least 50% of the expected diameter. The definition of an abdominal aortic aneurysm (AAA) is an aorta with a diameter >3 cm. Approximately 5% of the population older than 50 years has an AAA. These aneurysms are the fifth leading cause of death in men older than 55 years. Prophylactic AAA repair is intended to spare patients the possibility of rupture and death. Ruptured AAAs incur a mortality rate of 70% to 90%, with most deaths occurring before patients arrive at the hospital. Therefore, detection and repair of AAAs prior to catastrophic rupture can prolong the life of many patients. Because atherosclerosis is a systemic disease, severe cardiovascular and other comorbidities frequently accompany these lesions. In the event of an AAA rupture, perioperative homeostasis may be a challenge for anesthesiologists.

Pathophysiology

Although atherosclerosis traditionally was invoked as an etiology for AAAs, this concept has been recently revised. Aneurysms are now believed to result from inflammation that leads to dilation and subsequent plaque formation. Loss of elastin is one of the most common histologic findings, and increased serum activity of elastase has been observed in patients with aneurysms. Alterations in metalloproteinase gene expression and activity also are associated with AAA formation. Smoking also may act synergistically to cause elastin degradation. In addition, the presence of *Chlamydia pneumoniae* in the aortic wall may lead to the degradation of aortic elastin.

Gradual aneurysmal enlargement may be explained on the basis of Laplace's law (Fig. 82.1). The tension (T) on the aneurysm wall is the product of the transmural pressure (P) and the radius (R) of the vessel ($T = PR$). Therefore, a larger aortic diameter results in increased wall tension at a relatively constant arterial pressure. The tension will increase to a point at which the vessel collagen is incapable of sustaining the transmural pressure. Accordingly, risk of rupture can thus be stratified according to diameter. AAAs enlarge 0.5 cm/y or about 10% per year, so ongoing surveillance is necessary. Lesions <4 cm may be followed with annual imaging, as the risk of rupture at that size is unlikely. Once lesions reach 5 to 6 cm or larger, the risk of rupture increases to 5% to 6% per year, at which point repair is generally indicated. In addition to size, rapid

expansion and female gender also appear to increase the risk of rupture. Patients with lesions 4 to 5.5 cm represent an intermediate group, and the question here may be more of when, rather than whether, to repair them.

Preoperative evaluation

Most AAAs are silent clinically and discovered incidentally. Symptomatic patients may present with back, flank, groin, and abdominal pain. Less commonly, clinicians may discover AAAs during a search for a cause of lower-extremity embolus. On routine physical examination, AAAs that are 4 to 4.9 cm are detected in only 50% of cases. Large lesions often may be more readily palpated; however, large body habitus may render the physical examination unreliable. Ultrasound is a traditional modality for evaluating pulsatile abdominal masses or for following changes in an aneurysm over time. CT provides a better picture of the overall geometry of the lesion and more easily detects iliac artery aneurysms (Fig. 82.2). Formal angiography rarely is used as a preoperative study.

Most patients with AAAs have coexisting cardiopulmonary disease, and their life expectancy generally is shorter than that of age-matched controls. A thorough medical evaluation of patients preoperatively is required to decide whether and what kind of surgery should be done and to ensure that comorbid conditions are addressed. Cardiac complications are the most common complications after vascular surgery, with a myocardial infarction incidence of 12% to 14%. Preoperative cardiac revascularization may not decrease perioperative risk of myocardial infarction or long-term survival. In contrast, use of perioperative β -adrenergic antagonists has been shown to reduce the rate of cardiac complications. There is also evidence

Figure 82.1. Aneurysmal enlargement explained on the basis of Laplace's law. T, tension; P, transmural pressure; R, radius.

Figure 82.2. CT angiogram of a large AAA with mural thrombus.

that the addition of a statin may further reduce the risk of perioperative cardiac complications beyond β -blockade alone.

Assessment of the patient's tolerance to exercise and notation of any cardiac symptoms are crucial in risk stratification and in determining whether surgery should be delayed for further testing. Cardiac testing can safely be omitted in intermediate-risk patients with acceptable functional status. It is generally recommended that adequate preoperative β -blockade be provided, as evidenced by a patient's heart rate controlled between 60 and 70 bpm.

Since many patients with AAAs have a long history of smoking, pulmonary compromise is common. Patients with productive cough, those with bronchospasm, and those who are CO₂ retainers have higher rates of pulmonary complications. In this group of patients, epidural analgesia is particularly useful. Patients with AAAs also may have coexisting cerebrovascular disease. There is no evidence that correcting asymptomatic carotid disease improves neurologic outcome. Intervention should be entertained in symptomatic patients with transient ischemic attacks or small strokes. However, the timing of the two interventions should be patient specific, based on the relative significance of each lesion. Preoperative renal insufficiency is a strong predictor of increased operative risk, more so than diagnosed cardiopulmonary disease. Diabetes mellitus needs to be addressed and managed preoperatively, as perioperative hyperglycemia has been shown to predispose to cardiac events and may have a role in risk of postoperative infection.

In contemplating AAA repair, one must consider the patient's life expectancy, risk of rupture, and risk of perioperative death. For patients undergoing open operative repair, mortality is inversely related to both surgeon and hospital volume. Operative mortality can actually be predicted using the surgeon's average operative mortality and the patient's comorbidities. Patients who have a high risk of perioperative death and/or a short life expectancy may be managed nonoperatively. β -Adrenergic antagonists should be initiated because of accumulating evidence that they may decrease the rate of aneurysmal expansion.

Figure 82.3. Transperitoneal AAA repair with graft in situ.

Surgical approach

There are two basic approaches to open AAA repairs: transperitoneal and retroperitoneal. The transperitoneal approach via a traditional midline laparotomy incision with the patient in the supine position is best for ruptured aneurysms and also provides exposure to the right renal artery (Fig. 82.3). The retroperitoneal approach enables better exposure to suprarenal aneurysms and is the preferred approach in cases of extensive abdominal adhesions or a horseshoe kidney, which would prevent easy access to retroperitoneal structures. The patient requiring this approach is placed in a left-side up, modified decubitus position. This approach avoids violating the peritoneum and may result in faster return of bowel function, although it incurs the risk of an often troublesome postoperative bulge around the incision from denervation of flank muscles.

The development of endovascular repair has changed AAA management, especially for high-risk patients. The anesthetic considerations for patients undergoing the endovascular approach are reviewed in the next chapter. Finally, laparoscopic AAA repair is currently being investigated in Europe. Initial results in the literature are encouraging, with short recovery times similar to those of endovascular techniques. In practice, however, these techniques are not yet viable options.

Intraoperative management

Monitoring

In addition to routine noninvasive monitors, an arterial line is helpful during application and removal of the aortic cross-clamp and in the presence of significant bleeding. A triple-lumen catheter inserted in the subclavian or internal jugular vein may be useful when there is a need to administer multiple

medications. Routine placement of pulmonary arterial catheters is unnecessary. The use of such catheters may be restricted to patients with suspected pulmonary hypertension or significant cardiac disease, in whom it may be necessary to know the cardiac filling pressures and output to maintain optimal cardiac function. Intraoperative transesophageal echocardiography (TEE) is often useful in estimating volume status and identifying regional wall motion abnormalities among patients who are hemodynamically unstable.

Anesthetic technique

General anesthesia is required. More important than what drugs are used for induction and maintenance of anesthesia is that they are administered in a manner that ensures hemodynamic stability. It may be wise to avoid ketamine, given the preponderance of coronary artery disease in this group of patients. Epidural analgesia clearly is beneficial in this patient population, given the prevalence of pulmonary disease. Its use decreases postoperative intensive care unit requirements, postoperative pulmonary complications, and hospital stays. The associated decrease in sympathetic tone may complicate hemodynamic management. It seems easier to manage intraoperative hypotension if epidural analgesia is started after the aortic cross-clamp is removed and hemostasis is ensured.

Volume status

Clearly, it is important to assess the volume status of patients undergoing AAA repair throughout the intra- and postoperative course. Aggressive volume resuscitation is required to assist in maintaining optimal hemodynamics and to avoid postoperative renal impairment. Understanding the patient's unique cardiopulmonary status and ability to tolerate fluid shifts is the basis of volume management. Although vasoactive drugs may be needed, their use should be limited. Administration of phenylephrine doubles the incidence of wall motion abnormalities seen on echocardiography compared with patients whose blood pressures are maintained by fluid administration. Urine output cannot be used as an indicator of end-organ perfusion, given the presence of an aortic cross-clamp along with possible administration of diuretics. Even in the infrarenal position, the cross-clamp appears to impair blood flow to the kidneys.

Widespread opinion that central venous pressure (CVP) accurately reflects the volume status of patients is actually incorrect. Values of CVP, as well as those of pulmonary artery occlusion pressure (PAOP), do not correlate with the values of circulating blood volume or with responsiveness to fluid challenge (an increase in cardiac output secondary to the infusion of fluid). Loss of 10% to 12% of blood volume does not change systemic hemodynamic variables, including CVP, to a noticeable degree because such a blood loss is compensated by many mechanisms, including mobilization of blood from the splanchnic vasculature. Adequate CVP is a must for normal cardiovascular function; therefore, the body does everything needed to maintain it at adequate levels. In conditions of normal heart function,

CVP values often remain unchanged despite drastic changes in other variables of systemic hemodynamics. Only extreme values of CVP may have some clinical significance. The PAOP is an even worse indicator of volume status than the CVP, because it is far removed from the action of the mean circulatory filling pressure, which is very close to the pressure in small veins. However, the PAOP is a better indicator of left ventricular function than of volume status.

Dynamic variation in the arterial wave form during positive pressure ventilation may be a better predictor of fluid responsiveness than CVP measurements. Currently, there is discussion that plethysmographic waveform variation obtained from the fingertip, as in the case of systolic blood pressure variations, may predict responsiveness to a fluid challenge. Although such dynamic indices do not provide measurements of intravascular volume or preload, they help answer the clinically relevant question of where patients are on their Starling curves, and whether further volume administration would be helpful. Indeed, using such measures may even improve patient outcomes.

Finally, TEE also may be performed rapidly to evaluate both cardiac function and volume status. As in the dynamic variation seen in arterial waveforms during positive pressure ventilation, fluid responsiveness can also be predicted using respiratory variations in left ventricular stroke area by TEE. Comparing the use of pulmonary artery catheters with echocardiography in high-risk surgery patients, TEE may be the preferred method for rapid intraoperative cardiac evaluation when evaluating hypotension not responsive to volume boluses.

Interestingly, more recently, positive fluid balance after elective AAA repair was retrospectively associated with a higher rate of complications resulting in longer hospital stay. A follow-up prospective randomized trial appears to confirm these findings, arguing for a more restrictive fluid regimen.

Blood loss

The anesthesiologist should resuscitate bleeding patients while being mindful of coagulation parameters. The greatest portion of blood loss during the normal progression of an elective AAA repair usually occurs during the aortotomy, while controlling retrograde bleeding from the lumbar arteries. Although bleeding from graft anastomoses does occur, it generally is not copious. In contrast, inadvertent venous injury to the vena cava, inferior mesenteric vein, iliac veins, or left renal vein, especially at its confluence with its associated lumbar and gonadal veins, may be very difficult to control.

Documented risk factors for blood loss and transfusion in elective AAA repairs include body weight, renal impairment, low hemoglobin and platelet counts, iliac artery involvement, large aneurysm, bifurcated graft, large graft diameter, prolonged aortic clamping time, and long operation time. One can decrease transfusion of allogenic blood by using normovolemic hemodilution and intraoperative cell salvage. There is debate regarding an appropriate target hematocrit and the timing of transfusion. In the absence of acute myocardial ischemia,

allowing a hematocrit to fall to the mid-20 range is acceptable. Lower hematocrits leave a narrow margin in case of unexpected blood loss. Frugality with transfusions is important, given the associated immunosuppression and documented increase in nosocomial infections in vascular surgery patients. Massive blood loss and transfusions may result in coagulopathy that can exacerbate bleeding.

In cases of ruptured AAA, the coagulopathy may be severe and portends a poor outcome. There are data suggesting that proactive transfusion of platelets and plasma improves coagulation competence, reduces hemorrhage, and may improve survival in patients with ruptured aneurysms. Patients undergoing elective repair of AAAs demonstrate similar, albeit less dramatic, changes in platelet counts and coagulation parameters. Aortic surgery may lead to thrombocytopenia via platelet sequestration into the graft. Later, patients develop hyperfibrinogenemia and thrombocytosis. These changes may represent a hypercoagulable state that predisposes these patients post-operatively to thrombotic complications.

Cross-clamping

Obtaining proximal control prior to incising the aneurysm requires placing an aortic cross-clamp. This maneuver is the crux of many physiologic alterations specific to aortic surgery (Fig. 82.4). The degree of the changes seen relates to the level and the duration of the cross-clamp. Aortic cross-clamping predictably increases systemic vascular resistance, with an increase in blood pressure above the clamp. This increase not only is the result of a mechanical effect of the cross-clamp increasing resistance, but also is related to activation of the renin/angiotensin axis and release of prostaglandins, catecholamines, and other vasoactive substances. There is a decrease in venous capacity from active venoconstriction distal to the clamp that results

in an “autotransfusion” of volume into the circulation proximal to the clamp. A supraceliac position of the clamp produces splanchnic venous constriction and a substantial increase in venous return to the heart. Infraceliac clamping may be associated with a shift in blood volume from veins in the pelvis and lower extremities to the compliant splanchnic veins, which will attenuate preload changes.

The response to the clamp placement also depends on the ability of the heart to handle an increased preload from splanchnic venoconstriction. In healthy hearts, filling pressures appear to remain unchanged. Vasodilators such as nitroglycerin often are not needed to reduce blood pressure, as inhalation anesthetics generally suffice. If the cardiac function is abnormal, then a different hemodynamic profile may ensue. With an acute rise in afterload – and possibly also preload, depending on clamp position – cardiac output may decrease while filling pressures increase. Negative inotropic effects of volatile agents and β -adrenergic antagonists need to be carefully titrated in such patients. Collateral flow maintains some perfusion distal to the clamp, albeit at reduced levels. Any vasodilators given to treat proximal hypertension will exacerbate hypotension and ischemia distal to the aortic clamp. Administering vasodilators may worsen mesenteric and renal perfusion while not necessarily preventing wall motion abnormalities if the aorta is clamped proximal to the renal or celiac arteries. Therefore, the target blood pressure should be carefully selected to perfuse organs distal to the clamp without jeopardizing the myocardium.

Unclamping

Once the aortic graft is sutured in place, the aorta is unclamped, allowing restoration of distal perfusion (Fig. 82.5). This maneuver consistently produces a profound (70%–80%) decrease in vascular resistance and blood pressure. The left ventricular

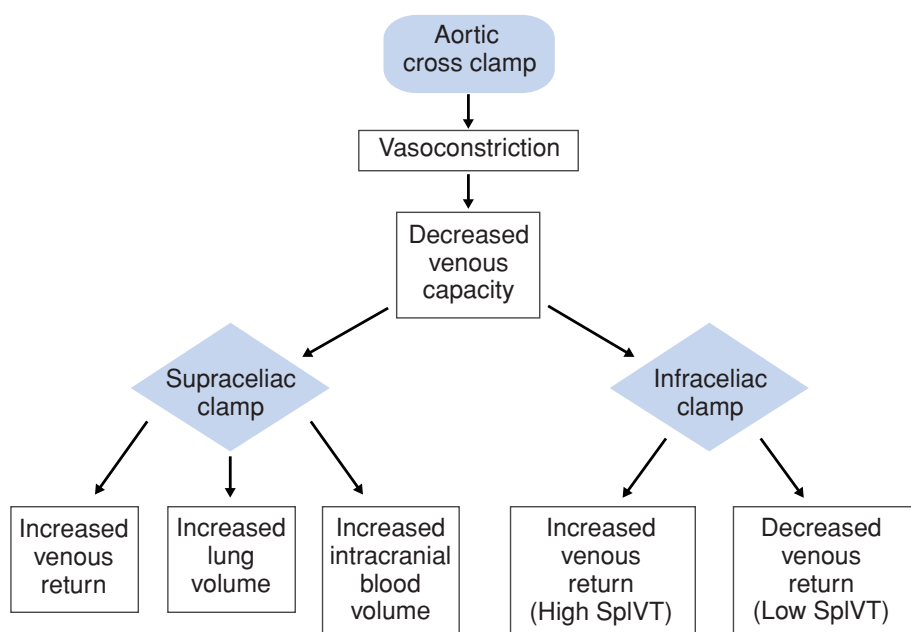

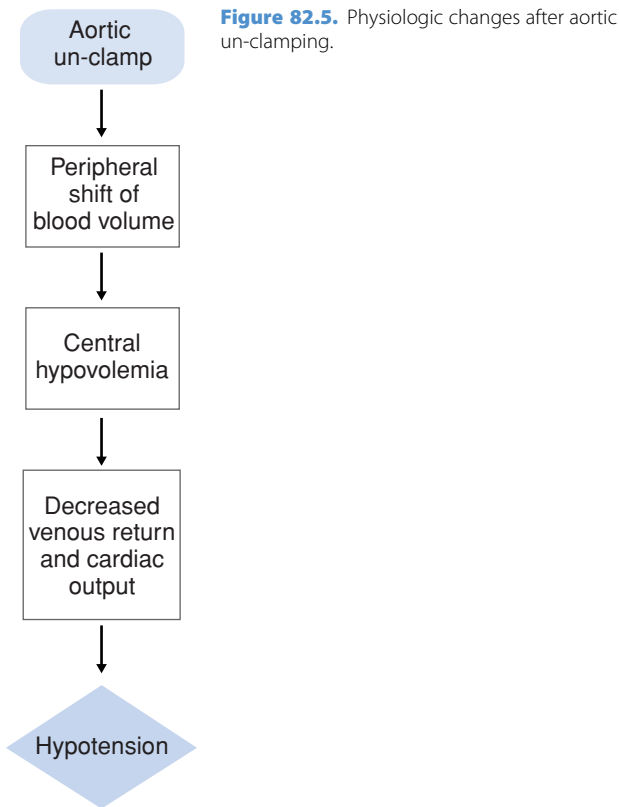

Figure 82.4. Physiologic changes with aortic cross-clamping. SplVT, splanchnic venous tone.

filling pressure decreases by 42% compared with baseline values and by 60% compared with values during clamping. Cardiac output may increase, decrease, or remain unchanged. Blood flow through the carotid arteries decreases, whereas blood flow through the femoral arteries increases. Reperfusion of the ischemic distal half of the body liberates products of anaerobic metabolism produced during the cross-clamp period. Prior to removing the cross-clamp, any vasodilators should be minimized or discontinued and the blood pressure should be allowed to rise moderately barring any contraindications. Preemptive loading of the vascular space with intravenous fluids will attenuate the fall in blood pressure with clamp removal.

Some anesthesiologists use nitroglycerin to dilate veins during the cross-clamp period to facilitate fluid loading without causing hypertension. This may decrease the degree of hypotension from aortic unclamping. Perhaps most importantly, the cross-clamp should be removed gradually to allow the body to adjust to the decrease in systemic vascular resistance and reperfusion of the pelvis and lower extremities. The drop in blood pressure with cross-clamp removal is more profound when a tube graft has been used for reconstruction, because both legs are reperfused simultaneously. Sequential clamp removal in a bi-iliac or bifemoral reconstruction is more easily tolerated. In addition to vasoconstrictors for blood pressure, calcium and bicarbonate may be used to offset the effect of potassium and lactate on the heart after reperfusion.

Figure 82.6. CT scan of a ruptured AAA.

Ruptured aneurysm

Ruptured aortic aneurysms present a more dramatic challenge for the anesthesiologist and surgical team. Rupture of the aneurysm into the peritoneal cavity is often a lethal event, and those patients do not survive to the hospital. Alternatively, a viable blood pressure in a patient with a ruptured aneurysm likely indicates that the rupture is contained in the retroperitoneum (Fig. 82.6). Patients are volume depleted and often hemodynamically unstable. Generally, they are taken immediately to the operating room for exploration and repair, after the suspected diagnosis is confirmed with ultrasound. Induction of anesthesia should be done cautiously, as a rapid induction of general anesthesia with medications that may both decrease vascular tone and have negative inotropic effects, in addition to positive pressure ventilation, may result in profound hypotension in volume-depleted patients. For this reason, the patient's abdomen is prepped and drapes are placed prior to induction. The surgeon should be poised to enter the abdomen and to gain control of the aorta just below the diaphragm to restore blood pressure. Vasoconstrictors may be needed as a bridge while blood is transfused.

Postoperative care and complications

Postoperatively, patients recover in the intensive care unit. The timing of extubation is decided by the anesthesia and critical care teams. Patients without lung disease or other contraindications may be extubated in the operating room. Epidural analgesia is particularly helpful in patients with poor lung function to minimize pain and achieve adequate ventilation. Preexisting

Mesenteric ischemia
Spinal cord ischemia
Infection of graft
Pneumonia and atelectasis

poor pulmonary function may be exacerbated by fluid administration and postoperative pain. Although underresuscitation should be avoided, similar care should be taken to avoid fluid overload, as this may result in prolonged ventilatory dependence.

Once patients have demonstrated hemodynamic stability without pharmacologic support and can breathe with only minimal oxygen supplementation, they generally can be cared for on a regular ward. Although some authors advocate advancing patients' diet early, this should be done carefully because postoperative ileus is common. Epidural analgesia can decrease the duration of postoperative ileus. Opioids should be titrated to patient comfort and respiratory rate. Patients generally can be transitioned to patient-controlled analgesia systems and eventually to oral opioid formulations. Nonsteroidal anti-inflammatory drugs and acetaminophen should be used, when possible, to reduce opioid requirements. This strategy will decrease the risk of delirium and improve gut motility.

As mentioned, perioperative myocardial ischemia is quite common in patients undergoing AAA repairs, and often occurs during clamp placement (Table 82.1). The anesthesiologist can minimize the risk of cardiac events by administering β -adrenergic antagonists. However, most myocardial infarctions actually occur postoperatively. Relative sympathetic suppression during general anesthesia and lack of such suppression postoperatively might partially explain this phenomenon. Perhaps more attention needs to be given to controlling heart rates in the postoperative period.

Postoperative renal insufficiency is relatively common after aortic surgery. Mortality is four to five times greater in patients with renal failure requiring dialysis than in those without renal impairment. The level of the cross-clamp affects the degree of ischemic insult. There is a 5% rate of renal failure in infrarenal versus 17% in suprarenal clamping. With suprarenal clamping, the renal blood flow decreases by 80%. Renal blood flow is decreased by 45%, with infrarenal occlusion suggesting that endogenous vasoconstrictors play a role in the altered renal perfusion. Altered renal blood flow persists at least an hour after cross-clamp removal. As might be expected, intraoperative urine output is not predictive of postoperative renal function in euvolemic patients. The presence of preoperative renal impairment is the most important factor in predicting postoperative renal failure. Current evidence has not shown the benefit of pharmacologic renal protective strategies. Such approaches have included dopamine, fenoldopam, angiotensin-converting

enzyme inhibition, thoracic epidural analgesia, prostaglandins, furosemide, and mannitol.

The incidence of mesenteric ischemia ranges from 0.6% in elective aortic surgery to 7% in ruptured AAAs. The mortality for postoperative bowel ischemia is about 50% overall, but it rises to 90% with full-thickness gangrene and peritonitis. It is highest in patients with a history of colon resection. In such patients, the collateral blood supply to the rectosigmoid area is compromised. Other factors that contribute to ischemia include the level and duration of aortic occlusion, preoperative renal dysfunction, intraoperative hypotension, the severity of the aortic disease, and lack of attention to bowel retraction during surgical exposure. Given the lethality of mesenteric ischemia, any blood in the stool must be evaluated with endoscopy. Finally, aorto-enteric fistulas are late gastrointestinal complications that may occur months to years after the initial operation. The fistula generally forms between the proximal anastomosis and the overlying duodenum. Patients with a history of AAA repair who present with gastrointestinal bleeding need to be evaluated quickly by endoscopy and possibly arteriography.

There is a paucity of literature on the effect of abdominal aortic cross-clamping on the central nervous system. Spinal cord ischemia occurs 0.2% of the time in elective surgeries involving the distal aorta and is more common in patients presenting with ruptured aneurysms. The spinal cord is supplied by two posterior spinal arteries that supply 25% of the spinal cord's blood flow and one anterior spinal artery that provides 75% of the total perfusion. The anterior spinal artery is supplied by radicular arteries, and collateralization is poor. The artery of Adamkiewicz is a radicular artery that provides blood to thoracolumbar spinal cord and joins the anterior spinal artery between T8 and T12 in 75% of cases and between L1 and L2 in 10% of cases. Thus, high cross-clamping of the aorta may impair spinal cord perfusion. Measures to prevent spinal cord ischemia include a short aortic occlusion time and maintenance of adequate blood pressure while the cross-clamp is in place.

Most postoperative infections involve the skin. Infection of the prosthetic device occurs in about 1% to 6% of patients. This may be a devastating problem requiring prolonged treatment with antibiotics and removal of the prosthesis, with an axillo-bifemoral reconstruction. Anesthesiologists can reduce the rate of graft infection by adhering to sterile technique during central line placement and ensuring that preoperative antibiotics are administered.

A successful outcome in aortic surgery requires a team approach with attention to detail throughout the entire perioperative period. As the major cause of perioperative mortality is cardiac related, prevention of perioperative myocardial ischemia should be a focus of the anesthesiologist caring for these patients. The use of β -adrenergic blockade, appropriate volume resuscitation, and administration of epidural analgesia affect patient outcome. Finally, the value of clinical experience caring for these patients must be emphasized given the complexity and rapidity with which physiologic changes occur.

Endovascular abdominal aortic aneurysm repair

K. Annette Mizuguchi

With the introduction of endovascular abdominal aortic aneurysm repair (EVAR) in 1991 by Parodi et al., treatment options for abdominal aortic aneurysms (AAAs) have expanded to conventional open surgical repair or endovascular repair. Clearly, as more vascular surgeons and interventional radiologists overcome the learning curve for the endovascular approach and as endografts with a better long-term record become available, more patients will be offered the endovascular approach.

Surgical considerations

Certain anatomic requirements must be met for a patient to be a candidate for the endovascular approach (Fig. 83.1). The procedure consists of endograft placement in the infrarenal aorta under fluoroscopic guidance and use of digital subtraction angiography (Fig. 83.2). Bilateral iliofemoral arterial access is obtained by either percutaneous or surgical exposure; the vascular sheath is introduced on one side, and arterial access is obtained on the contralateral side for angiography. Systemic anticoagulation is achieved with heparin to an activated coagulation time of 250 seconds (2–2.5 times the baseline value). During the procedure, the breath-hold technique is used to optimize the image quality of digital subtraction angiography.

Anesthetic considerations

All patients scheduled for EVAR have the potential for conversion to an open repair. Therefore, all patients should undergo a thorough preoperative evaluation and optimization of comorbidities similar to patients undergoing open AAA repair.

In addition to standard American Society of Anesthesiologists monitors, an arterial line to monitor the blood pressure and two large-bore intravenous lines are usually placed. The need for central access is dictated by the patient's preoperative status, the need for venous access, and the possibility of converting to an open repair. Blood should be typed, and crossmatched units should be in the room. Inotropic agents, vasopressors, and vasodilators should be readily accessible. Because the procedure is done under fluoroscopic guidance, special attention must be paid to minimizing radiation exposure. After the procedure, most patients are transferred to the recovery room rather than the intensive care unit.

The patient can be managed under local anesthesia with sedation, regional anesthesia (epidural, spinal, or combined spinal/epidural), or under general anesthesia. The surgeon's and anesthesiologist's preferences, as well as patient factors, dictate the choice of anesthetic technique. For local and regional techniques, patient cooperation and motivation are required (especially for the breath-hold technique during digital subtraction angiography). The various anesthesia techniques have not been shown to make a clear difference in intraoperative complication or mortality rates.

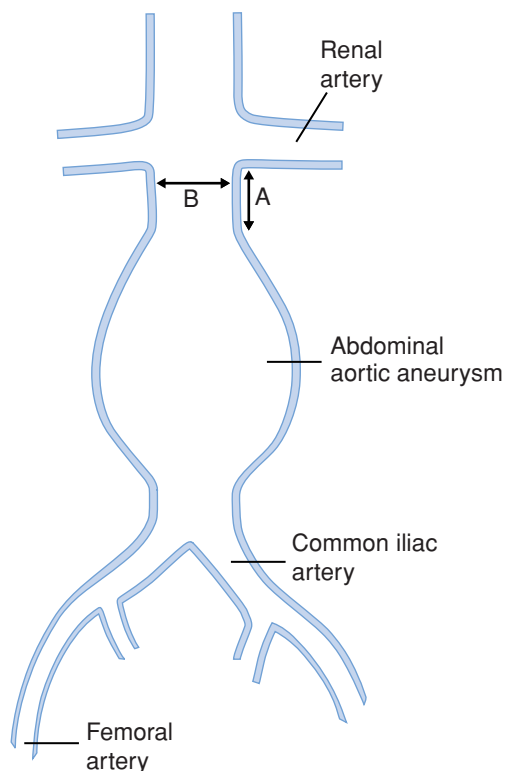

Figure 83.1. Anatomic requirements for infrarenal EVAR are listed as follows: the aneurysmal aortic neck ("landing zone") should be at least 15 mm (A); the infrarenal aortic neck diameter range should be 19 to 36 mm (B); one femoral artery must be free from significant occlusive disease and have a diameter > 7.7 mm; if the larger iliac is being used, it must be free from tortuosity or excessive calcification; the distal attachment site must be nonaneurysmal and of sufficient length to accommodate the graft; and there should be at least one straight iliac artery that can be used as a conduit for the delivery system.

Figure 83.2. Radiograph showing abdominal aorta pre-repair (A) and post-repair (B).

Unlike open repair, in which the aorta is cross-clamped and unclamped, EVAR is associated with relative hemodynamic stability. Large fluid requirements are not encountered because of the reduced blood loss and minimal third space fluid losses. Blood loss for EVAR has been reported to be around 100 to 500 ml, compared with 900 to 2300 ml for open repair.

Complications

Although EVAR is minimally invasive, it is associated with several significant complications (Table 83.1). *Endoleak* is defined as the presence of blood flow outside the endograft but within the aneurysmal sac, and it can occur in the acute setting during endograft implantation or anytime during the postoperative surveillance period (Table 83.2). Therefore, patients are subsequently followed up with surveillance CT scans at 1 month, 6 months, 12 months, and annually thereafter. Type I and III endoleaks require fairly urgent interventions because blood flow and sac pressure will continue to increase and lead to rupture. Type IV endoleaks usually resolve with time. The management of type II endoleaks is more controversial, because some will thrombose on their own whereas others will lead to

sac enlargement. Increases in aneurysm diameter and possible device migration are also followed up with surveillance CT scans.

Management of patients coming to the operating room for surgical intervention of a type I or III endoleak may be more complex. In addition to the fact that many of these procedures will be urgent or emergent in nature, and that these patients likely will have more significant comorbidities, which made them endovascular candidates in the first place, they may require a suprarenal or supraceliac cross-clamp for their surgical repair.

EVAR is associated with renal dysfunction, and the etiology is multifactorial. Contrast dye used during the procedure has been implicated, and the prevention of contrast-induced renal dysfunction with the use of hydration, *N*-acetylcysteine, or bicarbonate has been advocated. The position of the graft is another factor. With the use of suprarenal fixation devices, graft material may inadvertently be placed over the renal artery ostium, leading to renal dysfunction. Even with perfect device placement during the procedure, with time, device position may change and alter the relationship of the graft to the renal artery ostium, leading to renal dysfunction that is not seen immediately after the procedure.

Table 83.1. Complications of endovascular aneurysm repair

- Endoleak
- Migration of stent graft
- Surgical conversion
- Acute rupture: more likely during graft deployment but may occur at any time during EVAR
- Misdeployment, malpositioning, stent graft migration
- Embolic events
- Paralysis
- Local site injury
- Infection
- Groin wound healing problems
- Systemic injury

Endovascular repair of thoracic aortic aneurysms

Anesthetic considerations for endovascular repair of thoracic aortic aneurysms (TAAs) are similar to those for EVAR. The potential for conversion to an open repair and for major blood loss exists. Transesophageal echocardiography may be used to visualize the undeployed stent-graft in relation to the aortic pathology. Unfortunately, the echo probe interferes with fluoroscopic imaging and can be used only between fluoroscopic examinations. Certain TAAs require a combined approach:

Table 83.2. Types of endoleaks

Type of endoleak	Causes	Description	Recommended treatments
I	Seal failure	Occurs from the attachment sites at the proximal or distal ends of the graft and is a result of failure to seal attachment sites of the endograft to the native vessels. This type is associated with rupture and is treated aggressively.	Repair in the operating room.
II	Retrograde flow	Occurs from retrograde flow (back-bleeding) from tributaries that have not thrombosed such as lumbar or the inferior mesenteric artery following aneurysm exclusion. Most have a benign course and will resolve spontaneously.	Can be observed for 6 months if there is no sac expansion.
III	Graft defect	Occurs from defect within the graft from module disconnection or fabric tear. This type needs to be repaired immediately with a modular extension or covered stent.	Repair at the time of detection.
IV	Fabric porosity	Occurs through intact but porous fabric.	No specific treatment is necessary.

open surgical repair with cardiopulmonary bypass for the ascending aorta and an endovascular repair for the descending aorta. Similar to the open TAA repair, there is potential for paraplegia. Therefore, many surgeons and radiologists prefer to place a spinal drain prior to the procedure. However, the benefit of perioperative salvage spinal drain placement remains to be determined.

Future

Since its introduction, the field of endovascular repair has greatly advanced. Currently, many centers are treating most of their elective, infrarenal aneurysms endovascularly. Endografts are being developed that will accommodate aneurysms currently excluded because of anatomic restraints. It is foreseeable that with the advancement of the field, endovascular treatment will expand to include patients with ruptured or urgent aneurysms as well, including more complicated patients with various comorbidities and advanced age, who would otherwise have been deemed untreatable.

However, more studies comparing the outcome of long-term morbidity, mortality, and quality of life need to be made before definite conclusions can be made. At present, although randomized controlled studies indicate that short-term mortality is improved by 3% with EVAR, it was associated with a higher number of complications and reinterventions.

Peripheral vascular disease

Laura H. Leduc and James L. Helstrom

Atherosclerosis is one of the etiologies of peripheral vascular disease (PVD) and is associated with specific risk factors, including diabetes mellitus, hypertension, hypercholesterolemia, and tobacco use. PVD evolves from lipid deposits at sites of vessel injury that form plaques along the intimal lumen. Further lipid accumulation and hemorrhage into these plaques ultimately result in narrowing of the arterial wall and inadequate blood supply to tissues distal to the lesion. These lesions frequently occur at major arterial bifurcations.

Claudication

Claudication is the clinical description for *functional* ischemia. It is characterized by reproducible lower-extremity muscle pain induced by a defined amount of activity and relieved by rest. The symptoms result from the inability of the vasculature to provide blood flow commensurate with the metabolic demand of the exercising tissue. A subset of patients with claudication will go on to develop pain at rest or *critical* ischemia. In this circumstance, arterial perfusion is inadequate to meet the resting demands of tissue, which is an indication for surgical intervention.

Medical therapy for peripheral arterial disease is essential. Smoking is an independent risk factor for worsening of limb ischemia and continued progression of atherosclerosis.

The overall survival rate for patients with claudication is significantly lower than that for age-matched control subjects. Causes of death are most likely to be coronary and cerebral vascular accidents. In fact, evidence indicates that the incidence of perioperative cardiac events is higher after surgery for peripheral vascular conditions than for open aortic procedures. Therefore, it is imperative that these patients be managed with the same thorough preoperative risk assessment and intraoperative vigilance that would be used for patients undergoing other major vascular procedures.

Preoperative considerations

Patients undergoing peripheral vascular surgery are at high risk for perioperative complications including myocardial ischemia and infarction, respiratory failure, renal failure, graft failure, and death. Infrainguinal arterial bypass surgery is associated

with a 30-day mortality rate of nearly 6% and 1-year mortality exceeding 16%. Perioperative myocardial infarction (MI) occurs in 4% to 15% of patients undergoing peripheral vascular surgery and accounts for > 50% of perioperative mortality. Therefore, preoperative evaluation of the patient's cardiac status is of the utmost importance and is based on recommendations by the American College of Cardiology (ACC).

For major vascular procedures, no difference in outcome has been demonstrated between medical management for coronary artery disease (CAD) and interventional management including both percutaneous and surgical coronary artery bypass grafting procedures. Medical treatment typically takes the form of β -blockers, statins, and aspirin, as well as management of hypertension and/or congestive heart failure, if present.

History and examination

The history and physical examination usually focus on the cardiovascular system, as this is a major cause of mortality in this patient population. Specifically, clinicians should elicit a history of nocturnal dyspnea, orthopnea, or anginal symptoms, whereas the examination should elicit evidence of murmurs, heart failure, or bruits. Often, the most useful part of the cardiovascular examination is a conversation with the patient regarding his/her functional status. A patient's ability to achieve a minimum exercise capacity of four metabolic equivalents of task (MET) is consistent with adequate functional status and is a key decision point in the American Heart Association/ACC guidelines.

Preoperatively, blood pressure should be assessed in both arms, as a discrepancy due to subclavian artery stenosis or upper-extremity vaso-occlusive disease may confound intraoperative monitoring and management. A difference of >20% between mean values is considered significant. In these cases, blood pressure monitoring should be undertaken on the side with the higher blood pressure, as this is more likely indicative of aortic root pressure. Beyond the careful cardiac history and examination:

- A baseline electrocardiogram (ECG) should always be obtained as a means of comparison for demand ischemia that may develop intra- or postoperatively.

- A full neurologic examination should be completed, as there may be baseline deficits due to the increased incidence of cerebrovascular disease.
- Diabetic patients should be evaluated for autonomic neuropathies that may be associated with silent myocardial infarction, labile blood pressure, and delayed gastric emptying. In particular, brittle diabetics require intraoperative monitoring of blood sugars with possible insulin administration.
- Renal protection strategies, including hydration, sodium bicarbonate administration, and *N*-acetylcysteine prophylaxis, should be considered because baseline renal insufficiency may be exacerbated by administration of contrast dye.
- A coagulation profile should be considered given the widespread use of anticoagulation strategies in this population.

In cases of threatened limb loss, a thorough preoperative evaluation may need to be deferred, depending on the urgency of the procedure. In the absence of a thorough history, laboratory, and cardiac evaluation, underlying CAD and other comorbidities should be assumed and managed as carefully as possible without delay of the surgical intervention.

Medications

Patients taking β -blockers for the treatment of previous MI, angina, symptomatic dysrhythmias, or hypertension preoperatively should continue to do so throughout the perioperative period. Additionally, patients undergoing vascular surgery who are at high cardiac risk may also benefit from initiation of β -blocker therapy. Although several case reports have been published suggesting an association between continued statin therapy and postoperative rhabdomyolysis, a cause-and-effect relationship has not been well established. Moreover, given the anti-inflammatory benefits of these agents in the context of atherosclerotic disease and demonstration of clinically worse outcomes following discontinuation prior to major noncardiac surgery and in the presence of ischemia, these agents should be continued through the perioperative period in high-risk patients.

Careful consideration should be given to the decision to discontinue inotropic agents, because such action may precipitate symptomatic worsening of symptoms. Although ACE inhibitor treated patients may be at increased risk for severe postinduction hypotension, abrupt discontinuation may adversely affect blood pressure control. The decision to discontinue these agents perioperatively should be made on a case-by-case basis and weigh the risks of increasing afterload against the benefits of mitigating the potential hypotensive response to induction of anesthesia.

Finally, the decision to continue aspirin therapy perioperatively should be made in conjunction with the surgical team. Although continued aspirin therapy is associated with increased blood loss, this has currently not been linked to

increased postoperative morbidity or mortality. Indeed, aspirin discontinuation has been suggested to increase the risk for coronary events, with preliminary data pointing to a maximum risk at 10 to 12 days following cessation. Continued aspirin therapy is not a contraindication to neuraxial anesthesia, although concomitant intraoperative heparinization may increase the risk of epidural hematoma.

Evaluation of PVD

Clinically, PVD is characterized by deteriorating distal blood flow in the lower extremity. This is evaluated by measuring the ankle-brachial index (ABI). The ABI is obtained by comparing the systolic blood pressure in the upper extremity with the corresponding pressure in the ankle.

At this time, fluoroscopic angiography is the gold standard for diagnosis and operative planning for patients with peripheral arterial disease. However, magnetic resonance angiography has the potential to replace invasive angiography because image quality is excellent, yet the procedure is noninvasive, does not require operative time, and reduces the risk of contrast-induced nephropathy.

Surgical approach

Surgical literature suggests that native vein conduits are superior to prosthetic grafts over the long term. Venous mapping may be done preoperatively to identify targets for harvest. Vein harvested from the arms obviates the use of regional techniques for lower-extremity revascularization procedures.

The inflow source is often the common femoral, superficial femoral, or deep femoral artery. The target distal artery is usually at the knee level or below. The distal anastomosis usually is connected first, followed by the proximal anastomosis.

Infrainguinal bypass procedures are indicated for salvage of severely ischemic lower extremities. Patients may present with gangrene, ischemic ulceration, or rest pain. Patients who demonstrate acute symptom onset likely are suffering from thromboembolic disease, whereas those who present with gradual worsening of disease likely are suffering from arterial atherosclerosis causing progressive luminal narrowing. Patients are likely to re-present, as graft patency decreases over the long term.

Arterial embolectomy is likely to be performed under emergent circumstances; bypass revascularization is undertaken after longer periods of ischemia but is less effective. Thromboembolism causes acute arterial insufficiency and is often associated with MI, mitral stenosis, or atrial fibrillation. Thromboembolic disease also may result from thoracic or abdominal aortic aneurysms, severe atherosclerotic disease, or paradoxical emboli via a patent foramen ovale. In the lower extremities, emboli are likely to lodge at the iliac, femoral, or popliteal arteries.

Intraoperative heparinization is used to prevent clot formation associated with vessel cross-clamping. Because of the risk of graft failure, heparinization is often not reversed with

protamine. It is essential to consider this in the event of a traumatic needle placement for neuraxial anesthesia, as heparinization with concomitant aspirin use increases the risk of epidural hematoma. As patients return for repeated procedures, it is possible to see an increase in the incidence of heparin-induced thrombocytopenia. Therefore, familiarity with the risks and dosing of thrombin inhibitors will be of increasing importance.

Intraoperative considerations

Anesthetic techniques

Anesthetic options include both general and regional techniques. The decision as to which method is best should take into account patient preference, surgical technique, and operator prowess, as well as each patient's comorbidities. Patients presenting with peripheral artery embolism are likely to be anticoagulated at the time of diagnosis and thus are not candidates for neuraxial anesthesia.

When not contraindicated, administration of neuraxial anesthesia may reduce the incidence of perioperative mortality and cardiac and respiratory morbidity. Epidural anesthesia has been shown to modify the stress response associated with surgery, but there is not enough evidence to indicate whether this is of clinical significance. However, there is limited evidence to suggest an improved graft patency rate with regional anesthesia, which is desirable given an incidence of graft occlusion ranging from 2% to 20%.

Regional anesthesia

Regional anesthesia is an option for patients with a normal coagulation profile. It is worth considering either epidural or spinal catheters, because these allow repeated administration of local anesthetics during these procedures. Fluids must be administered judiciously, as they may lead to congestive heart failure in patients as the vasodilation caused by regional sympathectomy dissipates. Epidural test dosing in this population frequently is based on systolic blood pressure, because heart rate responsiveness is diminished in elderly patients and individuals taking chronic β -antagonists.

General anesthesia

Following adequate preoxygenation, induction of general anesthesia should minimize hemodynamic impact during placement of the endotracheal tube or laryngeal mask airway. This can be done with either propofol, given in incremental doses, or etomidate. The time to peak effect of propofol may approach 2 minutes, and an effective induction often can be achieved with doses of 1 mg/kg. If an arterial line has not been placed, the blood pressure cuff may be cycled every 1 to 2 minutes during periods of hemodynamic instability such as induction and emergence. A phenylephrine infusion may be placed inline prior to the induction of anesthesia, and esmolol and glycopyrrolate are useful adjuncts to traditional emergency medications. In patients with severe CAD or an ejection fraction

< 40%, consideration is given to using norepinephrine instead of phenylephrine because of the transient impairment of left ventricular systolic performance induced by phenylephrine.

Anesthetic maintenance

Anesthetic maintenance can be accomplished in a variety of ways, typically with use of inhaled agents. Recent data suggest that forgoing nitrous oxide is associated with improved wound healing and reduced pulmonary complications. However, these data have not been validated specifically in vascular patients and must be weighed against the hemodynamic stability afforded by nitrous oxide use. Invariably, vascular repair involves arterial cross-clamping, with resultant ischemia in the affected limb. Byproducts of limb ischemia include vasodilatory metabolic products and carbon dioxide. Reperfusion of the affected area causes formation and release of toxic compounds (including oxygen free radicals) that may lead to hemodynamic instability. Clinicians should be aware of these effects and have a plan for the use of vasoactive agents and/or volume infusion to maintain hemodynamics. Patients with obstructive lung disease also may have difficulty eliminating the additional carbon dioxide. This may be a serious issue in patients with underlying pulmonary hypertension and/or right ventricular dysfunction.

Monitoring

Patient comorbidities should determine monitoring requirements. At a minimum, standard American Society of Anesthesiologists monitors should be used. ECG monitoring should include a precordial V₄ or V₅ lead because this lead is particularly sensitive for demonstrating signs of myocardial ischemia. Invasive monitoring of arterial blood pressure often is used, for a variety of reasons; patient comorbidities and the surgical plan should drive decision making. Catastrophic drops in blood pressure may be encountered during anesthetic induction, in the case of loss of proximal arterial control of large vessels, or during reperfusion. Hemodynamic lability also may occur as a result of baseline hypertensive disease, dysrhythmias, or ventricular dysfunction. Central venous and pulmonary artery monitoring is not routine and should be based on individual patient comorbidities.

Postoperative considerations

Postoperative complications may include congestive heart failure, myocardial ischemia, hypothermia, and graft occlusion. Hypothermia should be avoided, as associated vasoconstriction may limit outflow to the graft and compromise graft patency. Patients should continue to be monitored for myocardial ischemia and failure in the postoperative period, because most cardiac complications arise 48 to 72 hours into the postoperative period. If a neuraxial technique has been used, patients should be monitored for formation of epidural hematoma. Moreover, anticoagulation may be important in the postoperative period, and careful communication between anesthetic and surgical teams to allow for the removal of any in

situ catheters is critically important. Expedient workup and intervention are required if epidural hematoma is suspected, because the risk of permanent neurologic damage increases with time.

Respiratory physiology

Shannon S. McKenna

The primary purpose of the respiratory system is to facilitate uptake of oxygen and removal of carbon dioxide from the blood. This gas exchange is necessary to support the metabolic functions of the cells and organs that comprise the human body.

Functional anatomy of the respiratory system

The thorax

The thorax is a semirigid asymmetric cylinder that increases and decreases in volume during the respiratory cycle. These changes in thoracic volume result in lung inflation and deflation. Bony support comes from the thoracic vertebral column, ribs, and sternum. The superior and inferior borders are the thoracic inlet and the diaphragm, respectively.

Respiratory muscles

The diaphragm is the primary inspiratory muscle. Its descent, with contraction, increases the vertical dimension of the thorax. Contraction of the external intercostal muscles elevates the ribs anteriorly, increasing the diameter of the thorax. The sternocleidomastoid and scalene muscles serve as accessory inspiratory muscles during labored breathing. Normally, expiration is passive and driven by elastic recoil. In some settings, expiration is active and driven by abdominal muscle contraction. The internal intercostals also assist in active expiration by pulling the ribs downward.

Airways and lung parenchyma

The tracheobronchial tree is a complex structure with 23 generations of division. Airways are described by both anatomic location and function. Anatomically, the two lungs are divided into a total of five lobes (three on the right). Each lobe is then divided into segments. There are 42 segments in total: 22 on the right and 20 on the left. Knowledge of the normal segmental anatomy of the lung is essential for proper use of lung isolation techniques during one-lung anesthesia.

From a functional standpoint, the first 17 divisions are progressively smaller conducting airways that carry gas but do not participate in gas exchange. The larger of these airways are supported by cartilaginous rings and have smooth muscle present in their walls. Their mucosa is ciliated columnar or cuboidal.

Around the 17th generation, the mucosa transitions to epithelium and alveoli began to appear, marking the beginning of the respiratory zone. Alveolar walls are thin, allowing close contact between type I alveolar cells and the dense pulmonary capillary network. Oxygen and carbon dioxide are exchanged by diffusion. Type II alveolar cells produce surfactant and can divide to replace damaged type I alveolar cells. The epithelial junctions are tight and water impervious in the absence of lung injury. The interstitial space contains elastin and collagen, providing architectural support and elastic recoil.

Pulmonary circulation

The lungs are supplied by a dual circulation. The bronchial arteries arise from the aorta and provide for the nutritive needs of the conducting airways. The pulmonary arteries carry mixed venous blood from the right ventricle to the pulmonary capillary network, where oxygen uptake and carbon dioxide elimination occur. Relatively large junctions in the pulmonary capillary endothelium permit filtration of large molecules such as albumin, as well as macrophages and neutrophils. Filtered fluid and cells are cleared by the pulmonary lymphatic system. Oxygenated blood is returned to the left atrium via the pulmonary veins. The details of gas transport are discussed in a separate chapter.

Mechanics of breathing

Airflow occurs secondary to the generation of pressure gradients from the upper airway to the alveoli. During spontaneous ventilation, contraction of inspiratory muscles causes an increase in thoracic volume. As a result, pleural pressure decreases. Subsequently, alveolar pressure drops and gas flows along the gradient (Fig. 85.1). During positive pressure ventilation, the ventilator applies positive pressure to the upper airways. Gas flows down the airways until alveolar pressure equilibrates with upper airway pressure. At this point, flow stops. Release, or lowering of the upper airway pressure, allows airflow reversal and expiration to occur.

Determinants of flow and volume

The elastic properties of the pulmonary system determine the lung volume that results from the application of any given static

Figure 85.1. Changes in intrapleural and alveolar pressures during normal breathing with corresponding changes in pulmonary flow and volume.

Figure 85.2. Pressure–volume relationships of the lung, chest wall, and lung and chest wall combined.

pressure. The elastic forces of the chest wall and lung move in opposite directions: the chest wall expands outward and the lung collapses inward. *Compliance* is the term that may be used to describe the change in volume that occurs with any given applied pressure. The compliance of both the chest wall and lung can be determined. The combination of the two creates the compliance of the pulmonary system as a whole (Fig. 85.2). Many diseases alter the compliance of the pulmonary system (Fig. 85.3).

Compliance describes the static inflation of the lung. Once flow is present (as is necessary for breathing), resistance to gas flow must be factored in. Gas flow through airways may be either laminar or turbulent. Turbulent flow typically occurs at higher flow rates, branch points, sharp angles, or abrupt changes in diameter. Helium, which has a lower density than oxygen or

air, may be used to decrease the resistance to flow in the setting of severe turbulence. Resistance is inversely proportional to the radius to the fourth power, and directly proportional to the length of the airway. Not surprisingly, therefore, bronchospasm, airway stenosis, obstruction, edema, and secretion accumulation all lead to increased resistance.

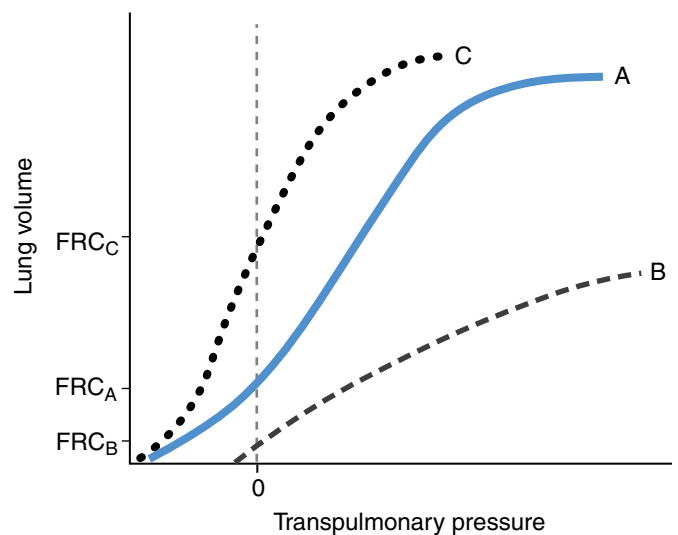

Figure 85.3. Pulmonary pressure–volume relationships in (A) normal lung, (B) severe restrictive disease, and (C) obstructive disease. Note that total lung capacity (indicated by the highest volume achieved), FRC, and compliance (curves) all change with disease.

Figure 85.4. Total work of breathing for a single breath to a lung volume of “x” for a pulmonary system with a compliance described by the depicted inspiratory pressure–volume curve.

Work of breathing

Work of breathing represents the total energy used to move the lung and chest wall. In most instances, active work occurs during inspiration only. Expiration is achieved using energy stored in the form of elastic recoil. At high minute ventilation or high resistance, expiration does become an active process. During inspiration, work is needed to overcome the elastic recoil of the lung and chest wall, the resistance to gas flow, and the frictional resistance of the tissue. Work may be calculated as the product of the change in volume and the change in pressure (Fig. 85.4). Normal tidal breathing by a healthy person accounts for only 2% to 3% of total body oxygen consumption. Increased tidal volumes will increase the work needed to overcome elastic recoil, whereas an increased respiratory rate increases the work needed to overcome resistance. As a result, patients with increased airway resistance tend to breathe at slower rates with larger tidal volumes to partially compensate for the increased work of breathing. The converse is true for patients with decreased compliance and stiff lungs or chest walls: they favor a rapid, shallow breathing pattern. Respiratory muscle fatigue, a primary cause of respiratory failure, may occur because of sustained increased loads, muscle atrophy from disease or disuse, or mechanical changes (such as a marked increase in functional residual capacity [FRC]) that foreshorten the muscle fibers and limit excursion with contraction, forcing a sustained increase in the respiratory rate.

Control of breathing

Neuronal control of breathing originates from respiratory centers in the pons and medulla and is influenced by multiple

Figure 85.5. Relationship between PaCO_2 and minute ventilation.

inputs from within the central nervous system. Rhythmic activity of the respiratory muscles maintains normal blood oxygen and carbon dioxide levels. Central chemoreceptors respond to changes in cerebrospinal fluid (CSF) pH. Because CO_2 freely crosses the blood–brain barrier, CSF pH changes with changes in arterial CO_2 concentrations. Minute ventilation increases with increasing arterial CO_2 in a nearly linear fashion (Fig. 85.5). Very high CO_2 levels will depress ventilation, however. Importantly, over time, bicarbonate is transported across the blood–brain barrier and permits the CSF pH to return to normal in the face of sustained hypercarbia. This mechanism is thought to account for the inappropriately low minute ventilation observed in chronic obstructive pulmonary disease (COPD) patients with chronic hypercarbia.

Several peripheral receptors also modulate ventilation. Chemoreceptors in the carotid bodies and aorta detect changes in arterial oxygen and CO_2 tension, as well as pH and perfusion pressure. Minute ventilation is increased in the setting of a falling PaO_2 or pH, or an increasing CO_2 level. The response to oxygen tension is not linear, however, and there is minimal effect until the PaO_2 is < 50 mm Hg (Fig. 85.6). Bilateral carotid body resection can completely ablate the hypoxic ventilatory drive. A variety of receptors located in the lungs themselves also modulate the neuronal control of breathing. Among other functions, these receptors can trigger coughing, bronchoconstriction, and sensations of dyspnea.

Several factors can change the ventilatory response to carbon dioxide and oxygen. The CO_2 response is blunted

Figure 85.6. Relationship between P_{aO_2} and minute ventilation.

during sleep, by aging, and by drugs such as opiates, barbiturates, and benzodiazepines. Concomitant hypoxia will increase the response to a given degree of hypercarbia. Interestingly, increased work of breathing, such as seen in the setting of narrowed airways, blunts the hypercarbic ventilatory response.

The matching of ventilation and perfusion

Distribution of ventilation

A portion of the inspired gas never reaches the respiratory zone. This gas occupies the upper airway, trachea, and other conducting airways. It is termed the *anatomic dead space*, and amounts to about 150 ml in an average adult. The remainder of the inspired volume has the potential to participate in gas exchange and is termed the *alveolar ventilation*. Not all gas that reaches the respiratory zone participates in CO_2 elimination, however. For example, gas flow to a set of alveoli that are not perfused contributes additional dead space. The total dead space in the

lung is referred to as *physiologic dead space* and can be calculated using Bohr's equation:

$$\frac{V_D}{V_T} = \frac{P_{aCO_2} - P_{ECO_2}}{P_{aCO_2}}$$

Physiologic dead space represents 20% to 30% of the tidal ventilation during quiet breathing in a healthy person. Certain lung diseases, such as COPD and acute respiratory distress syndrome, markedly increase the physiologic dead space, profoundly decreasing the efficiency of ventilation.

The distribution of ventilation is directly effected by gravity. In an upright individual, the inferior portions of the lung receive the most ventilation and the apical portions the least. When the subject is supine, the highest ventilation occurs in the posterior, most dependent regions.

Distribution of perfusion and the West zones

There is significant asymmetry of distribution of blood flow within the human lung. In the upright position, blood flow is directly influenced by gravitational forces and is lowest at the apex and highest at the base. When body position is changed, the distribution of blood flow tracks the changes in gravitational forces, with the most dependent portions of the lung seeing the greatest perfusion. Additionally, pulmonary capillaries are surrounded by alveoli, which are filled with gas at the alveolar pressure. The West zones describe the relationships among pulmonary alveolar, arterial, and venous pressures (Fig. 85.7). In zone 1, the alveolar pressure is higher than the arterial and venous pressures and the blood vessels are collapsed. This would occur in the setting of low arterial pressure (shock) or high alveolar pressure (positive pressure ventilation) and creates areas that are ventilated but not perfused, thereby increasing the amount of physiologic dead space. In zone 2, arterial pressure exceeds alveolar pressure, but alveolar pressure is still greater than venous pressure. As a result, blood flow is determined by the difference between arterial and alveolar pressures. Once zone 3 is reached, the venous pressure finally is greater than the alveolar pressure and flow is once again determined

Figure 85.7. West zones of the lung: (A) upright and (B) supine.

by the more customary difference in arterial and venous pressures. Some refer to a zone 4, which occurs in the most dependent areas of the lung where atelectasis and low lung volumes cause compression of the extra-alveolar vessels, resulting in an overall decrease in flow to the region.

Matching ventilation and perfusion

Gravity has an important role in the distribution of both ventilation and perfusion. However, gravity is not sufficient to ensure maximal matching of ventilation and perfusion, which is necessary for efficient gas exchange. This occurs primarily as the result of hypoxic pulmonary vasoconstriction. Through mechanisms not yet fully defined, low alveolar oxygen tension leads to vasoconstriction of the small arterioles supplying that region of the lung. Local blood flow is profoundly reduced. As a result, blood flow is matched to areas of higher ventilation and higher alveolar oxygen content. Inhaled nitric oxide will reverse the vasoconstriction but acts only locally and thus only in the regions where ventilation occurs.

Abnormalities in ventilation/perfusion matching: the primary cause of hypoxemia

Several separate processes may lead to impairment of pulmonary gas exchange. Abnormally low alveolar ventilation, termed *hypoventilation*, results in more oxygen being taken up at the alveolar capillary interface than is supplied to the alveoli, leading to hypoxemia. At the same time, less carbon dioxide is cleared and arterial hypercapnia occurs.

Shunt occurs when blood flows through areas of lung that are not ventilated because of atelectasis or disease of the parenchyma. Additionally, blood may bypass the pulmonary circulation altogether. This occurs via the bronchial circulation, right-to-left shunting in the heart, or coronary venous drainage. This deoxygenated blood mixes with oxygenated blood from the pulmonary veins in the left heart and decreases PaO_2 . Hypoxemia due to shunt can be identified by giving a patient 100% oxygen. Because the shunted blood bypasses the respiratory interface, the PaO_2 of the shunted blood does not increase and provision of 100% oxygen will not fully correct the hypoxemia. Shunt is not usually associated with hypercarbia, because even small increases in the PCO_2 result in compensatory hyperventilation, which drives the PCO_2 back to baseline.

Although hypoventilation and shunt both may cause hypoxemia, the most common cause of hypoxemia clinically is regional mismatching of ventilation to perfusion (V/Q). To appreciate the importance of V/Q matching, one must recognize that the concentration of oxygen, or any other gas, in an alveolus is dependent on the rate at which the gas is added (ventilation) and the rate at which the gas is removed (perfusion). End capillary blood exiting an alveolus that is poorly ventilated will have the characteristics of mixed venous blood – a high concentration of carbon dioxide and a low concentration of oxygen. On the other hand, blood exiting an alveolus with high

Figure 85.8. Distribution of ventilation and perfusion in a subject with normal lungs.

ventilation but poor perfusion will have a gas content that mirrors the inspired gas – high in oxygen and low in carbon dioxide. In an upright human, the V/Q ratio is highest at the apex and lowest at the base. In a healthy individual, the V/Q ratios in the lung are tightly distributed around the optimum ratio of 1.0, allowing for efficient gas uptake (Fig. 85.8). Pulmonary diseases broaden the distribution of the V/Q ratios, often with increases in the number of alveolar units with both the low and high V/Q ratios (Fig. 85.9). The overall result is worsened gas exchange, with the balance between hypercarbia and hypoxia being determined by the exact nature of the redistribution. A significant increase in the number of low V/Q units will result in hypercarbia, whereas an increase in the number of high V/Q units causes hypoxemia. In vivo, hypercarbia is a potent stimulus for hyperventilation. Most of the time, arterial CO_2 will remain near

Figure 85.9. Distribution of ventilation and perfusion in a patient with COPD.

Figure 85.10. Spirometric measurement of lung volumes. RV and FRC cannot be measured by spirometry.

normal at the expense of increased minute ventilation and energy expenditure.

Pulmonary function testing

Pulmonary function tests permit specific, objective evaluation of certain lung functions. They are used to help with diagnosis and also may be used to monitor treatment effects or disease progression. Pulmonary function testing has often been used as part of the preoperative evaluation of patients presenting for major surgery. These tests are most useful when used to evaluate patients with significant underlying pulmonary disease for major lung resection. In most other circumstances, pulmonary function tests do not add significant additional information to that obtained from a careful history and physical examination. They should not be routinely ordered as part of a general perioperative evaluation.

Spirometry measures lung volumes and flows. The tidal volume can be measured during relaxed breathing. A more useful volume is the forced vital capacity (FVC). To make this measurement, the patient is asked to breathe in as deeply as possible and then blow out as hard and fast as he or she can. The exhaled volume is the FVC. There is always some air left in the lung; this is termed the *residual volume* (RV), and it cannot be measured using spirometry. Total lung capacity is the sum of the FVC and RV and also cannot be measured with spirometry (Fig. 85.10).

Several useful measurements of flow can be determined using spirometry. The most commonly used clinically is the forced expiratory volume in the first second of expiration (FEV_1). Normally, 80% of the FVC is expelled in the first second. The combination of the FVC and FEV_1 , especially when normalized to the percent predicted based on gender, age, and body size, allows one to distinguish between restrictive and obstructive pulmonary diseases. In the setting of a restrictive disease, such as pulmonary fibrosis, both the FVC and the FEV_1 will be reduced, but the ratio of the two will essentially be unchanged. Obstructive disease, on the other hand, results in a relatively

preserved FVC, but the FEV_1 is decreased. Therefore, the ratio of the FEV_1/FVC will be markedly decreased. One problem with the measurement of the FEV_1 is that it is effort dependent. The flow during the middle half of expiration, termed the FEF_{25-75} , also can be measured and is thought to be much more independent of patient effort.

Another way to analyze the flows and volumes obtained via spirometry is to graph the data as flow–volume curves. Both expiratory and inspiratory curves can be displayed. Obstructive disease, restrictive disease, upper airway obstruction, and intrathoracic airway obstruction can be recognized from their classic flow–volume curves (Fig. 85.11 and Fig. 85.12). Of course, many patients have mixed disease and so may have flow–volume curves that are not characteristic of any one disease pattern.

Figure 85.11. Idealized flow–volume loop of a patient with normal lungs and a patient with significant COPD.

Figure 85.12. Idealized flow–volume loops in three types of upper airway obstruction.

Direct measurement of the RV or FRC can be done using either dilution of an inert gas (usually helium) or body plethysmography. Total lung capacity can also be measured this way. There are subtle differences between the two techniques. In particular, if there is a large portion of pulmonary gas that is trapped and does not communicate with the mouth, the gas dilution technique, which depends on distribution and equilibration of the gas throughout the lung, will yield erroneously

low volumes, which would be a particular concern in the setting of significant COPD.

It is important to realize that all the previously described measurements are measurements of ventilation. They do not measure gas exchange at the alveolar–capillary interface. This can be evaluated using the diffusing capacity for carbon monoxide (DLCO). The amount of carbon monoxide taken up in 1 minute will depend on the total area of the alveolar–capillary interface and on the thickness of this membrane. Interstitial lung diseases, such as pulmonary fibrosis and sarcoidosis, which thicken the alveolar interstitium, result in a decrease in DLCO. Likewise, any disease that decreases the total area of the alveolar–capillary interface will result in a decrease in DLCO. Carbon monoxide is taken up by red blood cells, so diseases that reduce the red blood cell flow through the capillaries will affect DLCO, even in the setting of a normal alveolar–capillary interface.

Oxygen and carbon dioxide transport

Swaminathan Karthik and J. Taylor Reed

This chapter focuses on the transport of oxygen and carbon dioxide at the blood and tissue level.

Oxygen transport

Hemoglobin

Hemoglobin plays a critical role in the transport of oxygen. Ninety-seven percent of oxygen is transported chemically bound to hemoglobin, and 3% is transported dissolved in the plasma.

Each hemoglobin molecule is made up of four chains. Each chain is composed of an iron-containing heme molecule and a polypeptide globin molecule. Variations in the amino acid sequence of the globin yield different hemoglobin chains, such as α , β , γ , and δ . Hemoglobin A (adult) is composed of two α - and two β -chains. Hemoglobin F (fetal) is composed of two α - and two γ -chains. Thus, each hemoglobin molecule has four iron atoms, each of which in their divalent form can bind a single molecule of oxygen. Methemoglobinemia occurs if the iron is oxidized to its trivalent form (Table 86.1). Carbon monoxide poisoning (Table 86.2) occurs when carbon monoxide binds to hemoglobin and displaces oxygen.

Diffusion gradient for oxygen

Oxygen diffuses along its concentration gradient from the alveoli, into plasma, and then into the red cells, where it is bound to hemoglobin (Table 86.3). An alveolar oxygen partial pressure of 104 mm Hg will yield a PaO_2 of about 95 mm Hg secondary to dilution with deoxygenated (shunt) blood from the thebesian and bronchial veins. Oxygen tension in interstitial fluid is around 40 mm Hg, and intracellular PO_2 averages around 23 mm Hg. This concentration gradient causes oxygen to flow into the cells.

Oxygen–hemoglobin dissociation curve

The presence of hemoglobin in blood greatly increases oxygen-carrying capacity. Hemoglobin does not take up oxygen in a linear fashion. With the binding of each successive oxygen molecule, hemoglobin's affinity for oxygen increases. This is referred to as cooperative binding. Plotting the oxygen saturation of hemoglobin against the partial pressure of oxygen yields

Table 86.1. Causes and treatment of methemoglobinemia

- Iron in heme moiety is in the ferric (Fe^{3+}) state
- Results in decreased affinity for oxygen and carbon dioxide
- Caused by nitrates, nitrites, sulfonamides
- Treatment: methylene blue (a reducing agent)

the classic sigmoid oxygen–hemoglobin dissociation curve (Fig. 86.1). Hemoglobin can be rapidly saturated or desaturated within a narrow range of partial pressures. At a $\text{PaO}_2 >$ about 80 mm Hg, hemoglobin saturation is $> 90\%$. At venous PO_2 of about 40 mm Hg, the hemoglobin saturation tends to be around 75%. The P_{50} , or the partial pressure at which hemoglobin is 50% saturated, is 26.5 mm Hg.

Bohr effect

Peripherally, saturated hemoglobin offloads oxygen and binds CO_2 and 2,3-diphosphoglycerate (2,3-DPG). This causes conformational changes at the oxygen binding site, decreasing its affinity for oxygen, further enhancing offloading of oxygen. When desaturated hemoglobin reaches the lung, CO_2 and 2,3-DPG are released and hemoglobin's high affinity for oxygen is restored.

The four common physiologic factors that shift the oxygen–hemoglobin dissociation curve are pH, PCO_2 , 2,3-DPG, and temperature. A decrease in pH or an increase in PaCO_2 shifts the dissociation curve to the right, facilitating delivery of oxygen to peripheral tissues; this is known as the Bohr effect. An increase in pH, or a decrease in PCO_2 , shifts the curve to the left, increasing hemoglobin's affinity for oxygen. Increased temperature shifts the curve rightward, enabling greater oxygen delivery (DO_2) to peripheral tissues in times of greater metabolic need, such as during exercise. Increased 2,3-DPG causes a rightward shift and is produced over hours to days during exposure to

Table 86.2. Etiology and treatment of carbon monoxide poisoning

- Binds to hemoglobin at same site as oxygen
- 250 times greater affinity than oxygen
- A PaCO of 0.6 mm Hg or FiCO of 0.1% may be lethal
- Treatment includes 100% oxygen and hyperbaric oxygen

FiCO , fraction of inspired carbon monoxide content.

Table 86.3. Partial pressures of gases in different parts of the body^a

	Partial pressure, mm Hg				
	Dry air	Distal airway end inspiration	Alveolar	Arterial	Mixed venous tissue
PO ₂	159.7	139.7	100	95	40
PCO ₂	0.3	0.3	40	40	46
PN ₂	600	573	573	573	573
PH ₂ O	0	47	47	47	47
Total	760	760	760	760	706 ^b

^a Conditions at sea level. Total atmospheric pressure 760 mm Hg; 21% oxygen, 78% nitrogen, small quantities of CO₂, inert gases (mostly argon, also helium). PO₂ in dry air is 159.7 (760 × 0.21).

^b PAO₂ = (760 – 47) × 0.21 – PACO₂/0.8. PO₂ decreases more than PCO₂.

PACO₂, partial pressure of carbon dioxide, alveolar; PAO₂, partial pressure of oxygen, alveolar; PH₂O, partial pressure of water; PN₂, partial pressure of nitrogen.

hypoxia. This is one of the compensatory mechanisms at high altitudes.

Oxygen delivery and consumption

Each gram of hemoglobin can carry 1.39 ml of oxygen. Thus, a person with a hemoglobin concentration of 15 g/dl carries 20.9 ml (15 × 1.39) of oxygen per 100 ml of blood if the hemoglobin is maximally saturated. Dissolved oxygen accounts for 0.003 ml of oxygen per mm Hg of oxygen per 100 ml of plasma. Venous hemoglobin, with a saturation of 75%, carries 15.7 ml of oxygen per 100 ml of blood. Oxygen consumption (VO₂) therefore is 5.5 ml per 100 ml of blood. Normal oxygen consumption in the resting adult human is approximately 275 ml/min.

$$\begin{aligned} \text{Content of O}_2 (\text{CaO}_2) &= \text{oxygen bound to hemoglobin} \\ &\quad + \text{oxygen dissolved in plasma} \\ \text{CaO}_2 &= [1.39 \times \text{hemoglobin (g/100ml)} \\ &\quad \times \text{O}_2 \text{ saturation}] + [0.003 \times \text{PO}_2]. \end{aligned}$$

Oxygen extraction ratio

Under normal circumstances, only 25% of oxygen delivered to peripheral tissues is extracted. This is the oxygen extraction ratio (OER); it can be calculated by the equation:

$$\text{OER} = \text{VO}_2 / \text{DO}_2$$

or

$$\text{OER} = (\text{CaO}_2 - \text{mixed venous oxygen content [CvO}_2]) / \text{CaO}_2.$$

When DO₂ decreases, or oxygen consumption increases, increased oxygen extraction will occur to maintain a constant VO₂ (line CB in Fig. 86.2). As DO₂ decreases to a critical threshold, VO₂ starts to fall linearly with falling DO₂ (line BA in Fig. 86.2), leading to anaerobic metabolism and an accumulation of lactate. In critically ill patients with impaired cellular respiration, this relationship is altered. Oxygen extraction appears to be impaired even when adequate DO₂ occurs. Thus, increased DO₂ is matched by increased VO₂ (line EF in Fig. 86.2). This reflects an oxygen debt that may respond to supranormal DO₂ and has been the basis of goal-oriented therapy.

Exercise physiology

A sixfold increase in cardiac output may occur during exercise. This, combined with a threefold increased oxygen extraction by tissues, results in an almost 20-fold increase in DO₂. Oxygen consumption in muscles is greatly increased, thus this increased DO₂ is needed to prevent lactate buildup.

Fetal oxygen transport

Fetal hemoglobin has greater affinity for oxygen and is thus left shifted compared with adult hemoglobin. This results in a P₅₀ of about 19 mm Hg, which is significantly lower than adult hemoglobin. This higher affinity maintains DO₂ to the fetus. Hemoglobin concentration is around 18 mg/dl in the fetus, which allows for a higher content of oxygen to be transported.

Figure 86.1. The hemoglobin–oxygen dissociation curve. Normal, left-shifted, and right-shifted curves.

Figure 86.2. Relationship between oxygen delivery and consumption in normal humans (ABC) and the critically ill (DEF). (From Leach RM, Treacher DF. The pulmonary physician in critical care: 2. Oxygen delivery and consumption in the critically ill. *Thorax* 2002; 57:170–177.)

Mixed venous saturation

Venous PO_2 tends to be around 40 mm Hg with a hemoglobin saturation of around 75%. Venous blood returning to the heart is from three sources: the superior vena cava, the inferior vena cava, and the coronary sinus. The heart and brain have higher extraction ratios. Venous blood from these organs has a lower oxygen saturation. Complete mixing is presumed to occur in the pulmonary artery, hence this saturation is called the *mixed venous saturation*. Mixed venous saturation can be used to calculate cardiac output and shunt fraction.

The Fick principle is a form of indicator dilution that uses oxygen to determine cardiac output. Arteriovenous oxygen content difference multiplied by cardiac output is the amount of oxygen used by tissues. Assuming that a constant amount of oxygen is used by tissue every minute (VO_2), arteriovenous content difference will vary inversely with cardiac output:

$$\text{Cardiac output} = \frac{\text{amount of oxygen absorbed}}{\text{arteriovenous oxygen content difference}}$$

or

$$Q = VO_2 / (CaO_2 - CvO_2).$$

Solving this for mixed venous oxygen saturation (SvO_2) yields this equation:

$$SvO_2 = \text{arterial oxygen saturation} - (VO_2 / Q \times 1.39 \times \text{hemoglobin} \times 10).$$

This equation ignores dissolved oxygen, which normally contributes very little to the total content of oxygen. A conversion factor of 10 is used to convert the units of hemoglobin

from milligrams per deciliter to milligrams per liter. Oxygen consumption is usually assumed to be 250 ml/min or 4 ml/kg body weight. From this equation, it is clear that the four factors that influence mixed venous saturation are cardiac output, hemoglobin concentration, arterial saturation, and O_2 consumption.

Oxygen toxicity

Complex defense mechanisms have been put in place to control cellular oxygen toxicity. The antioxidant systems are developed meticulously enough that oxygen radicals in fact are being used to defend against invading offenders, such as bacterial endotoxins.

Under normal atmospheric conditions, inspired oxygen fraction can be increased only moderately by hyperventilating or by increasing inspired oxygen fraction up to 100%, as is done routinely when administering anesthesia care (i.e., pre-oxygenation, before extubation, during a single-lung situation). Although this raises the hemoglobin saturation to 100% given normal arterial/mixed venous oxygen content difference, the increase of oxygen in physical solution is almost negligible. Thus, the increase in mixed venous PaO_2 while breathing 100% oxygen is trivial. However, mixed venous PaO_2 closely reflects tissue PaO_2 . Target values of oxygen tension on the mitochondrial level are still a matter of debate. Although some argue that men and women are derived from a life without oxygen and are adapted to a rather anaerobic environment in which there is a constant need to defend themselves against oxygen, the bottom line is that mitochondrial oxygen tension is probably very different in different tissues and might range from 3 to 20 mm Hg. Endothelial cells in contact with arterial blood are exposed to much higher oxygen tensions than, for example, bone marrow cells. We can assume that the range of oxygen tensions tolerated on a cellular level is rather wide.

Oxygen radicals

Superoxide radical production occurs in mitochondria through leakage of electrons to molecular oxygen as well as through activated phagocytes and within the hypoxanthine-xanthine oxidase system. Additionally, as a result of ischemia/reperfusion injury, reactive oxygen species (ROS) and reactive nitrogen species (RNS) are produced and widely distributed through the circulation. Biological targets for ROS/RNS are phagocytosed microorganisms, DNA, lipids, and sulfhydryl-containing proteins. Furthermore, ROS play an important role in cell signaling, differentiation, and apoptosis. Inappropriate activation of adherent and migrated neutrophils, however, clearly can produce harm against oneself, as suggested in the pathomechanisms of acute lung injury and other autoimmune diseases. Oxidative stress is increasingly recognized as being involved in several neurodegenerative diseases, such as Alzheimer's dementia, amyotrophic lateral sclerosis, and Parkinson's disease, as well as lipid oxidation and atherosclerosis.

Antioxidant systems

Antioxidant systems such as superoxide dismutase, catalase, the glutathione peroxidase system, and nonenzymatic endogenous antioxidants such as ascorbic acid, vitamin E, and surfactant act as radical scavengers but also protect the integrity of proteins and cell membranes. Their existence allows the sophisticated use of ROS to maintain the organism's integrity. Statins show great promise as regulators of ROS production by reducing NADPH oxidase activity, thus reducing nitric oxide scavenging and causing not only vascular dilation but also inhibition of leukocyte adherence and hence overall immunoregulatory effects. Antioxidants have been trialed as adjuvant therapeutics to adversely affect the impact of oxidative stress such as aging, cardiovascular disease, and cancer. Most nonenzymatic antioxidants can be perceived as a double edged sword because of their potential to act as pro-oxidants in an environment that combines oxygen with metals that may serve as redox-active transition metals (i.e., Fe^{2+}). This antiredox paradox may explain why large doses of supplemental antioxidants so far have failed to significantly alter life expectancy.

Clinical oxygen toxicity

Pulmonary oxygen toxicity has been appreciated for quite some time. Lung tissue is at the forefront of high inspired oxygen fractions. Airway inflammation and reduced vital capacity are known sequelae of breathing high inspired oxygen fractions for 24 hours. Structural changes leading to acute lung injury and pulmonary fibrosis representing irreversible changes of lung function and architecture are predominant in prolonged exposure to normobaric oxygen breathing. Elevated PaO_2 is of more predictive value than fraction of inspired oxygen content (FiO_2). A PaO_2 level of 255 mm Hg has been established as safe.

Reabsorption atelectasis is another pulmonary complication of 100% oxygen breathing, albeit much better established and defined. Lung zones with low ventilation–perfusion ratios collapse only a few minutes after breathing 100% oxygen. This is a frequent occurrence in daily anesthetic practice and remains well established for the induction phase, because preoxygenation and denitrogenization heighten the safety margin when apnea is induced and assisted ventilation commences. Whether the routine increase of FiO_2 to 100% before extubation is necessary or even harmful for reasons stated earlier (why induce atelectasis right before the transition is made from controlled mechanical positive pressure ventilation to spontaneous respiration in a patient at the beginning of recovery from surgery with all the insults to breathing taken together: diaphragmatic dysfunction, decreased functional residual capacity from anesthetic agents, supine position, opioid use, pain, etc.) is being questioned.

Finally, patient factors must be considered as well. The exposure to bleomycin renders a patient susceptible to oxygen-induced pulmonary fibrosis, respiratory failure, and even death when subsequently exposed to high inspired fraction of

oxygen. Although the molecular mechanism remains elusive, clinical practice has been not only to limit FiO_2 , but also to use intravenous fluids more judiciously, as this is another proposed factor supporting the development of acute lung injury and respiratory failure after bleomycin therapy.

Retrolental fibroplasia

Retrolental fibroplasia still puzzles providers caring for newborns. Initially recognized as a likely result of uncritically generous exposure of newborns to high inspiratory oxygen fractions, it remains the leading cause of blindness and vision impairment in children, even after adjustment of the neonatal resuscitation guidelines and the revelation that in newborns, treating hypoxia is just as critical as avoiding hyperoxia.

Benefits of increased perioperative FiO_2

Increased inspired oxygen tensions at normal atmospheric pressure are usually well tolerated in adults under anesthesia. Recent studies suggest improved outcome with regard to wound infections, partially based on the finding that PaO_2 plays a much more vital role in wound healing than hemoglobin-bound oxygen, because the microvasculature is disrupted and the diffusion-driving force is partial pressure gradient. In conjunction with the avoidance of vasoconstriction and its prerequisites, such as pain, hypothermia, and shock, tissue oxygenation can be optimized without a clinically relevant negative impact of intra- and postoperative delivery of FiO_2 in the range of 80%.

Carbon dioxide transport

Carbon dioxide is produced by the various tissues of the body as a waste product of metabolism. It is a nonpolar molecule that diffuses easily through lipid membranes and, as a result, can travel through the mitochondrial membrane, cytosol, cell membrane, extracellular space, and endothelium until it reaches the plasma. Once in the plasma, it travels in one of three forms: dissolved in plasma, converted to bicarbonate, or as a carbamino compound.

Dissolved in plasma

The solubility of carbon dioxide is 0.075 ml CO_2 /dl/mm Hg. When the venous PCO_2 is 45 mm Hg, the amount of dissolved CO_2 is 3.4 ml/dl. This accounts for roughly 9% of all carbon dioxide produced in the body, but can increase to nearly one third of the total amount during strenuous exercise. CO_2 is much too insoluble to be completely eliminated from the body in its unaltered state.

Conversion to bicarbonate by carbonic anhydrase

Once in the bloodstream, carbon dioxide diffuses through the red cell membrane, where it comes in contact with free floating carbonic anhydrase (CA). CA rapidly catalyzes the reaction:

Carbonic acid, the immediate product of this reaction, spontaneously and rapidly dissociates into bicarbonate and a proton. Although CO_2 undergoes this reaction spontaneously, CA greatly accelerates the reaction. CA is well placed in the red blood cell cytosol as hemoglobin buffers the hydrogen ion produced with little change in body pH.

Role of the Bohr effect on CO_2 transport

The affinity of hemoglobin for hydrogen ions is not constant. This is fundamentally important in shuttling carbon dioxide from the periphery to the lung. The Bohr effect (mentioned earlier) refers to the inverse relationship of oxygen and hydrogen ion affinity for hemoglobin. When oxygen dissociates from hemoglobin, the dissociation constant (pK_a) of specific amino acids is increased, causing a greater propensity for hydrogen ions to bind. This favors the transformation of CO_2 to bicarbonate and H^+ . This system is driven entirely by the relative concentrations of oxygen and hydrogen ions in the different areas of the body. In the lungs, the concentration of oxygen is high and the concentration of hydrogen ions is low because of the elimination of carbon dioxide. This promotes oxygen binding to hemoglobin and release of hydrogen ions, driving CO_2 formation and elimination. In the tissues, where CO_2 concentration is high because of metabolism, hydrogen ions are created and bound to hemoglobin, and oxygen is released.

Chloride (Hamburger) shift

As bicarbonate is continually being produced in the red cell, bicarbonate levels increase in the cytosol. A transport protein in the red cell membrane rapidly exchanges chloride ions from the plasma for bicarbonate ions. This feature of bicarbonate homeostasis has been termed the *chloride shift*. It prevents progressive intracellular alkalosis while maintaining electrical neutrality.

Carbamino compound formation

Carbon dioxide binds to amino groups on plasma proteins and hemoglobin to form carbamino compounds. The protein concentration in plasma is around 7%. The hemoglobin concentration in the red blood cell is around 30%; therefore, this type of transport is more prevalent inside the red blood cell. Carbamino compound formation accounts for the transport of 5% of the carbon dioxide in arterial blood but 30% of the carbon dioxide taken up in the capillaries.

When a carbamino compound forms, a hydrogen ion is released:

This hydrogen ion is immediately buffered by the imidazole groups of histidine residues on hemoglobin and on plasma proteins. Once in the lung, O_2 association causes a conformational change that releases H^+ and drives the reaction toward the release of CO_2 from the amino groups.

Figure 86.3. Carbon dioxide dissociation curve. The relationship between PCO_2 and total CO_2 content.

Carbon dioxide content versus carbon dioxide tension

Carbon dioxide in the dissolved form varies linearly with its partial pressure in the blood, whereas the total quantity of CO_2 in the blood is graphically illustrated as a flattened hyperbola (Fig. 86.3). In the physiologic range, this relationship is almost linear.

Haldane effect

The Haldane effect describes the relationship between the transport species of carbon dioxide and the binding of oxygen to

Figure 86.4. Carbon dioxide dissociation curve and the Haldane effect (shift from **A** to **B**). (From Guyton AC, Hall JE. *Transport of oxygen and carbon dioxide in the blood and body fluids*. In: *Textbook of Medical Physiology*. 10th ed. Philadelphia; 2000:472.)

hemoglobin. Binding of oxygen displaces CO₂ via changes in pK_a of the hemoglobin amino acids. Hydrogen ions bound to hemoglobin are released, favoring release of CO₂ from carbamino compounds. The CO₂ then diffuses down the concentration gradient into the alveoli and is subsequently eliminated via respiration (Fig. 86.4).

Lung isolation techniques

Shine Sun and Sarah H. Wiser

The anesthetic management of intrathoracic procedures and the care of critically ill patients who require differential lung ventilation necessitate facility with lung isolation techniques. In its most basic form, the goal of lung isolation is either to selectively interrupt ventilation to a section of the pulmonary tissue or to prevent soilage of the contralateral lung. Isolation may involve a portion of lung, as in lobar isolation, or an entire lung. Familiarity with the tools and techniques of lung isolation is essential. Equally important is the ability to quickly troubleshoot each technique and to know when circumstances favor one technique over another. This chapter focuses on the techniques used for lung isolation and the basic physiology of one-lung ventilation (OLV). Ventilatory settings and management of hypoxemia during OLV are considered in detail in the next chapter.

Indications for lung isolation

The indications for lung isolation are divided into absolute and relative indications (Table 87.1). This designation is somewhat artificial as some surgical procedures, although considered a relative indication, would be difficult if not impossible to perform without lung isolation.

Contraindications

Although no specific contraindications exist, it is important to be mindful of the clinical situation instead of applying a

“one size fits all” technique. For example, the use of a left-sided double-lumen tube (DLT) in the setting of an exophytic tumor involving the left mainstem bronchus is not recommended. The decision as to whether lung isolation is necessary and the selection of technique should be intimately tied to the clinical situation.

Anatomy

A basic understanding of the normal tracheobronchial anatomy is essential for successful lung isolation. Often a surgical bronchoscopy is performed at the beginning of a thoracic surgical procedure. This presents an opportunity for the anesthesia practitioner to become familiar with the patient’s anatomy. This familiarity is crucial to verify correct placement of the lung isolation device chosen. It has been demonstrated that anesthesiologists with only occasional lung isolation experience malposition the device 40% of the time, despite facility with fiber-optic bronchoscopy and a prior tutorial on lung isolation.

Normal anatomic features in the adult are as follows: The distance from the teeth to the carina averages 20 to 25 cm. From the carina, the left mainstem bronchus continues at a 45° angle before reaching its secondary carina. On average, the left mainstem bronchus is 54 mm long in men and 50 mm in women. The secondary carina of the left mainstem bronchus marks the division of the upper and lower lobar bronchi. Segmental anatomy is depicted in Fig. 87.1. It is important to realize that significant variability exists at the segmental level.

The right mainstem bronchus branches from the carina at a 10° angle and travels, on average, only 19 mm in men and 16 mm in women before dividing into the right upper lobe bronchus and the bronchus intermedius. Classically, the right upper lobe bronchus trifurcates almost immediately, creating what is often referred to as the “Mercedes-Benz” sign. In approximately one in 250 people, a variant known as a tracheal or “pig” bronchus may be present. In this instance, the right upper lobe arises directly from the trachea instead of the right mainstem bronchus. The length of the right mainstem bronchus is an important characteristic and should be noted during bronchoscopy, as a short right mainstem may make lung isolation with a right-sided tube more difficult. Distally, the bronchus intermedius gives rise to the middle and lower lobe bronchi and their respective segmental bronchi.

Table 87.1. Indications for OLV

Absolute

Isolation of lungs to prevent spillage from hemorrhage or infection
Therapeutic need to ventilate only one lung
Bronchopleural fistula
Unilateral cysts or bullae
Unilateral bronchial disruption or trauma
Unilateral lung lavage
Video-assisted thoracoscopic surgery

Relative

Lung isolation tools

Double-lumen tubes

The most common tool for lung isolation is the DLT. Although it has been through many variations since its initial introduction into clinical use by Carlens 50 years ago, the DLT still retains the basic structure. A DLT consists of two ventilating lumens bound together into one tubular structure. Each lumen, tracheal and bronchial, has a cuff to provide a seal. The bronchial lumen is longer, to allow endobronchial intubation, and its cuff is high

pressure/low volume. The tracheal lumen ends above the carina and uses a low-pressure/high-volume cuff (Fig. 87.2).

The proximal take-off from the right mainstem bronchus mandates sidedness in the design of DLTs. The right-sided DLT has a ventilating side port in the endobronchial lumen to allow ventilation of the right upper lobe (Fig. 87.3).

Figure 87.2. A left-sided Robertshaw-type DLT by Rusch.

Figure 87.3. Two views of the right-sided Robertshaw-type DLT from Rusch and Mallinkrodt. (Adapted from www.anaesthesiauk.com.)

Figure 87.4. Left-sided Carlens double-lumen ETT with carinal hook. (Adapted from Zadrobilek E, Fitzal S. The Robertshaw double-lumen bronchial tubes: fortieth anniversary of the first published description. *Internet J Airway Manag* 2 2002–2003. Available at: <http://www.adair.at/ijam/volume02/historicalnote03/default.htm>.)

The presence of a carinal hook, designed to prevent distal migration of the entire tube, is particular to the Carlens type DLT (Fig. 87.4).

Although the carinal hook may help prevent distal migration of the endotracheal tube (ETT), its presence also poses a risk for airway trauma, resulting in tracheobronchial disruption due to “catching” of the hook on tissues other than the carina. Furthermore, the carinal hook can make placement of the DLT through the glottis more difficult.

DLT sizes currently available depend on the manufacturer, but they typically include pediatric (26F, 28F) and adult (35F, 37F, 39F, 41F) sizes. The French catheter gauge size is equal to the external diameter of the DLT in millimeters multiplied by three. For example, a 39F DLT has a total diameter of 13 mm.

Size selection

Proper size selection of the DLT is important to provide good lung isolation while causing minimal trauma to the airway. A correctly sized DLT is one that (a) passes atraumatically through the glottic opening, down the trachea, and into the intended mainstem bronchus; (b) has good alignment of lumens with the appropriate bronchi for ventilation; and (c) provides a good seal at both the tracheal and bronchial cuffs. Despite the obvious importance in proper sizing, there is no consensus as to how to choose the best size. Studies have attempted to correlate DLT size selection with patient criteria including gender and height, left mainstem bronchus size or tracheal diameter on chest radiographs, and left mainstem bronchus measurement on CT scans. There still is no universally accepted method for determining DLT size preoperatively. Many centers choose to use patient height and gender as a guideline for initial DLT size selection. Included here is a rough guide for initial size selection based on patient gender and height (Table 87.2).

Placement

The placement of right- and left-sided DLTs is similar. The tube is packaged with a stylet in the endobronchial lumen to facilitate

Table 87.2. Rough DLT sizing guide based on patient height

DLT size	35F	37F	39F	41F
Female	≤ 5'1"	5'2"–5'11"	≥ 6'	–
Male	–	≥ 5'5"	5'6"–5'11"	≥ 6'

placement. The stylet should not be removed, and care should be taken to prevent it from protruding beyond the end of the DLT. Direct laryngoscopy is performed to allow for visualization of the glottis. A Mac blade is preferred, as it provides a greater space in the laryngopharynx for manipulation of the DLT. The DLT is held with the bronchial lumen curved superiorly. The tube is advanced under direct visualization until the bronchial cuff disappears past the vocal cords. At this point, the endobronchial stylet should be removed. Advancement of the DLT with the stylet in place increases the risk of tracheal disruption. The DLT is then rotated toward the desired side of endobronchial intubation and advanced until gentle resistance is felt. The tracheal cuff should now be inflated. The presence of end-tidal CO₂ verifies placement in the airway.

The DLT should not be forced, and stiff resistance should not be “pushed through.” Occasionally, it is difficult to advance the DLT once passed through the glottis. This issue can be managed by rotating the DLT 180° toward the desired mainstem bronchus. This directs the tip of the DLT toward the membranous portion of the trachea. If continued resistance occurs, it is advisable to place a fiber-optic bronchoscope through the bronchial lumen and position the DLT under direct visualization. Fiber-optic placement of DLT should be performed for any patient who has an endobronchial mass or extrinsic airway compression. Generally speaking, there should be a low threshold to abandon DLT placement in favor of an alternate plan. The inability to place a DLT may be a result of the patient’s inherent anatomy. Tracheal disruption, carinal dislocation, and endobronchial rupture or hemorrhage may occur with DLT placement.

If the initial intubation proved difficult, and a DLT is necessary, a tube exchange catheter may be used to place the DLT. The exchange catheter is placed through the single-lumen tube (SLT) to an average depth of 22 cm. The patient’s oropharynx is suctioned, the SLT is removed, and the DLT is threaded over the exchange catheter via the endobronchial lumen and advanced into the airway. Laryngoscopy helps suspend the soft tissues of the oropharynx, promoting passage of the DLT. During placement of the DLT, it is important not to allow the catheter to advance too deeply, as this may cause airway trauma. Bronchoscopy is then used for definitive positioning of the DLT.

Confirmation of placement

Before the widespread availability of fiber-optic bronchoscopes, differential inflation of cuffs and auscultation were the standard for confirmation of correct DLT placement. Although auscultation is rarely used as the primary confirmation technique now, it may be used if fiber-optic equipment is not available. With both

	If DLT is too distal left:	If DLT is too proximal:	If DLT is too distal right:
Action:	Breath Sounds Heard	Breath Sounds Heard	Breath Sounds Heard
Clamp right, both cuffs inflated	Left side only	Left and right	Right side only
Clamp left, both cuffs inflated	None or faint on either side	None or faint on either side	None or faint on either side
Clamp left, deflate distal cuff	Left side only	Left and right	Right side only

Figure 87.5. Types of malposition of the DLT and techniques for identification with auscultation.

cuffs inflated, ventilation of the endobronchial lumen should result in breath sounds only on the endobronchial side. Ventilation of the tracheal lumen should result in breath sounds only in the contralateral lung field. Gross malposition of DLTs can be identified by lung auscultation during differential clamping and balloon inflation, as illustrated in Fig. 87.5.

Multiple studies have demonstrated that auscultation alone is largely insufficient for the confirmation of proper DLT placement. Anywhere from 30% to 80% of DLTs originally confirmed by auscultation are actually malpositioned when evaluated by bronchoscopy. Therefore, fiber-optic bronchoscopy is considered the gold standard for confirmation of DLT placement.

When evaluating DLT positioning by bronchoscopy, one should have a systematic approach. For both left and right DLTs, bronchoscopy through the tracheal lumen should reveal the carina with the bronchial cuff only minimally visible from the orifice of the desired mainstem bronchus (Fig. 87.6a,b). Passing the fiber-optic scope through the endobronchial lumen of a left-sided DLT should reveal the secondary carina (Fig. 87.6c). If these lobar bronchi (which should be roughly equal in size) are not both visible, the endobronchial lumen may be too deep. Bronchoscopy through the endobronchial lumen of a

right-sided DLT should reveal the ventilating side port lined up with the orifice of the right upper lobe and the bronchus intermedius (Fig. 87.6d).

If the location of the DLT is uncertain by initial bronchoscopy, repositioning of the tube under fiber-optic guidance is most expeditious. The bronchoscope is placed down the endobronchial lumen until it emerges from the end of the tube. Both cuffs are deflated, and positive pressure ventilation is suspended. The DLT and bronchoscope are withdrawn as a unit until visualization of the carina is obtained. At this point, the bronchoscope is advanced down the desired mainstem bronchus, and the DLT is advanced over the bronchoscope. This will seat the endobronchial lumen into the desired bronchus. Bronchoscopy via the tracheal lumen will then confirm correct placement and allow for adjustment of the endobronchial portion of the tube.

Fiber-optic confirmation of DLT positioning should be performed after initial placement and following any alteration in patient positioning. Additionally, intraoperative evaluation of DLT positioning may be required, as the tube may become dislodged secondary to external manipulation from the surgical field.

Figure 87.6. Views via bronchoscopy of properly placed left- and right-sided DLTs. **(A)** View through the tracheal lumen of a left DLT in proper position, with the carina visible and the endobronchial cuff barely visible alongside. **(B)** View through the tracheal lumen of a right DLT in proper position, with the carina visible and the endobronchial cuff barely visible alongside. **(C)** View through the endobronchial lumen of a properly seated left DLT with the secondary carina, left upper lobe bronchus, and left lower lobe bronchus visible. **(D)** View through the endobronchial lumen of a properly seated right DLT with the right upper lobe visible through the Murphy eye in the bronchial cuff and the bronchus intermedius visible through the distal hole. **(A and C)** adapted from Slinger P. <http://www.thoracic-anesthesia.com/wp-content/uploads/buffalo-lung-isol-507.pdf>; **B and D** adapted from Campos JH, et al. Devices for lung isolation used by anesthesiologists with limited thoracic experience. *Anesthesiology* 2006; 104:261–266.)

Advantages

DLTs provide excellent lung isolation capabilities. DLTs compare favorably with other lung isolation techniques in a variety of ways. The large internal diameters allow for more laminar airflow patterns and quicker deflation of lung parenchyma. Additionally, the larger lumens facilitate (1) passage of suction catheters for clearance of secretions, (2) application of continuous positive airway pressure (CPAP) to the operative lung in cases in which persistent desaturation occurs during OLV, and (3) passage of a pediatric fiber-optic bronchoscope to directly observe bronchial clamping and suturing, thereby guiding surgical technique.

Disadvantages

Overinflation of the endobronchial cuff may lead to mucosal ischemia. When lung isolation is no longer necessary, it is prudent to deflate the endobronchial cuff to minimize the time of direct pressure on the endobronchial mucosa. If postsurgical pulmonary toilet or evaluation of anastomotic lines is required, bronchoscopy by an adult bronchoscope is best used.

The adult bronchoscope has a larger suctioning lumen and better fiber-optics. The need to use an adult bronchoscope necessitates removal of the DLT for an 8.0 or larger SLT.

Patient comfort for extubation may also be a determining factor for reintubation with an SLT prior to emergence. The large external diameter of the DLT combined with its placement distal to the carina makes the DLT more stimulating for emergence. The smaller lumens also may make breathing more difficult, which may result in coughing, wheezing, and ventilator dyssynchrony.

In cases in which airway edema is a concern, a DLT may be left in place until it is deemed safe to convert to an SLT. The decision to leave a DLT in place postoperatively should be weighed against the risk of mucosal injury, the relative unfamiliarity of intensive care unit personnel with DLTs, and the risk of inadvertent dislodgement of the tube. Typically, in experienced hands, the DLT can be changed safely to an SLT with the use of a tube changer.

Because the DLT is widely used for lung isolation, its large size, relatively rigid construction, and lack of customizability (beyond sidedness and size/length) sometimes preclude its use as the lung isolation technique for a given patient or procedure. In difficult airway situations, extubation from the initially placed SLT may be ill advised. In addition, congenital or surgical anatomic variants may preclude use of a DLT, which relies on relatively conserved anatomic parameters. In these situations, bronchial blockers provide more flexibility for lung isolation.

Bronchial blockers

Bronchial blockers are the other main category of lung isolation tools. There are several variants, including stand-alone devices or those bound to an SLT, but they are conceptually the same. The basic construction of the bronchial blocker consists of a small-diameter catheter with an inflatable occlusive balloon at its distal end. The blocker can be guided via fiber-optic bronchoscopy into the desired location for lung or lobar isolation. Because bronchial blockers must be used in conjunction with an SLT, the blocker can be removed or disabled, allowing for postoperative mechanical ventilation without the necessity for a tube change. The Fogarty catheter, Arndt and Cohen bronchial blockers (Cook Medical, Bloomington, IN), and Univent tube (Fuji Systems Corp., Tokyo, Japan) all fall into this category of lung isolation technology.

Fogarty catheter

The Fogarty embolectomy catheter, although not created for airway use, may be used to provide lung isolation. It has a long track record of use in thoracic procedures, both as a primary lung isolation device and as a rescue device for inadequately functioning DLTs. Commonly employed sizes include 8/14F or 8/22F; both catheters are 80 cm long. The numbers 14 and 22 refer to the inflated balloon diameter in millimeters. The balloons on the Fogarty catheter are low volume/high pressure. Given the ability of the balloon to withstand high pressure

without rupture, it is critical to inflate the balloon under direct vision to avoid airway rupture. The catheter itself is made of natural rubber latex and contains a central wire stylet. There is no central communicating lumen from the proximal end to the distal tip.

Placement

Placing a 45° bend in the wire stylet 3 cm from the tip facilitates placement. One of two techniques then may be performed to avoid an air leak around the catheter: (1) During laryngoscopy, the catheter can be placed in the proximal trachea and then an SLT placed alongside the Fogarty catheter, or (2) after intubation with an SLT, a swivel connector with a rubber diaphragm attached to the 15-mm connector of the SLT will allow passage of the embolectomy catheter within the SLT while maintaining ventilation. Proper positioning of the Fogarty catheter requires fiber-optic bronchoscopy. Under direct vision with a bronchoscope, the distal end is directed toward the desired bronchus while the catheter is advanced. Once positioned, the balloon at the distal end should be inflated to create a seal.

Advantages

Fogarty catheters are widely available, and many anesthesiologists have experience with their use for lung isolation. They may be used in a variety of situations, such as with an SLT, through a tracheostomy, nasotracheally, or alongside/inside a DLT. The catheter can be manipulated to provide selective lobar blockade. A Fogarty catheter may be placed within a DLT to rescue a poorly functioning or an ill-fitting DLT.

Disadvantages

Fogarty catheters may be quite difficult to place. Other disadvantages include (1) latex composition, precluding their use in patients with a latex allergy; (2) lack of any guidewire system to help position the balloon tip; (3) lack of a central lumen to allow for delivery of CPAP or suctioning of the distal airway; (4) reliance on absorption atelectasis for lung collapse after placement, and (5) easy dislodgement during positioning and surgical manipulation.

Univent tube

The Univent tube is constructed of medical-grade silicone. It is an SLT with a separate channel fused along the anterior concave surface that houses a sliding bronchial blocker (Fig. 87.7).

The blocker of the Univent tube incorporates a high-pressure/low-volume cuff. The blocker itself slides within the side channel and can be guided into the left, right, or secondary bronchi with the aid of a fiber-optic bronchoscope. It is important to note that even though the insertion of a Univent tube is akin to the placement of a standard SLT, the outer diameter is markedly larger than that of a comparably sized standard ETT. The increased external diameter is the result of the fused channel, which houses the bronchial blocker. The internal diameters of Univent tubes range from 6.0 to 9.0 mm. An 8.0 Univent tube has an external diameter of 13.5 mm.

Figure 87.7. A Univent tube.

Placement

Prior to placement, the bronchial blocker should be lubricated to facilitate passage through its channel. The blocker should then be completely retracted into its channel to prevent tracheal trauma. The Univent tube is then placed like a normal SLT into the trachea. The blocker is then guided into place under bronchoscopic visualization. The blocker will preferentially head to the right mainstem bronchus. To facilitate passage into the left mainstem bronchus, the entire Univent tube can be turned 90° to the patient's left so that the inherent curvature in the tube directs the blocker to the left. In lieu of moving the entire Univent tube, the bronchial blocker alone can be twisted to turn the distal tip toward the left. Rotation of the patient's head to the left also helps facilitate this placement. A final option for left-sided blockade is to advance the Univent under fiber-optic guidance so that the tip of the ETT enters the left mainstem bronchus. The bronchial blocker can then be advanced further into the left, and the SLT portion can be withdrawn back into the trachea while the blocker is held in place.

Advantages

Advantages include the ability to convert the Univent tube into a "standard" SLT without replacing the ETT, the ability to provide

both CPAP and suction through the small port located within the bronchial blocker, the less bulky nature of the tube relative to a DLT, and the feasibility of its use for fiber-optic intubations in the setting of a difficult airway.

Disadvantages

Unfortunately, even with fiber-optic guidance, placement of the Univent's bronchial blocker may be difficult. Although the small central lumen allows for intermittent application of suction to facilitate lung decompression, deflation still may be a slow process. The high-pressure cuff on the blocker may lead to mucosal ischemia with prolonged use. Last, the larger anterior–posterior outer diameter, created by the separate channel fused to the SLT, has been suggested as a potential source of postoperative vocal cord damage and paresis; therefore, the Univent is not recommended for prolonged postoperative intubation.

Arndt bronchial blocker

The Arndt bronchial blocker is a wire-guided endobronchial blocker, specifically designed as a stand-alone bronchial blocker for bronchial or lobar isolation. It is packaged as a unit including the blocker itself, a multiport connector, a CPAP adapter, and a syringe. The multiport connector is designed to fit onto the 15-mm connector of the ETT. It has a separate port for the fiber-optic bronchoscope, the blocker itself, and connection to the breathing circuit. The blocker port has a Luer-Lok system to allow for ventilation with minimal air leak while the blocker is in place (Fig. 87.8).

The Arndt comes in 5F/50-cm, 7F/65-cm, and 9F/78-cm size configurations, for use with minimum ETT sizes of 4.5, 7.0, and 8.0, respectively. All Arndt blockers are equipped with low-pressure/high-volume cuffs. Integral to the Arndt is a replaceable central flexible nylon wire protruding from the distal end as a loop, which when removed leaves a 1.4-mm lumen.

Placement

Placement of the Arndt bronchial blocker starts with the placement of the bronchoscope and blocker through their respective ports of the multiport adapter. Once the bronchoscope is fed through the wire loop and the loop is cinched tight, the multiport adapter can be connected to the ETT. The bronchoscope is then advanced into the targeted airway for occlusion, and the Arndt is slid off the bronchoscope. If the catheter encounters resistance during advancement, the most likely source is the carina. Repositioning the wire loop at the very tip of the bronchoscope may resolve this problem. Additionally, turning the patient's head contralateral to the desired side also facilitates placement. Once the blocker is in the desired location, the balloon can be inflated under direct vision.

Advantages

The wire is removable, which leaves behind a 1.4-mm central lumen to be used for the provision of CPAP or for suctioning to aid deflation. Akin to the Fogarty catheter, the Arndt shares the

Figure 87.8. An Arndt endobronchial blocker.

characteristics of being deployable in a variety of airway situations, as a DLT rescue device, and also may be used for selective lobar blockade.

Disadvantages

As with all other bronchial blocker devices, the Arndt bronchial blocker suffers from the occasional difficulty of obtaining adequate isolation on the right side (given the proximal origin of the right upper lobe), easy dislodgement during manipulation or patient positioning, slow deflation time, and its difficulty of use in ETTs with an internal diameter smaller than 7.0 mm.

Cohen bronchial blocker

The Cohen bronchial blocker is a relatively new bronchial blocker, approved by the US Food and Drug Administration in 2005 for use in lung isolation and available from Cook Medical, Bloomington, IN. It currently is supplied only in a 9F-circumference/62-cm length size, with a 1.6-mm central lumen and a spherical balloon at the distal end. It performs the same job as the other bronchial blockers but is unique mainly in the method used to control and direct placement.

Figure 87.9. A Cohen endobronchial blocker.

Placement

Instead of a wire loop or bend at the distal end of the blocker, the Cohen blocker has a control wheel on the proximal end for bronchial placement (Fig. 87.9).

This control wheel allows a user to turn the distal tip of the catheter toward the desired bronchus. The wheel can be turned counterclockwise only, and the distal tip follows the direction of the wheel. Unfortunately, the movement arc of the distal tip is confined to 90°. The advantages and disadvantages of the Cohen blocker are similar to those of other bronchial blockers. A specific disadvantage may be that the fine motor control needed to manipulate the wheel necessitates two skilled operators for placement: one to operate the bronchoscope and one to steer the blocker.

Fuji bronchial blocker

The manufacturers of the Univent tube have also released the bronchial blocker portion of the Univent as a stand-alone blocker unit, dubbed the Fuji Uniblocker. The Fuji is similar in function, advantages, and disadvantages to the other bronchial blockers discussed. Its unique features include its composition of silicone, the presence of a preformed Coudé tip at the distal end, and the largest central lumen of all the blockers at 2.0 mm. The Fuji blocker currently comes in only one size (9F diameter/51 cm length).

Other options

Centers that routinely perform operations requiring lung isolation will have the tools described earlier readily available. Occasionally, however, lung isolation must be provided in the absence of specialized equipment. It is important to remember that it is possible to advance a single-lumen ETT into the mainstem bronchus, which may provide lung isolation on an emergent basis. Blindly done, the ETT will preferentially favor the

right mainstem bronchus. If it is necessary to continue ventilating the left lung instead, advancement of the ETT can be done by turning the ETT to the left so that the original curvature of the tube angles toward the left. Bronchoscopy can greatly facilitate selective mainstem intubation.

One-lung physiology

Familiarity with the techniques to attain lung isolation is a powerful tool in the anesthesiologist's armamentarium. Equally, if not more important, is an understanding of the physiologic consequences of the lateral decubitus position and OLV.

Lateral decubitus position

The lateral decubitus position is the standard position for pulmonary resection. This position affects both perfusion and ventilation, thereby affecting ventilation-perfusion (V/Q) matching.

Perfusion

Perfusion is directly influenced by gravity. Lateral positioning increases blood flow to the dependent lung by about 10% and decreases flow to the nondependent lung proportionally. Typical redistributions of blood flow with lateral positioning are detailed in Table 87.3. This redistribution of pulmonary blood flow is not altered by the induction of anesthesia or paralysis.

Ventilation

Unlike perfusion, the effect of lateral positioning on ventilation depends on whether the patient is awake, anesthetized, paralyzed, or has an open chest.

Lateral position, awake and spontaneously breathing, closed chest

In a spontaneously breathing, laterally positioned patient with a closed chest, the V/Q ratio is preserved relatively close to 1. On assuming the lateral position, the compliance of the different lung zone changes. The lung is now oriented from superior to inferior (nondependent to dependent) rather than apex to base, but the standard gravitational effect on lung compliance (Fig. 87.10) remains the same. Because the dependent lung is located on the steep portion of the compliance curve, it receives greater ventilation with each breath than the nondependent lung. The combination of greater perfusion of the nondependent lung and greater ventilation there as well leads to minimal V/Q mismatch.

Table 87.3. Typical effect of lateral positioning on pulmonary perfusion

Position	Change in perfusion to right lung, %	Change in perfusion to left lung, %
Right lateral decubitus	55 to > 65	45 to > 35
Left lateral decubitus	55 to > 45	45 to > 55

Awake–closed chest

Figure 87.10. Minimal compliance changes in overall lung on assuming the lateral decubitus position. (Adapted from Morgan GE, et al. *Anesthesia for thoracic surgery*. In: *Clinical Anesthesiology*. New York: Lange Medical Books; 2006:585–613.)

Lateral, anesthetized, spontaneous ventilation, closed chest

Induction of anesthesia leads to a decrease in functional residual capacity. This reduction in lung volume causes a downward shift in the compliance curve for both the dependent and the nondependent lungs. The dependent lung will shift from the steep to the less compliant (horizontal) portion of the curve, and the nondependent lung will shift to the more favorable (steep) portion of the compliance curve (Fig. 87.11). Ventilation will now be greater to the nondependent lung. As a result, V/Q mismatch will increase.

Lateral, anesthetized, paralyzed, mechanical ventilation, closed chest

The introduction of muscle paralysis and mechanical ventilation further increases V/Q mismatch. The weight of the abdominal contents, mediastinum, and chest wall restricts the dependent lung, functionally decreasing its compliance and shifting ventilation to the nondependent lung. Stabilizing devices such as bolsters or bean bags compound this problem. Perfusion remains unchanged.

Lateral, anesthetized, paralyzed, mechanical ventilation, open chest

Opening of the chest wall decreases the confines of the nondependent lung, further increasing ventilation to that lung. The dependent lung remains restricted. Given that the nondependent lung was already receiving proportionately more ventilation than perfusion in the closed chest, opening the operative hemithorax serves only to worsen the V/Q mismatch.

Physiology of OLV

The changes in perfusion and ventilation discussed earlier are independent of lung isolation. Isolation of the operative lung introduces a large right-to-left intrapulmonary shunt. The mixing of deoxygenated with oxygenated blood widens the alveolar–arterial oxygen gradient and manifests as hypoxemia. In addition, shunt and V/Q mismatch exist in the dependent

Figure 87.11. Compliance shifts in the lateral decubitus position from awake to anesthetized states. (Adapted from Morgan GE, et al. *Anesthesia for thoracic surgery*. In: *Clinical Anesthesiology*. New York: Lange Medical Books; 2006:585–613.)

lung secondary to atelectasis and parenchymal disease, further impairing gas exchange.

As mentioned earlier, gravitational forces partially redistribute blood flow away from the operative lung. The remaining shunt is further decreased by hypoxic pulmonary vasoconstriction (HPV). HPV acts as a protective mechanism to diminish blood flow to areas of alveolar hypoxia via pulmonary arteriolar vasoconstriction. HPV can decrease the shunt fraction by 50% and reaches its maximum effect within 15 minutes, reducing a typical 40% shunt fraction to approximately 20%. This shunt is still large enough to cause significant hypoxemia. The fact that many patients tolerate OLV well is likely indicative of chronic redistribution of blood flow away from the diseased lung, which ultimately results in a much lower overall shunt fraction.

Various physiologic and pharmacologic agents may act on the pulmonary vasculature to alter the effects of HPV. Elevated pulmonary artery pressures due to increased airway pressures, hypoxia in the ventilated lung, hypercarbia, heart failure, or pre-existing pulmonary hypertension may diminish the effects of HPV. Extremely low pulmonary artery pressures also may hinder HPV if part of the dependent lung exhibits West zone I physiology, in which alveolar pressure exceeds pulmonary artery pressure. Alkalosis globally inhibits HPV, and acidosis globally accentuates it.

Pharmacologic agents may affect the efficiency of HPV. Inhalation agents have been shown to inhibit HPV in in vitro studies; however, in vivo studies have been conflicting at best. Clinically, the overall effect on HPV is felt to be insignificant in the doses used in the operating room. Vasodilating agents such as nitroglycerin, nitroprusside, dobutamine, calcium channel blockers, and hydralazine can hinder HPV. Vasoconstricting agents, if they increase the dependent lung pulmonary artery pressure, may lead to increased perfusion of the operative lung, which will increase the shunt fraction. This, however, may be offset by increased cardiac output, increased mixed venous oxygen saturation, and decreased zone 1 conditions in the dependent lung. Almitrine, a respiratory stimulant, augments HPV at lower doses and improves oxygenation. It is not available clinically in the United States.

Anesthetic management for pulmonary resection

Sarah H. Wisner and Philip M. Hartigan

Introduction

Pulmonary resection may be performed for a variety of malignant and nonmalignant indications. Broad generalizations can be made based on the specific lesion being resected (Table 88.1), but anesthetic management is largely dictated by the surgical approach, the anticipated extent of resection, and the patient's pathophysiology. Lobectomy is considered here as an archetype for management of pulmonary resection in general. Special considerations for pneumonectomy and for patients with severe lung disease are also discussed. In this broad practical review, emphasis is placed on information germane to anesthetic management.

Lung cancer is now the leading source of cancer-related deaths in North America. In the United States, more than 160,000 deaths from lung cancer occurred in 2008. Without surgery, 5-year survival from lung cancer remains stubbornly fixed at 10% to 15%. Pulmonary resection for lung cancer therefore is considered semi-elective.

Immediate preoperative evaluation

The formal preoperative evaluation generally takes place days to weeks prior to surgery. On the day of surgery, interval changes in health status should be sought, with particular attention paid to pulmonary symptoms (e.g., wheezing, sputum production, dyspnea). Unlike with nonthoracic surgery, the most frequent serious postoperative complications are respiratory in nature (atelectasis, pneumonia, respiratory failure). An experienced pulmonary surgical program should be able to select operable candidates based on published criteria. Risk modification may be accomplished by minor postponements to gain control of acute exacerbations of bronchospasm or significant infections. Malignant pleural effusions may increase in the interval between the preoperative imaging and the day of surgery, and in extreme cases, thoracentesis prior to induction can reduce risk. Cardiac disease is prevalent in this population composed largely of smokers, and interval changes in cardiac status should also be sought. Prior to entering the operating room, the team should have the clearest possible picture of the following:

- The surgical plan, including the best guess at the extent of incision

- The maximum tolerable extent of resection based on respiratory mechanics, cardiopulmonary reserve, and lung parenchymal function
- The plan for lung isolation and postoperative pain control
- The side of surgery, based on radiographic data consistent with written and verbal communications and consents involving surgeon and patient

Assessment of the maximum tolerable extent of resection is an evolving, imprecise science. Most surgeons place the most stock in the predicted postoperative forced expiratory volume in 1 second (ppoFEV₁). ppoFEV₁ is the preoperative FEV₁ proportionally reduced by the amount of proposed lung resection, and can be calculated as follows: $\text{ppoFEV}_1 = \text{preoperative FEV}_1 [1 - (\% \text{ functional lung tissue to be removed}/100)]$. The number of segments removed can be estimated by the location and extent of resection (Fig. 88.1). If ventilation-perfusion scans are available, this can be estimated with greater precision. Lung parenchymal function is assessed by diffusing capacity of lung for carbon monoxide (DLCO) or arterial blood gas assessments of gas exchange (PO₂, PCO₂). Cardiopulmonary reserve is estimated from oxygen consumption (MVO₂), exercise tolerance, or extent of desaturation during exertion. Patients are at high risk for postoperative respiratory failure if the extent

Figure 88.1. Distribution of lung segments between the right and left lungs.

Table 88.1. Anesthetic considerations for pulmonary resection for various lesions

Lesion type	Associated considerations
Squamous cell	Central lesions (predominantly) Mass effects (obstruction, cavitation, compression) Hypercalcemia
Adenocarcinoma	Peripheral lesions Distant metastases Growth hormone, corticotrophin Hypertrophic osteoarthropathy
Small cell	Central lesions (predominantly) Paraneoplastic syndromes Eaton-Lambert (myasthenic) syndrome Proximal limb weakness, improved with activity Increased sensitivity to depolarizing and nondepolarizing relaxants Poor response to anticholinesterases Fast growth rate and early metastases Rarely resectable at diagnosis
Carcinoid	Proximal, intrabronchial lesions Often misdiagnosed as asthma Carcinoid syndrome (rare) (see Table 88.3) "Benign," slow growth rate Prone to bleeding Potentially obstructive, with possible postobstructive pneumonia
Mesothelioma	Pleural based Direct extension to pericardium, diaphragm Often with associated effusion Difficult dissection associated with significant intraoperative hemorrhage Extrapleural pneumonectomy at risk for cardiac arrhythmias, compression effects, cardiac herniation Pleurectomy associated with large postoperative air leak
Thymectomy	Mediastinal location Potential mass effect, but rarely significant Associated with myasthenia gravis Weakness exacerbated by activity Destruction of acetylcholine receptors at neuromuscular junction Clinical behavior depends on state of treatment with anticholinesterases Undertreatment = myasthenic crisis Overtreatment = cholinergic crisis Generally resistant to succinylcholine and highly sensitive to nondepolarizing muscle relaxants Consider preoperative plasmapheresis
Lung volume Reduction surgery/bullectomy	Severe emphysema High risk for air trapping during OLV High risk for dynamic hyperinflation and volutrauma/pneumothorax High risk for hypercapnia High risk for postoperative respiratory failure
Lung abscess	Risk of cross-contamination of contralateral lung
Empyema	Potential septic physiology
Decortication	Potential for hemorrhage
Arteriovenous malformation	Congenital or acquired from trauma, surgery, portal hypertension, schistosomiasis Usually connects pulmonary arteries and veins (right-to-left shunt) Rarely between bronchial arteries and pulmonary veins (left-to-right shunt) Risk of embolic events, stroke, hemorrhage Associated with hereditary hemorrhagic telangiectasias Potential difficulty with one-lung oxygenation (esp. if bilateral arteriovenous malformations)
Lung cysts/bullae	Congenital Bronchogenic cysts Congenital cystic adenomatoid malformation Pulmonary sequestration Congenital lobar emphysema Acquired Bullous emphysema Pulmonary hydatid cysts Pneumatocele Potential for mass effects Potential for cross-contamination or septic physiology from infected cysts Potential to trap air during positive pressure ventilation if they communicate with the airway Risk of postoperative air leaks

of resection would leave them with a ppoFEV₁ < 30% of predicted, or if their lung function and cardiopulmonary reserve are significantly limited relative to the proposed amount of resection.

Anesthetic management of pulmonary resection patients needs to consider the anatomic and physiologic effects of the tumor and any associated treatment. Tumors of the chest may effect anesthetic management through mass effects or through metabolic or paraneoplastic effects (Table 88.1). Chemotherapy may leave patients with impaired renal function (cisplatin) or at increased risk of oxygen toxicity (bleomycin). Distorted or anomalous tracheobronchial anatomy may alter the plan for lung isolation. Factors that have been associated with desaturation during one-lung anesthesia are listed in Table 88.2. The most powerful predictor of intolerance of one-lung ventilation (OLV) is a proportionately high perfusion of the operative lung. Prior ipsilateral chest surgery will increase the likelihood of extending a minimally invasive incision because of the presence of adhesions.

Anesthesia for lobectomy and lesser resections

Introduction

Non-small cell lung cancers (NSCLCs; large cell, squamous cell, and adenocarcinomas) are the most common indication for pulmonary resection. Lobectomy is the currently accepted treatment for resectable (stage I–IIIa) NSCLC. Segmentectomy entails the anatomic dissection and excision of sublobar segments of lung, whereas wedge resection implies nonanatomic excision. Segmentectomy or wedge resection may be performed for diagnosis of a nodule, for therapy for very small lesions, or for patients who would not tolerate a lobectomy. Such parenchymal-sparing resections for malignant pulmonary lesions are controversial, although they increasingly are being employed. Sleeve lobectomy entails removal of a portion of the mainstem bronchus along with the lobe, followed by reattachment of the uninvolved lobe(s) (Fig. 88.2). Sleeve lobectomy and right-sided bi-lobectomy are parenchymal-sparing alternatives to pneumonectomy for patients in whom a simple lobectomy would fail to yield clean proximal margins.

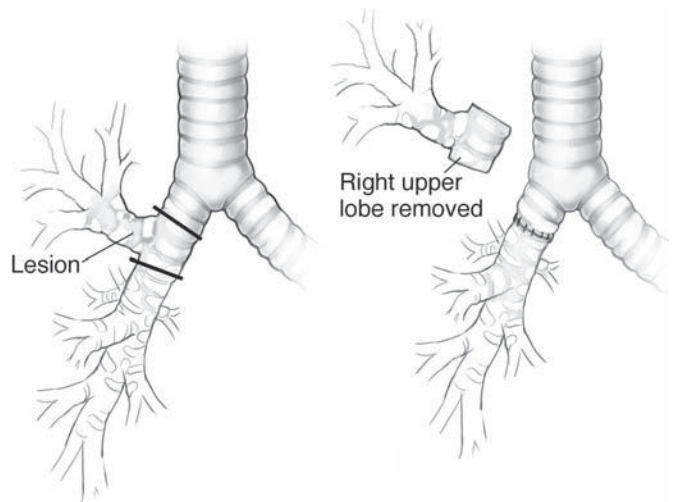

Figure 88.2. Right upper lobe sleeve resection.

Guiding and goals of anesthetic care for lobectomy and lesser resections include obtaining lung isolation, satisfactory one-lung gas exchange, avoidance of lung injury, hemodynamic stability, control of bronchospasm and secretions, rapid emergence and extubation, and excellent pain control. Early extubation with pain control that allows for deep breathing, effective coughing, and early ambulation is considered important to reduce pulmonary complications. High-quality lung isolation is instrumental to the surgeon's ability to visualize and operate through minimally invasive incisions.

Surgical approaches

The traditional posterolateral thoracotomy provides excellent access to the lung and hilum but involves an extensive incision; division of serratus anterior, latissimus dorsi, and intercostal muscles; and possibly resection of portions of the fifth or sixth rib. Increasingly, full posterolateral thoracotomy is reserved for excision of extensive masses or difficult dissections. Video and stapling instrument technology has enabled most resections to be performed via limited muscle-sparing thoracotomy or video-assisted thoracoscopic approaches. Video-assisted thoracoscopic surgery (VATS) generally entails the placement of three ports for the camera and instruments in a triangular pattern (Fig. 88.3). One "utility port" is often extended, as needed, to remove the specimen or to perform operative tasks. Therefore, the extent of the surgical incision varies from porthole to mini-thoracotomy, and may evolve over the course of the surgery as difficulties are encountered. The extent of pain and recovery are only loosely related to the extent of incision, possibly reflecting the influence of other variables, including retraction, intercostal nerve injury, and anesthetic care. Anterior thoracotomy, sternotomy, or clamshell incisions (bilateral anterior thoracotomies with transverse sternotomy) occasionally are used for anterior, mediastinal, or bilateral surgeries, and would entail supine or semi-supine positions.

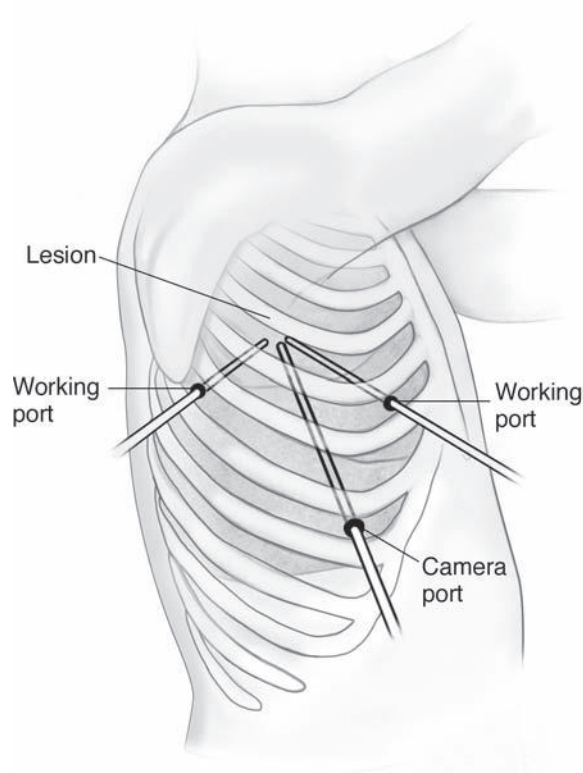

Figure 88.3. Thoracoscopic port placement with triangulation of the lesion of interest.

Preparation for induction

Although most pulmonary resections involve limited blood loss, the potential for major bleeding from hilar vessels must be considered. Invasive arterial blood pressure monitoring is indicated prior to high-risk inductions (see later), for sicker patients, and for more extensive or central surgery. Placement of thoracic epidural catheters and the extent of intravenous (IV) access and invasive hemodynamic monitoring are dictated by the anticipated extent of the surgical trespass and the physiologic fragility of the patient. Radiographic data, history of prior chest surgery (ipsilateral adhesions), and communication with the surgeon help define the risk of significant bleeding or the likelihood that a VATS approach will be extended to a thoracotomy.

Premedication is dictated by the clinical scenario. Sedation, as always, should be tailored to the needs and reserves of the patient. Inhaled bronchodilator treatments given in the immediate preoperative period are advocated for patients with a history of bronchospasm.

Epidural decisions

Thoracic epidural analgesia (TEA) is the most widely used means of controlling postthoracotomy pain. Compared with parenteral opiates, TEA is superior for control of the dynamic pain associated with deep breathing and coughing, and for

the preservation of lung function by spirometry. Evidence suggests that many pulmonary and cardiac complications, and possibly chronic postthoracotomy pain, are reduced by effective perioperative epidural pain control. TEA is generally not necessary for lesser resections performed through very limited VATS approaches. The indication for TEA is intermediate for more complicated VATS resections. Generally, any lobectomy (including VATS) requires at least a mini-thoracotomy just to remove the specimen, and the technical challenge of segmentectomy often warrants larger utility ports. Because the extent of the incision may be uncertain upfront, the preoperative decision to place a thoracic epidural catheter may be challenging. One approach is to place epidurals in all patients undergoing pulmonary resection, except those undergoing straightforward wedge resection. TEA should also be considered in the physiologically fragile patient, even when undergoing wedge resection. The usual contraindications for epidural catheters would apply (e.g., coagulopathy, patient refusal, overlying infection).

Not uncommonly, the extent of incision or resection may change intraoperatively in a patient without an epidural. Such patients may be allowed to emerge with reasonable comfort for immediate postoperative awake epidural placement by using intercostal nerve blocks combined with moderate narcotic analgesia. Although not without controversy, a compelling argument has been made that the risk/benefit ratio of TEA placement in the anesthetized patient is unfavorable in adult patients.

Special monitoring considerations for thoracic surgery

Left-sided thoracic procedures preclude formal diagnostic placement of electrocardiographic (ECG) leads. Moreover, the mediastinal shift, which occurs with an open chest and lateral decubitus position, alters the position of the heart relative to the chest wall, potentially further reducing ECG sensitivity to ischemia. Arterial catheters are widely used whenever OLV is prolonged or tenuous, or when hemodynamic management dictates. Central venous pressure (CVP) measurements may be confounded by the open pneumothorax or surgical manipulations and should be followed for trends as opposed to absolute numbers. A central venous line is often primarily indicated for patients with significant cardiac disease, for resuscitation in patients with poor peripheral intravenous access, or for postoperative management. Pulmonary artery (PA) catheters may be problematic during thoracic surgery. If the catheter tip is positioned in the atelectatic lung, both pressure and cardiac output measurements will be unreliable. There also is risk of the catheter getting caught in the surgical staple line. PA catheters are reserved for management of significant pulmonary hypertension or severe cardiac valvular disease. Transesophageal echocardiography may be a superior intraoperative monitor for such situations. The experienced thoracic anesthesiologist will pay close attention to capnogram waveform and

lung compliance changes as indicators of the degree of obstruction and early warning signs of tube malposition, accumulating secretions, or developing bronchospasm. Modern anesthesia machines offer continuous spirometry, which also may be very helpful in recognizing changing lung or airway function.

Special induction considerations for thoracic surgery

Aside from the usual considerations for induction (e.g., drug effects, aspiration, a secure airway), four issues deserve special consideration in thoracic patients: (1) bronchospasm, (2) air trapping, (3) mass effects on cardiac output, and (4) mass effects on airway patency. These issues are described as follows:

1. *Bronchospasm.* Smoking and chronic obstructive pulmonary disease (COPD), both of which are highly prevalent in thoracic patients, predispose to airway hyperreactivity. Airway manipulation at induction may be a potent trigger of bronchospasm in predisposed patients. Among the many strategies that have been proposed to circumvent this, adequate depth of anesthesia at the time of airway instrumentation is the most important. Narcotics and inhalational anesthetics have advantages over histamine-releasing agents. Preemptive bronchodilator treatments were mentioned earlier. The theoretic risk of β -adrenergic-blocking drugs is often overstated, and if indicated for cardiac reasons, such drugs should not generally be withheld for fear of bronchospasm. Recent upper respiratory infections or exacerbations of COPD should be under control for 2 weeks prior to surgery, if possible.
2. *Air trapping.* Expiratory flow limitation in patients with obstructive lung disease mandates long expiratory times to prevent air trapping, or auto-positive end-expiratory pressure (auto-PEEP). Failure to remember this during induction may result in sufficient auto-PEEP to cause hemodynamic instability or barotrauma. Patients with bullous emphysema or severe COPD ($FEV_1 < 40\%$ predicted) are particularly prone. Tension pneumothorax and cardiac arrest have been reported with induction of such patients. Bronchospasm, mass-induced dynamic airway obstruction, and the resistance of long, narrow endotracheal tubes (such as double-lumen tubes [DLTs]) also predispose to auto-PEEP.
3. *Mass effect on cardiac output.* Occasionally, thoracic tumors or effusions may affect cardiac output through their mass effect within the thorax. The supine position, induction of general anesthesia, and initiation of positive pressure ventilation may enhance this mechanism. Impaired venous return due to increased intrathoracic pressure, or impaired diastolic filling of the heart due to a tamponade-like effect of a mass or effusion, will be exacerbated by the reduction in functional residual capacity (FRC) associated with anesthesia, as well as the transition from negative to

positive pressure ventilation. Preinduction review of the chest CT is important in evaluating the potential effects of a large mass situated anterior to or compressing the heart or great vessels. Preoperative symptoms of positional dyspnea or lightheadedness may be clues. Preemptive vasopressors, careful choice of induction agents, positional adjustments, and fluid loading generally succeed in defending venous return and cardiac output during induction. Superior vena cava (SVC) compression, evident from CT scans or the signs of SVC syndrome, mandates a lower-extremity IV line prior to induction and may require cautious airway manipulation secondary to venous congestion of the head. Patients with large, positionally symptomatic anterior mediastinal masses are at increased risk and are discussed more thoroughly in [Chapter 91](#).

4. *Mass effect on airway patency.* The FRC reduction imposed by the supine position and induction of anesthesia translates to a reduction in the caliber of major airways. Extrinsic compression, or intrinsic obstruction, of airways by masses is thus exacerbated by induction and may result in total obstruction of major airways.

Lung isolation decisions

Many institutions prefer left-sided DLTs (L-DLTs) for most lobectomies or lesser resections of either side. If a left-sided pneumonectomy or sleeve resection is contemplated, the L-DLT may need to be withdrawn somewhat. The potential for disruption of the stump or anastomosis by the L-DLT is not trivial. Therefore, right-sided DLTs are recommended as a preferred option, anatomy permitting. The initial bronchoscopic examination by the surgeon to evaluate or rule out endobronchial pathology is an opportunity for the anesthesiologist to evaluate the anatomy and form a definitive plan for lung isolation. A bronchial blocker placed in the left mainstem will also work well for left pneumonectomies, but must be withdrawn at the time of bronchial cross-clamp to avoid being caught in the staple line. Pros and cons of the different lung isolation options are discussed in the previous chapter.

Positioning

Full lateral decubitus position is used for the vast majority of lung resections ([Fig. 88.4](#)). Vulnerable pressure points include the hips, shoulders, ears, and eyes. The neck should be maintained in axial alignment with the spine, using soft padding to support the head, with the ears and eyes protected. An axillary roll is traditionally positioned just below the dependent axilla to offload pressure from the head of the humerus on the neurovascular bundle. The nondependent arm must be supported with attention to avoid stress to the brachial plexus. Tape across the hip theoretically may cause a pressure necrosis of the femoral neck if too tight. The dependent leg is bent, and stabilizers (bolsters or beanbag system) are arranged to prevent anterior or posterior movement. Flexion of the table aids surgical access by widening the spaces between the ribs.

Figure 88.4. Lateral decubitus position.

Choice of anesthetics

No acknowledged “best” anesthetic regimen for thoracic surgery exists. Advocates of inhalation agent–based techniques cite their convenience, ease of titration, and bronchodilating properties. Potential disadvantages are that all current inhalational agents inhibit hypoxic pulmonary vasoconstriction (HPV) and depend on the lungs for their elimination. Despite HPV inhibition *in vitro*, volatile anesthetics exhibit minimal effects on oxygenation during OLV when used in clinically relevant dosages (< 1.5 minimum alveolar concentration). Moreover, excluding enflurane, there is no significant difference among agents with regard to OLV at comparable concentrations. Delayed or unpredictable elimination may occur because of the accumulation of inhalational agents within poorly ventilated lung units. Moreover, end-tidal agent levels may not reflect the presence of such “reservoirs” of agent.

Total IV anesthesia (TIVA) agents (usually propofol plus a short-acting narcotic) do not inhibit HPV and do not rely on the lungs for elimination. Elimination is not confounded by severe obstructive lung disease but may be delayed in prolonged cases if propofol doses accumulate, or if there is liver disease.

Operative events with anesthetic management implications

Incision is an opportunity to assess anesthetic depth, and entry into the chest allows the anesthesiologist to directly view the quality of lung isolation and collapse. If the lung is inflated and ventilating, the tube/blocker position is incorrect or the bronchial cuff is underinflated or ruptured. If the lung is inflated but not ventilating, the delayed collapse may be the result of adhesions, poor elastic recoil (emphysema), secretions, or malposition of the DLT. The inflation of the bronchial cuff should be reassessed, and a bronchoscope should be passed to confirm

tube position, suction secretions, and suction air from the operative lung. Patients with a severely reduced FEV₁ will have very slow collapse, and suctioning will have little beneficial effect because of the principle of flow limitation. If a blocker rather than a DLT was used, the onset of atelectasis may be somewhat delayed. The application of suction to the operative bronchus during apnea with the cuff deflated may encourage air egress in this situation. Insufflation of CO₂ into the chest under pressure to encourage lung collapse generally is not recommended because of the potential for a tension pneumothorax and hemodynamic compromise. Physically compressing the chest with surgical instruments may sometimes improve operative conditions. High-quality atelectasis may be instrumental to the success of a minimally invasive approach.

Often, surgeons must digitally palpate the lung to locate target nodules. When performed through thoracoscopic ports, this may sometimes be a challenge. Occasionally, a Valsalva maneuver to the dependent lung will raise the mediastinum and operative lung to allow the surgeon to reach and locate the nodule, thus avoiding extension of the incision. Evacuation of the stomach with an orogastric tube may also be helpful in allowing the diaphragm to move more caudally, giving the surgeon more room to maneuver. Manipulation of the tumor rarely may result in the release of vasoactive substances, such as with carcinoid tumors (Table 88.3).

The cross-clamping of vessels for lobectomies and lesser resections generally has little impact on hemodynamics, but the field should be observed at this time for bleeding. Stapling instruments have been known to misfire, resulting in incomplete division of vessels. Division of the lobar bronchus during lobectomy is also performed with a stapling instrument. Surgeons may request a bronchoscopic evaluation or a brief reexpansion of the remaining lobe(s) during cross-clamping, but prior to firing the staples, to assure that only the target lobe is within the staple line. Following removal of the specimen, many surgeons request a “leak test.” With saline in the chest cavity,

Table 88.3. Carcinoid syndrome

Signs and symptoms	Mediators	Treatment
Cutaneous flushing	Serotonin	Octreotide (somatostatin analogue)
Bronchospasm	Histamine	
Hypotension	Dopamine	Avoid adrenergic stimulation

such that the staple line is submerged, a brief period of positive pressure (< 30 cm H₂O) is delivered to the operative lung, and the stump is observed for bubbles.

Prior to chest closure, effective recruitment of the remaining lung to maximally obliterate the intrathoracic space is important, but care should be taken not to injure the remaining lung or “blow” open the lobar stump (or parenchymal staple line in the case of a wedge resection). Experience and extrapolation of intensive care unit (ICU) data suggest that exceeding 40 cm H₂O may be imprudent. Less than 30 cm H₂O is widely considered acceptable, but some patients may have tenuous staple lines or more delicate tissue. A bronchoscopic cleanout of secretions may allow more effective recruitment at lower pressures. Following recruitment and chest closure, two-lung ventilation should be resumed at volumes that account for the amount of remaining lung. Chest tubes should be placed on suction for the remainder of the case, unless a pneumonectomy was performed (see later).

Pathophysiology of OLV

Tight matching of pulmonary ventilation (V) and perfusion (Q) is essential for efficient gas exchange. V/Q relationships during typical pulmonary resection surgery are severely disrupted by OLV, the lateral decubitus position, an open pneumothorax, positive pressure ventilation, general anesthesia, paralysis, and underlying lung disease. These factors lead to shunt in the nondependent and dependent lungs, as well as V/Q mismatch in the dependent lung. PaO₂ (at a fraction of inspired oxygen content [FiO₂] = 1.0) in this scenario typically falls from the 400–mm Hg range to approximately 150 mm Hg. On average, nondependent lung blood flow (nondependent lung shunt) is reduced from 45% to 55% to approximately 20% of cardiac output, principally because of gravity and HPV. Shunt occurs in the dependent lung as a result of atelectasis imposed by the weight of the mediastinum, the upward pressure of the dependent hemidiaphragm, and the restrictive forces of the table and anterior/posterior stabilizers. Additional V/Q mismatch occurs in the dependent lung as a result of intrinsic parenchymal disease or disruptions in pulmonary blood flow or ventilation (e.g., DLT malposition, secretions, bronchospasm, inhibitors of HPV).

Hypoxemia during OLV

The reported incidence of hypoxemia during OLV has decreased from $> 20\%$ in the 1970s to $< 1\%$ currently because of improved DLT designs, bronchoscopic positioning of DLTs, and improved understanding of the physiology of OLV. Actions to minimize shunt in the dependent and nondependent lungs are the principal maneuvers to address hypoxemia during OLV, whereas V/Q mismatch due to parenchymal disease is more difficult to manipulate. Treatment of hypoxemia should be individualized based on the most likely cause(s) and the context of the surgery (Table 88.4). An FiO₂ of 1.0 should be assured. If the desaturation is abrupt or severe, reinflation of the

Table 88.4. Treatment of hypoxemia during OLV

Confirm FiO ₂ = 1.0

CPAP to operative lung
PEEP to nonoperative lung
Cross-clamp of pulmonary artery, or branch thereof

nondependent lung should be performed in coordination with the surgeon. If time permits, bronchoscopy should be performed to rule out tube malposition or obstructions from secretions, blood, kinks, and so on. PEEP delivered to the dependent lung may help by combating shunt in that lung, particularly in patients prone to atelectasis (see “Optimal PEEP”). Continuous positive airway pressure (CPAP; 2–5 cm H₂O) delivered to the nondependent lung generally improves oxygenation but may partially reinflate the operative lung. During a thorotomy, this may be acceptable, but during VATS approaches, it may limit surgical visualization and force extension of the incision. When surgical cross-clamp of the PA branch is imminent, marginal saturations may be tolerated briefly, knowing that cross-clamp likely will improve oxygenation by reducing nondependent lung shunt. The patient with hyperreactive airways may benefit from inline aerosolized bronchodilator treatments.

Hypoxic pulmonary vasoconstriction

During OLV, HPV is critical to reduce nondependent lung blood flow, as well as to fine-tune V/Q matching in the dependent lung. HPV is an exquisitely local phenomenon of the pulmonary microvasculature, responding primarily to low alveolar oxygen tension and secondarily to low mixed venous oxygen levels. Although its precise mechanism remains obscure, HPV is thought to be mediated by voltage-gated potassium channels. HPV is inhibited by most vasodilators and by all currently used inhalational anesthetic agents in a dose-dependent manner (in vitro). Hypercapnia and acidosis enhance HPV, whereas hypocapnia and alkalosis inhibit it. The net effect of any variable on oxygenation during OLV depends on its integrated effects on HPV (direct and indirect), cardiac output, and mixed venous oxygen tension, and cannot be easily predicted. Aside from avoiding obvious offenders (e.g., high-dose nitro dilator infusions), attempts to improve one-lung oxygenation by manipulation of HPV are rarely productive. Because inhalational anesthetic agents inhibit HPV and most intravenous anesthetics do not, TIVA has been proposed to improve oxygenation during OLV. Clinical studies are currently mixed on this matter, which is complicated by secondary effects on cardiac output and mixed venous oxygen saturation. Similarly, inhaled nitric oxide delivered to the dependent lung, which might be expected to improve one-lung oxygenation by reducing nondependent lung shunt, has produced mixed experimental results.

Figure 88.5. Relationship during OLV between airflow obstruction as measured by the FEV₁/FVC percentage and the occurrence of auto-PEEP. (From Ducros O, Moutafis M, Castellan M, et al. Pulmonary air trapping during two-lung and one-lung ventilation. *J Cardiothoracic Vasc Anesth* 1999; 13:35.)

Optimal PEEP

Excessive airway pressures in the dependent lung may redirect blood flow to the nondependent lung, increasing total shunt and reducing oxygenation during OLV. Thus, PEEP to the dependent lung is a double-edged sword. Whether PEEP will result in improvement or deterioration of oxygenation depends on the patient's preexisting physiology. Those with restrictive physiology of the dependent lung (e.g., pulmonary fibrosis, obesity) or young patients with normal lung elastic recoil likely would benefit from some PEEP. Those with severe obstructive disease often have unavoidable levels of auto-PEEP already at or beyond optimal PEEP. The risk of auto-PEEP during OLV is directly proportional to the severity of obstructive lung disease as measured by FEV₁/forced vital capacity (FVC) ratio (Fig. 88.5). The addition of extrinsic PEEP (ventilator delivered) to such patients will neither benefit oxygenation nor increase total PEEP until threshold levels (~ 75% of preexisting auto-PEEP) are exceeded. Beyond that threshold level, further increases in dependent-lung PEEP will increase airway pressures and nondependent lung shunt to the detriment of oxygenation. The degree of auto-PEEP is not measurable by standard anesthesia ventilators but can be detected by briefly disconnecting the circuit and observing for end-expiratory airflow. A useful strategy is to begin with low levels of extrinsic PEEP (< 5 cm H₂O) and to incrementally increase PEEP using oxygen saturation of hemoglobin (SpO₂) as a guide in patients who are hypoxemic during OLV.

Avoidance of ventilator-induced lung injury

Ventilator-induced lung injury (VILI) results from excessive overdistention (volutrauma) and/or from the shear stresses

Table 88.5. Recommended OLV strategies to avoid VILI

Tidal volume = 6 ml/kg ideal body weight
 PEEP in patients without auto-PEEP
 Limit plateau pressures to <25 cm H₂O
 Limit peak inspiratory pressures to <35 cm H₂O
 Intermittent recruitment maneuvers

of repeated collapse and reexpansion of lung units (atelectotrauma). Because the dependent lung during OLV is prone to intermittent atelectasis, and is free to hyperexpand with high airway pressures because of the open pneumothorax, theoretically it is especially vulnerable to VILI. A proportion of patients develop acute lung injury with no apparent cause following pulmonary resection. It has been postulated that VILI may account for some of these cases. Recommendations for single-lung ventilatory settings consequently shifted to lung-protective strategies (Table 88.5). There is no firm prospective evidence at this writing, however, that traditional OLV strategies (tidal volume = 10 ml/kg) are injurious or that protective strategies improve outcome. Isolated perfused rabbit lung preparations displayed reduced stigmata of injury (elevated lung water, PA pressures, and thromboxane A₁) with similar protective ventilatory strategies, compared with conventional OLV. Ultimately, ventilatory settings must be individualized, and a compromise often must be sought between optimal gas exchange and the perceived risk of lung injury. This balance is most tenuous in patients with severe obstructive lung disease, in whom temporary hypoventilation (permissive hypercapnia) is often necessary.

Fluid management and postpneumonectomy pulmonary edema

Barring unusual blood loss, conservative fluid management for pulmonary resection has become a widely entrenched practice. Published recommendations are for a target positive 24-hour fluid balance of < 20 ml/kg. This stems from the recognition that all pulmonary resections are potentially vulnerable to postpneumonectomy pulmonary edema (PPE). PPE occurs in 2% to 4% of pneumonectomies and is a diagnosis of exclusion with a high mortality (50%). Also referred to as acute lung injury (ALI) following pulmonary resection, it manifests in hours to days following pulmonary resection as radiographic pulmonary edema and impaired gas exchange and may progress to acute respiratory distress syndrome. It is more common following right pneumonectomy and less common following lobectomy. Other known causes, including cardiogenic and infectious causes, must be excluded. Low cardiac filling pressures and high protein content in bronchial lavage of such patients speak to an impairment of pulmonary capillary integrity. Postulated etiologies include oxygen toxicity, VILI, and unbalanced chest tube drainage. Impaired lymphatic drainage is undoubtedly contributory and may explain why left pneumonectomies are less vulnerable (lymphatic drainage is better preserved).

Intraoperative fluid administration by anesthesiologists had been postulated to be a cause but is now regarded as only a potentially exacerbating factor. If ALI occurs from any cause, excessive crystalloid would logically exacerbate gas exchange by increasing hydrostatic pressures across leaky pulmonary capillaries. The limited gas exchange reserves and lymphatic drainage of pneumonectomy patients make the process more difficult to reverse. This rationale for conservative fluid management must be individualized and always balanced against the imperative for sufficient intravascular volume to assure adequate end-organ perfusion and to tolerate thoracic epidural sympathetic blockade (if applicable).

Emergence strategies

The conclusion of surgery usually entails resumption of the supine position, exchange of the DLT for a single-lumen tube or laryngeal mask airway, and a cleansing bronchoscopy. The latter also serves to examine the lobar stump and to rule out other issues (e.g., torsion of the middle lobe following right lower lobectomy). The use of a high FiO_2 plus aggressive bronchoscopic suctioning predisposes to atelectasis, and efforts should be made to reexpand the lungs post bronchoscopy. Instrumentation of the airway may provoke bronchospasm. Augmenting anesthetic depth (e.g., with remifentanyl) and administering inline inhaled bronchodilators can combat this. Pulmonary mechanics should be optimized by raising the head of the bed prior to extubation. Any splinting from incisional or rib pain should be addressed aggressively with the indwelling epidural catheter, alternative nerve blocks (paravertebral or intercostal), intravenous narcotics, or adjuncts (e.g., nonsteroidal anti-inflammatory drugs, ketamine, dexmedetomidine). Supplemental postoperative oxygen is appropriate for all pulmonary resection patients, with the possible exception of those who received bleomycin therapy. The commonly held fear that oxygen will inhibit the respiratory drive of CO_2 -retaining COPD patients is unfounded.

Special considerations for pneumonectomy

Patient selection

Pneumonectomy is most commonly performed for NSCLC that is centrally located, adherent to hilar structures, or crossing a major fissure. Although more frequently the case in developing countries, pneumonectomy may also be performed for intractable hemorrhagic bronchiectasis or to remove a lung destroyed by suppurative disease or trauma. Mortality following pneumonectomy is generally 5% to 7%, compared with 2% to 3% for lobectomy (bi-lobectomy is similar to pneumonectomy). Resectability for pneumonectomy is defined by the stage (no contralateral or distant metastases). Operability is a clinical judgment based largely on perceived cardiopulmonary reserve and ppoFEV_1 . Criteria considered to indicate high risk are shown in Table 88.6. Violation of any of those criteria necessitates split lung function testing to more accurately

Table 88.6. High-risk criteria for pneumonectomy

$\text{PaCO}_2 > 45$ mm Hg (room air)
$\text{PaO}_2 < 50$ mm Hg (room air)
$\text{FEV}_1 < 2$ L
$\text{ppoFEV}_1 < 0.8$ L (or $< 40\%$ predicted)
$\text{FEV}_1/\text{FVC} < 50\%$ predicted

assess ppoFEV_1 , which is the metric most heavily relied upon. In contrast to lesser resections, cardiac complications following pneumonectomy are more frequent than pulmonary complications as causes of perioperative mortality. Complications of pneumonectomy are listed in Table 88.7.

Anesthesia-relevant surgical issues for pneumonectomy

Variants of pneumonectomy include intrapericardial pneumonectomy (in which pulmonary veins are divided proximal to pericardium), carinal pneumonectomy (in which the lung is removed with a sleeve of trachea, carina, and bronchus, and the contralateral bronchus is anastomosed to the trachea), and extrapleural pneumonectomy (EPP). EPP involves

Table 88.7. Postoperative complications of pneumonectomy

Category	Complication
Cardiovascular	Arrhythmia (esp. atrial fibrillation) Myocardial infarction Right ventricular failure Intracardiac shunt Deep vein thrombosis Pulmonary embolus Postpericardiotomy syndrome Cardiac herniation
Pulmonary	Postpneumonectomy pulmonary edema Pneumothorax Pneumonia
Pneumonectomy space	Bronchopleural fistula Empyema Postpneumonectomy syndrome Hemothorax Chylothorax
Oncologic	Recurrence Second primary
Neurologic	Recurrent laryngeal nerve injury Phrenic nerve injury Vagal nerve injury Paraplegia
Gastroesophageal	Gastric volvulus Esophagopleural fistula

en block resection of lung, ipsilateral visceral and parietal pleurae, hemidiaphragm, and pericardium, and is principally performed in selected centers for malignant pleural mesothelioma. All pneumonectomies require at least a muscle-sparing thoracotomy incision.

Catastrophic bleeding from loss of control of hilar vessels is a rare but possible event in any pneumonectomy. Risk increases with tumor proximity to the vessels. Intrapericardial division of vessels is associated with more arrhythmias, and synchronized cardioversion capability should be readily available. Following division of the vessels, the bronchus is divided as proximally as possible. This serves two purposes: it provides the greatest tumor-free margin and results in the shortest stump. Long bronchial stumps are associated with higher rates of breakdown and bronchopleural fistula formation. Bronchoscopic visualization of the carina by the anesthesiologist can help guide the surgeon's positioning of the bronchial cross-clamp. Reinforcement of the bronchial stump with a vascular flap, such as a pedicle of intercostal muscle, frequently is performed. A leak test, described earlier, is performed with the stump submerged in saline. Thereafter, attention to minimize peak inspiratory pressure stress to the staple line is widely considered prudent. Toward this end, immediate postoperative extubation is a priority. Prior to closure, if the pericardium and/or diaphragm have been removed, they are reconstructed with prosthetic patches.

Special monitoring issues for pneumonectomy

Generous IV access and invasive arterial blood pressure monitoring are generally recommended for pneumonectomy. Despite the caveats described earlier, some experts advocate central venous access. At the time of PA cross-clamp, the CVP seldom changes. This is a result partly of the remarkable compliance of the pulmonary vascular tree and partly of the fact that the forces of gravity and HPV largely reduce cardiac output to the operative lung prior to cross-clamp. An abrupt increase in CVP at the time of PA cross-clamp may indicate right ventricular intolerance of the increased afterload, but a failure of the CVP to change is no reassurance that the right ventricle will not subsequently fail. PA catheters are of limited value because of the pitfalls of interpretation discussed earlier.

Cardiac herniation and mediastinal shift

Following pneumonectomy, the chest is closed with a drain in place, but care is taken to prevent the inadvertent attachment of the drain to suction, as this may precipitate cardiovascular collapse from mediastinal shift or cardiac herniation. Cardiac herniation is the abrupt displacement of the heart into the empty hemithorax, resulting in torsion of great vessels and the loss of effective cardiac output. Cardiac herniation is most likely following right pneumonectomy with a pericardial defect that was inadequately reconstructed. Resumption of the supine position is a critical time when cardiac herniation may occur. In its most dramatic form, cardiac herniation results in abrupt cardiovascular collapse. Returning the patient to the lateral position in

Table 88.8. Causes of hypotension at the conclusion of pneumonectomy

Partial cardiac herniation
Tight pericardial patch (if applicable)
Mediastinal shift
Hypovolemia
Recent thoracic epidural bolus
Air trapping, auto-PEEP
Right ventricular failure
Myocardial ischemia
Tension pneumothorax

such a case is the appropriate therapeutic response. This will return the heart to its physiologic position and allow the surgeon to reopen and place or repair an inadequate pericardial patch. Inotropes, vasopressors, and closed chest cardiac massage are of no value to an empty heart herniated into an empty hemithorax.

Rarely, right-to-left intracardiac shunts develop following pneumonectomy as a result of mediastinal shift and rotation of the heart such that the inferior vena caval orifice aligns with the foramen ovale. Such patients may exhibit desaturation in the upright position (platypnea orthodeoxia). Postpneumonectomy syndrome is a rare, late complication from shifting of the mediastinum resulting in the extrinsic compression of the remaining mainstem bronchus.

Emergence

The same emergence strategies described earlier apply to pneumonectomy patients. Because there will always be at least a muscle-sparing thoracotomy incision, aggressive thoracic epidural (or paravertebral) blockade, as tolerated hemodynamically, is advantageous. Mild hypotension at the conclusion of surgery has many potential etiologies (Table 88.8), potentially resulting in diagnostic confusion. Of these causes, mediastinal shift resulting in partial embarrassment of venous return may be especially difficult to rule out. Some surgeons preemptively aspirate up to 200 ml of air from the chest drain. A portable chest radiograph in the operating room is most effective in ruling out mediastinal shift. Following extubation, many patients report a sense of dyspnea despite adequate air movement, which may partly be the result of disruption in their sense of the mechanics of breathing. Even the stable, comfortable, extubated pneumonectomy patient warrants postoperative monitoring in the ICU because of the dire and abrupt potential complications of the operation (Table 88.7).

Lung transplantation

Vladimir Formanek

Lung transplantation is an accepted therapeutic intervention for patients with end-stage lung disease. The anesthesiologist faces many challenges when caring for a patient who presents for transplantation. Individual cases may require the management of hypoxia or hypercapnia, invasive hemodynamic monitoring, treatment of pulmonary hypertension and right ventricular (RV) failure, familiarity with the management of cardiopulmonary bypass, use of inhaled nitric oxide (NO), and transesophageal echocardiography (TEE). Critical incidents are common, and they may challenge even the most experienced anesthesiologist.

Types of lung transplants

Lung transplantation encompasses a group of different operations selected based on recipient factors, donor organ availability, and the transplant center's preferences (Table 89.1).

Single-lung transplantation

The most common indications for single-lung transplantation (SLT) are chronic obstructive pulmonary disease COPD and pulmonary fibrosis. The operation involves a pneumonectomy and transplantation of a single donor lung. The nontransplanted native lung is left in situ. After pneumonectomy, the donor lung is implanted. This requires anastomosis of the bronchus, pulmonary artery (PA), and a cuff of left atrium containing the donor pulmonary veins to the recipient's left atrium. The bronchial circulation, lymphatics, and nerves are not restored. Cardiopulmonary bypass (CPB) is needed in fewer than 10% of cases, but CPB backup should be readily available. CPB may be necessary because of hemodynamic instability, hypoxia, or hypercarbia. SLT allows two recipients to benefit from one donor.

Bilateral lung transplantation

The most common indications for bilateral or double-lung transplantation (DLT) are cystic fibrosis, bronchiectasis, and other infectious processes that would result in soilage of the transplanted lung from the remaining native lung. Pulmonary hypertension is another common indication. Restoration of a normal pulmonary vasculature (via DLT) allows for optimal recovery of the right heart. Evidence shows that long-term

mortality and graft function are better after DLT; therefore, many centers now favor DLT for most patients. The operation is done through a clamshell, subcostal incision (Fig. 89.1) or through a median sternotomy. The anastomoses are the same as for SLT. The procedure may be done with or without CPB.

Heart–lung transplantation

Heart–lung transplantation is usually reserved for patients with pulmonary hypertension and congenital heart disease, Eisenmenger's syndrome, or primary pulmonary hypertension with RV dysfunction. The heart and lungs are transplanted en bloc, from a single donor, with CPB support. At present, heart–lung transplantation is a rare operation. According to the United Network for Organ Sharing (UNOS; <http://www.unos.org>) data, only 27 heart–lung transplants were performed in the United States in 2008.

Pediatric transplantation

The most common indications for lung transplantation in the pediatric population are cystic fibrosis, primary pulmonary hypertension, bronchopulmonary dysplasia, arteriovenous malformations, and hypoplastic lungs due to congenital diaphragmatic hernia. The procedure invariably is a DLT with the aid of extracorporeal circulation.

Living donor lung transplantation

Living donor lung transplantation involves the transplantation of two lobes from two donors into a single recipient. With the increasing disparity between the number of patients referred for transplant and the availability of suitable cadaveric donor organs, living donor transplantation developed as an alternative to cadaveric lung transplantation. Cystic fibrosis has been

Table 89.1. Types of lung transplantation currently performed in the United States

the most common indication. These patients are usually smaller in stature, allowing two lobes from average-sized adult donors to provide sufficient pulmonary tissue. The number of living related transplants peaked at 29 in 1999 and declined in subsequent years. According to UNOS data, none was performed in 2008. The operation requires meticulous care of three patients. The perioperative morbidity for donors is not insignificant, nor is the burden on operating room resources.

Donor organs

The Organ Procurement and Transplantation Network (<http://optn.transplant.hrsa.gov>) and UNOS are government-sponsored organizations that register all patients listed for transplantation. A centralized computer network links all organ procurement organizations and transplant centers. Procurement agencies facilitate matching of organs to recipients throughout the United States. The system is set up to allocate organs to the sickest patients while minimizing ischemic time. Many transplant-related statistics are maintained by UNOS and are available to the public through its Web site.

The lung allocation score system

The lung allocation score system is a relatively new method for allocating lungs. Each candidate is assigned a score of 0 to 100 based on his or her medical urgency and probability of survival after transplant. The system uses several disease-specific parameters and takes into consideration the likelihood of benefit and long-term survival. The information includes laboratory values, use of supplemental O₂, functional status, disease diagnosis, and comorbidities. Each candidate's information must be updated every 6 months. This system appears to better match limited organs to acute need, and may be the reason for the decline in living donor transplants.

Donor lung procurement and preservation

Donor lungs traditionally have come from brain-dead cadaveric donors with preserved lung function. Fewer than 20% of donors of other solid organs are considered suitable for lung donation. Management of the lung donor may involve strict fluid management, bronchoscopy to assess for bronchopulmonary infection, alteration of ventilator settings, arterial blood gas (ABG) monitoring, and chest imaging. Intensive management of marginal donors has been shown to improve the quality and to expand the pool of donor lungs.

Preservation of the lung during harvest requires that the allograft be cooled and flushed with a pulmoplegic solution. Some centers use high-dose steroids and/or pulmonary vasodilators as well. The harvested lungs are kept partially inflated. Ischemic times play a critical role. The time from organ harvest to reperfusion in the recipient should be as short as possible. The number of suitable recipients far exceeds available organ donors; therefore, the expansion of the donor pool is a major concern of all transplant centers. Donation of organs after cardiac death has further expanded the donor pool. Despite about an hour of warm ischemia, early results have been promising.

Recipient selection and indications

Lung transplantation is indicated for patients with end-stage lung disease, those who are failing maximal medical therapy, and those for whom no effective medical therapy exists. Because lung transplantation remains a complex therapy with a significant risk of perioperative morbidity and mortality, potential candidates should be well informed and able to demonstrate adequate behavior and willingness to follow guidelines from health care professionals. Referral for transplant assessment is advisable for patients with <50% predicted 2- to

Table 89.2. Breakdown of SLTs and DLTs according to indication

SLT (%)	DLT (%)
COPD (50)	Cystic fibrosis (28)
Idiopathic pulmonary fibrosis (28)	COPD (24)

Cystic fibrosis (2)	α_1 -Antitrypsin (8)
Retransplant (2)	Primary pulmonary hypertension (6)
Primary pulmonary hypertension (1)	Retransplant (2)
Other (10)	Other (18)

Data from the International Society for Heart and Lung Transplantation (<http://www.ishlt.org>) registries for 1995 through 2007.

3-year survival. The distribution of lung transplants by indication is reviewed in [Table 89.2](#); contraindications are listed in [Table 89.3](#).

Disease-specific indications

Disease-specific indications are as follows:

Pulmonary fibrosis: Diffusing capacity of lung for carbon monoxide (DLCO) < 39%, a decrease in pulse oximeter saturation to < 88% during the 6-minute walk test, and “honeycombing” on high-resolution CT.

COPD: History of hospitalizations for acute exacerbations with acute hypercapnia, $PCO_2 > 50$ mm Hg, pulmonary hypertension, cor pulmonale despite O_2 therapy, and forced expiratory volume in the first second of expiration (FEV_1) < 20% predicted.

Connective tissue disorders (eosinophilic granuloma, lymphangioleiomyomatosis, sarcoidosis): Hypoxia at rest and severe impairment of lung function and exercise capacity.

Cystic fibrosis: $FEV_1 < 30\%$ or a rapid decline of FEV_1 , exacerbations requiring an intensive care unit stay, increasing frequency of exacerbations requiring antibiotic therapy, and recurrent hemoptysis.

Bronchiectasis: Recurrent hemoptysis, pulmonary hypertension, and recurrent infection.

Primary or secondary pulmonary hypertension: Persistent New York Heart Association class III or IV on maximal

Table 89.3. Contraindications to lung transplantation

Contraindications

- Malignancy
- Advanced dysfunction of other organ systems
- Incurable chronic infection (e.g., HIV, hepatitis)
- Psychiatric conditions that preclude the ability to cooperate with posttransplant medical care

Relative contraindications

- Age > 65 y (no hard limit exists)
- Critical unstable condition
- Colonization with highly virulent organism
- Mechanical ventilation or ECMO with small chance for rehabilitation
- Severe chest wall deformity or pleural disease

Table 89.4. Essential studies during pretransplant evaluation

Chest radiography and CT scan of thorax
Pulmonary function test and ventilation–perfusion scan
ABG
Evaluation of renal and hepatic function
Electrocardiogram
Echocardiogram
Cardiac catheterization (as indicated for specific patients)
Complete blood count and coagulation studies
ABO blood typing
Viral serologies (e.g., HIV, hepatitis, cytomegalovirus)

medical therapy, cardiac index < 2, and failing therapy of intravenous (IV) pulmonary vasodilators.

Workup of the pulmonary transplant recipient

The clinical evaluation and assessment for transplantation should include characterization of the underlying lung disease, evaluation for other organ system dysfunction, and determination of the patient's ability to tolerate long-term immunosuppressive therapy. Essential studies are detailed in [Table 89.4](#). Patients with stable single-vessel coronary disease may still qualify for lung transplantation. Stents or angioplasty may be used in these patients.

Perioperative management

Patient monitoring

Essential and optional monitors are listed in [Table 89.5](#). Most transplant centers routinely use PA catheters for all lung transplants. Continuous monitoring of PA pressures and RV performance is considered essential by most clinicians. Additional evaluation of cardiac performance can be done with TEE. Placement of a central venous line (via a double-stick technique) at the same time the PA line is placed allows flexibility in the timing of removal of the PA line.

Preinduction

Patients usually arrive for the procedure well informed from previous pulmonary clinic visits. Most patients have had a complete workup, allowing the anesthesia care team to do a rapid but complete preanesthetic assessment. It is important to ascertain their NPO status (many have eaten within 8 hours of induction)

Table 89.5. Monitors used during lung transplantation

Essential monitors	Additional monitors
Standard ASA monitors (ECG, pulse oximeter, NIBP, $ETCO_2$)	TEE
Invasive arterial pressure (radial/femoral)	Depth of anesthesia
CVP/PA catheter	Cerebral oximetry
Serial ABGs	

CVP, central venous pressure; ECG, electrocardiogram; $ETCO_2$, end-tidal carbon dioxide; NIBP, noninvasive blood pressure.

and carefully evaluate the airway, as this component will likely not have been previously evaluated.

Light sedation, antacid prophylaxis, nebulized bronchodilators, and continued supplemental oxygen are likely appropriate. A large-bore IV and an arterial line should be placed. If CPB is unlikely, and time permits, a thoracic epidural catheter also may be placed preoperatively.

Induction and intraoperative management

Before inducing general anesthesia, it is essential to confirm timing with the transplant team. Once a decision is made to proceed, the choice of anesthetic technique and induction or maintenance drugs is less critical than the hemodynamic and pulmonary management.

After initial intubation with a single-lumen endotracheal tube, bronchoscopy is performed to clear secretions and assess anatomy. A double-lumen tube is then placed. Typically, a left-sided tube is used for everything except left SLTs, for which a right-sided tube is indicated if anatomy permits. Central venous and pulmonary artery catheters must now be placed expediently. After induction, prophylactic antibiotics and initial immunosuppression, which typically involves high-dose steroids plus an induction agent such as antithymocyte globulin (if the transplant center uses preimplantation induction), are administered.

Single-lung transplant

For SLT, the patient is positioned for a standard thoracotomy. The lung to be explanted is mobilized. Often, a test clamp of the PA is performed prior to explantation. If the patient does not tolerate one-lung ventilation (OLV) or the test clamp, then CPB will be needed. Once the new lung is implanted, it should be slowly reperfused and ventilated using the lung-protective ventilator setting and low fraction of inspired oxygen content (FiO₂). The bronchial anastomosis can be checked with fiberoptic bronchoscopy. The lymphatics are not anastomosed. Between the capillary leak from reperfusion and the impaired lymphatic drainage, transplanted lungs are very vulnerable to pulmonary edema. For this reason, intraoperative fluids are limited, and diuretics may be given in the operating room.

Double-lung transplant

For DLT, the patient is positioned supine, often with the arms suspended from an ether screen or similar device to allow adequate access for a clamshell incision. Dissection is performed using alternating OLV. If the procedure is done without CPB, one lung is excised and the first donor lung implanted. Then the procedure is repeated on the other side, while the patient is ventilated using the newly implanted lung.

To date, the use of CPB remains inconsistent among transplant centers. Some centers attempt to do most DLTs without CPB and use CPB only if necessary. The usual indications for CPB are high PA pressures, RV dysfunction, severely dilated

PAs in primary pulmonary hypertension, severe hypoxia with OLV, and severe hypercarbia and acidosis during OLV. Other centers always use CPB for DLT.

Proponents of CPB cite better vascular control, better hemodynamic stability, better gas exchange, less strain on the right ventricle, easier dissection, and less stress on the first implanted lung. Potential disadvantages are heparin exposure (heparin-induced thrombocytopenia), the potential for greater blood loss, the need for more transfusion, and the inflammatory response to the CPB circuit.

If CPB is used, cannulation may occur through the chest, or the femoral vessels may be used. Unlike during heart surgery, the patient is not cooled and the heart continues to beat. Dysrhythmias must be treated as they occur. Antifibrinolytic agents may be useful to minimize blood loss. The need for slow reperfusion, lung-sparing ventilation, and limited fluid administration are similar to that of SLT.

Treating pulmonary hypertension and RV dysfunction

The basic principles of pulmonary hypertension and RV dysfunction treatment are to avoid hypoxia, hypercarbia, acidosis, light anesthesia, and hypothermia, as all may cause pulmonary vasoconstriction and right heart strain. Systemic pulmonary vasodilator therapy with nitroglycerin, alprostadil, or sodium nitroprusside may be attempted. The major disadvantage is systemic hypotension and, potentially, reversal of hypoxic pulmonary vasoconstriction, resulting in hypoxia. Inotrope therapy to improve RV function and cardiac output may be achieved with dobutamine, milrinone, or epinephrine. Inhaled prostacyclin PGI₂ (iloprost) has been used with success to reduce pulmonary pressures and avoid CPB in select cases. Inhaled NO reduces pulmonary vascular resistance, thereby unloading the right heart. Because NO is rapidly bound to hemoglobin and inactivated, it has no systemic vasodilatory effect. NO also has some attractive anti-inflammatory properties: It interferes with neutrophil adherence to endothelium, inhibits platelet aggregation, and inhibits expression of several inflammatory mediators.

Transesophageal echocardiography in lung transplantation

TEE is used routinely at several transplant centers. It allows assessment of cardiac anatomy and function. Factors commonly assessed include right and left ventricular function, volume status, the interatrial septum for atrial septal defect or patent foramen ovale, pulmonary venous flow, and pulmonary arterial flow. RV dysfunction at the time of PA test clamping may direct the decision to proceed with CPB. TEE can be used to assist in cannulae placement and to confirm that the PA line is in the RV outflow tract or main PA and thus will not end up in the staple line during explant. TEE, of course, provides an excellent assessment of volume status and biventricular function. Finally, pulsed Doppler can be used to assess flow across the pulmonary venous anastomosis. Pulmonary venous obstruction is a rare but potentially fatal cause of postoperative graft failure.

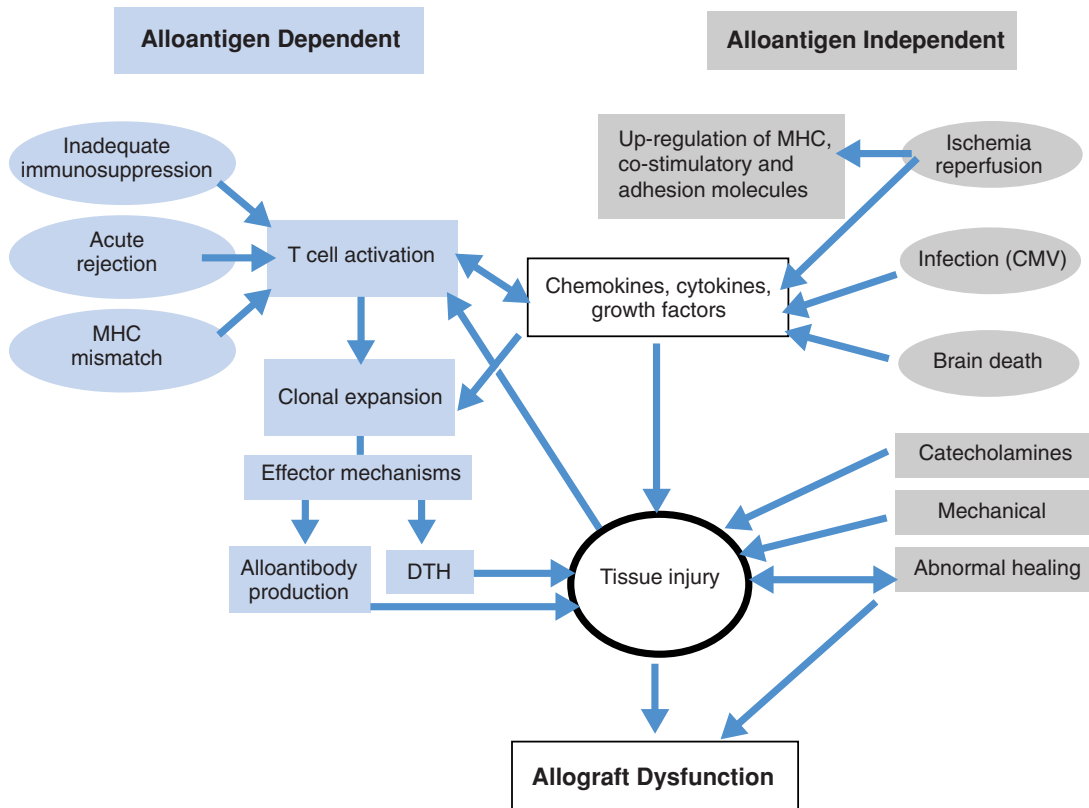

Figure 89.2. Transplant-related lung injury. (Adapted from McRae KM. Pulmonary transplantation. *Curr Opin Anaesthesiol* 2000; 13:53–59.)

Primary graft dysfunction

Primary graft dysfunction (PGD) is a serious complication that causes significant morbidity and mortality. Lung injury caused by ischemia and reperfusion leads to alveolar damage, pulmonary edema, and hypoxemia. Numerous factors, both alloantigen dependent and independent, contribute to the development of PGD (Fig. 89.2). Prevention is the key, but if PGD does occur, treatment is supportive using mechanical ventilation, diuresis, and inhaled NO. If all other measures fail, extracorporeal membrane oxygenation (ECMO) may be lifesaving. Initial ECMO results have improved with advancements in surgical technique, timely institution, and the improvement in membrane oxygenators.

Bronchoscopy and mediastinoscopy

Sharon L. Wetherall and Philip M. Hartigan

Introduction

Bronchoscopy and mediastinoscopy are surgical procedures commonly performed together under general anesthesia for diagnosis and staging of lung cancer. Bronchoscopy has other applications in and outside the operating room (Table 90.1). The anesthetic management should be tailored to the specific situation. Anesthesia for retrieval of aspirated foreign bodies is considered as an example.

Bronchoscopy involves the use of a lighted instrument to examine the tracheobronchial tree. Flexible fiber-optic bronchoscopes use fiber-optics to deliver the image to the proximal lens of a long, flexible scope. Video-bronchoscopes have a camera at the distal tip of the scope to capture the image, which is delivered by wires to a processor for video display on a monitor. Both use fiber-optics to deliver light to the distal end of the bronchoscope. Most models also have a working channel through which instruments or wires can be passed or suction applied. Rigid bronchoscopy involves the passage of a long, straight, rigid, tubular device through the mouth and glottis into the trachea or a main-stem bronchus (Fig. 90.1). The diameters vary but generally are larger than flexible bronchoscopes, allowing the passage of larger instruments. Indications for rigid bronchoscopy overlap considerably with those for flexible bronchoscopy (Table 90.2).

Anesthesia for flexible bronchoscopy

The anesthetic requirements for bronchoscopy *per se* are limited to blunting or ablating the airway reflexes as well as the powerfully noxious affective response to airway instrumentation. This may be accomplished through general anesthesia or topical anesthesia with sedation. When coupled with mediastinoscopy, general anesthesia with endotracheal intubation is most convenient. Large endotracheal tubes (ETT; >7.5 mm outer diameter) are required to accept adult flexible bronchoscopes without precluding adequate ventilation. Frequent suctioning via the bronchoscope complicates delivery of tidal volumes and anesthetic gases, thus the measurement of return volume and end-tidal CO₂ will be inaccurate. When suctioning is not used, the potential for air trapping due to the reduced functional cross-sectional area of the ETT is a hazard to be aware of. Because

bronchoscopy is often brief and can be easily interrupted if such problems occur, there is typically limited risk to the procedure. If the bronchoscopy becomes prolonged, use of intravenous anesthetic agents (total intravenous anesthesia [TIVA]) obviates the difficulties of volatile agent delivery.

Issues imposed by the target lesion itself (e.g., mass effect, airway compression, obstruction) or by the patient's coexisting diseases (e.g., severe chronic obstructive pulmonary disease, cardiac disease, pulmonary hypertension) may more profoundly affect anesthetic management decisions. In particular,

induction may convert a subcritical extrinsic tracheal obstruction into a life-threatening one, as the reduction of lung volumes from general anesthesia and the supine position reduce the caliber of airways (see [Chapter 91](#)).

Flexible bronchoscopy may be smoothly performed in an awake patient if topical local anesthesia is thorough. The conduit for the bronchoscope may be an oral bite block, an ETT, a laryngeal mask airway ([Fig. 90.2](#)), another supraglottic device, or the nasotracheal route. All these techniques allow visualization of the entire trachea. Attention to the recommended maximum tolerable doses of local anesthetics is imperative because of rapid absorption from mucous membranes. It should be assumed that the topically anesthetized airway is unprotected from aspiration for some period following application. Sedation, as always, should be tailored to the reserves, the requirements, and the response of the individual patient. Dexmedetomidine has been used with advantage for bronchoscopy in which preservation of respiratory drive is a premium. An antisialagogue such as glycopyrrolate aids in control of secretions, and preemptive bronchodilator treatments may be of benefit in the patient prone to bronchospasm.

Anesthesia for rigid bronchoscopy

Rigid bronchoscopy is far more stimulating than flexible bronchoscopy, and almost always requires general anesthesia. Positioning with a roll under the patient's back and full neck extension is necessary. Any instability of the cervical spine or any carotid arterial pathology that precludes neck extension is a contraindication. Dental guards should be used to protect the upper teeth. Full muscle relaxation considerably aids insertion of the rigid bronchoscope. As discussed previously, lesion-related or coexisting disease-related issues often dictate specific anesthetic considerations over and above those for rigid bronchoscopy itself. Trauma-related edema of the airway or vocal cords from the rigid scope may be ameliorated by steroids. During insertion of the bronchoscope, ventilation is temporarily interrupted, so hyperventilation and thorough denitrogenation prior to insertion are advised. Complications of rigid bronchoscopy include injury to the neck, teeth, cords, trachea, and bronchus. Pneumomediastinum/pneumothorax or

hemorrhage is possible if biopsy or endobronchial core-out is performed. Loss of airway is the principal risk if there is significant obstruction. Myocardial ischemia and arrhythmias may result from catecholamine surges from the tracheal stimulation. Ischemia is potentially exacerbated by hypoxemia and hypercarbia. Postoperative upper airway obstruction may result from trauma-related edema. If a laser is used, fire hazard issues need to be considered (see [Chapter 115](#) on laser surgery). If stents are being deployed or adjusted, there is a risk of total airway obstruction from a folded or malpositioned stent. Aspiration is also a risk.

Ventilation options during rigid bronchoscopy include (1) spontaneous ventilation, (2) positive pressure ventilation via the side port of a ventilating rigid bronchoscope, (3) jet ventilation or its variants (e.g., high-frequency jet ventilation, oscillatory ventilation), and (4) apneic oxygenation. Spontaneous ventilation may be preferred when variable obstructive lesions threaten loss of airway patency. Anesthetic depth must be sufficient to blunt the sensitive airway reflexes, and may be achieved by inhalational or intravenous agents and/or supplemental topical anesthetics. Most commonly, the anesthetic circuit is attached to the side port of a ventilating rigid bronchoscope. Delivery of oxygen and volatile agents and removal

Figure 90.2. View of the glottis through a laryngeal mask airway.

of CO₂ may be disrupted by surgical manipulations and distal airway obstructions, as well as by the intermittent opening of the proximal port by the surgeon. Not infrequently, once the scope is in place to ensure a patent airway, conversion to paralysis and positive pressure ventilation is performed. When side port positive pressure ventilation is employed, the proximal viewing port must be occluded, and moist gauze packing to the posterior pharynx is necessary to minimize the air leak at the glottis. Positive pressure breaths must be timed to coincide with the times the proximal viewing port is closed. With prolonged interruptions in ventilation, the anesthesiologist must estimate the increase in PaCO₂ (approximately 6 mm Hg/min during first minute, followed by 3 mm Hg/min thereafter) and communicate with the surgeon when resumption of ventilation is deemed necessary. Use of TIVA avoids interruptions in anesthetic delivery and prevents pollution of the operating room with volatile agent.

Jet ventilation may be performed via an injection needle mounted at the proximal end of a rigid bronchoscope. Oxygen from a high-pressure source exiting the needle entrains room air by the Venturi principle. The resulting fraction of inspired oxygen (FiO₂) and tidal volume is unknown, and exhalation is passive. There is risk of barotrauma as well as unrecognized hypoventilation. Monitoring of ventilation relies on observation of chest rise, arterial blood gas sampling, or transcutaneous CO₂ monitoring. Jet ventilation, in experienced hands, is a viable technique that allows the surgeon uninterrupted access to the working port of the rigid bronchoscope.

Anesthesia for retrieval of foreign bodies in the airway

Management of the patient with a foreign body in the airway requires a flexible approach that is well coordinated with the surgical team. Relevant data are often initially unknown, including the size and shape of the object, the location and extent of obstruction, the duration and degree of reactive mucosal edema, the stability of the object, and whether it impales the mucosa. Children under age 3 are the most common patients presenting with foreign body aspiration (FBA). Therefore, history frequently is limited to parental observation of sudden onset of coughing and dyspnea, or possibly stridor or wheezing. The stable patient should receive a chest radiograph and/or CT scan. Flow–volume loops can define whether the obstruction is intrathoracic (truncated expiratory limb) or extrathoracic (truncated inspiratory limb), but are used rarely because patients are often in respiratory distress and symptomatology often provides the same information. Inspiratory stridor indicates extrathoracic obstruction, whereas expiratory wheezing indicates intrathoracic obstruction. Occasionally, a cooperative, mature patient can be examined under local anesthesia with fiber-optic bronchoscopy. In all cases, general anesthesia, airway management, and rigid bronchoscopy should be immediately available. Coughing or manipulation of the foreign body may convert a partial obstruction to a life-threatening one.

The most common surgical approach to the patient with intrathoracic FBA is a combination of flexible and rigid bronchoscopy. Unlike most other forms of airway obstruction, foreign bodies are at risk of moving to a position that is more obstructive or more difficult to extract. A variety of retrieval tools are available, including baskets, snares, and balloon-tipped catheters that can be passed distal to the foreign body, inflated, and pulled back, as in balloon embolectomy. Aspirated organic matter (e.g., peanuts) may incite reactive mucosal edema that makes extraction more difficult. Friable foreign bodies may break apart with extraction attempts. Rigid bronchoscopy offers greater latitude and is the method of choice for difficult cases. If the object causes life-threatening tracheal occlusion, a solution of last resort is to push the foreign body into a mainstem bronchus and ventilate the contralateral lung. Rarely, it is necessary to surgically open the trachea or bronchus to remove the foreign body.

Anesthetic options range from sedation with local anesthesia for flexible bronchoscopy, to spontaneously breathing inhalation-based general anesthesia, to paralysis with positive pressure ventilation. Pediatric anesthesiologists are often most comfortable and skilled with inhalational inductions. Whether this provides protection against obstruction compared with general anesthesia with positive pressure ventilation is debated. When rigid bronchoscopy is performed, spontaneously breathing volatile agent–based anesthetics may be challenging because of air leak at the glottis and interruptions in gas delivery. Conversion to paralysis and positive pressure ventilation due to desaturation, inadequate depth of anesthesia, or coughing and bucking is frequently required. TIVA is favored by some as a more convenient means of maintaining anesthetic depth during rigid bronchoscopy.

Mediastinoscopy

Mediastinoscopy is a surgical procedure to examine the area between the lungs (mediastinum) using either a rigid or flexible lighted instrument. It is principally used for diagnosis or clinical staging of lung cancer. In some cases, mediastinoscopy has been replaced by other biopsy methods that use CT, ultrasound, or bronchoscopy to guide a biopsy needle to the abnormal tissue. Mediastinoscopy may still be needed when these methods cannot be used or when they do not provide conclusive results.

For cervical mediastinoscopy, the mediastinoscope is passed through an incision just above the manubrium, and advanced along a plane created by blunt dissection between the trachea and the pretracheal fascia (Fig. 90.3).

Anterior mediastinoscopy provides access to lymph nodes of stations 5 and 6 (anterior mediastinal and aortopulmonary window nodes), which typically are not accessible by cervical mediastinoscopy. Blunt dissection to the aortopulmonary window is performed through a 2-cm incision between the second and third ribs. Alternatively, level 5 and 6 nodes can be accessed through the cervical mediastinoscopy incision by creating a more superficial substernal plane beneath the

Figure 90.3. Cervical mediastinoscopy; insertion of a cervical mediastinoscope.

innominate and left carotid arteries, deep to the innominate vein and anterior to the great vessels (“extended mediastinoscopy”).

Anatomy of the mediastinum

The mediastinum is the region between the two pleural cavities extending from the thoracic inlet to the diaphragm. This region is further described in [Chapter 91](#).

Anesthesia for mediastinoscopy

Mediastinoscopy patients tend to fall into two groups: those with mediastinal masses (often for biopsy for diagnosis) and those with lymphadenopathy (for cancer staging or diagnosis). Patients with significant masses must be evaluated for compression of the airway, heart, or superior vena cava (see [Chapter 91](#)). Mediastinoscopy generally requires general endotracheal anesthesia with muscle relaxation. Subsequent anesthetic considerations are largely intuitive, and are driven by awareness of the potential complications ([Table 90.3](#)).

Hemorrhage is the most frequent serious complication. Sources of significant hemorrhage include the azygous vein, the pulmonary artery, and (rarely) the aorta or its major branches. The thin-walled pulmonary artery and azygous vein are vulnerable to avulsion injury as adherent lymph nodes are plucked off their surfaces. The proximity of major vessels emphasizes the importance of a motionless surgical field during biopsy. The response to hemorrhage depends on the magnitude, and ranges from packing and observation to emergent sternotomy or thoracotomy and cardiopulmonary bypass.

Cervical mediastinoscopy often results in compression of the innominate artery with potential compromise of right carotid blood flow. Patients at increased risk are those with coexisting carotid or cerebrovascular disease. A history of cerebrovascular accidents or known left carotid stenosis may warrant electroencephalographic monitoring. Placement of a pulse detector in the right arm (arterial line or pulse oximeter) is widely advocated as an identifier of innominate artery compression, but the actual efficacy of this maneuver is undocumented. Stroke following mediastinoscopy is extremely rare, possibly owing to the generally transient nature of innominate artery compression.

Figure 90.4. Endobronchial ultrasound.

Endobronchial ultrasound-guided transbronchial biopsy

Recent developments have improved the diagnostic resolution of ultrasound while decreasing the diameter of the probe, allowing for a bronchoscope-mounted ultrasound probe. Endobronchial ultrasound (Fig. 90.4) to guide transbronchial biopsy is the most recent development in evaluating mediastinal

structures. Anesthetic considerations are similar to those for bronchoscopy, except for two points:

1. There is potential for significant hemoptysis
2. There is potential for tracheal obstruction when the balloon tip is inflated with saline to improve resolution (may require intermittent apnea)

Management of mediastinal mass

Ju-Mei Ng

Introduction

The anesthetic considerations for patients with an anterior mediastinal mass vary according to the individual anatomy, pathology, and proposed surgical procedure. Fatal occlusion of the airway and cardiovascular collapse are well-recognized complications. The usefulness of clinical signs and symptoms, radiologic evaluation, and pulmonary function tests to determine perioperative risk are discussed, including some general principles of safe anesthesia for these patients.

Anatomy

The mediastinum extends from the thoracic inlet to the diaphragm and is bounded by the sternum anteriorly, the vertebral column posteriorly, and the parietal pleura laterally. It can be divided into four compartments: superior, anterior, middle, and posterior mediastinum, although the anterosuperior mediastinum may be considered a continuous space (Fig. 91.1).

Pathology

In adults, primary mediastinal masses are generally located in the anterosuperior mediastinum, with a predominance of lymphoma, thymoma, and germ cell tumors. In young children, posterior mediastinal masses of neurogenic origin are most common, whereas in adolescents, lymphomas arising from the anterior mediastinum predominate.

Symptoms and signs

Signs and symptoms are related to mass effect on, or invasion of, surrounding structures (Table 91.1). Most adult mediastinal tumors are asymptomatic or associated with vague complaints such as chest pain, dyspnea, and cough. In contrast, mediastinal masses are symptomatic in 70% of children.

Anesthetic concerns

The three main anesthetic concerns are tracheobronchial tree obstruction; compression of the pulmonary artery and heart, especially the right ventricular outflow tract (RVOT); and superior vena cava (SVC) syndrome. The most common complication during anesthesia for masses involving the vital mediastinal structures is airway obstruction. Each of these

complications is life-threatening and may cause acute deterioration and death during anesthesia if not handled with caution and expertise.

Tracheobronchial tree obstruction

The degree of airway obstruction depends on the location of the mass and extent of compression (Fig. 91.2).

Compression of the pulmonary artery and heart

RVOT obstruction and circulatory collapse may be triggered by altered positioning, induction of anesthesia, institution of positive pressure ventilation, hypovolemia, and reduced cardiac contractility (Fig. 91.3).

Positive pressure ventilation may cause dynamic hyperinflation because of expiratory gas flow obstruction. With

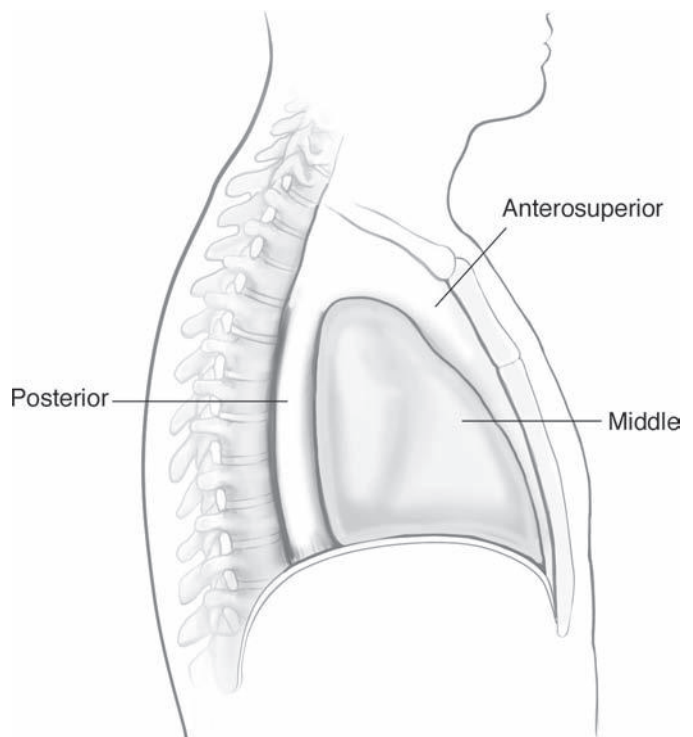

Figure 91.1. Compartments of the mediastinum.

Table 91.1. Signs and symptoms of structural compression by a mediastinal mass

Compression or infiltration of adjacent structures	Symptoms	Signs
Tracheobronchial tree	Cough Stridor Dyspnea Recurrent pulmonary infections Hemoptysis	Wheeze
Esophagus	Dysphagia	
RVOT	Dyspnea Syncope	
Recurrent laryngeal nerve	Hoarseness	Vocal cord paralysis
Sympathetic chain	Horner's syndrome	
Phrenic nerve		Elevated hemidiaphragm
SVC	Dyspnea Cough Syncope Orthopnea Stridor Headache Decreased mentation	Venous engorgement Upper body edema Plethora Cyanosis

Tracheobronchial Tree Compression

Supine posture

- Due to gravity, an anterior mass will exert greater pressure on the trachea
- ↑ Tumor size due to ↑ vascularity
- Dimensions of mediastinum ↓ due to cephalad movement of diaphragm
- Volume of heart and pulmonary vasculature ↑, limiting “free” space for tumor
- Gravity renders the airway more vulnerable to partial or total occlusion in tracheomalacia

Induction of GA

- Tone of intercostal muscles change
- Dimensions of rib cage ↓
- ↓ FRC
- Distending pressure of airways ↓

Mechanical ventilation

- Loss of transpulmonary pressure gradient maintaining airway patency
- Intrapleural positive pressure ↑ applied external pressure on airway
- May cause severe pulmonary distension if airway narrowing impairs expiration

Figure 91.2. Effects of anesthesia on tracheobronchial tree obstruction.

Compression of the PA and Heart

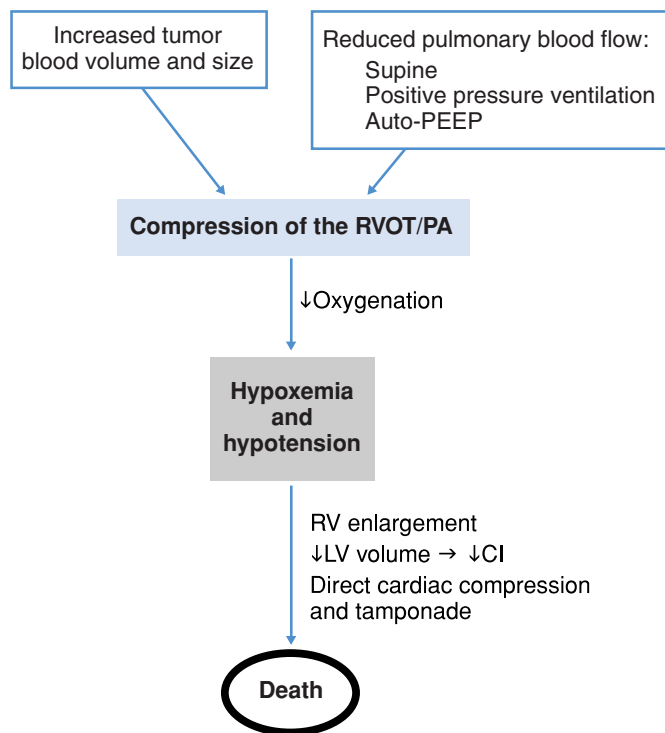

Figure 91.3. Effects of anesthesia on compression of the pulmonary artery and RVOT.

sufficient elevation of intrathoracic pressure, the gradient for venous return is reduced, as are right ventricular pressures, worsening the extent of vascular obstruction.

SVC syndrome

The combination of decreased venous return from the upper part of the body coupled with pharmacologic vasodilatation may result in severe hypotension. Coughing, straining, and supine or Trendelenburg positioning all exacerbate SVC syndrome (Table 91.2).

Preoperative evaluation

The main aims for the anesthesiologist are to delineate the extent of encroachment on other structures and to quantify any functional cardiopulmonary compromise caused by such encroachment. The anesthetic plan is then formulated by taking into account clinical signs and symptoms, radiologic evaluation, and pulmonary function tests (Fig. 91.4).

Table 91.2. Perioperative problems arising from SVC syndrome

	Perioperative concerns
Airway	Edema Airway congestion and hemorrhage
Venous access	Lower extremity Potential for massive hemorrhage

Preoperative Evaluation

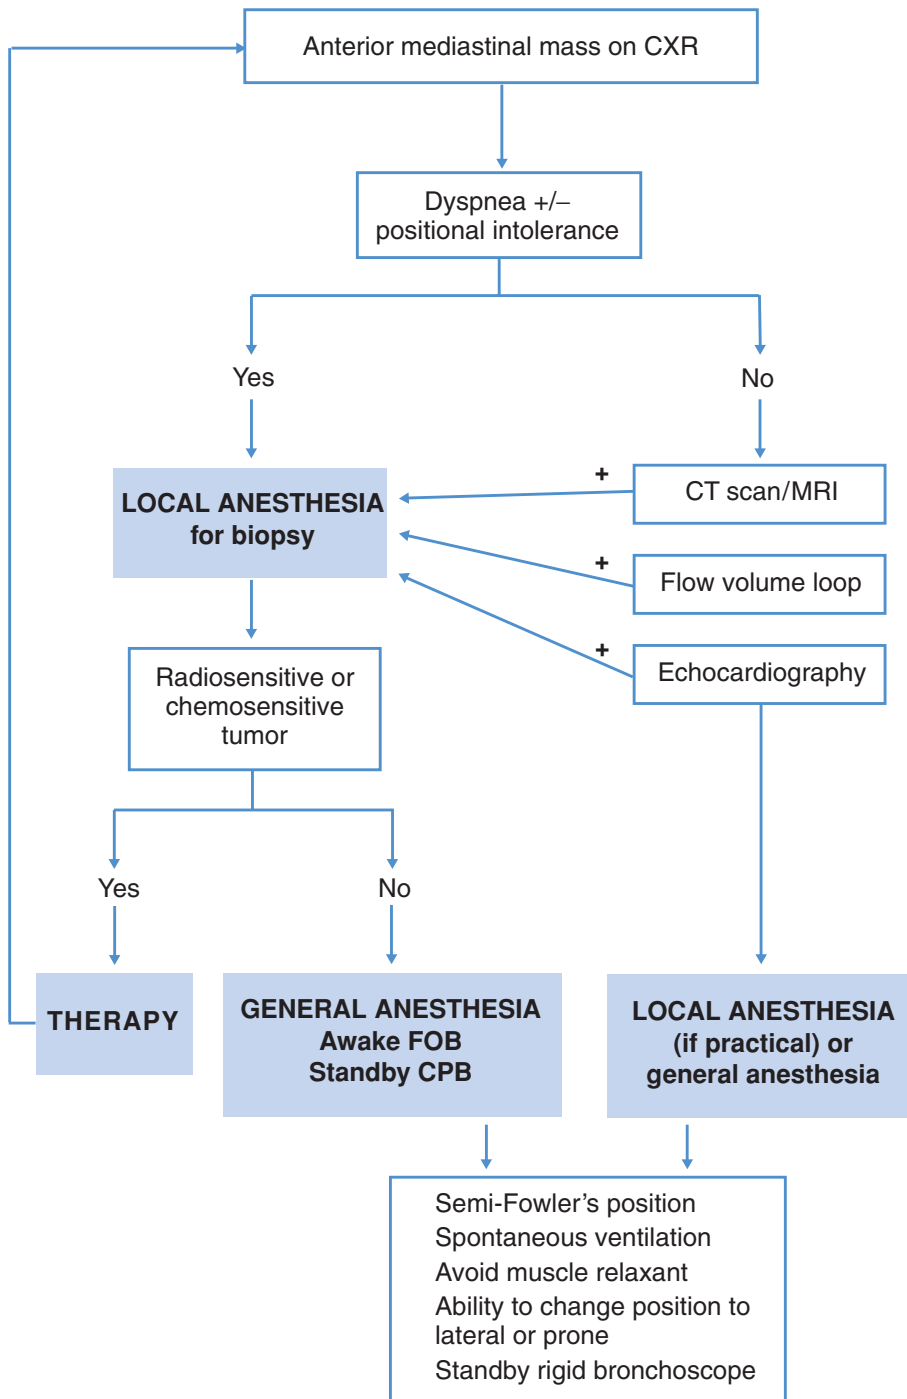

Figure 91.4. Preoperative evaluation of a patient with an anterior mediastinal mass.

Radiologic evaluation

A chest CT scan is indicated in all patients and helps identify the location of the mass, delineate margins, define the mass's relationship to adjacent structures, and determine the extent of tracheal or vascular compression. The tracheal cross-sectional area also can be estimated. MRI shows more extensive disease

than does CT in 25% of patients, and accurately assesses tumor involvement of cardiac structures.

An increase in the ratio of the transverse diameter of a mediastinal mass to that of the chest has been associated with increased respiratory complications. However, this measurement may be imprecise, and the relation of the mass to the tracheobronchial tree likely is more important. The cross-sectional

area of the trachea has been related to the extent of perioperative respiratory complications. There was total airway obstruction in five of eight children under general anesthesia with tracheal area $< 50\%$ predicted, but general anesthesia was well tolerated in children with tracheal area $> 50\%$ predicted. Postoperative respiratory complications were related to tracheal compression of more than 50% on the preoperative CT scan.

Pulmonary function testing and postural flow–volume loops

Traditionally, part of the preoperative assessment of patients with an anterior mediastinal mass has been to perform postural spirometry. This approach stemmed from the finding that an increased midexpiratory plateau when changing from the upright to the supine position is pathognomonic for a variable intrathoracic airway obstruction and an indicator of patients who are at risk for airway collapse during induction of anesthesia (Fig. 91.5).

Pulmonary function testing gives information about functional impairment but does not accurately predict airway morbidity and does not describe anatomic abnormality. Moreover, studies of flow–volume loops have shown poor correlation with the degree of airway obstruction and may not be any better than symptoms and a CT scan at predicting perioperative complications. In clinical practice, postural spirometry probably does not offer any additive benefit in predicting perioperative complications in a minimally symptomatic population beyond that which is obtained from chest imaging.

Figure 91.5. Effects of fixed and variable obstructions on flow-volume loops.

Peak expiratory flow rate

The risk of perioperative complications was increased more than 10-fold when the peak expiratory flow rate (PEFR) was 40% or less of predicted. A combination of obstructive and restrictive patterns (mixed pulmonary syndrome) was associated with a high rate of postoperative respiratory complications. In a prospective evaluation of 31 children before 34 procedures, Shamberger et al. found that all patients did well under general anesthesia if their tracheal cross-sectional area and PEFR were $> 50\%$.

Echocardiography

Patients with cardiovascular symptoms, or those unable to give an adequate history, should also undergo transthoracic echocardiography to assess for cardiac, systemic, or pulmonary vascular compression. Echocardiography reliably identifies pericardial thickening and masses adjacent to the pericardium, and can evaluate myocardial dysfunction due to tumor compression or infiltration.

Anesthetic management

Acute management

When a patient presents with acute symptoms, it is important to maintain the sitting posture (or most comfortable position) and provide humidified oxygen. If available, heliox (20% oxygen + 80% helium) may be helpful because it can decrease the density of the inspiratory gas and reduce airway resistance. Steroids have been used successfully to decrease tumor size without affecting the accuracy of histologic diagnosis post administration. The possibility of preoperative chemo- or radiotherapy may be considered. Figure 91.6 shows anesthetic management of anterior mediastinal masses.

Diagnostic procedures

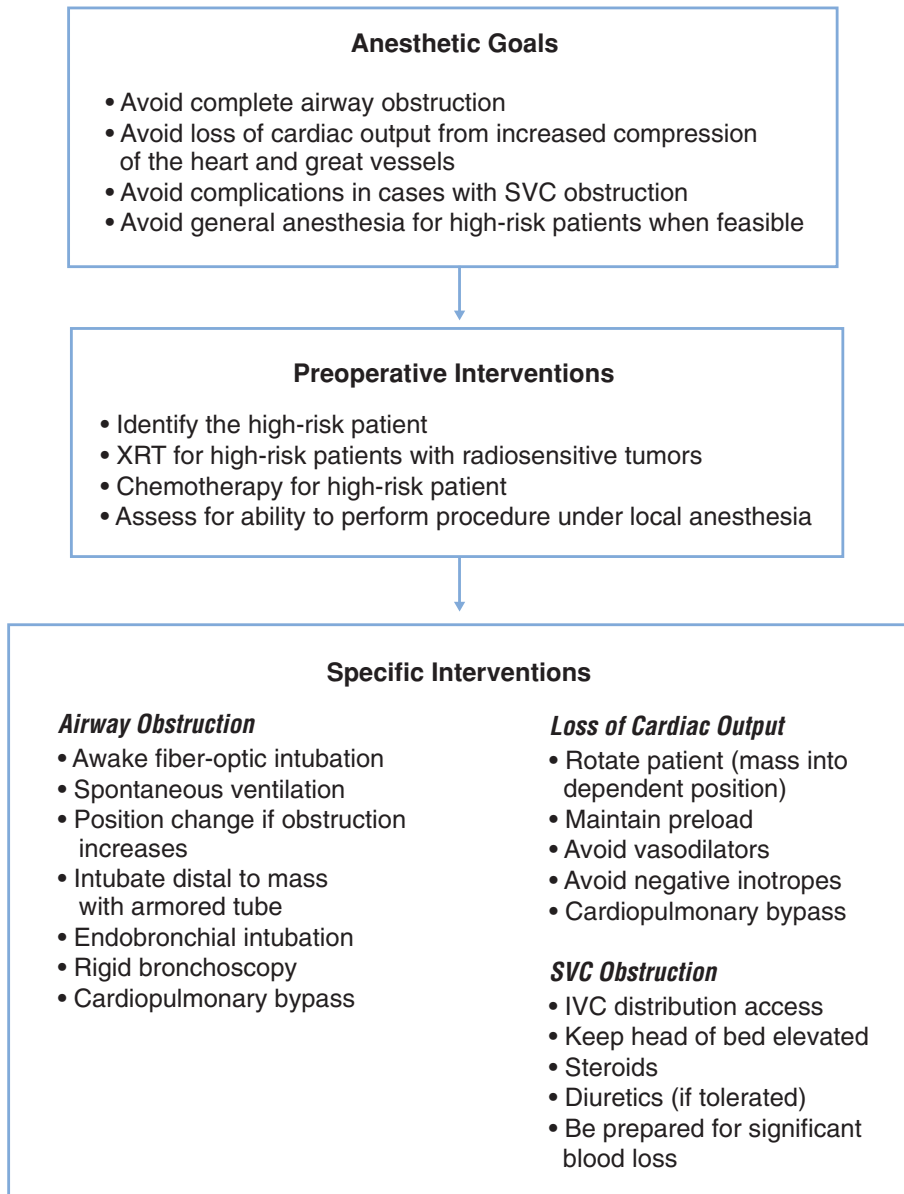

Tissue biopsy is likely the first procedure for most patients, and tissue may be obtained from biopsy of peripheral or metastatic lesions. This avoids an intrathoracic procedure and the need for a general anesthetic. Awake CT-guided needle biopsy (under local anesthesia and sedation as required) and awake anterior mediastinoscopy with local anesthesia in adults are performed relatively frequently.

Induction and intubation

Although there is a need to individualize management on a case-by-case basis, there are some general principles. Depending on the level, extent, and severity of obstruction, awake fiberoptic video-bronchoscopy may be used. This approach allows both the anesthesia and surgical teams to view the lesion and assess the airway dynamics, degree of airway compression, and effect of changes in posture. An appropriately sized endotracheal tube can then be passed beyond the lesion. A routine intravenous induction and intubation may be

Management of Mediastinal Masses

Figure 91.6. Anesthetic management of an anterior mediastinal mass.

performed in patients with no symptomatic, radiologic, or bronchoscopic evidence of airway obstruction. In the pediatric population, an inhalational induction is frequently used. In adults, stage II events may be common during inhalational induction, and it may be difficult to abort midcourse. Other techniques that have been described include the laryngeal mask airway, rigid bronchoscopy, and use of a distal jet ventilation catheter.

Ventilation

It is important to remember that positive pressure ventilation-induced dynamic hyperinflation may worsen obstruction.

Low-frequency or high-frequency jet ventilation has been used successfully. The strategy also depends on the site of compression and whether an appropriately sized single- or double-lumen endotracheal tube or single-lumen endobronchial tube can successfully stent open the airway. Laryngoscopy and rigid bronchoscopy have been used successfully to relieve obstruction. In the postoperative period, corticosteroids, racemic epinephrine, or heliox may be useful.

A stepwise induction of anesthesia is important; it allows the patient to be awakened quickly if airway or vascular compression develops. Repositioning of the patient may be helpful in relieving airway compression.

SVC syndrome

There are no data to support any particular induction and intubation technique. The use of an antisialagogue, a bronchodilator, or racemic epinephrine and maintenance of the sitting position appear to be helpful.

Perils of biopsy under local anesthesia

Anxiety, pain, or high sympathetic tone may increase ventilatory demand and worsen airflow dynamics by inducing turbulent flow across the obstruction. A variety of techniques have been used. Ketamine has been shown to preserve chest wall tone and functional residual capacity.

Neuroanesthesia

Linda S. Aglio, editor

Principles of neurophysiology

Dennis J. McNicholl and Lee A. Kears Jr.

Autonomic nervous system: anatomy and receptor pharmacology

The autonomic nervous system (ANS) controls the visceral, involuntary, “auto-pilot” functions of the body – functions that are not under conscious control. Understanding the effects of drugs used in the practice of anesthesia is built on a foundation of the anatomy and physiology of the ANS. Broadly, the ANS is subdivided into the central ANS (hypothalamus, medulla oblongata, and pons) and the peripheral ANS. The peripheral ANS is then further subdivided into the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS) (see Figs. 92.1 and 92.2).

Sympathetic nervous system (“thoracolumbar” division of the peripheral ANS)

The SNS is a “high-gain” system in the sense that activation of a presynaptic nerve fiber results in mass activation of postganglionic nerve fibers. The ratio of preganglionic to postganglionic fibers in the SNS is approximately 1:200. Sympathetic fibers are distributed throughout the body. Cell bodies in this division of the peripheral ANS originate in the intermediolateral columns of the thoracolumbar spinal cord and travel via spinal nerves T1–L2. Autonomic reflexes function similarly to somatic reflexes with the exception that the efferent limb is unipolar in the somatic arc and bipolar in the autonomic arc (see Fig. 92.3).

Anatomically, synapses in the SNS occur in the paravertebral ganglia (a.k.a. the sympathetic chain or sympathetic trunk ganglia, of which there are 22 pairs) and the prevertebral ganglia (3 unpaired: celiac, superior mesenteric, and inferior mesenteric ganglia). The paravertebral ganglia are connected to the spinal nerves by white rami communicans (myelinated preganglionic fibers which carry signals from the lateral horn cells of the spinal cord into the paravertebral ganglion) and gray rami communicans (unmyelinated postganglionic fibers which continue the signal from the paravertebral ganglion out to the spinal nerves). The paravertebral ganglia are also connected to each other by nerve trunks to form longitudinal chains; this connection allows for nerve fibers to travel up or down several ganglia before synapsing. Preganglionic fibers are short, and

postganglionic fibers are long. One exception is for the adrenal medulla, which has no postganglionic fibers – preganglionic fibers enter the adrenal medulla and synapse on cells that secrete neurotransmitters directly into the bloodstream.

Functionally, all preganglionic fibers in the SNS are cholinergic (i.e., release acetylcholine). Postganglionic fibers in the SNS are adrenergic (i.e., release epinephrine or norepinephrine) or dopaminergic (i.e., release dopamine). Effects of activation of adrenergic receptors are shown in Table 92.1.

Parasympathetic nervous system (“craniosacral” division of the peripheral ANS)

In contrast to the SNS, the PNS is a “low-gain” system; its activation results in a discrete and limited effect. The ratio of preganglionic to postganglionic fibers in the PNS is approximately 1:2. Preganglionic nerves in the PNS are long, and postganglionic nerves are short and are usually located on or in their intended effector organs. Cell bodies in the PNS originate in the midbrain (cranial nerve [CN] III), medulla oblongata (CN VII, IX, and X), and sacral spinal cord (S2–S4). CN X accounts for approximately 75% of parasympathetic activity. The pelvic nerves (S2–S4) supply the distal colon, bladder, and genitalia.

As with the SNS, all preganglionic PNS nerves are cholinergic. All postganglionic nerves of the PNS are also cholinergic. Cholinergic receptors are classified according to their response to nicotine or muscarine. Nicotine is the prototypical ganglionic stimulant, and nicotinic receptors can be further subdivided into N_N (subscript “N” denoting Neuronal-type) receptors found in autonomic ganglia, adrenal medulla, and central nervous system (CNS), and N_M (subscript “M” denoting Muscle-type) receptors located at the neuromuscular junction. Muscarine is a compound isolated from the mushroom *Amanita muscaria* and was the first parasympathomimetic to be studied. The muscarinic receptors have been subdivided into five receptor subtypes (M_1 – M_5). Most notably, the M_2 receptor subtype, when activated, leads to a slowing of spontaneous depolarization in the sinoatrial (SA) node and slower conduction through the atrioventricular (AV) node.

A comparison between the SNS and PNS is shown in Table 92.2.

Figure 92.1. The autonomic nervous system.

Autonomic control of the heart

Cardiac output can increase by more than 100% through sympathetic stimulation of cardiac accelerator fibers (derived from spinal nerves T1–T4); elevation in both the heart rate and contractility contributes to this increase. By comparison, cardiac output can be decreased to almost zero by parasympathetic stimulation. This effect, however, is primarily mediated via heart rate decrease; contractility is less affected by parasympathetic stimulation.

Sympathetic innervation of the heart is diffuse and abundant, resulting in a robust response when activated. Cardiac output can increase two- to threefold with sympathetic stimulation. Parasympathetic input to the heart, via the vagus nerve,

is more discrete (SA and AV nodes). Therefore, parasympathetic/vagal input to the heart affects rate more than pumping capacity – strong vagal stimulation can decrease heart rate to almost zero but the strength of cardiac contraction by only 20% to 30%.

Autonomic control of blood vessels

With the exception of capillaries, all vessels are innervated with sympathetic fibers and can therefore vasoconstrict to cause an increase in blood pressure. This effect is more prominent in the venous system, which contains more blood volume (~64%) at any given time compared with the arterial system. There is no clinically relevant parasympathetic control of blood vessels.

Figure 92.2. The craniosacral (parasympathetic) and thoracolumbar (sympathetic) nervous systems. Parasympathetic preganglionic fibers pass directly to innervate their organ. Postganglionic cell bodies are located near or within the innervated viscera. This limited distribution of parasympathetic postganglionic fibers emphasizes the limited effect of parasympathetic function. In the sympathetic nervous system, the postganglionic neurons begin in either the paired sympathetic ganglia (i.e., the paravertebral ganglia) or one of the unpaired collateral plexuses (i.e., the celiac, superior mesenteric, inferior mesenteric ganglia). One preganglionic fiber influences many postganglionic neurons. Activation of the SNS therefore produces a more diffuse physiologic response.

Table 92.1. Adrenergic receptors

Receptor	Synaptic site	Anatomic site	Action	LV function and stroke volume
α_1	Postsynaptic	Peripheral vascular smooth muscle	Constriction	Decreased
		Renal vascular smooth muscle	Constriction	
α_2	Presynaptic	Coronary arteries, epicardial Myocardium	Constriction	Improved
		Renal tubules	Positive inotropism 30%–40% of resting tone Antidiuresis	
α_2	Postsynaptic	Peripheral vascular smooth muscle release	Inhibition of NE	Improved
		Coronaries	Secondary vasodilation	
α_2	Postsynaptic	CNS	Inhibition of CNS activity	Decreased
		Coronaries, endocardial	Sedation	
α_2	Postsynaptic	Gastrointestinal system	Decrease in MAC	Improved
		CNS	Constriction	
β_1	Postsynaptic (NE sensitive)	Renal tubule	Inhibition of insulin release	Improved
		Myocardium	Decrease in bowel motility	
β_1	Postsynaptic (NE sensitive)	Sinoatrial (SA) node	Inhibition of antidiuretic hormone	Improved
		Ventricular conduction	Analgesia	
β_1	Postsynaptic (NE sensitive)	Kidney	Promotion of Na ⁺ and H ₂ O excretion	Improved
		Coronaries	Positive inotropism and chronotropism	
β_2	Presynaptic (NE sensitive)	Myocardium	Renin release	Improved
		SA node ventricular conduction vessels	Relaxation	
β_2	Postsynaptic (extrasynaptic) (EPI sensitive)	Myocardium	Acceleration of NE release	Improved
		Vascular smooth muscle	Opposite action to presynaptic α_2 agonism	
DA ₁	Postsynaptic	Bronchial smooth muscle	Constriction	Improved
		Renal vessels	Positive inotropism and chronotropism	
DA ₁	Postsynaptic	Blood vessels (renal, mesentery, coronary)	Relaxation	Improved
		Renal tubules	Relaxation	
DA ₂	Presynaptic	Juxtaglomerular cells	Vasodilation	Improved
		Sympathetic ganglia	Natriuresis	
DA ₂	Postsynaptic	Postganglionic sympathetic nerves	Diuresis	Improved
		Renal and mesenteric vasculature	Renin release (modulates diuresis) Minor inhibition	

NE, norepinephrine; EPI, epinephrine

Control of circulation is affected by 1) sympathetic chain ganglion (T1–L2), 22 pairs in total, and 2) peripheral nerve fibers originating from T1 to L2 which then travel via the sympathetic chain to the vasculature.

Cerebral physiology

Cerebral metabolic rate

The cerebral metabolic rate (CMR) of oxygen (CMRO₂) is defined as the amount of oxygen consumed by the brain in normal, conscious young men (rates are similar for young women). Of all organs, the brain and the heart are at highest risk for ischemia due to their high oxygen utilization and relatively low physiologic reserve. With respect to the brain, this susceptibility stems from its high metabolic demand and its lack of significant

anaerobic metabolism to support function in times of decreased oxygen or glucose substrate. The window of time for development of severe irreversible brain damage from hypoxemia is approximately 3 to 8 minutes at normal body temperature. In normal physiology, CMRO₂ depends on the functional state (ranging from seizure activity to the comatose or anesthetized state) and body temperature. At normal body temperature, resting CMRO₂ is 3.5 ml O₂/100 g/min. Hypothermia decreases CMRO₂ significantly. At a body temperature of 18°C to 20°C, complete burst suppression of the electroencephalogram (EEG) can be seen. Conversely, hyperthermia increases CMRO₂, however only up to a point (~42°C/103°F). Beyond this range, CMRO₂ actually decreases, likely due to neuronal breakdown and enzyme degradation. Therefore, at the extremes of temperature, CMRO₂ declines.

Figure 92.3. Somatic and autonomic reflex arcs. Somatic arcs are unipolar, in contrast to autonomic arcs, which are bipolar.

Cerebral blood flow

Due to the high metabolic demands of the brain (i.e., $CMRO_2$), cerebral blood flow (CBF) is disproportionately high (compared to other organs on a gram-for-gram basis). Distribution of that blood flow will change depending on which regions of the brain are metabolically more active; CBF and metabolism are coupled in normal physiology. Blood flow to the cortex (mostly gray matter) is considerably higher than blood flow to subcortical areas (mostly white matter). The mechanism for this coupling is not completely understood; however, it does allow for manipulation of the CBF by extrinsic influences such as carbon dioxide [CO_2] and mean arterial pressure [MAP] regulation (chemoregulation and mechanoregulation, respectively).

CBF is autoregulated in normal patients with MAP between 60 and 150 mmHg. As a starting point, normal homeostasis with a $PaCO_2$ of 40 mm Hg corresponds to a CBF of

~50 ml/100 g/min. With a $PaCO_2$ increase from 40 to 80 mmHg, CBF would double to ~100 ml/100 g/min. With a CO_2 decrease from 40 to 20 mmHg, CBF would be halved (down to ~25 ml/100g/min). In situations in which CBF becomes altered by elevated or depressed CO_2 levels, CBF will return to normal after approximately 6 to 8 hours, even if the $PaCO_2$ remains abnormal. In patients who are chronically hypertensive, the CBF autoregulation curve is shifted to the right, and maintenance of higher MAPs is required to avoid relative hypotension and cerebral hypoperfusion. Other circumstances can also disrupt CBF autoregulation: trauma, hypoxia, ischemia, and iatrogenic influences (e.g., anesthetic agents, systemic vasodilators/vasopressors).

Changes in CO_2 levels will affect CBF. Hypoventilation leads to elevated levels of CO_2 , causing a lower pH, cerebral arteriolar vasodilatation, and increased CBF. Under normal conditions, $CMRO_2$ and CBF are inextricably coupled. This arrangement can be negated, however, under circumstances of physiologic disruption. The most common example is that of ischemic stroke. In this setting, early in the course of the stroke, autoregulation of cerebral perfusion is altered in the tissues marked by the damaged ischemic core as well as the “penumbra,” the area immediately contiguous with the core. The peri-infarct zone, depending on its size and location, tends not to be uniformly injured, varying between areas demonstrating increases in $CMRO_2$ and those showing distinct reductions in $CMRO_2$ and oxygen extraction fraction (OEF). Postischemic hyperperfusion is a common finding in human stroke imaging studies and animal stroke models, where damaged areas without $CMRO_2$ regulation receive excessive blood flow and volume independent of the metabolic requirements of the area. This luxury perfusion can cause further damage to the area, leading to edema and hemorrhagic extravasation into core ischemic and adjacent areas. Clinical management of CBF by CO_2 manipulations may become quite complicated when attempting to provide the optimal blood flow to injured brain in this disorder. Hyperventilation, for example, may vasoconstrict the normal blood vessels and shunt needed nutrients away from the damaged areas that are still viable and have an increased $CMRO_2$ requirement but where blood vessels supplying flow to that area are already maximally dilated. This “inverse steal” or “Robin

Table 92.2. Comparison: sympathetic vs. parasympathetic nervous systems

Anatomic/physiologic parameter	Sympathetic nervous system	Parasympathetic nervous system
Alias	Thoracolumbar (T1–L2)	Craniosacral
Energy mode	Energy expenditure	Energy conservation/restoration
Amplification response	High-gain system	Low-gain system
Target effect density	Diffuse, mass effects	Discrete, limited effects
Preganglionic length	Short	Long
Postganglionic length	Long	Short
Preganglionic neurotransmitter	ACh	ACh
Postganglionic neurotransmitter	ACh, EPI, NE, DA	ACh

ACh, acetylcholine; EPI, epinephrine; NE, norepinephrine; DA, dopamine

Figure 92.4. Cerebral blood flow is affected by cerebral perfusion pressure (PP), arterial carbon dioxide partial pressure (PaCO₂), and arterial oxygen partial pressure (PaO₂).

Hood effect” may cause further damage to an already injured but salvageable location.

The effect of hyperventilation on CBF to minimize brain edema and increased intracranial pressure (ICP) has its limits. Cerebral ischemia can result from significant hyperventilation (PaCO₂ ~20 mm Hg); therefore, the clinical benefit of hyperventilation to less than 30 mm Hg is lost.

Changes in PaO₂ can also affect CBF, but only at the lower end of the PaO₂ scale. A PaO₂ of less than ~50 mm Hg actually causes a significant increase in CBF, but with one greater than ~60 mm Hg there is no appreciable change in CBF (see Figure 92.4).

Hypothermia decreases neuronal metabolic demand and thereby decreases CBF. Hyperthermia causes the opposite effect.

Hematocrit in the normal range does not have a clinically significant effect on CBF. Some increase in CBF can be seen at lower hematocrit ranges (~30%–34%) due to decreased blood viscosity and decreased cerebrovascular resistance. This relative hemodilution effect can be clinically beneficial in the setting of focal cerebral ischemia, where maximal vasodilatation already exists. By contrast, hemoconcentration is not a particular concern unless at extreme levels (hematocrit ~>55%), in which case it becomes an issue for other organ beds as well.

Cerebral blood volume

Cerebral blood volume (CBV) in the normal brain is approximately 5 ml/100 g of brain tissue, which is approximately 70 ml for a normal adult brain. Changes in CBV and CBF usually parallel each other, especially for ranges of CBF that are autoregulated. At lower MAPs there is an increase in CBV as the cerebral vasculature dilates to maintain constant flow. Similarly, during cerebral ischemia, CBV increases. At higher MAPs, in the range beyond the upper limit of autoregulation, CBV and CBF both increase.

Cerebral perfusion pressure

Normal cerebral perfusion pressure (CPP) is approximately 80 to 100 mm Hg. A somewhat unusual physiologic formula exists for CPP, because the formula itself can change depending on the state of the variables that contribute to it.

For patients with intracranial hypertension, the expression of CPP is:

$$\text{CPP} = \text{MAP} - \text{ICP} \quad (\text{Eqn. 1})$$

For patients without intracranial hypertension, the expression for CPP is:

$$\text{CPP} = \text{MAP} - \text{CVP} \quad (\text{Eqn. 2})$$

For any case in which the cranium is open, the expression for CPP is:

$$\text{CPP} = \text{MAP} \quad (\text{Eqn. 3})$$

Table 92.3 indicates this difference in how CPP is determined depending on the clinical circumstances. In any case, the factor that contributes most to CPP is MAP.

Table 92.3. Determination of cerebral perfusion pressure

	MAP (mm Hg)	ICP (mm Hg)	CVP (mm Hg)	CPP (mm Hg)
Pt. #1 – normal	80	10	5	70
Pt. #2 – head injury	80	20	5	60
Pt. #3 – heart failure	80	10	20	60
Pt. #4 – open cranium	80	0	5	80

For the supine patient, MAP should be measured at the circle of Willis, which is approximated by zeroing the transducer at the level of the tragus. For a patient undergoing surgery in the seated position, the transducer should be zeroed at the highest point of the skull.

When not maintained in the normal range, CPP can be detrimental due to cerebral ischemia secondary to hypoperfusion at one extreme, and disruption of the blood–brain barrier from vessel rupture with resultant ischemia and cerebral edema at the other extreme.

Intracranial pressure

Normal (ICP) in humans is ≤ 10 mm Hg. Although there is some degree of compliance in the intracranial space, the reserve is limited, and further additions of volume would ultimately result in an exponential increase in pressure. The balance of ICP is dynamically influenced by the three intracranial components – brain, cerebrospinal fluid (CSF), and blood. Swelling of the brain parenchyma or growth of a brain tumor can increase ICP. Blocked drainage of CSF by mass effect on outflow tracts or by decreased absorption through the arachnoid villi can increase ICP. Finally, increased blood volume via vasodilatation, hemorrhage, or hematoma can also increase

ICP. The head-down position in particular will increase ICP solely by allowing gravity to affect cerebral blood volume, an important consideration for placement of central lines into the internal jugular or subclavian veins. Alone or in combination, these effects can rapidly become fatal, either through ischemia from hypoperfusion or by herniation of brain tissue. Although ICP is used to guide clinical management, it does not provide direct information regarding neuronal function or potential for neuronal recovery in the injured brain. Clinically, the fastest method for reducing ICP is CSF drainage via a lumbar or intraventricular drain. Other methods include elevation of the head (via gravity-provoked venous drainage), hypocapnia induced by hyperventilation, and medication interventions such as barbiturates, osmotic diuretics, or corticosteroids selectively used for brain tumors.

Cerebrospinal fluid

Secretion function

Secretion of cerebrospinal fluid (CSF) occurs mainly in the choroid plexus via active transport of sodium ions, which in turn brings chloride and subsequently water (by osmosis) into the subarachnoid space.

Cushion function

The specific gravity of CSF and that of the brain are nearly identical, allowing for flotation of the brain in the CSF medium. The brain and CSF move as a unit when struck, cushioning the insult to the brain parenchyma from its striking the inner surface of the skull.

Excretory function

CSF is reabsorbed by the arachnoid villi, emptying into the sagittal venous sinus and thereby into the bloodstream. There are no true lymphatics in brain tissue, so any protein leakage from parenchymal capillaries in the brain will be absorbed into the subarachnoid space and thus be reabsorbed by the arachnoid villi.

CSF pressure

Normal CSF pressure is 10 mm Hg for a supine patient. This value can range from 5 to 15 mm Hg in normal patients; however, in pathologic states this can increase to 40 mm Hg or higher. Such high pressures can be caused by mass effect from an intracranial tumor compressing the brain, blocking the normal flow of CSF. In other cases the filtering function of the arachnoid villi can become dysfunctional secondary to inflammation or physical blockages of the villi due to increased numbers of cells in the CSF, as is the case with infection or intracranial hemorrhage.

Blood–brain barrier

The first line of defense the brain has against molecules and ionized particles entering the interstitium of the brain is the

blood–brain barrier (BBB). Anatomically, this barrier consists of tight junctions between brain capillary endothelial cells, in contrast to fenestrations found in vascular endothelium in other areas of the body. Disruption of this barrier by chronic disease processes (e.g., intracranial tumors, uncontrolled systemic hypertension) or by acute events (e.g., hypertension from direct laryngoscopy, trauma, or inadequately managed acute pain) can have devastating if not fatal consequences. Severe hypertension of even very short duration poses significant risk. Substances that are unimpeded by the BBB include water, lipid-soluble compounds (e.g., volatile anesthetics), and gases (e.g., oxygen [O₂], carbon dioxide [CO₂], nitrous oxide [N₂O]). The BBB is an effective, although not complete, barrier to charged particles (e.g., electrolytes), polar compounds (e.g., glucose, mannitol, amino acids), and larger molecules (e.g., proteins). Access to the brain interstitium can be obtained by these particles and compounds through facilitated diffusion (as is the case for glucose), active transport (as is the case for ions), or pinocytosis (as is the case for larger particles such as proteins). Certain areas of the brain are not protected by the BBB, notably the area postrema (with attendant implications for postoperative nausea and vomiting), the pineal gland, and some areas of the hypothalamus.

Anesthetic agents: effects on cerebral physiology

Knowledge of the effects of the various anesthetic agents, alone or in combination with each other, is critical to proper selection of drugs for patients with disturbance of anatomic or physiologic cerebral function (see Fig. 92.6).

Inhalation agents

Volatile anesthetics

All of the volatile anesthetics cause a dose-dependent decrease in CMR. The effect of volatile anesthetics on CBF is somewhat more complicated. CBF is reduced at lower concentrations of volatile anesthetics (~0.5 minimum alveolar concentration [MAC]) due to lower CMR. CBF is increased, however, at higher concentrations of volatile anesthetics (~>1.0 MAC) due to the dilating effects of volatile anesthetics on the cerebral vasculature. The balance between these two divergent impacts on CBF is achieved at ~ 1.0 MAC, at which point CBF is neither increased nor decreased; it remains unchanged.

CMR

All of the volatile anesthetics cause a reduction in CMR. The degree of reduction varies somewhat, with isoflurane, sevoflurane, desflurane, and enflurane causing similar decrease in CMR of approximately 50%. Maximal reduction occurs at 1.5 to 2.0 MAC, and this corresponds to EEG suppression. Compared to all the other volatile anesthetics, halothane causes the smallest decrease (~25%) in CMR. Another noteworthy exception among the volatile anesthetics is enflurane – while it does cause

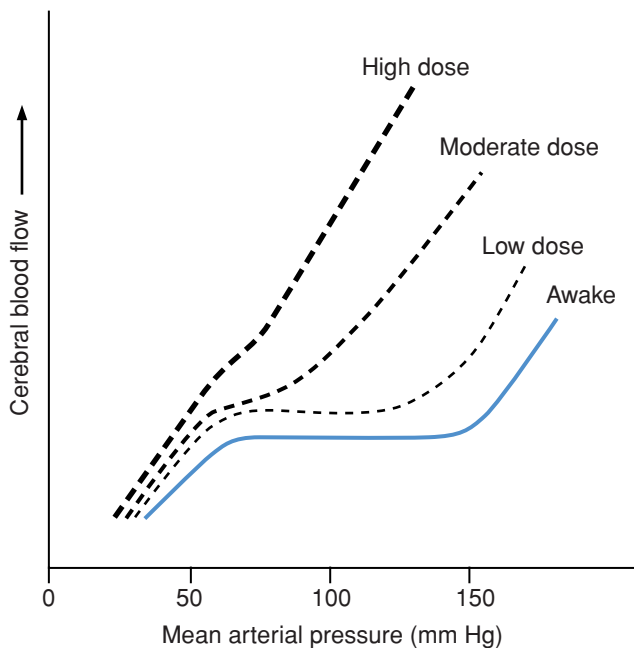

Figure 92.5. Cerebral autoregulation is depressed by the volatile anesthetics in a dose dependent manner.

a reduction in CMR, it also has the capacity to cause seizure-type EEG activity with a concomitant increase in CMR.

CBF

CBF is augmented by volatile anesthetics due to their direct vasodilatory action on the cerebral vasculature. Autoregulation of CBF becomes increasingly blunted with increasing concentrations of volatile anesthetics. The normal autoregulation curve becomes almost linear, with a continuous positive slope, as seen in Fig. 92.5. The approximate order of cerebral vasodilation potency of the volatile anesthetics is halothane (191% increase in CBF at 1.1 MAC) >> desflurane ≈ isoflurane (19% increase in CBF at 1.1 MAC) > sevoflurane. After continued delivery of volatile anesthetic to animals for 2 to 5 hours, CBF returns

to normal levels, but this phenomenon has not been shown in humans. Although all the volatile anesthetics cause an increase in CBF, halothane is notable for causing the largest increase in CBF.

ICP

Isoflurane is unique among the volatile anesthetics in its ability to cause CSF absorption, with resultant decrease in ICP.

N₂O

The effect of N₂O on cerebral physiology depends in large part on the manner in which it is administered; its effects differ if it is administered alone or in combination with an intravenous anesthetic or volatile anesthetic. When administered alone, increases in CBF and ICP do occur and are substantial, owing to the cerebral vasodilation effects of N₂O. These effects, however, are attenuated to negligible levels when N₂O is delivered in conjunction with most intravenous anesthetics (ketamine being the notable exception). When administered with volatile anesthetics, CBF is increased beyond what would be expected if the volatile anesthetic were given alone. This effect can be mitigated by other interventions such as induced hypocapnia (response to CO₂ is preserved with N₂O administration) or barbiturate infusion. In summary, N₂O in the clinical setting of reduced intracranial compliance can be appropriate if used judiciously with other available agents or techniques.

Intravenous agents

Intravenous anesthetics

Parallel reduction in CBF and CMR is the general rule with the effects of intravenous anesthetic agents on cerebral physiology. For this reason, flow and metabolism are said to be “coupled.” In contrast, flow and metabolism are not coupled for volatile anesthetics, and this allows for “luxury perfusion” (i.e. increased CBF with decreased CMR) when volatile agents are employed. Intravenous agents also allow for retained response

Table 92.4 Normal values

Parameter	Normal range/values	Notes
ICP	≤10 mm Hg (≤13.6 cm H ₂ O)	
CPP	80–100 mm Hg	
CSF volume	150 ml	Approximately half the volume in cranium and the other half in the spinal CSF space
CSF production rate	0.3–0.4 ml/min (18–24 ml/hr)	Daily turnover of approximately 3–4 volumes of CSF. Rate of formation = rate of reabsorption in normal physiology
CSF pressure	5–15 mm Hg (6.8–20 cm H ₂ O)	Supine position. Average CSF pressure is 10 mm Hg (13.6 cm H ₂ O)
CNS volume	1600–1700 ml	Space occupied by brain, spinal cord, and CSF
Brain mass – newborn	350 g	
Brain mass – adult	1350 g	
CMRO ₂ – adult	3.5 ml O ₂ /100 g/min	
CMRO ₂ – child	5.2 ml O ₂ /100 g/min	
Brain – % of body weight	2%	
Brain – % of cardiac output received	15%–20%	
CBF autoregulation	MAP 60–150 mm Hg	
CBF: gray matter	80 ml/100 g/min	
CBF: white matter	20 ml/100 g/min	
CBF: average (adult)	50 ml/100 g/min	~675 ml/min for average adult
CBF: average (child)	95 ml/100 g/min	
CBF: average (infant)	40 ml/100 g/min	
Δ in CBF with Δ in temp.	CBF ↑or↓ 5%–7% per 1°C ↑or↓ in temp.	
Hematocrit range for optimal cerebral O ₂ delivery	30%–34%	In the setting of focal cerebral ischemia
CBV	5 ml/100g	~70 ml in a normal brain

to CO₂ as well as retained cerebrovascular autoregulation. One caveat about the barbiturates and propofol is that clinically significant decreases in MAP can result from their use, and consequently CPP can be decreased. Etomidate (0.3 mg/kg) may decrease MAP by up to 15% via decreases in systemic vascular resistance; however, CPP is maintained. Etomidate may be considered the induction agent of choice in high-risk patients with significant cerebrovascular disease in whom preservation of normal blood pressure is critical. Among the intravenous anesthetic agents, ketamine is the notable exception – it causes a parallel increase in CBF and CMR. In fact, ketamine is the only anesthetic agent in clinical practice today that has the ability to increase CMR. In patients with a history of epilepsy, caution is advised with the use of ketamine, etomidate, and methohexital as seizure foci can be activated even with small doses.

Opioids

When added to the anesthetic regimen, opioids have a generally benign effect on cerebral physiology, a finding that is fairly consistent among the various opioids when CO₂ levels are kept constant. CBF is either unchanged or only slightly decreased with opioid administration. Alfentanil (50 mcg/kg) has been reported to activate seizure foci in patients with epilepsy, and meperidine has the known risk of CNS toxicity due to accumulation of its metabolite normeperidine.

Neuromuscular blockers

Efforts should be made to prevent coughing or “bucking” on the endotracheal tube, as this causes significant increases in ICP. Succinylcholine can cause increased ICP, regardless of the

state of intracranial compliance. This effect on ICP appears to be mediated by cerebral stimulation caused by increases in muscle afferent activity. Use of succinylcholine in neurosurgical patients is not contraindicated, however. A defasciculating dose of nondepolarizing neuromuscular relaxant may be used in an attempt to mitigate this increase in ICP from succinylcholine. Alternatively, a full paralyzing dose of nondepolarizing muscle relaxant can be used to avoid the ICP increase altogether, as there would be no afferent activity from the muscle spindle. Succinylcholine should be avoided in patients with hemi- or paraplegia due to the risk of hyperkalemia.

Among the nondepolarizing muscle relaxants, histamine release is the prime concern, as this can cause systemic vasodilatation leading to decreased MAP and cerebral vasodilatation leading to increased CBF and ICP – all culminating in lower CPP. Some of the benzylisoquinolinium compounds can cause histamine release. The worst offender in this regard is *d*-tubocurarine. Other benzylisoquinolinium compounds such as mivacurium, metocurine, and atracurium have the potential to release slight amounts of histamine. Cisatracurium, by comparison, has negligible histamine-releasing effect. Atracurium’s metabolite laudanosine has been implicated in epileptogenesis in animals but not in humans; thus the impact of this finding is of limited concern in clinical practice.

The steroidal nondepolarizing muscle relaxants lack effect on ICP. Whereas pancuronium can increase heart rate and blood pressure, vecuronium is devoid of such hemodynamic changes and is therefore the muscle relaxant of choice for patients in whom attention to intracranial compliance is warranted.

ICP can be reduced by pharmacologic interventions (e.g., barbiturates, osmotic diuretics, corticosteroids), hyperventilation-induced hypocapnia, or simply by elevation of the head (via gravity-provoked venous drainage). The most expeditious method for reducing ICP, however, is CSF drainage via an intraventricular or lumbar drain (if one is already in place).

Anesthetic agents with inherent seizure risk

Seizure activity can result in dramatic increases in CMR (up to 400%). Anesthetic agents that can pose a potential seizure risk to patients include:

1. Enflurane. Its ability to produce seizures is potentiated by hyperventilation and by inspired concentrations of 2% to 3% (MAC of enflurane is 1.68%). Clinically, this property of enflurane has been used to aid in the surgical resection of silent epileptogenic foci (by activating them) in patients with epilepsy.
2. Sevoflurane (especially in children).
3. Ketamine. It can cause selective activation of the thalamic and limbic areas of the brain.
4. Methohexital. It can activate seizure foci in patients with temporal lobe epilepsy and can be used to accommodate a request by a surgeon performing an awake craniotomy for seizure surgery.
5. Etomidate. In small doses, it can activate seizure foci (without causing convulsant-like motor activity) in patients with a history of epilepsy. Therefore, it can be used for intraoperative mapping of seizure foci. Conversely, etomidate possesses anticonvulsant properties and has been used to terminate status epilepticus.
6. Atracurium. Via its metabolite laudanosine, it has been shown to be epileptogenic in some animal models, although it must be emphasized that epileptogenesis is highly unlikely in humans.
7. Meperidine. Particularly if administered in high doses and/or for extended duration, it has been implicated in CNS toxicity owing to its metabolite normeperidine.
8. Alfentanil. Even in small doses, it can activate seizure foci in patients with a history of epilepsy.

Neurophysiology normal parameters

For a summary of normal parameters for neurophysiologic variables, see Table 92.4.

Cerebral protection

Grace Y. Kim

Introduction

The brain has a high metabolic demand but is limited in its storage of oxygen, glucose, and adenosine triphosphate (ATP). When cerebral blood flow (CBF) decreases to below the threshold of ischemia, brain ischemia occurs within 3 to 8 minutes. Thus, the window of opportunity for therapeutic intervention is short.

Ion homeostasis

Resting membrane potential is kept negative by the active sodium–potassium pump. Pumping ions against the concentration gradient consumes most of the energy in the brain. Ca^{2+} ions function as second messengers during cell excitation. When the presynaptic terminal is depolarized, voltage-dependent Ca^{2+} channels open and Ca^{2+} ions enter the terminal. Vesicles containing neurotransmitters fuse with the terminal membranes and their content is released into the synaptic cleft. When the postsynaptic neurons are depolarized by excitatory neurotransmitters, action potentials are generated. If the transmitters are inhibitory, however, the neurons are hyperpolarized and action potentials are not generated.

The free Ca^{2+} concentration in the intracellular cytoplasm is much lower because most of the intracellular calcium is stored in mitochondria and endoplasmic reticulum. This gradient is maintained by active transport of calcium out of the cytoplasm and into the mitochondria. During ischemia, the inhibition of this energy-requiring step increases the free Ca^{2+} ions in the cytoplasm and initiates a cascade of reactions.

Cerebral metabolic function

There are two types of metabolic functions in a neuron: electrical activity and basal cellular homeostasis. Fifty-five percent of the total energy is used for electrical activity, and 45% is used for basic cellular homeostasis. The brain has little reserve in high-energy phosphate compounds such as phosphocreatine and is dependent on continuous production of ATP. During ischemia, stored phosphocreatine is preferentially used to preserve ATP levels. Phosphocreatine is depleted within 1 minute, glucose within 4 minutes, and ATP storage within 5 to 7 minutes. Most of the ATP

Table 93.1. Cerebral ischemia

Type of ischemia	Affected area	Clinical scenario
Global ischemia	Whole brain	Cardiac arrest, anoxia
Focal ischemia	Some areas of the brain	Stroke, temporary clipping

is produced from oxidative phosphorylation of glucose in mitochondria.

Cerebral ischemia

Cerebral ischemia is divided into global and focal ischemia. Global ischemia occurs during cardiac arrest when there is complete cessation of blood flow. Focal ischemia occurs when the blood flow is interrupted in a part of the brain (Table 93.1).

Cerebral blood flow during ischemia

When CBF is low, brain cells first increase oxygen extraction to preserve their function. When maximal oxygen extraction occurs, brain cells shut off electrical activity to save energy. This shutoff occurs when CBF is between 15 and 18 ml/100 g/min. Further reduction in CBF to less than 10 ml/100 g/min causes basic cellular functions to cease and ion pumps to fail. The area of the brain with CBF between these two ranges is called the *penumbra*, which has the potential for full recovery if the flow is restored quickly. When CBF decreases below 10 ml/100 g/min, irreversible neuronal death occurs. This catastrophic event occurs during a cardiac arrest if the circulation is not restored in 3 to 8 minutes. Global ischemia progresses so rapidly that neuronal death occurs before a penumbra zone has time to form. The survival of the penumbra depends on the duration and extent of ischemia as well as the efficacy of the collateral circulation. When autoregulation is impaired, CBF becomes pressure dependent and the maintenance of adequate cerebral perfusion pressure (CPP) is critically important. Augmentation of blood flow by induced hypertension or by inverse steal may potentially reduce the extent of focal ischemia (Fig. 93.1).

CBF is regulated by metabolic demand. Cerebral metabolic activity can be measured from jugular bulb blood samples. When CBF is less than the minimal blood flow necessary for survival of neurons, it is called the *ischemic flow threshold*. It

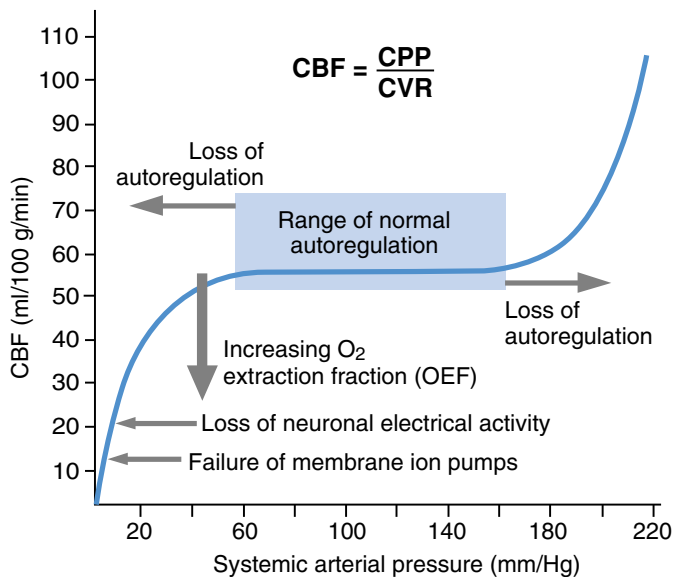

Figure 93.1. Cerebral blood flow during ischemia. Zabramski JM, Albuquerque FC. Cerebral protection. In: Le Roux PD, Winn HR, Newell DW, eds. *Management of Cerebral Aneurysms*. Philadelphia: Saunders; 2004:548.

occurs at 8 to 10 ml/100 g/min with isoflurane–nitrous oxide anesthesia. In animal studies, reversible paralysis occurs when CBF is less than 23 ml/100 g/min, and permanent paralysis occurs when CBF is less than 8 to 9 ml/100 g/min. Different areas of the brain show selective vulnerability. For example, the limbic system and cerebellum are particularly susceptible to ischemia. This selective vulnerability may be explained by different levels of metabolic activity in different parts of the brain. There is believed to be a 24-to-72-hour window of time between neuronal ischemia and permanent necrosis during which a clinician can intervene.

When ischemia occurs, pyruvate enters an anaerobic pathway and is metabolized to lactate. Cells become acidotic from increased levels of lactic acid and consume more ATPs to maintain the electrochemical gradient in mitochondria. It is not clear whether lactate has direct neurotoxic effects, but the continuous production of lactic acid is postulated as the mechanism of intracellular acidosis, which promotes the cascade reactions of ischemic injury.

Pathophysiology of cerebral ischemia

With the failure of the sodium–potassium pump, the ion concentration gradient is lost, resulting in loss of cellular membrane integrity. When the blood–brain barrier (BBB) is disrupted, cells begin to swell and cerebral edema ensues. Furthermore, Ca^{2+} ions are no longer pumped out of the cell or into the inner membrane of mitochondria. Increasing the intracellular Ca^{2+} level activates phospholipases, proteases, and endonuclease. Phospholipases damage cell membranes, producing free fatty acids (FFA), proteins, and oxygen radicals. Lipid peroxidation is the final outcome of the damage. The release of excitatory neurotransmitters allows further entry of calcium through

excitatory neurotransmitter channels and creates a vicious cycle of neuronal damage.

The level of excitatory neurotransmitters, glutamate and aspartate, is elevated in the ischemic brain. The areas where excitatory neurotransmitter receptors are concentrated are more susceptible to ischemic injury. *N*-methyl-D-aspartate (NMDA) receptors, one type of glutamate receptor, allow movement of Ca^{2+} and are involved in ischemic neuronal injury. FFA are further metabolized to arachidonic acid, which produces prostacyclin in endothelial cells and thromboxane A_2 in platelets. During ischemia, the activity of prostacyclin synthetase is inhibited, and the amount of thromboxane A_2 is increased. Thromboxane A_2 , a potent vasoconstrictor and platelet aggregator, is known to worsen hypoperfusion.

The brain has a limited amount of free radical scavengers. The level of free radicals increases during reperfusion when oxygen becomes available. Free radicals may be formed from iron present in the intracranial blood. Superoxide reacts with hydrogen peroxide to produce highly reactive hydroxyl radicals. This reaction is catalyzed by Fe^{2+} . In addition, when the brain becomes ischemic, the level of nitric oxide (NO) increases dramatically within minutes. The effect of NO is either beneficial or harmful depending on its source of production in that endothelial release of NO is neuroprotective, whereas neuronal release of NO worsens ischemia. NO stimulates the production of excitatory neurotransmitters and, when combined with superoxide radicals, produces the most damaging free radicals called *peroxynitrite*.

For a brief period of time, ischemia is followed initially by reactive hyperemia, which is caused by the release of vasoactive substances during ischemia and the subsequent increased metabolic demand during recovery. During reperfusion, a variety of vasoconstrictive mediators are released contributing to the secondary injury. Ca^{2+} and thromboxane A_2 are particularly implicated in postischemic vasoconstriction. Reperfusion injury includes hypoperfusion secondary to tissue edema, vasospasm, intracellular acidosis, intracellular calcium overload, and production of excitatory neurotransmitters and free radicals. Other vascular changes include platelet activation, prostaglandin synthesis, endothelial swelling, and thrombosis from platelet aggregation. Furthermore, a variety of inflammatory mediators are activated and exacerbate neuronal injury. The role of inflammation can be beneficial or detrimental. It is well-known that the biochemical process during reperfusion perpetuates cellular injury and determines the ultimate outcome.

Neuronal death involves the process of necrosis, apoptosis, or both. Necrotic death starts almost immediately after ischemia and causes significant inflammation that damages the surrounding tissue. In contrast, apoptotic death occurs days after the initial insult and is a more organized form of cell death. In addition, structural reorganization continues for a long period of time through the process called *diaschisis*. Apoptosis and inflammation play important roles in the regeneration of neurons (Fig. 93.2).

Figure 93.2. The effects of anesthetics on cerebral physiology. Patel P, Drummond JC. Cerebral physiology and the effects of anesthetics and techniques. In: Miller RD, ed. *Miller's Anesthesia*. 6th ed. Philadelphia: Elsevier Churchill Livingstone; 2005:837.

Strategy of cerebral protection

Cerebral protective strategies are focused on two types of injury: ischemic and reperfusion. Each type offers unique opportunities for therapeutic interventions. The main strategies include decreasing cerebral metabolism, inducing hypertension through collaterals, maintaining membrane ion channels, decreasing Ca^{2+} influx, inhibiting excitatory neurotransmission, preventing lipid peroxidation, maintaining BBB integrity, and preventing intracellular acidosis.

Physiologic intervention

Induced hypertension

The theory behind induced hypertension is based on the Hagen–Poiseuille equation:

$$Q = \frac{\Delta P \pi r^4}{8L\eta}, \quad (\text{Eqn. 1})$$

where Q = blood flow, ΔP = pressure gradient, r = radius, η = viscosity, and L = length.

During ischemia, cerebral vessels are maximally dilated and become pressure dependent. In contrast, they are constricted during vasospasm. In either case, the diameter of the blood vessel is fixed. The only parameters that can be manipulated are the pressure difference and blood viscosity. Because CBF is linearly proportional to the pressure gradient, induced hypertension improves CBF in the ischemic area.

Induced hypertension is routinely used during burst suppression. The mechanism of action is explained in the following diagrams (Fig. 93.3). When the blood flow is interrupted, CBF is maintained by vasodilation of the collateral circulation (Fig. 93.3b). When the collateral flow becomes insufficient, CBF drops below the ischemic threshold (Fig. 93.3c). If the blood pressure increases, the collateral blood flow increases to above the ischemic threshold (Fig. 93.3d). The major collateral system is the circle of Willis, which is incomplete for most patients.

The blood flow through collateral pathways increases over time during chronic ischemia. In acute ischemia, however, a pressure gradient is necessary, and augmented blood pressure redirects the flow. In global ischemia, blood pressure control has no effect because there is no circulation. In focal ischemia, the vessels in the ischemic area are maximally dilated, and there is no benefit of vasodilators. Further vasodilation may even worsen the ischemia by shunting blood to the normal brain. Induced hypertension is most effective when the cerebral vasculature has impaired autoregulation. There are potential risks of induced hypertension. If the BBB is damaged, it may cause extravasation of fluid and worsen ischemia. Another serious complication is the conversion of cerebral infarct to hemorrhagic stroke.

Hypothermia

Hypothermia has been used as a cerebral protective strategy for many years. Its mechanism of action is a decrease in the energy requirement for electrical and basal metabolic activity. The cerebral metabolic rate (CMR) is temperature-dependent, and the degree of protection is also temperature-dependent. CMR

Figure 93.3. Cerebral blood flow. (A) Normal; (B) with occlusion; (C) occlusion with collateral failure; (D) occlusion with collateral failure after induced hypertension. Induced hypertension is most effective when the cerebral vasculature has impaired autoregulation. There are potential risks of induced hypertension. If the BBB is damaged, it may cause extravasation of fluid and worsen ischemia. Another serious complication is the conversion of cerebral infarct to hemorrhagic stroke. Young W. *Clinical Neuroscience Lectures*. Munster, IN: Catherart Publishing; 1999.

decreases 4% for each decreased degree Celsius. The maximum decrease occurs between 27°C and 14°C, the temperature range at which electrical activities cease. With further reduction in the temperature, the basal metabolic rate continues to decrease. At 15°C, the temperature used for circulatory arrest, CMR decreases to 10% of normal. Deep hypothermic circulatory arrest has been used safely for up to 60 minutes. In addition, hypothermia inhibits excitatory neurotransmitters, lipid peroxidation, and free radicals. More recent studies suggest that the role of hypothermia in inhibiting the biochemical steps of ischemic cascade is more significant than its effect on decreasing CMR.

The clinical advantage of mild hyperthermia remains inconclusive. The Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST) demonstrated no benefit of mild (33°C) intraoperative hypothermia prior to aneurysm clipping in “good-grade patients” with a preoperative World Federation of Neurological Surgeons score of I, II, or III. Furthermore, hypothermia failed to improve neurologic outcome in patients with traumatic brain injury. By contrast, mild hypothermia in comatose survivors of cardiac arrest has demonstrated a better neurologic outcome. The major risk of hypothermia is coagulopathy. Mechanisms include platelet dysfunction, splenic sequestration, and decreased activity of the enzymes involved in the coagulation pathway. Hypothermia also causes sludging of red blood cells and shifts the hemoglobin–oxygen dissociation curve to the left (Table 93.2).

Mild hypothermia in the range of 33°C to 34°C has been used without significant additional morbidity. The temperature is easily controlled with a circulating water blanket underneath and a convection air blanket above the patient’s body. A rebound intracranial pressure (ICP) increase should be watched for during rewarming. Brain-injured patients often develop hyperthermia. Even though hypothermia has not conclusively proven to be a cerebral protective strategy, hyperthermia has consistently been shown to produce adverse effects and should be prevented.

Normoglycemia

The brain has limited stores of glucose, which is the only metabolic substrate for the brain in a normal situation. When

Table 93.2. Complications of deep hypothermia (18–22°C)

Cardiovascular	Myocardial depression, arrhythmia, hypotension, ↓tissue perfusion, ↓ADH, ↑viscosity, vasoconstriction
Coagulation	Thrombocytopenia, platelet dysfunction, fibrinolysis, sludging
Metabolism	Slow metabolism of anesthetic agents, prolonged neuromuscular blockade
Shivering	Increased O ₂ consumption
Surgical	Increased wound infection

AHD, antidiuretic hormone. Modified from Kass IS, Cottrell JE. Pathophysiology of brain injury. In: Cottrell JE, Smith DS, eds. *Anesthesia and Neurosurgery*, 4th ed. St. Louis, MO: Mosby, 2001: 75.

the blood glucose level is less than 20 mg/dl, an isoelectric line is observed on the electroencephalogram (EEG). With further reduction in the glucose level, neuronal injury ensues. Hyperglycemia has been shown to exacerbate neurologic injury following both focal and global ischemia, although the cause-and-effect relationship has not been clearly established. During ischemia, glucose undergoes anaerobic glycolysis and produces lactate. Pre-ischemic hyperglycemia theoretically provides additional substrates and produces more lactate. Incomplete ischemia continues to provide limited perfusion and produces more lactate compared with complete ischemia, therefore worsening acidosis in the brain. In addition, hyperglycemia during ischemia reduces the level of adenosine in the brain. Adenosine is known to inhibit the release of excitatory neurotransmitters and vasodilate cerebral vessels. The target for glucose levels of between 100 and 180 mg/dl is achieved with insulin infusion. Frequent checks of blood glucose levels are mandatory to avoid hypoglycemia.

Normocapnia

Hypocapnia may increase the risk of cerebral ischemia by reducing CBF, whereas hypercapnia may compromise CPP by increasing ICP. Thus, the goal is to maintain normocapnia. Prophylactic hyperventilation in patients with traumatic brain injury is associated with a worse outcome and is no longer used. When the patient has signs of impending herniation or a tight brain, however, mild hyperventilation may be used temporarily for ICP control and brain relaxation, respectively.

Pharmacologic intervention

Barbiturates

Barbiturates remain the gold standard agent for cerebral protection in focal ischemia. Burst suppression is used to prolong the ischemic time during temporary clipping of a cerebral aneurysm. Barbiturates are also used for refractory intracranial hypertension and cerebral edema. One possible mechanism for cerebral protection is the decreased energy consumption for neuronal transmission. Thiopental decreases CBF and reduces CMR to a maximum of 50%. When all the neuronal activities cease, as demonstrated by isoelectric EEG, there is no further decrease in CMR. There are other protective mechanisms, such as inverse vascular steal, blocking Na⁺ channels, reducing Ca²⁺ influx, blocking excitatory neurotransmitter release, and inhibiting free oxygen radical formation. In global ischemia, both neuronal and metabolic activities are shut down by ischemia itself in 30 seconds, and barbiturates have not been shown to be beneficial.

During burst suppression, thiopental is given prior to the placement of temporary clips. Thiopental is titrated with burst-suppression EEG tracing. When burst suppression is achieved, there is no further activity to be suppressed, and an additional dose of barbiturate does not offer more cerebral protection. During this time, blood pressure is maintained at 20% to 30%

above the baseline to increase the collateral flow to the potentially ischemic area.

Etomidate and propofol

Etomidate and propofol reduce CMR and CBF, but they lack the protective mechanisms offered by barbiturates. The major advantage of etomidate is its well-known hemodynamic stability. The disadvantages are myoclonic movement that may appear as a seizure activity and potential adrenocortical suppression. Propofol has the advantage of a quick wake-up but has the side effects of seizure-like activity and myoclonus.

Volatile agents

Volatile agents offer some benefits regarding neurologic outcome within the range used clinically. In global ischemia the effect is transient, but in focal ischemia it is persistent. Volatile agents reduce CMR by suppressing neuronal activity and increase CBF. The recent discovery that deep anesthesia may promote apoptosis by blocking synaptic transmission and inhibiting neurogenesis is intriguing, however. Indeed, some studies have suggested that cumulative deep anesthesia time appears to be an independent predictor of increased postoperative mortality. Thus, reducing cumulative deep anesthesia time may offer some cerebral protection.

Calcium channel blockers

Cerebral arteries depend on the extracellular calcium source for their contraction, whereas systemic arteries use the intracellular calcium instead. For this reason, cerebral arteries are sensitive to calcium channel blockers. Two of the most widely studied drugs are nimodipine and nicardipine. Both drugs have a vasodilating effect and improve CBF.

Several randomized studies show that patients treated with nimodipine after subarachnoid hemorrhage (SAH) have a better neurologic outcome than does the placebo group. Nimodipine has been used extensively for the treatment of vasospasm, but cerebral angiography has not demonstrated the improvement of vasospasm. The mechanism of cerebral protection is not clearly understood, but may involve improved regional blood flow and blocking Ca^{2+} into cells and mitochondria. Prophylactic nimodipine is a standard treatment for patients with SAH. In contrast, nicardipine decreased the incidence of clinical vasospasm, but showed no difference in the outcome at 3 months.

Other potential drugs

Neurotransmitter modulators may play an important role in inhibiting the cascade of ischemic reactions. Early clinical studies of glutamate antagonists, especially NMDA receptor antagonists, did not show significant clinical benefit. Ketamine binds phencyclidine-binding sites of NMDA receptors and is found to block the action of glutamate. Magnesium also blocks NMDA

receptors and prevents calcium influx and excitatory amino acids. The randomized trial of magnesium loading within 12 hours of acute stroke, however, did not improve the outcome despite the neuroprotective effect shown in several animal models. Free radical scavengers such as vitamins C and E are under investigation. Studies of tirilazad mesylate, a potent free radical scavenger, have not shown a benefit in clinical trials of ischemic stroke. Inhibitors of inducible NO synthase (iNOS) have shown some promise in reducing cerebral ischemia. Lidocaine blocks sodium influx, and in an animal model it has shown benefits in transient focal cerebral ischemia even when administered 45 minutes after the onset of ischemia. It has been found that erythropoietin is produced in the ischemic penumbra. Recombinant human erythropoietin treatment appears to reduce the size of the cerebral infarct.

Conclusion

Many new cerebral protective agents that have shown some promise in laboratories have shown conflicting results or have failed to demonstrate benefits in clinical studies, partly because the window of opportunity for therapeutic intervention is narrow and the injured brain continues to undergo structural reorganization over a long period of time. These observations have led to a new concept of “the neurovascular unit” consisting of neurons, microvessels, and supporting cells as a potential target for cerebral protection instead of neurons alone. Surrounding microvessels, astrocytes, glial cells, and inflammatory mediators in the neurovascular unit are likely to play a critical role in modulating the ultimate outcome of ischemic injury. Other promising concepts include pre-ischemic preconditioning of the brain and enhancing endogenous repair of neurons.

At present, there is no panacea for cerebral protection. The most important strategy is prompt restoration of oxygenation and circulation. Careful surgical planning can also prevent unnecessary ischemic events. It appears that maintaining the physiologic parameters in the optimum range is far more important than any pharmacologic intervention. Further understanding of the pathophysiology of cerebral ischemia will help us to find better cerebral protective strategies in the future (see Table 93.3).

Table 93.3. Cerebral protection strategy

Physiologic	Pharmacologic
Induced hypertension	Barbiturate
Avoid hyperthermia	Nimodipine
Mild hypothermia	Prostaglandin synthesis inhibitor
Normoglycemia	Mg^{2+}
Normocapnea	Vitamins C and E
Normal pH	Lidocaine
Avoidance of seizure	Erythropoietin
ICP control

Craniotomy

Elizabeth M. Rickerson and Lisa J. Crossley

Preoperative evaluation

A comprehensive evaluation preceding surgery should be conducted for every anticipated craniotomy, as is performed in all major surgeries. Particular attention should be paid to the patient's baseline neurologic examination and functional status, as well as to the location of the lesion(s) and the presence or absence of mass effect. The presence of specific symptoms such as headache, decreased level of consciousness, visual disturbances, papilledema, and seizures should be determined and documented; these symptoms may be indicative of increased intracranial pressure (ICP) or other pathologies. Evaluation of neuroimaging studies to discern the location and size of the lesion as well as any subclinical evidence of intracranial hypertension helps with the assessment of operative needs for exposure and the potential for intraoperative hemorrhage. In general, peritumor edema with mass effect great enough to cause a shift in the midline structures will require intraoperative efforts to decrease the ICP. Effacement of the lateral ventricles by tumor burden or expansion of the ventricles by obstructive hydrocephalus indicates that any maneuver resulting in an increased intracranial volume could cause a disproportionate increase in ICP. Small, superficial lesions generally cause minimal difficulty with regard to exposure and hemorrhage, whereas larger lesions or lesions that are deeper in the brain provide a greater challenge for surgical exposure as well as a greater potential for blood loss (Table 94.1).

For non-emergent cases, cardiac optimization prior to surgery is necessary for many reasons. Commonly used techniques used in neuroanesthesia to reduce ICP can stress the heart. Hyperventilation decreases venous return and hypocarbia functionally reduces coronary blood flow. Diuretics ultimately cause further reductions in cardiac output but can transiently increase blood volume and worsen pulmonary function in patients with cardiac failure.

Fluid and electrolyte imbalances are common in craniotomy patients because of poor oral intake, steroids, and diuretics. These imbalances should be optimized prior to surgery. Seizure prophylaxis and treatment may also be required. Patients with seizure disorders are usually on anticonvulsants; blood levels of these drugs should be checked in any patient with signs of toxicity or a history of recent seizures.

Preoperative medications

Sedative medications can blunt the ventilatory drive, leading to hypercarbia and increased ICP, which may not be tolerable in many craniotomy patients. In general, preoperative medications for anxiolysis are given at the discretion of the anesthesiologist when the patient is under direct supervision or upon induction in the operating room. In current clinical practice, the use of preoperative steroids has made it relatively safe to administer sedatives to many patients with brain tumors.

Monitoring and access

Standard American Society of Anesthesiologists monitors should be used for all craniotomy cases. Additional monitors should be used depending on the particular surgery. Intravenous access (preferably on an arm that can be accessed after the patient is prepped and draped) with one or two large bore peripheral intravenous catheters (more depending on anticipated blood loss) is desirable. Arterial catheters are often used in craniotomies and can be placed prior to surgery if tight blood pressure control during induction is a concern; alternatively, the arterial catheter can be placed postinduction. Transduction of the arterial catheter at the level of the external auditory meatus in the supine or prone patient gives a good approximation of the mean arterial pressure (MAP) at the circle of Willis. MAP approximates cerebral perfusion pressure (CPP) until the cranium is open at which time $CPP = MAP$ in the brain (except in the regions of the brain where retractors and packing compress the brain directly). An arterial catheter can also help with the management of blood gases, electrolyte imbalances, and glucose control.

The use of central venous catheters is not routine for craniotomies but is generally helpful in cases when a significant amount of blood loss is anticipated. Central venous pressure (CVP) monitoring can also be useful in the management of intravascular fluid status in patients undergoing resection of large suprasellar tumors who might be at risk for diabetes insipidus. A pulmonary artery catheter may be indicated for patients with severe cardiopulmonary disease. Central venous catheters are often placed in the subclavian veins because access to the neck can be limited and the neck may be rotated substantially, which could obstruct venous outflow.

Table 94.1. Mechanisms of increased intracranial pressure

1. Mass lesions	Hematoma, tumor, abscess
2. CSF accumulations	Hydrocephalus <ol style="list-style-type: none"> Impaired absorption – meningitis, subarachnoid hemorrhage, etc. Obstructive – congenital, due to tumors and other masses Increased production – choroid plexus Papilloma
3. Albin M. *Textbook of Neuroanesthesia with Neurosurgical and Neuroscience Perspectives*. New York: McGraw-Hill; 1997.

Neuromuscular “twitch” monitors used to guide dosing of muscle relaxants should be used with care for patients with paresis as they can have increased numbers of acetylcholine receptors at the end plates of lower motor neurons. This can make the degree of neuromuscular block with nondepolarizing agents appear less than it actually is. If possible, the twitch monitor should be placed away from the paretic limb(s); if that is not possible, interpreting the twitch monitor results must be done with care to prevent overdoses of neuromuscular blocking agents.

Depending on the location of the lesion, intraoperative monitoring of brainstem evoked potential responses, auditory evoked responses, visual evoked responses, somatosensory evoked responses, motor evoked potentials, and electromyography (EMG) may be useful in guiding surgical resection. Surgery may also be performed under local anesthesia to allow ongoing monitoring of function if areas of the cortex that control speech and/or motor functions are involved.

Induction and maintenance of general anesthesia

There are a variety of approaches to the induction and maintenance of anesthesia for craniotomies. The most commonly accepted methods are designed to accomplish the following goals:

- (1) A smooth induction with tight hemodynamic control with minimal coughing and straining;
- (2) “Full stomach” precautions in patients undergoing emergency craniotomy;
- (3) The ability to achieve hypocapnia quickly and efficiently;
- (4) The avoidance of hypoxia and hypercarbia;
- (5) Emergence from the anesthetized state with minimal coughing and straining to prevent increased ICP and bleeding in the surgical site; and
- (6) A rapid emergence to allow an immediate postoperative neurological examination.

Hypotension during induction usually can be avoided by preinduction volume loading (10 ml/kg normal saline) with

adjustments based on the patient’s cardiac and volume status. Barbiturates, often used for induction, are potent vasoconstrictors that decrease cerebral blood flow (CBF) and may improve recovery from cerebral ischemia. When consciousness is lost, the patient should be manually hyperventilated until the neuromuscular blocker to facilitate endotracheal intubation has taken effect and it is safe to proceed with intubation. When the dura has been opened, anesthetic requirements are often lower as the brain parenchyma is devoid of sensation. Iso-osmolar fluids such as normal saline are preferable to hypo-osmolar solutions such as lactated Ringer’s because of the effect on ICP: Normal plasma osmolarity is 280 to 307 mOsm/L. The osmolarity of lactated Ringer’s is 273 mOsm/L, which can cause a transfer of fluid into cells and increased ICP. The osmolarity of normal saline is 308 mOsm/L, and should therefore not increase ICP substantially. Hypothermia may confer some protection from cerebral ischemia (although human trials to date have not shown a benefit of hypothermia). Hyperthermia should be avoided.

Succinylcholine is generally avoided because of the brief increase in ICP during muscle fasciculations; however, in instances of a difficult airway assessment, the use of succinylcholine may be warranted. A defasciculating dose of a nondepolarizing muscle relaxant may decrease or eliminate this transient increase in ICP. Ketamine increases CBF and ICP and is rarely used for craniotomies. Most of the other intravenous anesthetics (opioids, barbiturates, benzodiazepines, etomidate, and propofol) are cerebral vasoconstrictors and thereby reduce CBF. Etomidate has been associated with myoclonic activity and is best avoided in seizure-prone patients. For patients with a history of seizures, atracurium or cisatracurium and meperidine should also be avoided because of their epileptogenic metabolites, laudanosine and normeperidine, respectively. Calcium channel blockers such as nimodipine can improve cerebral vasospasm after subarachnoid hemorrhage.

Nitrous oxide (N₂O) is most likely a cerebral vasodilator; vasodilation can be attenuated by hyperventilation and intravenous agents. There is controversy regarding the use of N₂O and its potential for causing a clinically significant tension pneumocephalus; it should probably not be used in cases where

pneumocephalus is known to exist as it diffuses more rapidly into air-filled spaces than nitrogen is able to diffuse out. There is also controversy as to whether N₂O should be used in the sitting position because of the higher risk of venous air embolism (VAE) associated with the sitting position. If a VAE has been detected, it is good practice to discontinue N₂O because of its potential to expand the size of the entrained bubble. Volatile anesthetics produce a dose-dependent reduction in cerebral metabolism. Isoflurane is the most potent of the volatiles in this respect and can produce an isoelectric electroencephalogram (EEG) at lower concentrations.

Elevated ICP tends to force the brain out through craniotomy incisions and can lead to both poor surgical access and neuronal injury. Intracranial hypertension with significant midline displacement might be indicative of increased ICP despite appropriate hyperventilation. Therapy consists of using osmotic diuretics to increase the osmolality of the blood relative to the brain and pull water across the blood–brain barrier (BBB). An intravenous infusion of mannitol at a dose of approximately 0.5 to 1 g/kg before opening the skull is often used when the patient's baseline osmolality is <290 mOsm/kg. Furosemide can be used alone or as an adjunctive therapy with mannitol. Furosemide is usually given prior to mannitol as mannitol can cause an initial increase in ICP by drawing fluid intravascularly. Cerebral spinal fluid (CSF) can also be removed with either a ventriculostomy tube or a spinal catheter placed in the lumbar subarachnoid space to permit drainage.

Available data do not lend support to any one combination of anesthetic maintenance agents as long as the goals stated earlier in this chapter are accomplished. One approach is to infuse a short-acting opioid infusion (sufentanyl, remifentanyl, or fentanyl) with 70% N₂O and minimal isoflurane. Remifentanyl usage requires that adequate longer acting narcotics be given to prevent postoperative hypertension secondary to inadequate pain control. Before the dura is closed, the blood pressure should be restored to pre-induction levels to verify adequate hemostasis. In instances where the brain is swollen and the dura cannot be closed, the patient should be transported to the intensive care unit (ICU) on controlled ventilation. If new neurological deficits are noted on immediate postoperative examination, immediate surgical re-exploration or a CT scan may be required; this may or may not require re-intubation.

Awake craniotomy

Craniotomies can also be performed under local anesthesia with or without sedation; this is often done for seizure surgery or if the lesion is close to areas of the brain that control speech and motor function. In these cases, an anesthetic should be chosen that both provides anxiolysis and patient comfort and allows for ongoing interaction with the patient. One approach is to use a dexmedetomidine infusion; another option is to use the more traditional conscious sedation combination of midazolam and fentanyl or sufentanyl. Access to the airway can be

extremely limited, thus care must be taken to avoid depressing the ventilatory drive entirely.

Fluid management

Fluid management for craniotomies requires an understanding of how fluid shifts across the BBB. In the peripheral vasculature, the endothelial junctions of the capillaries are highly permeable and allow the passage of water, ions, and most low-molecular-weight substances. In these tissues where electrolytes pass freely, water moves in the direction of transcapillary concentration gradient of the larger plasma proteins. In contrast, the brain and spinal cord are isolated from the intravascular compartment, and the endothelial junctions are tight enough to prevent even the passage of ions. Fluid movement is governed by the osmolar gradient, which is determined by the relative concentrations of all osmotically active particles, including the electrolytes. The sodium concentration of the fluid to be infused thus becomes quite important. So-called free-water solutions, i.e., solutions without electrolytes (5% dextrose in water), will lower plasma osmolality, drive water across the BBB into the brain, and increase brain edema and ICP. Dextrose-containing fluids are avoided because of their propensity to worsen neurologic outcome during focal ischemia. Of the isotonic crystalloids, lactated Ringer's solution is mildly hyponatremic, and when large volumes are infused rapidly, ICP can increase. Normal saline is therefore the isotonic crystalloid of choice. When the BBB is intact, mannitol can be used to dehydrate the brain and decrease ICP; doses of 0.25 to 1.5 g/kg increase plasma osmolality, and water moves from the brain into the vasculature. Mannitol administration can transiently increase ICP: With the acute increase in plasma osmolality, the cerebral vasculature may initially vasodilate. As stated earlier, furosemide can be given prior to mannitol to attenuate this affect.

Glucose control

The optimal range of serum glucose in traumatic brain injury remains unclear, according to recent studies. In one study, a serum glucose level ≥ 200 mg/dl was associated with a 3.6-fold increase in mortality. This study recommended maintaining serum glucose levels ≤ 180 mg/dl, which was associated with only a 4.3% incidence of hypoglycemia compared to an 18.7% incidence of hypoglycemia in patients undergoing intensive insulin therapy.

Transsphenoidal surgery

Pituitary tumors less than 10 mm in diameter are usually approached transsphenoidally. The pituitary gland lies in the sella turcica of the sphenoid bone and is bordered by several important structures including the carotid artery and cranial nerves (CN) III, IV, V₁, and VI. The stalk of the pituitary gland is close to the optic chiasm, and visual evoked potentials may need to be monitored intraoperatively if the tumor involves or lies close to the optic nerve. The surgical approach is through

the nasal cavity and nasal septum, then through the roof of the sphenoid sinus to access the sella turcica. There are several problems that can be encountered with the transsphenoidal approach. Prior to surgery, the tumor may actively secrete one or more of the pituitary hormones (anterior pituitary: adrenocorticotropic hormone [ACTH], thyroid-stimulating hormone [TSH], growth hormone [GH], follicle-stimulating hormone [FSH], luteinizing hormone [LH], and prolactin; posterior pituitary: vasopressin and oxytocin). Abnormalities should be investigated prior to any procedure and corrected to the extent possible. Consultation with an endocrinologist may be advisable. As with any surgery in the nasal cavity, the mucosa can bleed heavily and may require topical or injected vasoconstrictive agents. Blood and tissue debris from the nasal cavity can accumulate in the oropharynx, esophagus, and stomach. Risks of the surgery include hemorrhage from damage to the carotid artery or sinus, CSF leak, pituitary hypofunction, and cranial nerve damage. Prophylactic glucocorticoids are usually administered.

Epilepsy surgery

Patients whose seizures are inadequately controlled by medical management undergo extensive noninvasive evaluation including CT, MRI, and PET scanning. A careful evaluation of the patient's concomitant medical problems, as well as an understanding of the ability of anesthetic agents to promote or suppress seizures, is important during management of these patients. Patients may require evaluation of the seizure focus through intraoperative mapping and electrocorticography. For mapping procedures, awake patients are managed using monitored anesthesia care. Low concentrations of propofol or dexmedetomidine can be used for sedation during intraoperative mapping; propofol usage is discontinued before mapping starts. Alternatively, low doses of methohexital or alfentanil can be used to activate seizure foci. Midazolam and high doses of propofol or barbiturates should be avoided during intraoperative mapping procedures as they may impair detection of seizure foci. Surgical procedures used in seizure management consist of craniotomy for placement of grid or strip electrodes, left vagal nerve stimulators (patients with intractable complex partial seizures), resection of specific seizure focus (e.g., anterior temporal lobectomy), and interruption of seizure circuits (e.g., corpus callosotomy). Patients are managed with general anesthetic regimens consisting of either inhaled anesthetics (isoflurane, N₂O/oxygen) and fentanyl, or total intravenous anesthetics using propofol, remifentanyl, or fentanyl and muscle relaxants. Complications (hemorrhage, neurologic deficits) seen after surgical resections directly relate to the site of the epileptic focus and are usually independent of the anesthetic technique.

Infratentorial craniotomy

Posterior fossa masses present several challenges not always encountered with surgery for supratentorial masses. First, the

posterior fossa is an enclosed space in which the tumor burden/lesion is often in direct contact with highly critical structures, leaving little or no room for error. The posterior fossa contains the cerebellar hemispheres, upper medulla, pons, and the lower midbrain. CN III–XII can be accessed in the posterior fossa. The entire blood supply to neural structures is through the verteobasilar system, and the foramina of Magendie and Luschka provide outflow for CSF from the ventricular system. Second, in addition to the risk for neuronal damage, proximity to the brainstem nuclei can trigger significant intraoperative hemodynamic instability usually manifested by bradycardia due to increased vagal tone. Depending on the assessment of the relative risk of cranial nerve damage, intraoperative neurophysiologic monitoring (brainstem auditory evoked potentials [BAEPS], somatosensory evoked potentials [SEP], EMG) may be necessary. Third, the posterior fossa cannot be easily accessed in the conventional supine position, so surgery must be performed in an alternate position which may require different techniques of monitoring and positioning.

Lesions in the posterior fossa can present with a wide variety of symptoms. Elevated ICP may occur because of mass effect or hydrocephalus secondary to obstruction of CSF flow. Nonspecific symptoms include listlessness, headache, fatigue, vomiting, anorexia, personality changes, dysmetria, hemiparesis, and cranial nerve deficits. Bulbar palsies with vocal cord paralysis and swallowing/gag dysfunction can occur. Brainstem involvement can cause respiratory changes including apneustic or ataxic breathing and hyperventilation. Ultimately, herniation will cause loss of consciousness, respiratory changes, bradycardia, hypertension, and death. Tumors of the posterior fossa occur more frequently in children; 50% to 55% of all pediatric brain tumors are infratentorial.

Positioning for craniotomy

A variety of positions are used for craniotomies based on the location and size of the lesion. Each position has its own risks and benefits; close attention must be paid to padding and nerve damage must be avoided in all positions. The eyes should be covered with waterproof protection and be free of external pressure, and the position of the endotracheal tube should be rechecked after final positioning because of limited access to the airway during the procedure. In any head-up position, hypotension during anesthesia may be especially harmful for patients with limited cerebral autoregulation, impaired cerebral perfusion, carotid stenosis, or previous carotid endarterectomy. Zeroing of the transducer for arterial blood pressure requires a different reference point in the sitting position, namely at the highest point of the skull, as opposed to the tragus of the ear for the supine position (see Chapter 93). Intravascular volume depletion is also a consideration, and fluid administration prior to induction as well as lower extremity compression stockings may be useful.

Lateral

This position is good for access to many lateral lesions, the cerebellopontine angle, and the anterior and lateral foramen magnum. Risk for VAE is low in this position, but bleeding from the sinuses can be rapid. Disadvantages of the lateral position also include postoperative brachial plexus and popliteal nerve damage and careful positioning and padding should be performed.

Prone

This position is good for access to midline lesions (especially of the posterior fossa). Disadvantages and complications of the prone position include difficult ventilation, limited access to the endotracheal tube and airway, pressure necrosis, and potential for blindness. The mechanism of blindness after surgeries in the prone position is unclear; it may be due to retinal artery thrombosis. VAE is a potential problem in this position because the head is usually elevated above the heart, but there is a lower incidence as compared with sitting.

Park bench semiprone

This position is useful in emergent cases because positioning can be done rapidly. It allows access to the cerebellar hemispheres but can also be used for midline lesions.

Sitting

This position allows excellent exposure for posterior fossa surgeries, offers improved CSF and venous drainage, and produces less bleeding. The risk of VAE is highest in this position, and monitoring for air embolism is mandatory. Additional risks include quadriplegia, especially in elderly patients with spinal stenosis, and supratentorial hemorrhage in the subcortical white matter (the exact mechanism of this complication is unknown). Relative contraindications to the sitting position – such as intracardiac defects, pulmonary arteriovenous malformations, and carotid stenosis – should not be overlooked. This position has fallen out of favor with most surgeons because of the higher risks associated with it.

Supine

This position allows distribution of the patient's weight over a larger area. The head is often laterally rotated and flexed, which is not always possible with elderly patients or patients with severe joint disease. Risks of this position include impaired jugular venous drainage and brain edema.

Venous air embolism

In the sitting position, the head is elevated above the right atrium, which decreases both dural sinus pressure and venous bleeding. The sinuses are tented open by their attachments to the dura, and, when opened, large volumes of air can be

entrained into the venous system. Hypovolemia can contribute to the problem because a lower CVP increases the negative pressure gradient between the head and the right side of the heart.

Morbidity and mortality of VAE are directly related to the amount of air entrained. The lethal dose in humans is estimated to be approximately 300 cc. An air bolus may result in an air lock in the right side of the heart, leading to right ventricular outflow tract obstruction, decreased cardiac output, acute right ventricular dilatation and failure, dysrhythmias, myocardial infarction (MI), cerebral ischemia, and death. There can also be occlusion of the pulmonary vascular bed with resultant increases in pulmonary vascular resistance, pulmonary arterial mean pressure, and right heart afterload. Right ventricular failure causes the cardiac output to decrease, and left ventricular filling is impaired by the displaced interventricular septum. Ventilation–perfusion mismatch is manifested by a falling end-tidal CO₂ and a rising CO₂ concentration. Monitoring for VAE in the sitting position is strongly recommended.

The most sensitive noninvasive monitor for VAE is the precordial Doppler ultrasound. The probe is placed over the right atrium, and its position is tested via injection of air, sodium bicarbonate, or agitated saline. When a VAE occurs, a characteristic “mill wheel” murmur is heard. Transesophageal echo is the most sensitive detector of VAE, but this monitor is invasive, operator dependent, cumbersome and requires continual observation. Because of its sensitivity, noninvasive nature, and ease of interpretation, the precordial Doppler is usually favored over the transesophageal echocardiograph. Capnography is another useful monitor for detecting VAE and is used in conjunction with the precordial Doppler. It is noninvasive and sensitive, but decreases in end-tidal CO₂ are nonspecific. It is of note that a significant decrease in end-tidal CO₂ often occurs with a sudden low cardiac output event. This is caused by decreased pulmonary blood flow and CO₂ elimination during the low cardiac output state, which can be confused with a pulmonary air embolus.

A pulmonary artery catheter can detect the pulmonary hypertension caused by a VAE and is more sensitive than capnography; however, it is quite invasive, and optimal placement for detection may not allow for aspiration in case of air entrainment.

Adequate hydration and the avoidance of drugs that dilate venous capacitance are some of the techniques that the anesthesiologist might use to prevent VAE. In addition, positive end-expiratory pressure (PEEP) may increase the chance of a paradoxical air embolus in a patient with a patent foramen ovale (PFO). If a VAE is detected or suspected, notify the surgical staff to have them irrigate the operative site (“flood the field”) and apply material to occlude potential air entry sites. Treatment of VAE also includes placing the patient in the head-down position, discontinuing N₂O, increasing oxygen flow, and attempting to aspirate air via an atrial catheter. Prompt cardiovascular support should be dictated by the clinical picture

(increase intravenous fluid administration and start vasopressors as needed). Jugular compression is also recommended to increase cranial venous pressure and cause back bleeding rather than air entrapment, but obstruction of CBF, dislodgement of carotid plaques, venous engorgement leading to cerebral edema and bradycardia are potential consequences. External cardiac massage can disrupt a large air lock if cardiovascular collapse has occurred. The administration of PEEP in this instance might be beneficial in elevating the venous pressure in the head to values greater than zero; however, the entire clinical picture should be taken into account with regard to paradoxical air emboli.

Subarachnoid hemorrhage (SAH) occurs when a cerebral blood vessel ruptures by trauma or spontaneously. The most common cause of spontaneous SAH is a ruptured cerebral aneurysm. Other causes include bleeding from arteriovenous malformation (AVM) and hypertension.

Cerebral aneurysm

Introduction

Epidemiology

The prevalence of cerebral aneurysms in the United States is estimated at 1% to 5%. Each year 27,000 people sustain ruptured aneurysms in this country. Ruptured aneurysms occur in middle age, between the ages of 40 and 60 years with a slight female predominance. Rebleeding risk is high, and approximately half of all ruptured aneurysms will rebleed in the first 6 months after the initial episode. The overall mortality rate is 25%, and more than 50% of survivors suffer significant neurologic morbidity. The major causes of mortality and morbidity are the direct effects of the initial bleed, rebleeding, vasospasm, and surgical complications. Incidental findings of asymptomatic cerebral aneurysms are not uncommon. Unruptured aneurysms carry a risk of bleeding at 1% to 2% per year. The management of patients with unruptured intracranial aneurysms is controversial. The current recommendation is to clip asymptomatic aneurysms unless the size is less than 3 mm or the risk of surgery exceeds the benefit.

Risk factors

The risk factors of aneurysm ruptures include increasing size, age, hypertension, family history, connective tissue disease (Ehlers–Danlos syndrome and fibromuscular dysplasia), polycystic kidney disease, cocaine use, pregnancy, other intracranial vascular anomalies, coarctation of the aorta, smoking, and strenuous activity.

Presentation

Ruptured aneurysms present as subarachnoid, intracerebral, intraventricular, or subdural hematomas. The common symptoms are sudden onset of severe headache (i.e., “the worst headache I’ve ever had”), altered mental status, stiff neck, photophobia, neurologic deficits, nausea, and vomiting.

Patients with a giant aneurysm may present with a mass effect of the aneurysm. When a patient with sentinel bleeding develops a mild headache or subtle neurologic changes, early diagnosis and clipping can result in a good outcome. Seizures usually occur shortly after the rupture in up to 13% of cases and pose an increased risk of rebleeding.

The Hunt–Hess classification is used to estimate the prognosis. The World Federation of Neurosurgeons’ SAH scale adds the presence of motor deficits and the Glasgow Coma Scale. The important factors determining the final outcome include the Hunt–Hess classification, age, the presence of vasospasm, and the size and location of the aneurysm (Table 95.1).

Diagnosis

A noncontrast CT is the most sensitive imaging method. If the CT is negative, a lumbar puncture is performed to look for xanthochromia. A diagnostic cerebral angiogram is necessary to assess the size, location, and anatomy of the aneurysm and the presence of multiple aneurysms. Negative angiography occurs in 10% to 20% of SAH patients and needs to be repeated. Thrombosed aneurysms may not appear on the angiogram. The amount and distribution of blood in the subarachnoid space are

Table 95.1. Hunt–Hess classification of clinical grade for SAH*

Grade	Description	Mortality, %
0	Unruptured aneurysm	–
I	Minimal headache or slight nuchal rigidity	2
II	Moderate to severe headache, nuchal rigidity, cranial nerve palsy	5
III	Drowsiness, confusion, or mild focal deficit	15–20
IV	Stupor, hemiparesis, early decerebrate rigidity, and vegetative disturbance	30–40
V	Deep coma, decerebrate rigidity, moribund appearance	50–80

*Serious systemic diseases (hypertension, diabetes, coronary artery disease, chronic pulmonary disease) and severe vasospasm seen on arteriography place the patient in the next less favorable category.

classified by the Fisher grading scale and are the best predictors of vasospasm (Table 95.2).

Types of aneurysm

The blood supply to the brain is divided into anterior circulation from two internal carotid arteries and posterior circulation from two vertebral arteries. Anterior circulation supplies most of the cerebrum, and posterior circulation supplies the visual cortex, cerebellum, and brainstem. The communication between the two systems forms the circle of Willis. Approximately 80% of cerebral aneurysms are located in the anterior (carotid) circulation and 20% in the posterior (vertebrobasilar) circulation. Anterior circulation aneurysms carry a better prognosis compared with posterior circulation aneurysms (Fig. 95.1).

Cerebral aneurysms are divided into three groups: saccular, fusiform, and dissecting. Saccular aneurysms are the most common type. Fusiform aneurysms are often associated with atherosclerosis or degenerative connective tissue disorder. A dissecting aneurysm develops at a tear between the endothelial and medial layers, often due to trauma. Aneurysms caused by trauma or infection are uncommon and are usually located at

the distal vessels. An aneurysm is considered large when its size is greater than 12 mm and giant when greater than 25 mm.

Pathophysiology

The etiology of cerebral aneurysms is structural abnormality caused by hemodynamic factors and genetic predisposition. Histologically, cerebral aneurysms are deficient in the middle muscular layer and internal elastic lamina of the vascular wall. According to La Place's law, the tension on the wall of blood vessels is the product of the pressure times the radius of the chamber, and the tension is inversely related to the thickness of the wall. Larger arteries are exposed to higher wall tension than are smaller arteries. When a weak area in a large artery is subjected to high wall tension, it forms an outpouching that gradually forms an aneurysm. As the size of the aneurysm increases, a vicious cycle ensues where the wall compliance decreases further whereas the tension increases, sometimes to the point of rupture. Aneurysms usually occur at the bifurcations of major arteries where the supporting adventitia is thin and the pulsatile pressure is maximal. Increased blood pressure (BP) and turbulent blood flow promote the aneurysm formation and rupture. The location, size, and wall thickness of the aneurysm determine the risk of rupture.

Patients with ruptured cerebral aneurysms present with varying clinical conditions, ranging from a mild headache to a deep coma. Severe headache is due to a sudden increase in intracranial pressure (ICP). Loss of consciousness occurs when cerebral perfusion pressure (CPP) suddenly drops from elevated regional ICP. When the ICP approaches the diastolic BP, the cerebral blood flow (CBF) decreases dramatically and limits further leakage of blood. Some patients regain consciousness as ICP adjusts itself by a compensatory mechanism. When

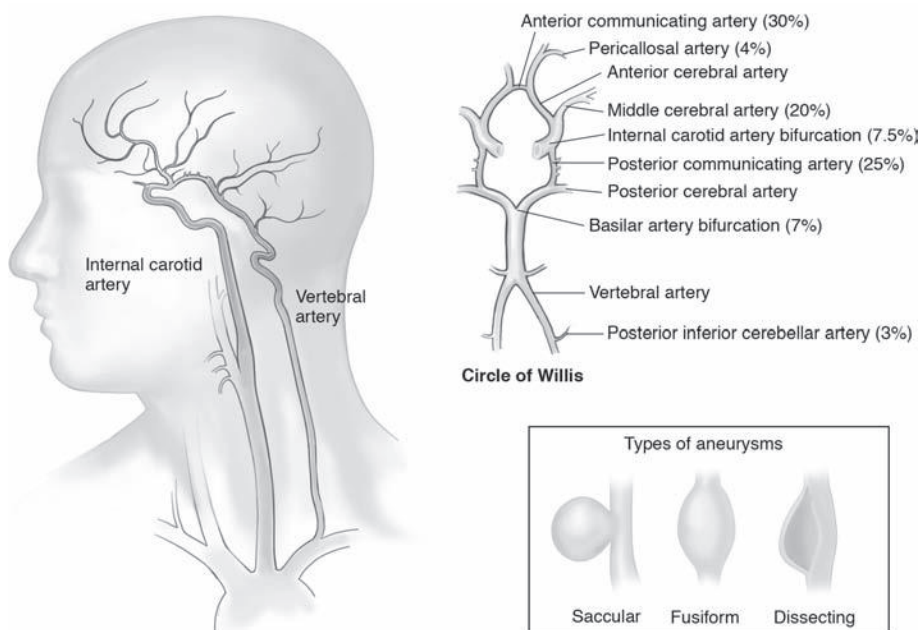

Figure 95.1. The anatomy of cerebral circulation. Adapted from Brisman JL, Song JK, Newell DW. Cerebral aneurysms. *N Engl J Med* 2006; 355(9):929.

the bleeding is extensive, many patients unfortunately continue to have low CBF and progress to a coma.

Patients with poor clinical grades of SAH tend to demonstrate impaired autoregulation, and their cerebral vessels are pressure-dependent. Furthermore, they have impaired cerebrovascular reactivity to carbon dioxide (CO₂) and may not respond to hyperventilation. This group of patients tends to demonstrate higher incidences of vasospasm, intracranial hypertension, and multiorgan dysfunction.

Complications

Rebleeding

The risk of rebleeding is high: 2% to 4% in the first day and 15% to 20% by the second week. The mortality from rebleeding is also high, 60%. There is a high risk of rebleeding during cerebral angiography. The incidence of intraoperative aneurysm bleeding is 6.7% per aneurysm; 5.3% occurring prior to dissection, 39.8% during dissection, 46% during clipping, and 8.8% post-clipping.

The risk of rebleeding is proportional to the wall tension of the aneurysm called the *transmural pressure*. It is the pressure difference between the inside and the outside of the aneurysm sac. The transmural pressure has the same numeric value as the CPP, which is the difference between mean arterial pressure (MAP) and ICP.

$$\begin{aligned} \text{Risk of rebleeding} &\propto \text{Transmural pressure} \\ &= \text{MAP} - \text{ICP} = \text{CPP} \end{aligned} \quad (\text{Eqn. 1})$$

Transmural pressure increases when there is a sudden change in MAP or ICP. When autoregulation is impaired, CBF becomes pressure-dependent, and an abrupt increase in systolic BP can promote rebleeding. Elevated ICP may protect the aneurysm from rupture to a certain extent. For this reason, ICP should not be decreased too rapidly before the dura is open. The timing of mannitol infusion and cerebrospinal fluid (CSF) drainage is decided carefully to avoid a sudden decrease in ICP.

The International Cooperative Study on the Timing of Aneurysm Surgery showed no differences in the outcome between early (0–3 days) versus late (11–14 days) surgery. The further evaluation of the results from the North American centers, however, indicated that early surgery within 3 days of SAH offered a good recovery in lower grade patients. Most neurosurgeons prefer early surgery to reduce the risk of rebleeding and to treat vasospasm effectively.

Vasospasm

Vasospasm is a leading, but potentially treatable, cause of morbidity after SAH. Vasospasm occurs between days 4 and 12 with a peak at day 6 to 7. With the general trend of early clipping, vasospasm is a postoperative problem in most cases. Patients in vasospasm may present with subtle mental status change or

focal neurologic deficits. Whether the neurologic condition is reversible depends on the severity and frequency of vasospasm and the adequacy of the collateral flow.

The diagnosis is made by clinical examinations and confirmed by an angiography. Angiographically detected vasospasm is not always correlated with clinical vasospasm. Angiographic vasospasm occurs in 70% of patients, and symptomatic vasospasm occurs in 30%. A greater than 50% decrease in the diameter of an artery on an angiography is considered severe vasospasm. Vasospasm can occur in the vessels near the ruptured aneurysm as well as in distant vessels. Transcranial Doppler has been used to diagnose vasospasm and to continuously monitor the efficacy of treatment. Flow velocity is expected to decrease as vasospasm improves.

Several vasoactive mediators have been suggested as a cause, particularly the breakdown product of hemoglobin, oxyhemoglobin. Intracranial blood can promote free radicals by using iron in hemoglobin and activate cascade reactions involving vasoactive substances leading to the vasoconstriction of cerebral arteries.

The main strategies for the treatment of vasospasm are early removal of blood clots, triple H therapy (hypertension, hypervolemia, hemodilution), and use of nimodipine. The benefit of triple H therapy is not scientifically proven, yet a good outcome has been reported in some clinical studies. The rationale for triple H therapy is to increase CPP and CBF in the ischemic area through the collateral circulation. Some believe that improving cardiac output is more beneficial than increasing MAP. Triple H therapy has many complications such as pulmonary edema, myocardial ischemia, electrolyte imbalance, cerebral edema, and catheter infection. For patients with neurogenic stunned myocardium, triple H therapy is guided by invasive hemodynamic monitoring to avoid heart failure (Table 95.3).

Hemodynamic management during vasospasm depends on whether the aneurysm has been clipped. If the aneurysm has been clipped, BP is raised to 160 to 200 mm Hg. If the aneurysm has not been clipped, BP is maintained below 120 to 150 mm Hg. Vasopressors such as phenylephrine or dopamine are used to titrate the BP. Intravascular volume expansion is achieved with central venous pressure (CVP) of 10 to 12 mm Hg or pulmonary capillary wedge pressure (PCWP) of 12 to 18 mm Hg. During ischemia, blood viscosity increases secondary to the low flow state. Improved viscosity from hemodilution improves CBF. The hematocrit of 30% to 35% offers the optimum balance between viscosity and oxygen-carrying capacity. If the patient develops vasospasm prior to surgery, maintenance of adequate CPP is critical, and deliberate hypotension is avoided intraoperatively.

Prophylactic use of nimodipine improves the outcome after SAH, even though there is no evidence suggesting that it prevents vasospasm. The mechanism may involve dilation of collateral circulation as well as prevention of calcium influx. Nicardipine decreases cerebral vasospasm, but there was no difference in the neurologic outcome at three months. For

Table 95.3. Treatment of vasospasm

Surgical	Clot removal, early clipping
Hemodynamic	Hypertension, hypervolemia, hemodilution
Pharmacologic	Nimodipine, nicardipine
Endovascular	Intra-arterial verapamil/papaverine, angioplasty

severe vasospasm, intra-arterial injection of verapamil or papaverine relaxes the vessel wall. The effect of papaverine is short-lived, requiring multiple procedures, and is known to be neurotoxic. Refractory vasospasm is treated by transluminal balloon angioplasty, which offers long-lasting effects but carries serious potential complications such as rupture, thrombosis, and dissection of the vessel or displacement of the clip. Stellate ganglion block decreases cerebral vascular tone without affecting chemoreceptor function or autoregulation. Arterial flow velocities and zero flow pressure decrease, but CO₂ reactivity is maintained. These responses to stellate ganglion block could represent a therapeutic advantage in treating cerebral vasospasms in the future.

Intracranial hypertension

Mild intracranial hypertension is common, and for most patients ICP returns to normal. Acute obstructive hydrocephalus occurs in up to 20% of patients and is commonly due to intraventricular blood clots causing mechanical obstruction of CSF flow. Other causes include the mass effect of intraparenchymal hematoma and ischemic changes from vasospasm. Cerebral vasospasm, when not treated promptly, increases ICP further and exacerbates cerebral edema. Vasospasm can also cause vasodilation in the distal vessels and increase the cerebral blood volume. A comatose patient with dilated ventricles mandates emergency ventriculostomy placement. Because of a risk of herniation, lumbar drain is contraindicated in patients with intracerebral hematoma, however. Hydrocephalus usually presents as a delayed complication from obliteration of arachnoid granulations, the site at which CSF is resorbed (Table 95.4).

In general, the patient with intracranial hypertension arrives in the operating room with an ICP monitor which allows measurement of ICP as well as CSF drainage. Hyperventilation effectively lowers ICP and is used as a temporary measure in an acute setting of intracranial hypertension. Its vasoconstrictive effect dissipates within 12 hours. One important caveat is that an acute decrease in ICP, either by hyperventilation or CSF drainage, increases transmural pressure and risks rebleeding.

Table 95.4. Causes of intracranial hypertension after SAH

Cerebral edema secondary to ischemia
Loss of autoregulation

Treatment

All ruptured aneurysms require either surgical clipping or endovascular coiling. The decision of clipping versus coiling depends on the anatomy of the aneurysm, neurologic condition, and comorbidity. According to the International Subarachnoid Aneurysm Trial (ISAT), clipping offers a lifetime treatment of aneurysm at a slightly higher risk of neurologic morbidity. Endovascular treatment is a preferable treatment modality for basilar artery aneurysms and for patients with poor Hunt–Hess grades or significant comorbidities. The drawback of an endovascular approach is a higher incidence of incomplete obliteration, recanalization, and rebleeding. New techniques using stent-assisted coils, bioactive coils, and coils of complex shapes are under investigation.

Anesthetic management

Preoperative consideration

Patients with poor clinical grades frequently present with multi-organ dysfunction. Cardiac, pulmonary, and renal systems are commonly affected by the high sympathetic discharge associated with SAH. A thorough assessment of underlying medical conditions (see Table 95.5) and new SAH-related conditions are important in determining the optimum CPP range, the safety of transient hypotension, osmotherapy, and fluid status. The timing of rupture should be noted to assess the perioperative risk of vasospasm.

The CT and cerebral angiogram should be reviewed to assess the size and location of the aneurysm, enlargement of ventricles, and the presence of multiple aneurysms. The overall surgical plan, need for cerebral protection, and positioning are discussed with the surgeon prior to surgery.

Table 95.5. Preoperative evaluation of patients with SAH

History	Onset of bleeding, loss of consciousness, seizure, comorbidity
Medications	Calcium channel blockers, BP medications, seizure medications, osmotherapy
Vital signs	Baseline BP, oxygenation, urine output, central venous pressure, intracranial pressure
PE	Heart and lung, IV access, invasive catheters, ICP monitor
Neurology	Hunt–Hess classification, neurologic deficits
Laboratory tests	Check complete blood count (CBC) and prothrombin time/partial thromboplastin time (PT/PTT), treat coagulopathy, treat electrolyte abnormality, check the baseline renal function, note serum osmolality, treat hyperglycemia, check troponin level
Blood	Type and cross-match four units, plasma or platelets if needed
Chest radiograph	Rule out pulmonary edema or aspiration pneumonia, check the placement of the central line
EKG	Note preoperative EKG changes, arrhythmia
CT	Ventricle size, cerebral edema, Fisher grading
Angiogram	Size and anatomy of aneurysm, presence of multiple aneurysms

Neurologic evaluation

The presence of intracranial hypertension should be noted. Without knowing ICP, the true CPP remains unknown. Even when the patient does not have an ICP monitor, ICP can be estimated by a clinical examination. It is important to document the admission neurologic condition such as mental status, motor deficits, and visual field changes. Seizure medications need to be at a therapeutic level.

Pulmonary evaluation

Neurogenic pulmonary edema (NPE) develops in 1% to 2% of patients with SAH and can be potentially life-threatening. The pathophysiology of NPE is not well known. Pulmonary edema is more common in poor-clinical-grade patients. It is believed that intracranial hypertension stimulates the sympathetic system, and the release of catecholamines from the hypothalamus and medulla appears to be a contributing factor. Elevated pulmonary hydrostatic pressure, leaky membranes, or both have been suggested as an etiology. The patient with NPE presents with dyspnea and hypoxemia. Hypoxemia is due to intrapulmonary shunting and manifests as a wide A-a gradient refractory to oxygen therapy. Hypoxemia dramatically increases CBF and should be corrected immediately. High positive end-expiratory pressure (PEEP), despite a potential detrimental effect on ICP, is recommended to treat hypoxemia whenever necessary. Elevation of ICP from PEEP is more likely due to hypercapnia from an increase in dead space ventilation than to venous outflow obstruction. Unless PEEP is greater than 10 to 12, it is unlikely to increase ICP. As ICP is normalized, NPE resolves in time.

Other differential diagnoses of respiratory failure include aspiration pneumonia. Altered mental status places SAH patients at a high risk of aspiration. The clinical presentation and chest radiograph from aspiration pneumonia may be similar to those of NPE. Pulmonary edema may develop during triple H therapy from overzealous hydration. Patients with SAH are at a moderate risk of developing thromboembolism and may develop pulmonary embolism. Nosocomial pneumonia is another possibility for ventilator-dependent patients.

Cardiac evaluation

Cardiac dysfunction is well-described in patients with a variety of acute intracranial pathology but particularly with aneurysmal SAH. Overactivity of the sympathetic system and an increased level of norepinephrine appear to cause demand ischemia or direct tissue damage. It is postulated that excessive catecholamine release “stuns” the myocardium, causing a reversible wall motion abnormality, usually beyond single coronary vessel territories, which normalizes over time. Severe SAH-induced ejection fraction reduction with large areas of akinetic myocardium coupled with only mild troponin elevations is typical and sets it apart from concomitant acute coronary syndrome. There might be significant overlap with NPE.

More than half of patients show abnormal electrocardiogram (EKG) findings such as ST/T wave changes and prolonged Q-T intervals. EKG changes may be indistinguishable from true myocardial ischemia. EKG abnormalities are correlated with the severity of the neurologic injury, but are not considered an independent predictor of outcome. In contrast, troponin elevation is a good predictor of left ventricular dysfunction and peaks immediately following the SAH. Brain natriuretic peptide (BNP) correlates well with regional wall motion abnormalities as well but also reflects the severity of diastolic dysfunction, reduced ejection fraction, and pulmonary edema. Arrhythmias are present in more than 90% of patients with SAH. Frequent premature ventricular contractions (PVCs) are the most common types of arrhythmia. Atrial flutter, atrial fibrillation, and ventricular arrhythmias are also associated with SAH. Prolonged Q-T increases the incidence of ventricular arrhythmias.

If the patient has an abnormal EKG or elevated troponin, no further workup is necessary unless the patient develops hemodynamic instability or has multiple cardiac risk factors. EKG changes do not affect the surgical outcome and usually normalize within 10 days. For hemodynamically unstable patients, however, cardiac echocardiogram or pulmonary artery catheter placement is considered. The risk of cardiac catheterization and intervention is too high for patients with unclipped aneurysms (Fig. 95.2).

Electrolyte evaluation

A variety of electrolyte abnormalities are common secondary to hypothalamic dysfunction when SAH occurs near the circle of Willis. The most common abnormality is hyponatremia. Other electrolyte abnormalities include hypokalemia, hypocalcemia, and hypomagnesemia and should be corrected promptly.

Hyponatremia is due to either cerebral salt wasting (CSW) or inappropriate secretion of antidiuretic hormone (SIADH). CSW is a more common cause of hyponatremia in SAH patients and is characterized by volume contraction and negative sodium balance. The etiology of CSW is presumed to be due to atrial natriuretic factor (ANF) or brain natriuretic peptide (BNP). In both cases, the urine osmolality is greater than the serum osmolality, and the urine sodium is greater than 20 mEq/L. The major difference between CSW and SIADH is volume status. A central venous catheter is useful in identifying patients with volume depletion. If hyponatremia is present during the vasospasm period, the distinction between these two conditions is critical. The treatment goal is the same, however: euvolemia and correction of hyponatremia with isotonic fluids. The rate of correction should not exceed 0.5 to 1 mEq/L/h to avoid central pontine myelinolysis.

Central diabetes insipidus (DI) is associated with hypothalamic or pituitary dysfunction secondary to hematoma or a mass in the sellar area. The diagnosis is made by hypernatremia, copious urine output, dilute urine, and hypovolemia. Treatment requires replacement of free water loss with hypotonic saline such as half normal saline until euvolemia is maintained. Refractory DI requires treatment with desmopressin.

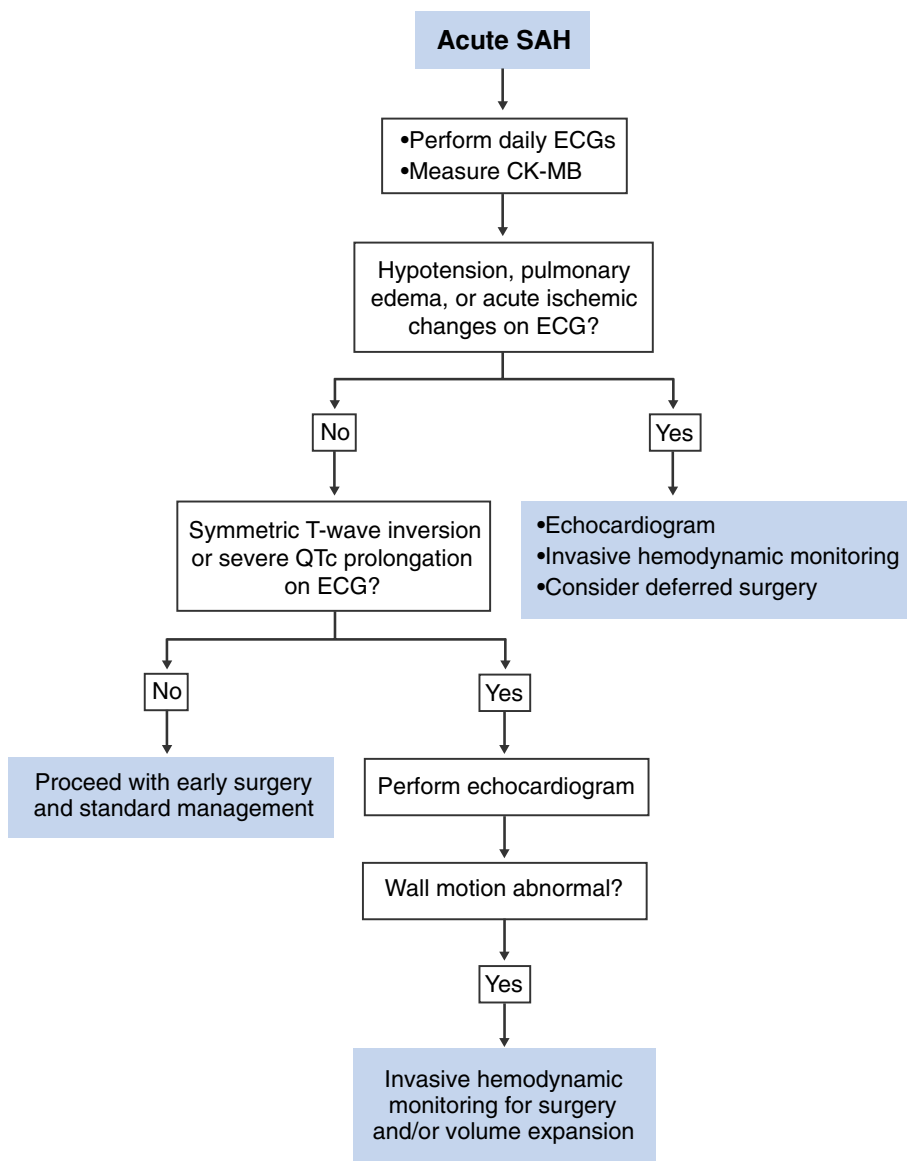

Figure 95.2. Algorithm for the detection of left ventricular dysfunction after SAH. Adapted from McKhann GM II, Mayer SA, Le Roux PD. Perioperative and intensive care of patients with aneurysmal subarachnoid hemorrhage. In Le Roux PD, Winn HR, Newell DW, eds. *Management of Cerebral Aneurysms*. Philadelphia: Saunders; 2004:431–454.

Premedication

Anxious patients with hypertension are sedated in a well-monitored setting. Patients with increased ICP, however, should not be sedated. Hypercapnia caused by respiratory depression is a potent stimulus for cerebral vasodilation and may increase ICP further. For example, a PaCO₂ of 60 mm Hg increases CBF by 50%.

Monitoring

In addition to American Society of Anesthesiologists (ASA) standard monitoring, an arterial catheter is indicated prior to induction for a ruptured aneurysm. For an unruptured aneurysm, it can be placed after induction as long as the BP is closely monitored. When an ICP monitor is available, an arterial catheter is zeroed at the level of the foramen magnum, approximately at the level of the circle of Willis. A baseline EKG

should be recorded as reference. A CVP catheter is desirable for patients who are at high risk of vasospasm or have underlying cardiovascular conditions. Trendelenburg position during CVP catheter placement should be limited to less than 10° tilt to avoid an increase in ICP.

Neurophysiologic monitors are useful in assessing the adequacy of cerebral perfusion as well as regional ischemia. Commonly used neurophysiologic monitoring devices include electroencephalogram (EEG), somatosensory evoked potential (SSEP), and brainstem auditory evoked potential (BAEP). The choice of neurophysiologic monitoring is based on the vulnerable vascular territory. EEG monitors cortical activity. SSEP assesses sensory conduction to the cortex and is used for anterior and posterior circulation aneurysms. BAEP monitors the auditory pathway through the brainstem and is reserved for posterior circulation aneurysms. Neurophysiologic monitoring

Table 95.6. Cerebral monitoring

Cerebral function	EEG SSEP BAEP
Cerebral blood flow	Jugular bulb catheter Transcranial Doppler

guides the safe duration of temporary clip placement and the adequacy of BP. When cerebral ischemia is suspected, the surgeon may need to reposition the temporary clips, consider temporary reperfusion, or institute the cerebral protective strategy. Despite high false-positive and -negative predictive rates, SSEP and BAEP are the only cortical neurophysiologic monitoring modalities available during burst suppression. The monitoring of CBF with a jugular bulb catheter or transcranial Doppler is less common (Table 95.6).

Induction

The goal of induction is to keep the transmural pressure of the aneurysm at baseline, usually in the range of 60 to 80 mmHg. The risk of rebleeding from hypertension needs to be weighed against the risk of ischemia from hypotension. For patients in vasospasm, the BP is maintained slightly higher than baseline. The attempt to control ICP should not be too vigorous until the dura is open.

Any technique that meets the anesthetic goals is appropriate. A combination of thiopental or propofol, a generous amount of narcotics, and long-acting muscle relaxants is a commonly used technique. Fentanyl at 3 to 5 $\mu\text{g}/\text{kg}$, or sufentanil at 0.4 to 0.6 $\mu\text{g}/\text{kg}$ or remifentanil at 0.5 to 1.0 $\mu\text{g}/\text{kg}$ are typical doses for induction. Prior to intubation, BP is kept 20% below the baseline to prevent the usual increase in BP with intubation. Esmolol, lidocaine, remifentanil, or an additional dose of thiopental or propofol all effectively blunt the hemodynamic response to laryngoscopy. Propofol does not offer much advantage due to the long duration of the surgery and the additional doses of thiopental that may be used during temporary clipping. Patients who arrive in the operating room with nicardipine infusions tend to develop hypotension upon induction.

Most anesthetics affect cerebral vasculature and change cerebral blood volume. When the compliance of the brain is poor, even a small degree of vasodilation or vasoconstriction has a dramatic impact on ICP. In that situation, the use of intravenous (IV) anesthetics is desirable. The advantage of total IV anesthesia (TIVA) techniques is a reduction in both CBF and cerebral metabolic rate (CMR). If ICP is severely elevated, TIVA with propofol and remifentanil is a good choice as long as CPP is maintained. When volatile anesthetics are used, the cerebral vasodilatory effect is counterbalanced by the simultaneous cerebral vasoconstrictive effect secondary to the decrease in CMR. In fact, CBF remains almost unchanged at 1 minimum alveolar concentration (MAC).

The use of succinylcholine is recommended if the patient has a potentially difficult airway. The transient increase in ICP

with succinylcholine is partly due to muscle fasciculation and is blunted by pretreatment with a small dose of nondepolarizing agent. If the patient has signs of impending herniation, rocuronium or mivacurium is an alternative. Laryngoscopy is performed when the patient is fully paralyzed. Coughing and bucking may dramatically increase the ICP. Tapes around the head cannot be used to secure the endotracheal tube for posterior fossa craniotomy. Good venous drainage is checked when the head is positioned. Considering the long duration of the surgery, all pressure points should be carefully padded.

Rebleeding during induction is a disaster. The surgical and nonsurgical stimulation in neurosurgery is highly predictable. Rebleeding occurs most frequently during laryngoscopy, pinning of the head holder, positioning, incision, raising of the bone flap, dural opening, dissection, and clipping. Avoiding an abrupt change in transmural pressure and providing a relaxed brain combined with careful planning of local blood flow may reduce the risk of rebleeding.

If the patient has an ICP monitor in place, it should be observed continuously until the dura is open. Hyperventilation decreases ICP effectively; however, it is not without risk. Hypocarbia increases the risk of ischemia by vasoconstriction, and PaCO_2 should never be dropped below 25 mm Hg. Another effective way of controlling ICP is CSF drainage. Accidental drainage of CSF is avoided because it may cause rebleeding or subdural hematoma.

Maintenance

The goal during the maintenance phase is to maintain adequate CPP, provide a “slack brain,” offer cerebral protection if necessary, and, most importantly, be prepared for complications. An inhalational agent under 1 MAC with an infusion of fentanyl/sufentanil/remifentanil is commonly used. An opioid infusion provides stable hemodynamics and reduces the use of inhalational agents. The cerebral effects of different volatile agents are similar. The use of nitrous oxide (N_2O) remains controversial. N_2O increases CBF and ICP. Its vasodilatory effect is more pronounced when used with isoflurane in humans. It also increases CMR unlike other volatile agents. If N_2O is used simultaneously with IV anesthetics, however, the increase in CBF and CMR is attenuated. Animal studies have shown that N_2O may increase the risk of cerebral infarction in focal ischemia. For the above reasons, when the patient has a “tight brain” or is at a risk of focal ischemia, N_2O is often omitted.

The brain is unique in that there is little pain perception in the brain parenchyma. This observation is easily made during awake craniotomy. From skin incision to dural opening, however, the surgery is intensely stimulating and adequate amounts of narcotics are needed. Fortunately, the amount of narcotics given during this early period seems to make little difference in the quality of wake-up. After the dura is open, surgical stimulation becomes minimal and the narcotic infusion can be minimized. For closure, β -blockers, lidocaine, and remifentanil effectively blunt the hemodynamic response to stimulation and

offer a rapid wake-up. During a posterior fossa craniotomy, sudden changes in BP and heart rate should be watched for when the brainstem or cranial nerves are retracted.

In general, carbon dioxide (CO₂) is maintained in the low end of the normal range. If ICP is elevated, mild hyperventilation is used to maintain PaCO₂ between 30 and 35 mm Hg. After the dura is open, ICP is no longer an issue because it becomes 0 mm Hg. At this point, MAP is equal to CPP. The surgeon may still request mild hyperventilation even after the dura is open. The indication for hyperventilation in that setting is for brain relaxation, not for ICP control. Excessive retraction pressure caused by a “tight brain” can cause brain ischemia. A “slack brain” is provided by mild hyperventilation, osmotic diuresis, optimal head positioning, lowering inhalational agent use, and CSF drainage. Hyperventilation should be discontinued as soon as brain relaxation is satisfactory and should not be used during temporary occlusion or vasospasm (Table 95.7).

Hypovolemia is prevalent in 36% to 100% of SAH patients, and the severity of hypovolemia is correlated with the clinical grade. Aneurysm surgery frequently requires diuresis and volume expansion. In a brain with an intact blood–brain barrier (BBB), the plasma osmolality from small ions determines the movement of water. The contribution of oncotic pressure to the total plasma osmolality is negligible, and colloid solution has no additional benefit over crystalloid. The fluid of choice is isotonic crystalloid without glucose. Blood sugar is often elevated from the use of dexamethasone and should be maintained at less than 150 mg/dl with an insulin infusion.

Osmotherapy reduces the bulk of the brain by removing interstitial fluid. Mannitol is usually given after the dura is open because the sudden drop in ICP can potentially cause rebleeding. It is important to keep the patient in a euvolemic state whenever mannitol is used. Mannitol becomes less effective if the patient is dehydrated or if the serum osmolality is greater than 320 mOsm/L. In addition, mannitol causes vasodilation and transiently increases intravascular volume. The usual dose is 0.25 to 1.0 g/kg. For those patients with low ejection fraction or renal failure, a smaller dose should be considered. The onset time is 10 to 15 minutes, and the duration is approximately 2 hours. Mannitol is effective only when the BBB is intact. When the BBB is disrupted, mannitol leaks into the interstitial space and increases the brain water content. Furosemide decreases CSF production and has a synergistic effect with mannitol. The effect of mannitol should be assessed by the improvement of brain relaxation rather than the urine output. Excessive brain relaxation can cause subdural hematoma by tethering bridging veins.

The most serious intraoperative complication during the final stage of dissection by the surgeon is hemorrhage. The incidence of intraoperative rebleeding is 10.7% for ruptured aneurysms and 1.2% for unruptured aneurysms. A transient reduction in MAP to 50 mmHg assists the surgeon in visualizing the field and gaining control over bleeding. If the dissection is near complete, the surgeon may be able to apply temporary clips to the feeding vessel or quickly place a

permanent clip on the aneurysm. In some situations, the unilateral carotid artery is manually compressed if the aneurysm is located in the anterior circulation. Acute hypotension from hemorrhage or induced hypotension can cause brain ischemia. It is important to restore intravascular volume aggressively whenever hypotensive techniques are used. As soon as the bleeding is under control, BP is increased to the normal range. Communication with the surgeon and vigilant observation of the surgical field through a video monitor is critically important.

If the surgeon decides to use temporary clips, cerebral protection strategies are instituted. The risk of neurologic injury depends on the ischemic time, adequacy of collateral circulation, and cerebral protection strategy. The most commonly used methods are burst suppression, mild hypothermia, and induced hypertension. The frequency and dose of thiopental are titrated based on the EEG monitor. Burst suppression is stopped when the permanent clips are placed. During temporary clipping, the BP is increased to greater than 20% to 30% above the baseline using phenylephrine. Normocapnia is maintained over this period. The efficacy of induced hypertension is improved when the intravascular volume is restored. The transient change in SSEP during temporary clipping is often reversed by induced hypertension. The patient is often allowed to be mildly hypothermic, although a recent study demonstrated that intraoperative mild hypothermia failed to show improved neurologic outcome in “good-grade” patients after SAH.

Blood pressure control

Aneurysm surgery involves meticulous BP control. A history of long-standing hypertension, carotid disease, and renal insufficiency may increase the risk of intraoperative hypotension. In systemic circulation, the activity of the autonomic nervous system plays an important role, but in cerebral circulation, the effect of the autonomic nervous system is less significant. Hypotensive techniques are rarely used with the advances in microsurgical techniques and are used only when the aneurysm is ruptured inadvertently or when bleeding occurs during dissection. When temporary clips are used, BP is increased to improve perfusion in the watershed area through the collateral circulation.

Phenylephrine is the most commonly used drug to increase BP. In the event of hypertensive overshoot after the administration of a vasopressor, vasodilators should be used with

Table 95.8. Common pharmacologic therapy for BP control

Hypotensive agents	Dosage	Action	Advantages/disadvantages
Phenylephrine	0.25–1 µg/kg/min	α-agonist	Rapid onset/offset, reflex bradycardia
Nitroprusside	0.5–10 µg/kg/min	NO-mediated arterial ≫ venous, vasodilation	Rapid onset/offset, cyanide toxicity, ICP elevation, rebound hypertension, pulmonary shunting, unsafe in pregnancy, should be protected from light
Nitroglycerin	1–10 µg/kg/min	NO-mediated venous vasodilation	Rapid onset/offset, ICP elevation, rebound hypertension, pulmonary shunting
Esmolol	50–200 µg/kg/min	Selective β ₁ -blockade	Rapid onset/offset, no effect on cerebral vasculature
Labetalol	0.5–2 mg/min total 300 mg	α ₁ -, β ₁ -, and β ₂ -blockade	Long acting, no effect on cerebral vasculature, bronchospasm, cardiac depression
Nicardipine	5 mg/h, max 15 mg/h	Coronary and peripheral vasodilation	Slow offset, minimal cardiac depression, reflex tachycardia less common
Volatile agents	Titrate between 0.5 and 1.0 MAC	Vasodilatation, myocardial depression	Increase ICP, cerebral edema

NO, nitric oxide.

Modified from Barash PG, Cullen B, Stoelting R, eds. *Clinical Anesthesia*, 5th ed. Philadelphia: Lippincott Williams & Wilkins, 2006:781.

caution in patients with intracranial hypertension. Nitroprusside and nitroglycerin offer the best BP control. When nitroprusside is abruptly discontinued, rebound hypertension may occur and the anesthesiologist must be prepared to manage it. Nitroglycerin may be used for patients with coronary artery disease or pregnancy, although it does cause an increase in cerebral blood volume and a concomitant increase in CSF pressure. The advantage of β-blockade in the management of acute hypertension is its lack of vasodilation, the ease of use, and the rapid reduction in heart rate and myocardial contractility. This is especially true for short-acting β-blockers such as esmolol, which has a rapid onset and a very brief duration of action. The use of longer acting β-blockers is postponed until blood loss is unlikely. If the patient has left ventricular dysfunction or is treated with triple H therapy, however, β-blockers should be used with caution. Nicardipine is a good alternative when β-blockers are contraindicated (Table 95.8).

Emergence

When the permanent clips are safely placed and the threat of bleeding or rupture is over, a plan for emergence is made. The important factors in considering the need for postoperative intubation are preoperative neurologic condition, intraoperative events such as rupture and hemorrhage, amount of thiopental used during burst suppression, body temperature, total amount of narcotic used, and the possibility of intraoperative ischemic events. For patients with basilar aneurysms, brainstem function needs to be assessed prior to extubation.

The goal for emergence is timely wake-up without BP swings. The patient should be awake enough to allow adequate neurologic evaluation. BP is kept within 20% of the baseline, usually less than 140 mmHg systolic. N₂O is discontinued when the dura is closed to avoid pneumocephalus. Delayed awakening increases the possibility of intraoperative ischemia, hematoma, pneumocephalus, residual hypothermia, and electrolyte abnormality.

The goal for fluid status is euolemia or slight hypovolemia. Postoperative hypertension is avoided to prevent cerebral edema or bleeding. β-blockers are effective in attenuating the high sympathetic tone. Although mild hypertension is not of great concern when the aneurysm is clipped, the incidence of multiple aneurysms is high, and hypertension needs to be treated promptly. During transport, the patient needs to be fully monitored. Delayed respiratory depression causes hypercapnea leading to high ICP and hypertension.

Surgical considerations

Controlling blood flow into the aneurysm is essential for safe clipping. The common strategies are placement of temporary clips, circulatory arrest, and revascularization.

Temporary clips

When the aneurysm is large, has complex shapes and branches, has a fragile wall, or is present in an area where dissection is difficult, the local blood flow is controlled first. Temporary clip placement avoids the systemic effects of deliberate hypotension and makes the final dissection less risky. It also allows the removal of the thrombus inside and decompression of a giant aneurysm. Temporary clips are placed on the feeding artery or on each side to trap the aneurysm. The disadvantage is the risk of cerebral ischemia, especially when perforators come off the trapped vessel. If the ischemic time is prolonged, intermittent occlusion is an option. The intermittent reperfusion technique is controversial because it may reduce the ischemic injury but increase the reperfusion injury. An ischemic time of 15 to 20 minutes is considered safe (Fig. 95.3).

Circulatory arrest

When the risk of cerebral ischemia is too high, aneurysms are clipped under circulatory arrest. This technique is reserved for giant aneurysms and basilar tip aneurysms. The patient requires cardiopulmonary bypass or complete circulatory arrest with

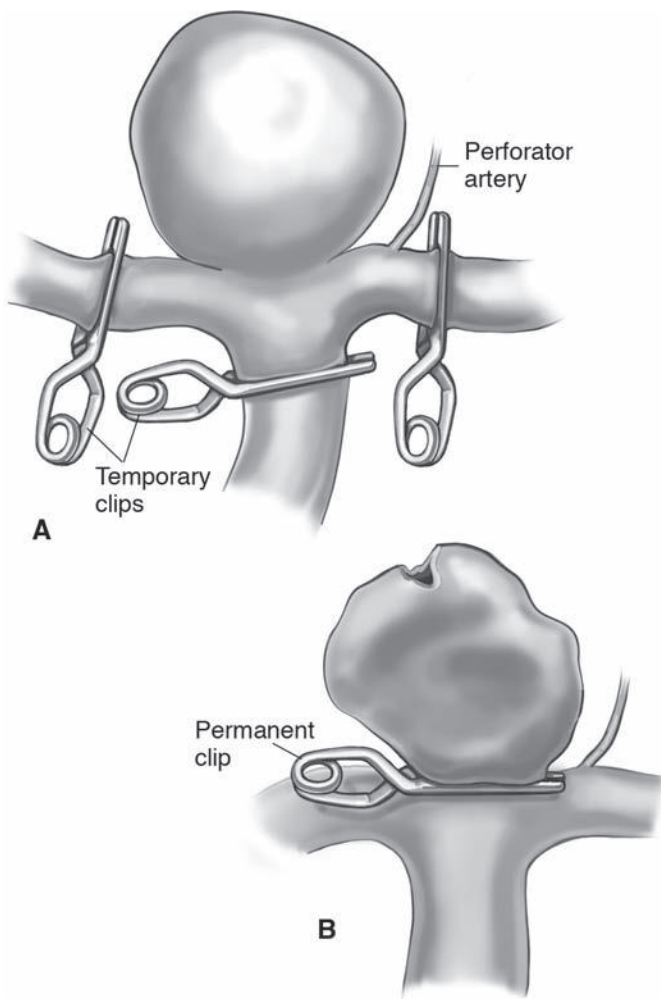

Figure 95.3. Temporary clips. Adapted from Ellegala DB, Day AL. Ruptured cerebral aneurysms. *N Engl J Med* 2005; 352(2):122.

profound hypothermia ($<22^{\circ}\text{C}$). The patient is prepped for femoral–femoral bypass or open chest bypass. The femoral–femoral bypass with low flow is most commonly used and has lower morbidity. The decision to proceed with circulatory arrest is made after the aneurysm and the nearby perforators are dissected. The circulatory arrest time should be kept to less than 60 minutes.

Revascularization

Revascularization is used when the parent vessel needs to be sacrificed to obliterate the aneurysm. Revascularization anastomosis using an extracranial artery, high flow vein, or adjacent intracranial artery has been used.

Endovascular aneurysm coiling

Interventional neuroradiology has been revolutionized in the past decade and allows treatment of complex neurovascular diseases through peripheral access. Common procedures include diagnostic angiography, coiling of ruptured aneurysm,

embolization of AVM, balloon angioplasty, and stenting. The procedure involves placement of a large introducer sheath by a transfemoral artery approach. A guiding catheter is advanced into the carotid or vertebral artery. At that point, a superselective microcatheter is introduced over a guide wire, with the guidance of road mapping, into the cerebral circulation. Detachable platinum coils of different sizes are advanced through the microcatheter to the aneurysm, and coils are deployed by electrothrombosis. The aneurysm sac is gradually packed with smaller coils until it is completely obliterated (Fig. 95.4).

There is a significant overlap in anesthetic management between clipping and coiling. Diagnostic cerebral angiography is usually done while the patient is awake. Dexmedetomidine is a good choice for sedation because it maintains respiratory drive. General anesthesia with paralysis is used for other procedures. The depth of anesthesia required for endovascular procedures is much less than that for open surgery. The special considerations for endovascular coiling are immobility, anticoagulation, allergy to contrast or protamine, and, most importantly, management of complications. If there is difficulty with an arterial catheter for invasive arterial BP monitoring, the side port of the femoral sheath can be used, but it may underestimate the systolic BP and overestimate the diastolic BP due to the coaxial catheter inside. All IV catheters should have extensions for easy access. N_2O is avoided because of potential enlargement of air bubbles in the microcatheter.

Anticoagulation with heparin is necessary for all neurovascular procedures because a blood clot on a catheter may cause an embolic event. The goal for heparinization is activated coagulation time (ACT) of greater than 250 seconds. The commonly used contrast is nonionic with high osmolality. The incidence of mild reactions with nonionic contrast has decreased, yet life-threatening reactions continue to occur. The risk factors for contrast nephropathy include use of a large amount of contrast, dehydration, concomitant use of other nephrotoxic drugs, and preexisting renal insufficiency. A large amount of fluid from flushing through the catheter needs to be counted as additional fluid intake.

Catastrophic complications may occur during the procedure. The incidence of rupture during coiling is 1.4% to 2.7%, with mortality exceeding 30%. If the aneurysm ruptures, BP should be maintained at the baseline and additional help should be summoned emergently. Rapid correction of anticoagulation is necessary to minimize hemorrhagic complications, whereas mild hypertension with possible thrombolysis is necessary for occlusive complications. Other serious complications are intimal dissection, perforation, and parent vessel thrombosis.

The endovascular approach to treating cerebral aneurysms has become a superior option for selective patient groups and is widely used at present. The technique presents many new challenges to anesthesiologists working in a remote location. Because the microsurgical and endovascular approaches have their advantages and disadvantages, it is likely that both techniques will remain as important treatment options. It is critical

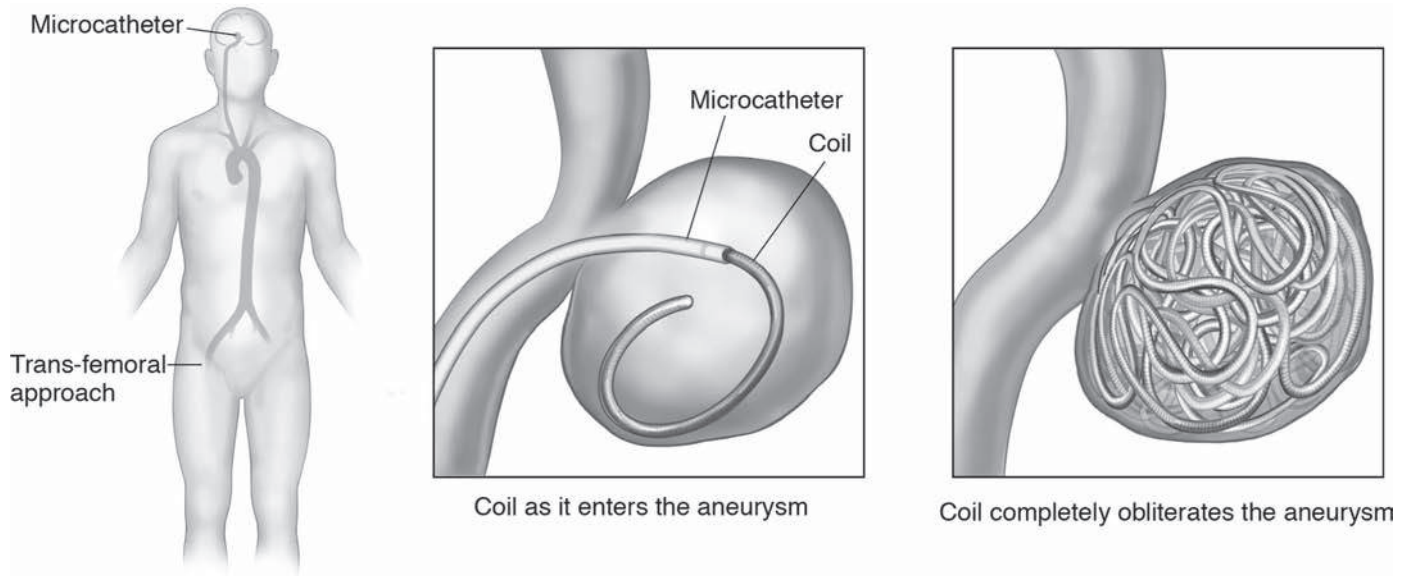

Figure 95.4. Endovascular aneurysm coiling. Adapted from Brisman JL, Song JK, Newell DW. Cerebral aneurysms. *N Engl J Med* 2006; 355(9):928–939.

for anesthesiologists to be familiar with the management of intracranial aneurysms in both settings.

Arteriovenous malformation

Introduction

AVM is a tangle of blood vessels consisting of arteries and veins, but without capillaries (Fig. 95.5). AVM is caused by a congenital vascular anomaly and tends to grow in size over time. Most AVMs become symptomatic and will bleed with age. Patients with AVM usually present with hemorrhage, seizure, and chronic cerebral ischemia. AVM hemorrhages are usually

Figure 95.5. Arteriovenous malformations of the brain.

intracerebral, but are occasionally subarachnoid and intraventricular. The most common cause of SAH in children is AVM. An infant with the vein of Galen AVM may present as having congestive heart failure and hydrocephalus. AVM occurs in younger patients between ages 20 and 50, and, as a result, the lifetime risk of morbidity and mortality remains high without surgical resection.

The initial workup of choice is a noncontrast CT to detect acute hemorrhage followed by an angiography to evaluate the anatomy of AVM, associated aneurysms, and the pattern of venous outflow.

The risk of rebleeding is slightly higher during the first year. It is reported as 6% to 20% in the first year then 2% to 4% per year thereafter, with overall mortality of 1% per year. Mortality from the initial bleeding is as high as 30%. The risk factors for hemorrhage are previous hemorrhage, deep venous drainage, deep location, intranidal or multiple aneurysms, small size, and high perfusion pressure in the feeding artery or draining vein. In contrast to a ruptured cerebral aneurysm, AVM bleeding rarely causes vasospasm. The recent advances in embolization techniques allow complete obliteration of AVMs even in areas that are surgically difficult to access.

Pathophysiology

AVM is a low-resistance vascular system. Blood is preferentially shunted toward the AVM bed, the pathway of least resistance. The risk of rebleeding is lower than that of cerebral aneurysm because the perfusion pressure in the feeding arteries is only 45% to 70% of the systemic BP. In contrast, the venous system is exposed to higher pressure. As a result, both the feeding and the draining vessels become dilated over time. The feeding arteries

gradually develop medial hypertrophy, and aneurysms develop frequently on the feeding arteries in 10% of the patients. When the AVM is large, the low vascular resistance can even lead to high-output cardiac failure. A smaller AVM has higher perfusion pressure and is associated with a higher incidence of hemorrhage compared with a larger AVM.

High blood flow into AVM steals blood from the adjacent brain which compensates for chronic ischemia by maximal vasodilation. The vessels in the surrounding brain lose autoregulation or shift the curve leftward. The hypoperfused brain also promotes angiogenesis, which results in abnormal vessels with impaired autoregulation. When the AVM is resected, blood flow is redirected to other areas where small vessels are unable to vasoconstrict and easily become hyperemic. In contrast, the perfusion pressure in draining veins decreases dramatically after resection and predisposes thrombosis. This phenomenon of cerebral hyperperfusion in the setting of normal CPP is called *normal perfusion pressure breakthrough* (NPPB).

Intracerebral hemorrhage from NPPB carries a high morbidity. The risk of developing NPPB is related to the size and the extent of increased blood flow in the AVM bed. NPPB is more common in large AVMs such as the vein of Galen AVM. Angiographic findings of large, high-flow shunts, multiple large-diameter feeding arteries, and AVMs located in the border zone predict hyperemic complications. Staged embolization allows time for the chronically vasodilated vessels to regain autoregulation.

Treatment options

AVM is treated with microsurgical resection, embolization, stereotactic radiosurgery, or a combination of different modalities. Surgery offers a permanent cure. Embolization is considered for surgically risky AVMs or for patients with major comorbidities. The preoperative embolization for a high-flow AVM can be coordinated with surgery to minimize the risk of intraoperative blood loss. Not all feeding arteries, however, are accessible to an embolization catheter, and the technique is limited by recanalization when used alone. For large AVMs, a staged embolization is considered to avoid sudden restoration of blood flow to the normal brain. A partially embolized AVM carries a higher risk of bleeding than an untreated AVM. Complete resection is important, and an intraoperative angiography is routine for confirmation. Radiosurgery is reserved for small lesions in an eloquent area.

The Spetzler–Martin grading system has been used to assess surgical risk. Spetzler–Martin grade I to II lesions are treated by surgical resection, and grade III lesions are treated by embolization followed by surgical resection (Table 95.9).

Anesthetic management

The risk of rebleeding from AVM is not usually higher immediately after bleeding. Because most of the cases are surgically resected as elective cases, it allows optimization of preexisting medical conditions. On the other hand, when a patient

Table 95.9. Spetzler–Martin grading system of AVMs

Size of AVM	Eloquence of adjacent brain	Pattern of venous drainage
Small (<3 cm) 1*	Non-eloquent 0	Superficial only 0
Medium (3–6 cm) 2	Eloquent 1	Deep component 1
Large (>6 cm) 3		

*The sum of the scores is equal to the grade.

Spetzler RF, Martin NA. A proposed grading system for arteriovenous malformations. *J Neurosurg* 1986; 65:476–483.

presents with severe intracranial hypertension from a large hematoma, the surgery is done on a more urgent basis. The overall anesthetic management of AVM resection is similar to that of aneurysm clipping: careful BP control, slack brain, euolemia, normoglycemia, and rapid emergence.

Preoperative considerations

The preoperative assessment includes the presence of intracranial hypertension, neurologic deficits, and control of seizures, in addition to the preexisting medical conditions. The size and location of the lesion are noted as well as the presence of other associated aneurysms. Large AVMs with high flow are identified to estimate the risk of NPPB. If the AVM is located in a delicate and risky brain area, the surgery may require two steps: the mapping of the AVM bed under awake craniotomy and the subsequent resection under general anesthesia. Several large-bore IV catheters are needed, and blood products should be available for potential hemorrhage.

Induction

During induction, the risk of rebleeding from systemic hypertension is much lower than that from a cerebral aneurysm because the perfusion pressure within AVM is lower. The frequent presence of an aneurysm in the feeding artery mandates careful BP monitoring, however. In addition, the compliance of the vasculature is abnormal, and avoidance of cerebral vasodilation is recommended. For an elective resection, ICP is usually normalized. The primary goal during induction is to maintain CPP and ICP in the optimum range. An arterial catheter is placed prior to induction. A combination of thiopental/propofol, fentanyl/sufentanil/remifentanyl, and long-acting muscle relaxants is commonly used.

Maintenance

A balanced anesthetic technique with an inhalational agent and narcotic infusion has been used most often. Fentanyl/sufentanil/remifentanyl infusions provide stable hemodynamics and reduce the requirement for inhalational agents. The concentration of the volatile agent is kept at less than 1 MAC to preserve autoregulation. Judicious use of mild hyperventilation and osmotic therapy provides a relaxed brain and facilitates surgical dissection. Cerebral protective strategies are considered for large AVMs.

Table 95.10. Complications of interventional neuroradiologic embolization/coiling

Complications	Clinical scenario	Treatment
Hemorrhagic	Perforation	Reversal of heparin
	NPPB	Lowering of blood pressure
	Dissection	Rapid delivery of coil, emergency craniotomy
Occlusive	Thromboembolic	Thrombolysis, mechanical lysis, anticoagulation
	Vasospasm	Raising of blood pressure
	Coil fracture	Retrieval/reposition of coil
Miscellaneous	Contrast reaction/nephropathy	Pretreatment, careful fluid management
	Groin hematoma	Compression, evacuation of hematoma

Modified from Varma MK, Price K, Jayakrishnan V, et al. Anaesthetic consideration for interventional neuroradiology. *Br J Anaesth* 2007; 99(1):75–85.

Intraoperative hemorrhage is more common during AVM resection than in aneurysm clipping. Dural arteriovenous fistulas involving major sinuses and the great vein of Galen malformation tend to bleed easily. Vasopressors and vasodilators should be readily available to keep the BP in a tight range. Until the AVM bed is completely resected and adequate homeostasis is obtained, it is prudent to use short-acting drugs such as nitroprusside, nitroglycerin, or esmolol. When massive blood loss occurs, the BP needs to be lowered rapidly to facilitate surgical hemostasis. Preoperative embolization decreases the incidence of major bleeding. The extent of blood-flow increase in the remainder of the brain after AVM resection can be estimated with intraoperative use of transcranial Doppler.

Emergence

Smooth emergence is paramount to avoid hypertension. BP should be maintained at or slightly lower than the baseline during the early postoperative period to avoid NPPB. Postoperative bleeding into the AVM resection bed can cause neurological catastrophe and result in high mortality. Although the vessels surrounding the AVM have impaired autoregulation, they remain responsive to PaCO₂. Respiratory depression secondary to excessive narcotics use should be watched for because hypercapnia may worsen cerebral edema. If extensive brain swelling is of concern, the patient should remain intubated and hyperventilated.

Endovascular embolization

Anesthetic management of AVM embolization is similar to that of cerebral aneurysm coiling. Embolization is done under either general anesthesia or monitored anesthetic care. The advantages of general anesthesia are high-quality imaging and the absence of movement. In contrast, monitored anesthetic care allows frequent neurologic examinations and provides the information about the true function of the potentially risky area in the

brain. Dexmedetomidine is a reasonable choice because of the lack of respiratory depression. However, its selective α_2 -agonist effect tends to cause hypotension and BP monitoring through a radial arterial or femoral coaxial catheter is mandatory. Occasionally, the neurointerventional radiologist may request deliberate hypotension for a brief time to deposit embolic materials in a more controlled manner. If inadvertent embolization into feeding vessels occurs, induced hypertension is necessary to augment perfusion through the collaterals. NPPB may occur when the feeding arteries are obliterated or venous outflow is obstructed due to inadvertent embolization. Hemorrhagic and thrombogenic complications during the procedure are treated as shown in Table 95.10.

Anesthesia for electroconvulsive therapy

Lambertus Drop

Major depressive disorder (MDD) is diagnosed in approximately 14 million adults in the United States each year, and, according to the World Health Organization, depression will be the second most common cause of disability in the world by the year 2020. The consequences of depression are considerable as MDD not only affects quality of life but also increases the severity and mortality of other medical conditions. MDD typically is a relapsing disease, although less frequently with a combination of electroconvulsive therapy (ECT) and antidepressants than with ECT alone. An important clinical problem is intolerance to the side effects of antidepressant drugs. In such cases, ECT may be a suitable and more effective alternative treatment, resulting in a more rapid onset of remission of depressive symptoms, especially in the elderly population.

Although older textbooks advocate that antidepressants be discontinued 14 days prior to the start of ECT, several studies have shown the length of time in that recommendation to be excessive. Generally all antidepressants and benzodiazepines should be discontinued 2 to 4 days prior to the day of the first ECT treatment. Special mention is made of lithium carbonate, which must be discontinued prior to ECT because its combination with ECT is known to produce a state of severe confusion. Also neuroleptics should be discontinued, which are prescribed to many patients with delusional or psychotic depression. Their known side effects include orthostasis and Parkinsonism.

Electroconvulsive therapy

With ECT, an electrical stimulus is applied unilaterally or bilaterally to the scalp with the purpose of eliciting a grand mal motor seizure, which is modified by intravenous (IV) hypnotics and neuromuscular blocking drugs while the lungs are manually ventilated with oxygen.

Physiologic changes with ECT

Seizure activity is associated with profound physiologic changes in the autonomic nervous system and in cerebrovascular and cognitive function.

The hemodynamic response recorded after ECT is biphasic immediate and delayed, and both parts of the response involve both the parasympathetic and sympathetic systems.

Typically, the parasympathetic response comes first, with short-lasting bradycardia because of sinoatrial (SA) node inhibition, and is accompanied by increased salivation. Increased sympathetic tone then follows with self-limited tachycardia and hypertension. To gain insight in their magnitude, a retrospective analysis of 23,000 clinical data points in 227 patients at Massachusetts General Hospital has revealed that post ECT, more than a quarter of patients had systolic blood pressures exceeding 220 mm Hg, heart rate was between 120 and 140 bpm in 20% of patients and between 140 and 160 bpm in 15% of patients. Such a profound hyperdynamic state may be explained by enhanced sympathetic outflow in the brain, augmented by significant increases in circulating norepinephrine and epinephrine. Hypotension after ECT is so rare that, when it occurs, a search for its cause is indicated. This search may reveal inadequate fluid intake (typical for depression), but cardiac pump failure due to cardiac ischemic events must also be considered, especially in the elderly population. The delayed response is manifested as post-ECT bradycardia as a result of sustained enhanced parasympathetic tone. This is most often self-limited, but heart rates occasionally fall below 40 bpm, requiring 0.2 mg of IV glycopyrrolate. The most common arrhythmias during and after ECT are premature ventricular contractions (observed in 30% of patients) and T-wave flattening, which are self-limited. These changes are benign, and cardiac enzyme elevation is notably absent after uncomplicated ECT. In individual patients with previously known coronary artery disease, progressive elevations of the ST segment have been observed, and these changes were key to the diagnosis of myocardial injury.

Pulmonary gas exchange

During both tonic and clonic phases of an unmodified grand mal seizure, there is no effective breathing. With anesthesia and muscle relaxation, controlled ventilation provides adequate oxygenation during the ECT session as shown by pulse oximetry values.

Cerebral blood flow (CBF) is augmented by a factor of up to 5, and cerebral metabolic rate is increased. The degree of cerebral vasodilation is disproportionately greater than the increase in metabolic rate, accompanied by a temporary loss of cerebrovascular autoregulation. There is also increased

intracranial pressure, but the magnitude of cerebral hypertension is uncertain, and the CBF adjustment may be inadequate in the presence of cardiac arrhythmias. Besides increased CBF rate there also is increased blood flow velocity as determined by transcranial Doppler ultrasonography, with an increase of 240%. Despite these seemingly ominous events, cellular injury in the brain does not occur with ECT when adequate oxygenation and cerebral perfusion pressure are maintained.

Because of hypothalamic stimulation that occurs with ECT, there is an increased release of several hormones, including adrenocorticotropic hormone (ACTH), vasopressin, prolactin, and cortisol. Effects of ECT on blood glucose levels in diabetic patients are variable, and close monitoring of blood glucose levels is advisable. Diabetic patients maintained on NPH insulin are given half of the daily dose, and an IV infusion with glucose-containing solution is begun. Oral intake is then allowed later in the day. In contrast, some practitioners allow the daily insulin dose to be postponed until shortly after ECT has been administered.

Intragastric pressure

Because ECT is associated with elevation of intragastric pressure, patients with gastric reflux or severe heartburn should receive a proton pump inhibitor alone by mouth or in combination with citric acid/sodium citrate immediately prior to ECT.

Intraocular pressure

Intraocular pressure is reported to more than double during ECT. This can be problematic in patients with glaucoma. Accordingly, an ophthalmologic consult should be obtained when ECT is contemplated in this patient population. Echothiophate, a commonly prescribed drug for glaucoma, is administered in the form of eyedrops. Echothiophate is a potent inhibitor of plasma pseudocholinesterase and its systemic resorption may cause prolonged apnea from decreased enzymatic breakdown of succinylcholine.

Efficacy and indications

A generalized grand mal motor seizure is essential to the therapeutic efficacy of ECT and clinicians aim for a minimum seizure duration of 20 to 30 seconds. Indications for ECT include the lack of response to antidepressants, intolerance to their side effects, and a good clinical response to ECT previously. Unresponsiveness to antidepressants in the face of severe symptoms of major depressive disorder is an urgent indication for an ECT session, especially when malnutrition and dehydration coexist (secondary to anorexia or in combination with catatonia). Delusional and psychotic depression is a strong indication for ECT before beginning extensive drug treatment. Indications for ECT include the lack of response to antidepressants, intolerance to their side effects, a good response to ECT previously, and an urgent indication is established with unresponsiveness to antidepressants especially when malnutrition and dehydration

Continued fatigue
Feelings of hopelessness
Low self-esteem
Preoccupation with death and suicide

coexist (secondary to anorexia or in combination with catatonia). Delusional and psychotic depression is a strong indication for ECT without extensive drug trials. Although comparative predictors for good responses to a drug regimen versus ECT are not firmly established, a good response to ECT may be expected with symptoms listed in Table 96.1. Central to these symptoms is the loss of interest in activities that used to give pleasure. The efficacy of ECT is dependent on details of the ECT procedure with success rates ranging from 20% to 80%. Such a wide range is possibly related to the total number of treatments that may be arbitrarily limited in some patients to lessen the most important side effect: short-term memory loss. Variables contributing to efficacy also include electrode placement, dosage, and duration – clearly all determined by the treating psychiatrist. Efficacy assessment of ECT may be performed by means of the standard Hamilton rating scale.

Seizure threshold

Seizure threshold for ECT treatment may be defined as the lowest energy level required to elicit an epileptic seizure, and is determined by successive stimulation, starting at a low level of energy with increments until a seizure is produced. Neurotransmitters and their receptors clearly are major determinants of the seizure threshold. The seizure threshold is of major clinical interest for two principal reasons. First, the seizure threshold may be manipulated with drugs or interventions with actions that either elevate or lower it. For example, benzodiazepines, propofol, fosphenytoin, and hypoxia elevate the seizure threshold, whereas theophylline, caffeine, hypocapnia, and high partial pressures of oxygen lower it. In young patients, the seizure threshold is lower than in the elderly population and the seizure threshold progressively increases over the course of a series of treatments with ECT. These variables are taken into account when determining the energy level to be delivered. Precise control of the energy level delivered with avoidance of excessive levels, coupled with routine use of unilateral electrode placement are essential to eliminate severe post-ECT mental confusion, agitation, or memory loss. Because reliable predictors of ECT efficacy are not available, lifting of depressive symptoms does not occur in all patients. Improvement of mood after ECT occurs in at least 80% of patients, however.

Patient workup

A proper clinical evaluation includes a detailed history, physical examination, chest radiograph, electrocardiogram (ECG), and routine laboratory tests, including hematocrit and WBC. Tests of hepatic and kidney function may be indicated in elderly and ill patients. The clinical examination of the depressed patient may be limited because detailed information on discomfort or limitation of function often remains hidden or at least is difficult to obtain. Upon indication, specialized consultation and investigations may include cerebral CT and MRI, and study of cardiac function including stress test and echocardiogram. Antihypertensive regimens are optimized if applicable, and, in anticoagulated patients, coumadin is adjusted to yield international normalized ratio (INR) values between 2.5 and 3. The stability of blood sugar levels should be ascertained in diabetic patients. If ECT is offered early in the morning, the insulin dose may be held in diabetic patients until after the treatment. In asthmatic patients, theophylline is discontinued in view of the risk of status epilepticus when a high serum theophylline level is present at the time ECT is to be administered. In most patients there is a favorable response to inhaled corticosteroids or β_2 -adrenergic agonists. For pregnant patients, an obstetrical consultation should be obtained. Additional recommendations pertaining to ECT for pregnant patients appear later in this chapter.

Treatment plan

Obtaining informed consent may pose a challenge in a depressed patient, especially when severe motor retardation is present, but the patient, a guardian, or family members must give informed consent for the application of ECT and, separately, for the administration of anesthesia. Brief and ultrabrief pulse stimulation are characterized by a rapid upstroke of the stimulus intensity followed by a rapid offset, with a square waveform. The stimulus is administered by a monitored ECT device (MECTA Corporation, Tualatin, OR) in which individually set variables are stimulus frequency, pulse width, total stimulus duration (depending on age), and number of immediately preceding treatments. The electrical stimulus produces a generalized seizure which spreads throughout the cerebral cortex and is followed by electrical silence of about 1 minute.

Clinically, the ECT patterns of stimulation with brief pulse and ultrabrief pulse predominate, primarily because of a lesser incidence of post-ECT complications, e.g. confusion and amnesia as compared to sine-wave stimulation. Traditionally, an initial series of 6 to 12 treatments on average are given with a sequence every other day (Mon–Wed–Fri), followed by reassessment. If remission is achieved, a regimen with antidepressants is usually required following the ECT treatment. Because ECT is also effective with application spaced at 1- (or more) week time intervals, maintenance ECT is a valuable alternative to maintenance with antidepressants, but comparative

Table 96.2. Standard anesthesia protocol

Premedication	No atropine No benzodiazepines
Monitors	Noninvasive blood pressure ECG Pulse oximetry
IV access	20–22 gauge IV catheter
Induction	Methohexital 0.75 mg/kg
Muscle relaxation	Succinylcholine 0.75 mg/kg
Mask	Ventilation oxygen
Muscle relaxation confirmed	Foot sole reflex
Bite block	Between molars bilaterally
Terminate seizure (if > 2 min)	Propofol, midazolam, lorazepam

data are not available. In the event of incomplete remission, more treatments with the same frequency as the initial series (or on a weekly or biweekly basis) may be indicated.

Augmented seizures

If attempts to induce seizures using standard technique are unsuccessful, several pharmacological interventions are available using agents that can produce or facilitate seizure activity. Some practitioners believe that selecting etomidate (0.2 mg/kg) instead of methohexital is useful. Others have administered caffeine (125–250 mg IV), but it may be remembered that this drug has the potential for an exaggerated response manifested by hypertension, tachycardia, and cardiac arrhythmias.

Anesthesia procedure

Anesthesia protocol

A fasting period of 6 to 8 hours is recommended. Because elderly patients with depression and forgetfulness may not be reliable or cooperative, nursing supervision of the fasting period is important. Hydroxyzine (50–75 mg) or promethazine (25–50 mg) may be administered for pretreatment sedation. Benzodiazepines and barbiturates are not used because of their seizure threshold-elevating effects. A standard anesthesia protocol is shown in Table 96.2. Because the seizure threshold is unknown in the first treatment, it may be necessary to administer more than one stimulus. If the first stimulus fails to elicit a seizure, the power is increased with the subsequent stimulus such that a value at least 50% over threshold is reached. A sequence of more than one stimulus carries the risk of severe bradycardia, however, because the parasympathetic effects of the nonconvulsive first stimulus may not be followed by sympathetic stimulation if a seizure fails to occur on the second attempt. In view of this potentially dangerous possibility, glycopyrrolate is always administered prior to the first ECT. It is preferred over atropine because of a lesser degree of tachycardia and because it is a quaternary compound that does not cause delirium by crossing the blood–brain barrier. IV access is established with a small-bore Teflon catheter configured as a heparin

Table 96.3. Anesthetic agents suitable for ECT

Drug	Dose	Seizure threshold	Seizure duration	Comments
Methohexital	0.5–1 mg/kg IV	Minimal anticonvulsant effects	↔	<ul style="list-style-type: none"> – Induction agent of choice by APA – Short duration of action – Pain upon injection

lock. A steel needle (“butterfly”) is not dependable in the event that IV drugs are needed after ECT. Following IV administration of methohexital (0.75–1.0 mg/kg) and succinylcholine (0.75–1.0 mg/kg), the lungs are manually ventilated by mask with 100% oxygen. (See Table 96.3.) These dosages are remarkably constant throughout the course of treatment in all patients. Suitable alternatives include thiopental (3–5 mg/kg), propofol (1–2 mg/kg), and etomidate (0.15–0.3 mg/kg). Succinylcholine is not given to patients with pseudocholinesterase deficiency, extensive recent burns, patients within 6 months after stroke or with known susceptibility to malignant hyperthermia, or patients with muscular dystrophy. Succinylcholine may have a prolonged action in patients treated with donepezil hydrochloride for Alzheimer’s disease or echothiophate for glaucoma. Suitable alternative muscle relaxants are rocuronium (0.6–1 mg/kg), vecuronium (0.1 mg/kg), or mivacurium (0.15–0.25 mg/kg), the effects of which may be reversed with neostigmine. The absence of leg withdrawal in response to stimulation of the foot sole is used to establish adequate muscular relaxation.

Airway management

Dentures should be removed prior to induction of anesthesia. The placement of a face mask for preoxygenation may not be ideal because of heightened anxiety. At the first sign of lowered consciousness, the lungs are manually ventilated with 100% oxygen. A laryngeal mask airway may also be used. Immediately before application of the stimulus, two locally made rolls of cotton gauze are placed bilaterally between the molar teeth to prevent damage to teeth or gums. Placement of a cuffed endotracheal tube may occasionally be necessary in selected patients, including those with a tracheostomy, those who are pregnant, and those with active gastric reflux or a gastric sphincter mechanism that is incompetent because of a gastric feeding tube or a surgical colon interposition procedure relating to a prior suicide attempt with lye ingestion.

Although the motor seizure is essential to the efficacy of ECT, the peripheral manifestations are eliminated with succinylcholine. To monitor the seizure duration and to be certain that the seizure is generalized, a tourniquet or blood pressure cuff is applied around the ipsilateral (in the case of unilateral ECT) arm or leg prior to succinylcholine or a nondepolarizing muscle relaxant administration and inflated to pressures above systolic. This maneuver prevents the neuromuscular blocker from reaching receptors below the tourniquet, thereby allowing observation of the motor seizure activity in this localized peripheral muscle area.

Cardiovascular function

If reduced arterial pressure is present before ECT, sequential blood pressure measurements are taken in supine, sitting, and standing position. If cardiac pump failure relating to ischemic heart disease is the cause of the hypotension, it is prudent to postpone the ECT session and obtain a cardiology consult. The tachycardia and hypertension typically observed after ECT may be effectively attenuated with the β -blocking drugs esmolol and labetalol (mixed α - and β -blocking agent); these drugs also can prevent cardiac arrhythmias. Also remarkable is that their potential side effects, such as exaggerated bradycardia post ECT, unmasking cardiac failure, or asthma, are not seen with these clinical dosages. A clinically useful alternative is sublingual nifedipine (10 mg) approximately 15 minutes before application of the ECT stimulus. Propranolol should not be administered in this setting because of the risk of cardiac arrest immediately after the seizure.

Recovery

After the seizure, patients are taken in the side position to the recovery area, a plastic face mask with an oxygen reservoir is fitted to the face, and ECG, oxygen saturation, and blood pressure are monitored and recorded for 30 minutes.

Side effects and complications of ECT

The most common side effect is a reversible short-term memory loss, which is more often seen with bilateral electrode placement. Post-ECT agitation and confusion, possibly as an expression of a residual seizure, may be successfully treated or prevented with lorazepam (1–2 mg IV), midazolam (1–2 mg IV), or propofol (50–100 mg), alone or in combination.

Complications include congestive heart failure, myocardial ischemia, and augmented hypertension. Cardiac arrhythmias occur in more than 30% of patients.

Pulmonary complications

Because the airway, in almost all patients, is managed with a face mask during ECT, pulmonary aspiration is possible. Endotracheal intubation is therefore performed in patients with known gastrointestinal reflux disease. Patients are turned in lateral decubitus position after ECT. Cognitive complications occur frequently and are primarily those involving memory losses for recent events, which typically are self-limiting. Status epilepticus rarely occurs spontaneously when seizures continue beyond 120 seconds immediately post-ECT stimulus. Headache typically responds well to ketorolac (30 mg IV). Muscle pain is reported by many patients after the first ECT treatment, but not after subsequent treatments.

Special considerations

Recent myocardial ischemic event

Common practice is to observe a 3- to 6-month waiting period before a course of ECT is undertaken in patients with documented myocardial injury, although strong supporting data are not available.

Coronary artery disease

The diagnosis of coronary artery disease is common in many elderly patients presenting for ECT. In such patients, the hemodynamic changes typical for ECT may lead to symptomatic coronary insufficiency with cardiac ischemia as shown by persistent changes in ST segment from baseline on the ECG, followed by cardiac pump failure, even though a given patient may not report any ischemic symptoms before ECT. In these patients, pretreatment with β -blocking drugs may eliminate rate-dependent coronary insufficiency. Clearly, overt chest pain and anginal symptoms require consultation with a cardiologist to advise on additional specific cardiac studies to be performed and on an optimal medical regimen.

A pacemaker may be present in patients with symptomatic bradyarrhythmias, second- or third-degree atrioventricular (AV) block, and sinus node malfunction. An external converter magnet should be readily available, and the serum potassium level should be within the normal range. In addition, the pre-ECT ECG may be examined for a 1:1 capture and a chest radiograph may be examined for intact electrode wires.

Drugs that should be readily available include atropine and isoproterenol. ECT does not ordinarily interfere with pacemaker function because of improved electrical shielding of the pulse generator units; in addition, the ECT stimulus is applied at a distance from the location of the generator unit, and, if interference does occur, the unit changes to a fixed mode. Drugs used in anesthesia for ECT are safe relative to pacemaker function, although, theoretically, the muscle fasciculations after succinylcholine could cause some interference.

Cardiac transplant recipients may receive ECT, but the data are limited. A hypersensitivity of the denervated heart to catecholamines after orthotopic transplantation has been shown not to be of practical concern.

Abdominal aortic and cerebral aneurysms pose an important risk in patients presenting for ECT because of the marked increase in arterial pressure and heart rate typical for ECT. They have been considered contraindications to ECT in the past, but ECT may be successfully administered with special management. Risk factors include marked increased in arterial pressure and blood flow velocity, but a direct correlation between aneurysm rupture and hypertension has not been established. Although the predictors for and mechanism of aneurysm rupture are unknown, the combination of β -blocker pretreatment (atenolol 25–50 by mouth per day, for 2–3 days prior to ECT) to reduce shear stress at the aneurysm site and sodium nitroprusside infusion (to reduce arterial pressure and blood flow velocity) immediately prior to and during treatment has proven useful to successful management and outcome. If sodium nitroprusside is used, it is mandatory that intra-arterial monitoring be employed since the arterial blood pressure may undergo profound changes from moment to moment. Such patients also should be observed for a prolonged period after ECT, possibly staying overnight at the treatment facility or transferred to a hospital setting with appropriate monitoring facilities.

Arteriovenous malformations

Because these lesions are low-pressure lesions (in sharp contrast to aneurysms), they are less likely to have major cerebral consequences in combination with ECT. Close observation with frequent blood pressure measurements is advisable.

Brain tumor

ECT has been successfully administered in the presence of a brain tumor.

In the presence of critical aortic stenosis, ECT poses a challenge because of the catecholamine surge and increased cardiac output. The classic triad of symptoms consists of angina, dyspnea on exertion, and syncope, making ECT quite dangerous in such patients. If ECT must be done, the patient should be extensively monitored and transferred afterward to a hospital or ICU setting for extended observation.

ECT has been successfully administered in the presence of severe pulmonary hypertension.

Pregnancy

ECT produces no complications for pregnancy or delivery and has no adverse effects on growth and development during infancy and beyond.

Case reports suggest that ECT is safe for mother and fetus even in the third trimester of pregnancy, and no premature labor has been reported. With each ECT treatment, fetal well-being may be monitored by means of ultrasonography, and attention is directed to adequate hydration and lateral uterine displacement to prevent hypotension. Antacids and endotracheal intubation are advocated to prevent pulmonary aspiration.

Anesthesia for Renal and Urinary Tract Diseases

Paul D. Allen, editor

Renal physiology

Edward R. Garcia

The kidneys are both excretory and secretory organs that tightly regulate the volume and composition of body fluids by precise excretion of excess water and waste products. This chapter describes basic anatomy and physiology of the kidney and ways to measure kidney function.

Anatomy and function

The kidneys are paired organs lying in the retroperitoneal space. Each kidney has an outer cortex and an inner medulla. At the medial border of each kidney is the hilum, which opens into the renal pelvis and continues down as the ureter into the bladder. The renal cortex contains approximately 1 million nephrons, which give it a granular appearance. Each nephron begins in a renal corpuscle, which in turn is composed of a glomerulus, a tuft of capillary loops, enclosed in Bowman's capsule. Plasma is filtered out of the glomerulus (ultrafiltrate = plasma – the proteins), and this filtrate is passed out of the Bowman's space into the proximal tubule ultimately forming urine.

Important homeostatic functions of the kidney include the secretion of erythropoietin (stimulates red cell production in the bone marrow), of renin (regulates extracellular fluid volume), and of vitamin D (active form) and prostaglandins.

The paired kidneys receive blood flow at approximately 1.25 L/min (25% of cardiac output); most of this flow supplies the renal cortex (90%). The majority of this blood flow (1 L/min) goes to the glomeruli and results in the production of 125 ml/min of filtrate (glomerular filtration rate [GFR]). Water, crystalloids, and molecules less than 30,000 daltons are filtered freely through the membranes. GFR is the clinical measure of renal function which gives a gross assessment of the amount of filtration and, therefore, excretion that the kidneys can perform. In normal adults, the GFR averages 90 to 140 ml/min for men and 80 to 125 ml/min for women. GFR normally declines with age, decreasing to approximately 80 ml/min at 60 years of age and to 60 ml/min at 80 years.

Normal age-related decline of GFR is usually of little clinical consequence and does not affect the kidneys' excretory or homeostatic ability under normal conditions. As mentioned earlier in the text, the initial step in the formation of urine is the production of ultrafiltrate at the glomerulus. The efferent arterioles provide the high resistance to blood flow needed to create high glomerular hydrostatic pressure and drive the filtrate into

the Bowman's capsule. At 120 ml/min, the total amount of filtrate produced is 173 L/day, whereas normal urine production is approximately 1.5 L/day. Therefore, 99% of the filtrate produced is reabsorbed, and only the remainder is excreted as urine.

Renal blood flow autoregulation

Afferent arterioles likely play a predominant role in renal autoregulation, resulting in near-constant renal blood flow (RBF) and GFR. Autoregulation of RBF in response to blood pressure changes occurs by:

- Native response of smooth muscle cells (myogenic mechanism) that contract in response to increased or decreased stretch. An increase in afferent vascular resistance decreases GFR, whereas a decrease in afferent vascular resistance increases GFR. An increase in efferent vascular resistance increases GFR, whereas a decrease in efferent vascular resistance decreases GFR.
- Tubuloglomerular feedback (TGF) mechanism
- Sympathetic nervous system control (vasoconstriction, T4–L1)
- Renin–angiotensin effect
- Antidiuretic hormone (ADH; vasoconstriction)
- Prostaglandins – prostaglandin E₂ (PGE₂) and prostaglandin I₂ (PGI₂) (vasodilators)

Autoregulation allows RBF and GFR to remain relatively constant as mean arterial pressure (MAP) varies between 80 and 180 mm Hg. The ability to autoregulate blood flow to maintain renal perfusion pressure and GFR becomes impaired when MAP drops below 70 mm Hg.

Reabsorption and secretion

Following the production of ultrafiltrate, a series of reabsorption and concentration steps (Fig. 97.1) occur along the nephron to reclaim water and electrolytes. These steps occur under the control of a number of hormones and factors as discussed in the next section. The renal cortex receives almost 1 L/min of RBF, whereas the medulla receives only 250 to 300 ml/min. The renal medulla, in the region of the tubule, is among the most metabolically active tissues in the body but is relatively poorly perfused. Thus, it is a region of low blood

67% of reabsorption occurs immediately with Na, Cl, K, water and solutes absorbed in the proximal convoluted tubule, along with essentially all filtered proteins and glucose

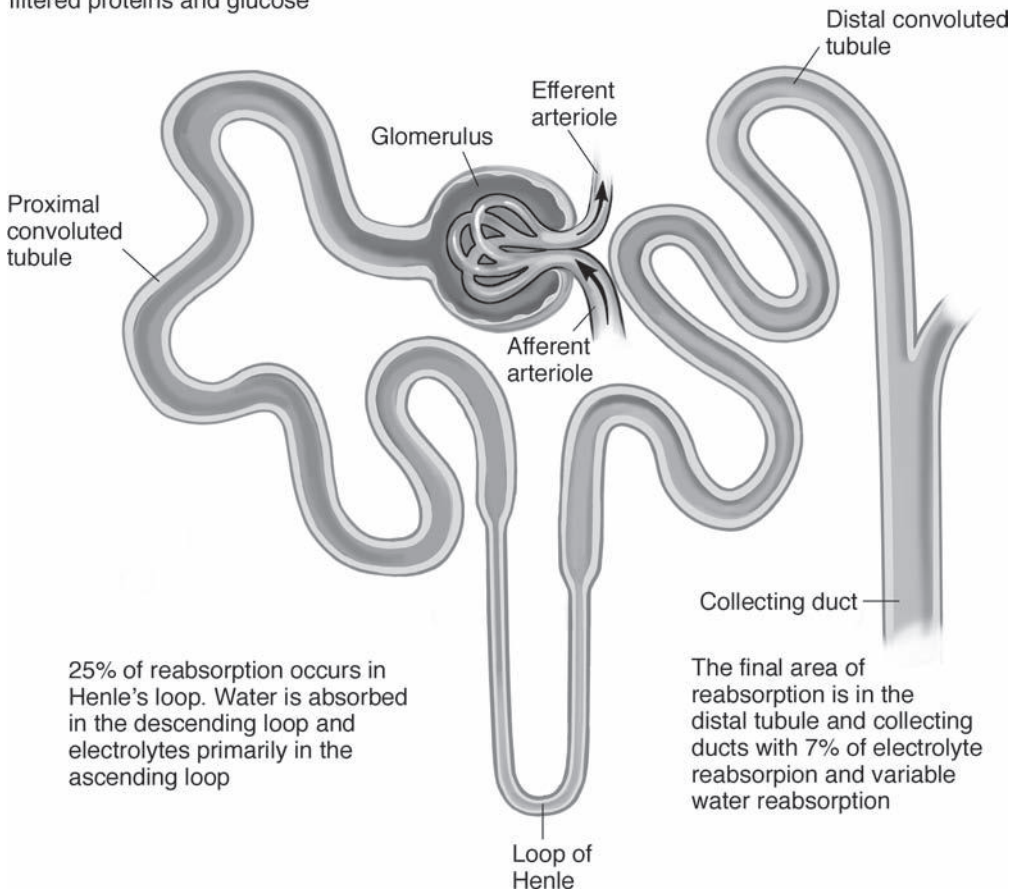

Figure 97.1. Electrolyte and water reabsorption at various locations along the nephron.

flow and relative hypoxia with a high percentage of O₂ extraction ratio, and is vulnerable to ischemic injury from hypoperfusion. The filtration fraction (GFR/RPF) measures the efficacy of reabsorption. Sites of reabsorption and/or secretion of various substances are summarized in [Table 97.1](#).

Table 97.1. Reabsorption/secretion of various substances in the renal tubule

Substance	Proximal tubule	Loop of Henle	Distal tubule	Collecting duct
Glucose	R			
Urea	R (50%)	S		R
Sodium	R (65%)	R (25%)	R	R
Chloride	R	R	R	
Potassium	R (65%)	R (20%)		S
Bicarbonate	R (80%)	R		R
Calcium	R	R		
Magnesium	R	R	R	
Phosphate	R			
Amino acids	R			

R, reabsorption; S, secretion.

Regulation of GFR, tubular reabsorption Tubuloglomerular feedback(TGF)

The juxtaglomerular apparatus (JGA) is composed of the macula densa of the thick ascending limb (TAL), the extraglomerular mesangial cells, and the granular cells of the afferent and efferent arterioles, which produce renin. As the filtrate flows through the TAL, changes in flow are sensed by the JGA, triggering TGF involving a flow-dependent signal from the macula densa. Increased “distal delivery” results in afferent constriction and decreased GFR, whereas decreased filtrate flow in the TAL increases both RBF and GFR. The Na⁺/K⁺/2Cl⁻ cotransporter in the luminal membrane of the macula densa senses changes in luminal electrolyte concentrations (dependent on Na⁺ and Cl⁻ concentration and flow) and initiates TGF. The precise mechanism that then controls this translation of luminal signal into regulation of afferent and efferent arteriolar constriction has yet to be clearly elucidated. Thromboxane, nitric oxide, and angiotensin II have all been identified as possible effectors, though recent studies suggest that adenosine and

Figure 97.2. Regulation of GFR and sodium and water reabsorption.

possibly ATP may be the primary mediators. Only oscillatory blood pressure signals evoke a regulatory response. Nonpulsatile flow such as that on cardiopulmonary bypass or on ECMO tends to decrease RBF and GFR and increase renin production via TGF.

Renin–angiotensin II

Renin is released from smooth muscle cells in the afferent and efferent arterioles, stimulated by hypotension at afferent arteriolar baroreceptors, increased sympathetic stimulation, and decreased NaCl delivery to the macula densa (Fig. 97.2). Renin catalyzes the conversion of angiotensinogen to angiotensin I for subsequent conversion to angiotensin II. Angiotensin II, a potent arteriolar vasoconstrictor, stimulates (1) aldosterone secretion by the adrenal cortex and (2) ADH secretion and thirst, and enhances NaCl reabsorption by the proximal tubule. Sympathetic stimulation and catecholamine release (e.g., following hemorrhage) stimulates reabsorption of NaCl and water throughout the nephron. The α_1 -adrenoreceptors are located primarily on the afferent arteriole, and their activation results in afferent constriction and stimulation of granular cells to release renin.

Measures of renal function

Plasma creatinine is often used as a measure of renal function (Table 97.2). The serum creatinine concentration is dependent on production (dependent on lean body mass and, therefore, relatively constant from day to day) and its elimination by the kidney. Creatinine is also secreted, to a small extent, in the proximal tubule, so this tends to overestimate the GFR. In most clinical situations, however, creatinine clearance and serum creatinine concentration provide a relatively adequate measure of GFR and overall renal function, respectively. A decrease in GFR

Table 97.2. Common parameters to measure renal function

$$\text{Creatinine clearance} = \frac{C_u \times \text{urine flow rate}}{C_p} \quad (\text{Normal} = 110 - 150 \text{ ml/min})$$

$$\text{RPF} = \text{Clearance of PAH} = \frac{\text{PAH}_u \times \text{urine flow rate}}{\text{PAH}_p}$$

$$\text{RBF} = \frac{\text{RPF}}{1 - \text{hematocrit}}$$

C_u , urine creatinine concentration; C_p , plasma creatinine concentration; PAH_u , para-aminohippurate urine concentration; PAH_p , para-aminohippurate plasma concentration.

may be the first and only sign of renal dysfunction. Because of renal adaptation, a 50% loss of nephrons will reduce GFR by only approximately 20% to 30%. This decrease in GFR from 125 to 100 ml/min results in an increase in plasma creatinine from 1 to approximately 1.2 mg/dl. This change in creatinine appears to be minor, but reflects a loss of a quarter of GFR and a large percentage loss of nephrons. Contrast this to an increase in plasma creatinine from 1.5 to 2 mg/dl, which correlates to only a 15 ml/min decrease in GFR. If a more precise measure is required, the GFR can be quantified by measuring inulin clearance; inulin is administered by continuous infusion, freely filtered at the glomerulus (neither reabsorbed nor secreted), then its concentration in the urine is measured. This procedure is rarely performed as it is time consuming and expensive, so clinically, nuclear medicine techniques such as iohexol clearance are more practical.

Effective renal plasma flow (RPF) is calculated by measuring para-aminohippurate (PAH) clearance, which is essentially fully cleared (by filtration and secretion) in one passage through the tubules (receiving the plasma flow). RBF is calculated as $RPF / 1 - \text{hematocrit}$. Fractional excretion is the amount of a substance that is excreted from the total that is filtered. A fractional excretion greater than 1.0 indicates net tubular secretion, whereas that less than 1.0 indicates net tubular reabsorption.

Blood urea nitrogen (BUN) is elevated not only in kidney disease but also in dehydration, in gastrointestinal bleeding, and with a high protein diet. Normal BUN levels are 10 to 20 mg/dl, and a normal serum creatinine/BUN ratio is 1:20.

Anesthetic care for urologic procedures obligates attention to unique considerations superimposed on basic perioperative patient management. In a broad sense, the anesthesia care provider must have a thorough understanding of (1) the neuroanatomy (Fig. 98.1) subserving pain sensation to the urinary tract; (2) the major vascular structures in association with, or in close proximity to, the renal–urinary axis; (3) renal function and perioperative renal protection; and (4) an appreciation for the medical comorbidities that may be related to or independent of the specific urologic surgical intervention. Because regional anesthesia is often employed during urologic surgery, the anesthesiologist must bear in mind the spinal levels that conduct nociceptive input from the urinary tract (Table 98.1).

Transurethral endoscopic procedures

Diagnostic and therapeutic procedures

Cystoscopy is the most commonly performed urologic procedure. Cystourethroscopy is used to examine and treat lower urinary tract disease involving the urethra, prostate gland, and bladder. Ureteroscopy is used to evaluate the upper urinary tract, including the ureter, renal pelvis, and kidneys. These procedures may be classified as diagnostic when performed for biopsies or radiographic evaluation of the urinary tract and renal collecting system. As such, they are often simple and brief in duration. They involve minimal surgical stimulation, making them amenable to conscious sedation or local anesthetic techniques. More complex endourologic procedures are often therapeutic, involving tumor resection, ureteral dilatation, stenting, or stone extraction. These techniques are used to diagnose and treat many conditions including hematuria, recurrent urinary tract infections, prostatic hyperplasia, nephrolithiasis, trauma, obstruction, and cancer, often necessitating general or regional anesthesia.

Anesthetic technique

The anticipated extent of surgical stimulation, length of procedure, patient comorbidities, and surgeon and patient preference influence the choice of anesthetic management.

General anesthesia

Laryngeal mask airways may be used safely as most healthy patients are able to spontaneously ventilate in the lithotomy and Trendelenburg positions. Alternatively, general endotracheal anesthesia may be indicated for patients at risk for aspiration or for those having procedures of longer duration (>2 h) or procedures requiring muscle relaxation.

Regional anesthesia

If a central neuraxial anesthetic is used, a T6 or a T10 level is necessary for upper tract and lower tract instrumentation, respectively. Both spinal and continuous epidural techniques may be used, although considerable majorities of procedures end well within the finite duration of a single-shot spinal anesthetic.

Figure 98.1. Anatomy of the urinary tract.

Table 98.1. Pain conduction in the genitourinary system

Organ	Sympathetic	Parasympathetic	Spinal levels of nociception
Kidney	T4–L1	Vagus nerve	T10–L1
Ureter	T10–L2	S2–S4	T10–L2
Bladder	T11–L2	S2–S4	T11–L2 (dome), S2–S4 (neck)
Prostate	T11–L2	S2–S4	T11–L2, S2–S4
Penis and urethra	L1 & L2	S2–S4	S2–S4
Scrotum (cutaneous)	Not significant for nociception	Not significant for nociception	S2–S4
Testicles	T10–L2	Not significant for nociception	T10–L1

Conscious sedation

This method may be used for certain patients undergoing short procedures, mainly simple cystourethroscopies, depending on surgeon and patient preference.

Local anesthesia

Some minor cystoscopic procedures may be performed using local anesthetic lubricant jelly, which is tolerated particularly well in female patients, owing to the comparatively shorter length of their urethra.

Anesthetic considerations

Lithotomy position

Elevation and abduction of the lower extremities is associated with (1) a decrease in functional residual capacity, (2) an acute increase in venous return, (3) an increase in mean arterial blood pressure without a major change in cardiac output, and (4) the possibility of neuropathies or neuropraxias. The common peroneal nerve is particularly at risk and when injured manifests as foot drop and sensory deficits over the dorsum of the foot. Additionally, both spinal lidocaine (as well as other local anesthetics) and the lithotomy position are observed risk factors for the development of transient neurologic symptoms (TNS). Of note, rapidly lowering the legs at the end of the procedure acutely decreases venous return, resulting in hypotension.

Obturator reflex

Stimulation of the obturator nerve by electrocautery current conducted through the lateral bladder wall may result in abrupt external rotation and adduction of the thigh. An important consideration of using a regional anesthetic technique is that it does not abolish this reflex. The obturator reflex can be reliably blocked by using either nondepolarizing neuromuscular blockers at levels that suppress the twitch response during general anesthesia or an obturator nerve block.

Autonomic hyperreflexia

Individuals who have sustained a prior spinal cord injury characterize a patient population that frequently requires endourologic procedures for the treatment of neurogenic bladder dysfunction, recurrent urinary tract infections, and complications of long-term indwelling urinary catheters. This unique patient demographic is at risk for the development of autonomic hyperreflexia (AH; especially injuries at T6 and above), especially with higher thoracic spinal cord injury. The severe hypertension, bradycardia, and arrhythmias that typify AH are often elicited by mild interventions, such as the mere insertion of a cystoscope. AH can be prevented with general or regional anesthesia and, in the event of its occurrence, treated with intravenous (IV) antihypertensive agents.

Transurethral resection of the prostate

Transurethral prostate resections are primarily indicated for symptomatic benign prostatic hyperplasia (BPH). A resectoscope (a modified cystoscope with a cutting and coagulating metal loop) or a cystoscope with a laser fiber is inserted through the penis into the prostatic urethra. The substance of the prostate gland is then dissected incrementally with the resectoscope or green light laser, and the removal of resected tissue from the surgical field is facilitated through continuous irrigation. As resection proceeds, especially with the resectoscope, prostatic venous sinuses are opened and variable amounts of irrigation fluid can be absorbed into circulation. Several factors influence the degree of systemic absorption of the irrigation fluid (Table 98.2). The procedure ends with irrigation of the bladder to remove residual prostatic debris and placement of an indwelling urinary catheter. The newer surgical techniques employing laser resection and laser vaporization of the prostate have greatly diminished the complications associated with classic resectoscope TURP (transurethral resection of the prostate) procedures.

Anesthetic technique

Regional anesthesia (specifically spinal anesthesia) has been classically advocated as the anesthetic technique of choice for resectoscope TURP. If spinal or epidural anesthesia is used, a T10 dermatome anesthetic level is needed to block the pain from bladder distention by the irrigating fluid. The early mental status changes that result from the progression of TURP syndrome (see next section, Complications of TURP) can be detected promptly with this approach. Despite this advantage,

Table 98.2. Factors influencing the amount of irrigation fluid absorbed during TURP

Duration of resection (20 ml of fluid are absorbed per minute of resection time on average)
Number and size of venous sinuses breached
Prostatic venous pressure
Hydrostatic pressure (height of irrigation fluid relative to patient)

to date no difference in perioperative morbidity and mortality has been shown when comparing regional versus general anesthesia for transurethral prostate resection. Furthermore, the hemostatic proficiency of newer green light laser TURP techniques has increased considerably and has diminished the historic superiority of spinal anesthesia.

Complications of TURP

The breach of prostatic venous sinuses and subsequent intravasation of irrigation solution account for the majority of potential complications of TURP (Table 98.3). In addition, bleeding, mechanical perforation, and bacteremia may also occur. Initial management includes notifying the surgeon and quickly ending the procedure; supporting the patient's airway, breathing, and circulation; measuring serum electrolytes; and obtaining (1) a measurement of arterial blood gas and (2) a 12-lead electrocardiogram (ECG).

Complications that arise from fluid absorption are related to the volume, osmolarity, intrinsic toxicity, and temperature of the irrigation solution used. As such, circulatory overload, hypo-osmolar hyponatremia, glycine and/or ammonia toxicity, hyperglycemia, and/or hypothermia may occur. The term *TURP syndrome* refers to the collective symptoms of volume overload, hyponatremia, and cerebral edema.

All currently available irrigation solutions used to preserve visibility of the surgical field are somewhat hypo-osmolar. Distilled water offers excellent visibility with an osmolality of 0 mOsm/L, but significant absorption can cause severe hemolysis, hemoglobinuria, and hyponatremia. Conversely, crystalloid solutions, such as 0.9 normal saline and balanced salt solutions (lactated Ringer's) are iso-osmolar and cause little (if any) dilutional, hemolytic, or toxic effects when absorbed. The presence of dissociated sodium and chloride ions, however, disperse electric current and render electrocautery ineffective for TURP. Table 98.4 outlines the properties of irrigation solutions currently in use.

Lithotripsy

Urinary calculi in the bladder and lower ureters are usually treated with cystourethroscopy, stone extraction, stenting, and intracorporeal laser lithotripsy (i.e., holmium:yttrium, aluminum, and garnet [Ho:YAG] laser). Stones in the upper two-thirds of ureters or kidneys may be treated with extracorporeal shock wave lithotripsy (ESWL) or percutaneous nephrolithotomy.

Anesthesia technique

1. *Monitored anesthesia care* – Usually is adequate for newer lithotripters, because they cause less discomfort. A variety of techniques are acceptable, including propofol infusion with opioid supplementation.
2. *Regional anesthesia* – Continuous epidural and spinal anesthesia were commonly employed for the

first-generation lithotripters using water immersion, as they were associated with high intensities of pain. Regional anesthetic techniques for this procedure require a sensory level of T6.

3. *General anesthesia* – Allows for control of diaphragmatic excursion, as spontaneous ventilation moves the stone in and out of the shock waves focus.

Anesthetic considerations

ESWL relies on high energy, repetitive sound waves focused on renal calculi resulting in stone fragmentation. Tissue destruction can occur if the shock waves are focused at air-tissue interfaces (i.e., lung and gastrointestinal tract). The patient is positioned such that the lung and intestines are out of range from the shock wave focus. If safe positioning proves unfeasible, it is a contraindication to the procedure (Table 98.5). Bruising and ecchymosis of the skin also may occur during ESWL. Rarely, a large perinephric hematoma may develop.

Patients with a history of dysrhythmias and those with pacemakers or internal cardiac defibrillators may be at risk for developing arrhythmias induced by shock waves. Synchronization of the shock waves to approximately 20 ms after the R wave from the ECG, corresponding to the ventricular refractory period, decreases the incidence of arrhythmias during ESWL.

The number of shocks determines the length of the procedure and, in conjunction with the patient's heart rate, predicts the time remaining for the procedure. Adequate IV hydration with occasional diuretic supplementation may aid passage of stone fragments.

Urologic laser surgery

Laser surgery is effective in treating many urologic problems, including condyloma acuminatum, ureteral strictures, interstitial cystitis, BPH, ureteral calculi, and superficial carcinoma of the penis, ureter, bladder, and renal pelvis. A description of the various types of lasers used in urologic procedures is provided in Table 98.6. The application of operative lasers mandates the use of safety goggles and vigilance against the potential for inadvertent thermal injury to the patient and all operating room personnel.

Urologic oncology

Most major, open surgical procedures in urology are performed as a treatment modality for malignancies related to the prostate, bladder, or kidney.

Prostatectomy

Radical prostatectomy has become a common procedure owing to the high prevalence of prostate cancer and improved surgical techniques. The entire prostate gland, bladder neck, ampullae of the vas deferens, and seminal vesicles are removed, after which the bladder is anastomosed to the membranous urethra with an indwelling urinary catheter in place to maintain patency

Table 98.3. Complications of TURP

Complication	Mechanism	Manifestations	Management
Circulatory overload	Excessive intravasation of irrigating solution	Hypertension with compensatory bradycardia. If severe enough to cause LV dysfunction, may manifest as hypotension, dyspnea, pulmonary edema, and elevated PCWP.	Fluid restriction and loop diuretics (furosemide); consider halting the procedure as soon as is feasible. Severe cardiorespiratory compromise may warrant controlled mechanical ventilation and inotropic support.
Hypo-osmolar hyponatremia	Dilution of serum Na ⁺ concentration and osmolality leading to cerebral edema	CNS effects in order of increasing severity: restlessness, agitation, confusion, seizure, and coma. Cardiovascular effects manifest at Na ⁺ levels < 120 mEq/L and include hypotension, wide QRS, and dysrhythmias.	Mild cases (Na ⁺ < 120 mEq/L) require fluid restriction and loop diuretics (furosemide). Severe cases (Na ⁺ < 120 mEq/L) may require controlled mechanical ventilation, inotropic support, and 3% hypertonic saline infusion with serial evaluation of Na ⁺ , although rapid correction of Na ⁺ (> 100 ml/h of 3% NS) may cause central pontine myelinolysis.
Glycine toxicity	Glycine may declare its effects as a central inhibitory neurotransmitter when excessive plasma levels are achieved.	Primarily CNS toxicity with transient visual disturbance and blindness	Visual disturbance after TURP mandates immediate attention and an ophthalmology consult. In addition, other causes of perioperative visual loss must be entertained (stroke, acute glaucoma, ischemic optic neuropathy, and corneal abrasion).
Ammonia toxicity	Ammonia is the hepatic metabolite of glycine. Excessive absorption of glycine solution may result in hyperammonemia.	CNS effects causing depressed mental status, delayed awakening, and coma	Depressed mental status requires attention to oxygenation, ventilation, and hemodynamics. Secondarily, blood gas analysis, serum glucose, electrolytes, and ammonia levels should be assessed.
Hyperglycemia	Related to the use of sorbitol irrigation solution. Sorbitol is metabolized to fructose and may cause hyperglycemia, particularly in diabetic patients.	Symptoms are related to hyperglycemia and may include alteration in mental status, DKA, hyperosmolar nonketotic coma, and polyuria.	Insulin therapy guided by serial evaluation of serum glucose concentration. Intravascular volume replacement and supplemental potassium as needed.
Hypothermia	Fluid at room temperature will cause excessive heat loss through continuous irrigation and absorption.	Decreased core body temperature (~1°C/h of surgery), shivering	Prevention is key, and warmed irrigation fluid should be used. Forced-air warming blankets and opiates help treat postoperative shivering.
Bleeding and coagulopathy	Blood loss through prostatic venous sinuses. Systemic fibrinolysis may occur with the release of tissue plasminogen activator and urokinase from the prostate gland. DIC may also occur from absorption of prostate tissue, which is rich in thromboplastin.	Persistent blood loss in surgical field or hematuria postoperatively. Anemia, tachycardia, and hypotension when severe	Serial evaluation of hematocrit, platelets, and coagulation profile. Blood product administration as warranted
Perforation	Inadvertent bladder perforation with resectoscope leading to extraperitoneal leakage of irrigation fluid, blood, and urine. Intraperitoneal leakage may also occur depending on location of bladder and/or prostate perforation.	Extraperitoneal leakage: periumbilical, inguinal, or suprapubic pain; surgeon may note irregular return of irrigation fluid. Intraperitoneal: upper abdominal pain or referred diaphragmatic irritation noted as shoulder pain, pallor, diaphoresis, nausea and/or vomiting, hypotension. Signs are reliable only with spinal anesthetic (<T9 sensory level).	Small perforations may be managed with catheter drainage. Large perforations require prompt open laparotomy for repair.
Bacteremia and sepsis	Bacteria may be introduced directly into circulation through open prostatic venous sinuses.	Fever, chills, rigors, hypotension, and tachycardia	Antibiotic therapy with broad-spectrum agents

LV, left ventricular; PCWP, pulmonary capillary wedge pressure; CNS, central nervous system; NS, normal saline; DKA, diabetic ketoacidosis; DIC, disseminated intravascular coagulation.

Table 98.4. Irrigation fluids used for TURP

Solution	Osmolality, mOsm/L	Precautions
Glycine 1.5%	220	Glycine toxicity, hyperammonemia, transient visual loss
Sorbitol 3.5%	165	Hyperglycemia, infection
Mannitol 5%	275	Acute circulatory volume expansion, osmotic diuresis
Cytal (sorbitol/mannitol mixture)	178	Same as for sorbitol and mannitol

of the urinary tract. The commonly used retropubic approach involves either a low midline or Pfannenstiel incision with the patient in the supine position. This approach carries the risk of moderate blood loss as the dissection enters the territory of the dorsal venous complex of the penis as well as branches of the hypogastric veins.

Laparoscopic radical prostatectomy offers all the attendant advantages of minimally invasive surgery weighed against the risks of peritoneal insufflation, although no unequivocal difference in mortality has been demonstrated when compared to open prostatectomy. Skilled urologists have gained even greater surgical precision with robot-assisted laparoscopic prostatectomy. This procedure appears to have a lower incidence of ileus and blood transfusion than does the standard retropubic approach.

Anesthetic technique

Open procedures for prostate resection are amenable to both general and regional anesthesia. Although no difference in mortality has been demonstrated between these techniques, employing a central neuraxial block as the primary anesthetic may offer a reduction in blood loss, lower incidence of deep vein thrombosis (DVT), and improved postoperative analgesia, in addition to a potential risk reduction for tumor recurrence. A T8 sensory level should be sought if a spinal or epidural anesthetic is chosen. Lower abdominal operations such as the retropubic approach to prostatectomy may result in as much as a 30% decrement of functional residual capacity (FRC) postoperatively after general anesthesia. Regional techniques may help attenuate this expected degree of pulmonary dysfunction. General anesthesia, however, offers the advantages of predictable

Table 98.5. Contraindications of ESWL

Absolute	Relative
Distal obstruction to the renal calculi	Large calcified aortic or renal artery aneurysm
Bleeding disorder or anticoagulation	Untreated urinary tract infection
Pregnancy	Pacemaker or automated implantable cardioverter-defibrillator (AICD) implant
	Morbid obesity

anesthetic duration and efficient control of oxygenation and ventilation, as well as a lack of visible responses to hypotension associated with rapid blood loss.

Laparoscopic and robotic prostatectomy is best conducted using general anesthesia with endotracheal intubation. The expected physiologic effects of peritoneal insufflation of carbon dioxide (CO₂) mandate airway control and management of ventilation and oxygenation. These effects, in particular decreased pulmonary compliance, are exaggerated in steep Trendelenburg position. Robot-assisted laparoscopic prostatectomy also bears the disadvantage of limited patient access and long surgical duration. Securing all patient monitors, having adequate IV access, and paying strict attention to patient padding and positioning are essential prior to commencing with robot-assisted surgery. Currently, it is believed that laparoscopic approaches to prostatectomy incur less blood loss, provide a faster resumption of bowel function, and expedite hospital discharge.

Orchiectomy

Testicular cancer is the most common malignancy in men between 15 and 34 years of age. Radical orchiectomy is performed for both definitive diagnosis and as the initial step of treatment. Subsequent treatment depends on the histology and stage of the tumor. Radical orchiectomy can be performed with a regional or general anesthetic. It is important to gain at least a T6 level to block sympathetic innervation. Patients with testicular cancer who receive bleomycin chemotherapy are at risk for developing progressive pulmonary fibrosis. These patients may be at increased risk for postoperative respiratory failure with general anesthetic if they are exposed to high concentrations of inspired oxygen or if an excessive amount of IV fluid is administered.

Nephrectomy

Renal cell carcinoma has a peak incidence between the ages of 50 and 60 years with a 2:1 predilection for men. The tumor is frequently associated with paraneoplastic syndromes including hypercalcemia, erythrocytosis, hepatic dysfunction, and hypertension. Surgical removal is the only effective treatment. In approximately 5% of these patients, the tumor invades the inferior vena cava (IVC). Depending on the extent of tumor invasion into the central circulation, cardiopulmonary bypass with deep hypothermic circulatory arrest may be required for complete excision.

The kidney is usually approached via a lumbar flank, transabdominal midline, or thoracoabdominal incision. A radical nephrectomy includes removal of the kidney, surrounding fascia, adrenal gland, and upper ureter. Consequently, the patient should have adequate volume repletion to maintain perfusion to the remaining kidney. Open nephrectomies are usually performed in the “kidney rest position” or lateral flexed position. The patient is placed in lateral decubitus position with the operating table extended for maximal separation between the iliac crest and the costal margin. The kidney rest is then elevated to

Table 98.6. Lasers used in urologic procedures

CO₂ laser	Intense heat with vaporization, minimal tissue penetration; unable to penetrate water	Limited to cutaneous lesions of external genitalia
Argon laser	Poorly absorbed by water, but selectively absorbed by Hgb and melanin	Coagulation of bleeding in the bladder
Pulsed dye laser	Generates a pulsed output	Useful for destroying ureteral calculi
Nd-YAG laser	Deep tissue penetration via protein denaturation with minimal vaporization; can be used in water or urine	Excellent for lesions of the penis, urethra, bladder, ureters, and kidneys
KTP-532 laser	Frequency-doubled Nd-YAG laser, does not penetrate tissue as deeply	Better cutting effect for lesions

Hgb, hemoglobin; Nd-YAG, neodymium-doped yttrium aluminum garnet.

raise the nondependent iliac crest for improved surgical exposure. The physiologic effects of patient positioning for radical nephrectomy are outlined in [Table 98.7](#).

A preoperative ventilation–perfusion (V/Q) scan can detect preexisting embolization of the thrombus. A level I thrombus extends into the IVC below the liver. A level II thrombus extends into the IVC, to the liver, but below the diaphragm. Last, a level III thrombus extends into IVC, above the diaphragm, and into the right atrium. A level II or III thrombus suggests the potential for a massive blood transfusion (usually 10–15 units, possibly exceeding 50 units of packed red blood cells [PRBCs]). Therefore, venous access should be obtained accordingly. Central venous cannulation should proceed with caution, however, as the potential to dislodge and embolize tumor thrombus exists. A level III thrombus is a contraindication for flotation of a pulmonary artery catheter. Cardiopulmonary bypass may be employed when the tumor occupies more than 40% of the right atrium.

Anesthetic technique

General endotracheal anesthesia is the customary anesthetic choice for this procedure. A midthoracic epidural (T7–9) may be used adjunctively for postoperative pain control. Extensive fluid shifts and blood loss are to be expected as a result of wide surgical exposure and the manipulation of major vascular structures. Therefore, abundant venous access and direct arterial monitoring are recommended. The patient's baseline hematocrit and renal function should be determined preoperatively. Even in the absence of elevations in blood urea nitrogen (BUN) and creatinine concentration, anesthetic drug doses may need to be adjusted. These dose adjustments address the fact that the

Table 98.7. Physiologic changes associated with lateral flexed position

Decreased FRC in the dependent lung
 V/Q mismatching as a result of increased blood flow to the dependent lung with greater ventilation to the nondependent lung
 Increased dead space ventilation proportional to the duration of procedure
 Elevation of kidney rest may decrease venous return by compressing IVC
 Inadvertent entry into the pleural space, a potential for a pneumothorax
 Venous air embolism may occur through venous structures located above the level of the heart

unaffected kidney has yet to initiate compensatory responses to the loss of up to 50% of functional renal tissue.

Cystectomy

Bladder cancer occurs in patients with an average age of 65 years, and it is three times more common in men than in women. Transitional cell carcinoma of the bladder is the second most common cancer of the genitourinary tract. The standard of care for bladder cancer with muscular invasion is radical cystectomy.

Anesthetic considerations

Radical cystectomy is usually performed with a midline incision extending from the symphysis pubis to the xiphoid process. All the anterior pelvic organs, including the bladder, prostate, seminal vesicles, and proximal urethra, are removed in men. In women, the bladder, urethra, uterus, cervix, ovaries, and anterior vaginal wall may also be removed. At the end of the procedure a urinary diversion, which involves implanting the ureters into a segment of bowel, is performed. The bowel is left in situ (ureterosigmoidostomy) or attached to a cutaneous stoma or urethra. The isolated bowel can function as a conduit (ileal conduit), and these channels can be constructed from jejunum, ileum, or colon. The bowel may alternatively be reconstructed to form a reservoir (neobladder). Reservoirs may include ureterosigmoidostomy, small bowel (T-pouch), or large bowel (Indian pouch).

Anesthetic technique

This surgical procedure may be associated with large intraoperative blood loss and fluid shifts, implicating the need for large-bore IV access, and possibly a central venous catheter as well as an arterial line. A minimum time of 4 to 6 hours is usually estimated for this procedure. General endotracheal anesthesia with muscle relaxation is the mainstay of anesthetic management, with optional midthoracic epidural anesthesia for postoperative analgesia. Neuroaxial anesthesia may potentially produce hyperactive bowel (from unopposed parasympathetic activity), making the construction of a urinary reservoir technically difficult for the surgeon. This problem may be minimized

through the use of glucagon, papaverine, or an anticholinergic (glycopyrrolate). Reduction in urine output from prolonged contact with bowel mucosa may result in hyponatremia, hypochloremia, hyperkalemia, and metabolic acidosis in jejunal conduits. Hyperchloremic metabolic acidosis may occur in colonic and ileal conduits. Ureteral stents, adequate volume replacement, and induced increases in urine output may help alleviate this issue postoperatively.

Kidney and pancreas transplantation

Thomas Edrich and Sayeed Malek

Kidney transplantation

End-stage renal disease (ESRD) requiring hemodialysis (HD) is caused most frequently by diabetes mellitus, glomerulonephritis, polycystic kidney disease, and arterial hypertension. The first attempt at kidney transplantation in humans in 1933 by a Ukrainian surgeon, Voronoy, failed due to organ rejection. Success was achieved in 1954 when the immunologic barrier was circumvented by transplanting between identical twins, at the Peter Bent Brigham Hospital in Boston. It was the introduction of effective immunosuppressants, such as azathioprine, glucocorticoids, antilymphocyte agents, and cyclosporine, however, that improved patient outcome. In comparison to HD, kidney transplantation is now associated with superior quality of life and better patient survival. It is also more cost-effective.

Prospective kidney recipients undergo rigorous preoperative cardiac testing to exclude significant treatable coronary artery disease, because cardiovascular disease is the leading cause of death for adult kidney transplant recipients. Revascularization may be preferable before kidney transplantation because cardiopulmonary bypass would be detrimental to a newly transplanted kidney.

The number of kidney transplants has increased steadily over the past two decades. In 2004, the number of kidney transplants from deceased donors in the United States exceeded 10,000 for the first time. However, both the wait list and wait time have increased as well. According to the United Network for Organ Sharing (UNOS) data, there are more than 72,000 patients on the deceased donor kidney transplant waiting list in the United States.

Preoperative preparations

Patients may arrive for a scheduled transplant (i.e., living related or unrelated donor), or they may be called in on a moment's notice when an organ from a deceased donor becomes available. Close communication with the transplant surgeon is paramount to coordinate the timing as well as preoperative medication.

The current practice at the author's institution includes the preoperative initiation of maintenance immunosuppression using mycophenolate mofetil, which inhibits B and T lymphocytes. One dose is given the night before, and one the morning

before surgery. For unanticipated transplants, a single preoperative dose is administered.

Establish which immunosuppressant the surgeon will require intraoperatively: for patients who will receive intraoperative thymoglobulin (rabbit antithymocyte globulin), one dose of acetaminophen should be administered as prophylaxis for commonly occurring fever, chills, headache, and malaise. If an alternative T-lymphocyte antagonist such as basiliximab will be used intraoperatively, then no acetaminophen will be needed.

Intraoperative considerations

Induction of anesthesia should be timed sufficiently early to allow for the possibility of difficult central venous access. This will require tight communication with the surgical team harvesting the organ or with the team transporting the organ from the outside hospital.

Induction of anesthesia should involve medications that do not depend on renal function for their clearance and should take the common comorbidities of renal patients into account, as discussed earlier in [Chapter 7](#). After anxietyolysis with midazolam, patients who have not fasted or may have delayed gastric emptying due to diabetic or uremic gastropathy receive gastric acid neutralization with citric acid/sodium citrate followed by rapid-sequence induction (RSI) of anesthesia. Safe medications typically include thiopental, propofol, fentanyl, and hydromorphone. Morphine and meperidine should be avoided, as the active metabolites morphine 3- and 6-glucuronide and normeperidine are dependent on renal excretion and can cause over-narcotization (morphine) and seizures (meperidine). Succinylcholine is administered if the serum potassium level is not elevated and if there are no contraindications, such as concurrent neuromuscular disorders, history of burns, or malignant hyperthermia. Rocuronium can be an alternative to succinylcholine if RSI is required. Otherwise, an awake fiber-optic intubation may be advisable.

Central venous access is used for both intraoperative and postoperative assessment of volume status in an attempt to maximize cardiac output to the new kidney. Patients with ESRD on HD often have had previous central lines, making intravascular thrombi and strictures more likely. Ultrasound may clarify the

vascular anatomy and facilitate central venous catheter placement into the internal jugular vein. Occasionally, patients may have an indwelling central line in place already – such lines should be accessed with sterile precautions because their use represents a considerable risk of infection. Also, any heparin-containing locking solution must be withdrawn (withdraw > 5 ml) before use to avoid systemic anticoagulation. An arterial line is not required routinely unless warranted by comorbidities.

Immunosuppressants, such as methylprednisolone sodium succinate and the T-lymphocyte antagonist basiliximab or thymoglobulin, are administered after induction but before the transplanted kidney is reperfused. Diphenhydramine can be given before thymoglobulin to attenuate side effects.

Implantation of the kidney

The kidney is typically placed in a heterotopic position while leaving the native kidneys in place as shown in Fig. 99.1. The right iliac fossa is chosen most frequently because of the more superficial location of the iliac vein on this side. After vascular anastomosis of the renal artery to the external or internal iliac artery and the renal vein to the external iliac vein, the donor ureter is anastomosed to the bladder. A triple-lumen Foley urinary catheter can be used to fill the bladder during the uretero-neocystostomy.

Reperfusion of the new kidney

Before the cross-clamp is released, the intravascular filling and cardiac output should be optimized. Our practice is to

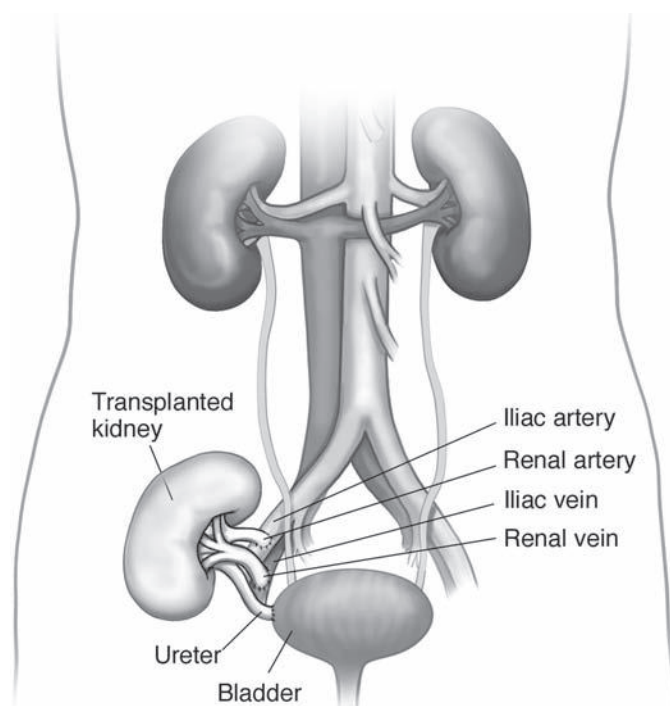

Figure 99.1. Kidney graft in the right iliac fossa.

administer 4 to 8 liters of crystalloid in the prereperfusion period, attaining a central venous pressure (CVP) of 15 and a systolic blood pressure greater than 140 mm Hg or mean arterial pressure (MAP) greater than 70 mm Hg while avoiding all vaso-pressor medications. If necessary, a low-dose dopamine infusion (i.e., <5 µg/kg/min) is started. Dopamine is advantageous compared to other inotropes because it improves renal perfusion while minimizing vasoconstriction and graft ischemia.

Postoperative course

Patients are usually extubated and recover in the postanesthesia recovery unit at our institution. Close monitoring of urinary output is recommended. Maintenance of an appropriate intravascular volume optimizes renal function and is facilitated by monitoring the CVP. It is generally wise to avoid the use of medications that may alter the prostaglandin-mediated vasoregulation in the new kidney (these medications include ketorolac, celecoxib, and nonsteroidal anti-inflammatory drugs). Epidural anesthesia is also avoided to minimize risk of hypotension and because the incision is relatively small.

Pancreas and kidney–pancreas transplantation

Type-1 diabetes affects more than 2 million people in the United States with approximately 30,000 new cases diagnosed each year. It is the sixth leading cause of death and the leading cause of kidney failure and blindness (in adults aged 20–74 years). The total estimated cost of diabetes in the United States for 2002 was \$132 billion, with \$92 billion in direct medical costs.

Simultaneous pancreas–kidney (SPK) transplants from deceased donors are an option for diabetic patients with ESRD, enabling the patient to become insulin- and dialysis-free. Acute rejection rates are lower than those in pancreas transplantation alone (PTA). Other options include pancreas transplantation after living-donor kidney transplantation (PAK), simultaneous deceased-donor pancreas and living-donor kidney transplant (SPLK), and living-donor simultaneous (partial-) pancreas–kidney transplant.

Pancreas transplantation alone is indicated in nonuremic patients in whom complications, such as ketoacidosis or hypoglycemic episodes, continue despite intensive insulin therapy. Here, the risks of transplantation and subsequent chronic immunosuppression may be justified to achieve insulin independence.

Anesthetic management of patients receiving pancreas transplants alone, after, or simultaneously with a kidney transplant is similar to that of patients receiving kidney transplantation, with a few differences as detailed below.

Preoperative initiation of immunosuppression using mycophenolate mofetil is followed by intraoperative immunosuppression with methylprednisolone and thymoglobulin given after induction of anesthesia but before implantation of the

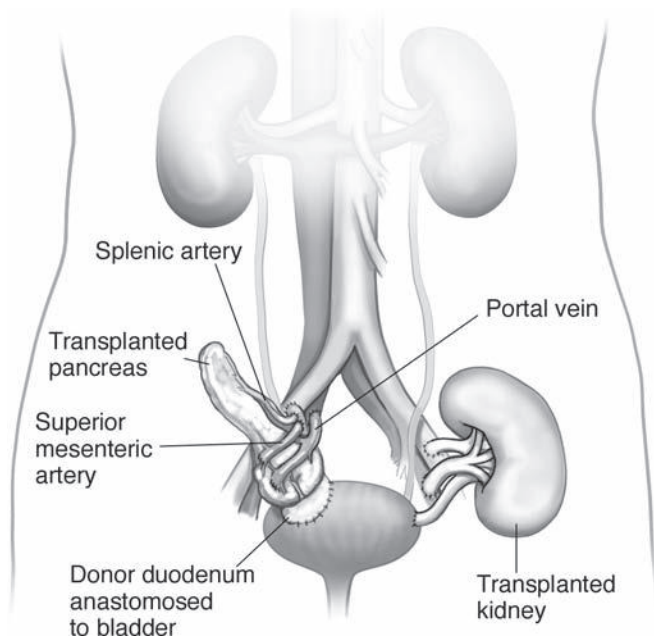

Figure 99.2. Combined kidney and pancreas transplantation. Pancreatic secretions are drained from a short segment of donor duodenum into the jejunum.

pancreas and/or kidney (premedicate with acetaminophen and diphenhydramine). In addition, all medications, such as perioperative antibiotics and dopamine, should be available in a dextrose-free form, and any insulin pumps should be discontinued. It is our practice to place both central venous line and arterial line for intraoperative and postoperative management. Baseline lipase and amylase levels should be recorded for reference for later rejection monitoring.

Implantation of the pancreas most frequently occurs into the right iliac fossa with the donor portal vein anastomosed to the recipient iliac vein. Arterial perfusion is supplied via anastomosis from the recipient iliac artery to a brief section of donor iliac artery which is, in turn, anastomosed to the donor splenic artery and donor superior mesenteric artery. As shown in Fig. 99.2 (which shows both pancreas and kidney transplants), the donor pancreas can be maintained in continuity with a section of donor duodenum which is anastomosed to the recipient's small bowel for drainage of the exocrine secretions. Alternatively, the duodenum section can be anastomosed to the recipient's bladder. An advantage of the bladder drainage is the ability to measure the exocrine function of the pancreas in the urine. A drop in urine amylase can indicate rejection and will occur before hyperglycemia occurs. Serum amylase will often increase but is less sensitive than urine amylase. Complications such as acidosis (loss of alkaline pancreas secretions), infection, urethritis, and hematuria are frequent. Drainage into the small bowel (as shown in Fig. 99.2) has fewer long-term complications and is performed more frequently in SPK. In these patients, rejection almost always affects both organs, so serum creatinine is used as an indicator for both kidney and pancreas rejection.

A simultaneously transplanted kidney is typically positioned in the opposite iliac fossa and anastomosed as described earlier in this chapter.

Reperfusion of the new pancreas can cause hypotension from diffuse bleeding from the graft as well as from vasodilation from mediators in the pancreas. It is our practice to maintain a MAP of 70 mm Hg or greater when the cross clamp is removed using crystalloids and blood as needed. In contrast to the kidney transplants, in pancreas transplants overhydration is generally avoided so as to reduce the risk of pancreas edema. Therefore, we use low-dose dopamine ($<5 \mu\text{g}/\text{kg}/\text{min}$) if a CVP of 10 to 14 does not suffice to maintain a MAP of 70.

Endocrine function of the pancreas is expected to begin soon after reperfusion, and glucose levels are monitored every 30 minutes. Any glucose or insulin administration should be communicated clearly to the surgical team because it will alter the assessment of the graft. Note that epidural anesthesia is not routinely employed (1) so that risk of hypotension is minimized and (2) because of the possible perioperative use of intravenous heparin.

Anesthesia management for the living-kidney donor

Related or unrelated donors are usually healthy and currently undergo a mortality risk of 0.05%. If possible, the left kidney is explanted due to presence of a longer renal vein. A laparoscopic technique is commonly employed, thus minimizing postoperative pain. Most commonly, general anesthesia is used without a regional technique as these patients can typically be discharged from the hospital on the second postoperative day.

Anesthesia for General Surgical Procedures

Warren S. Sandberg, editor

Anesthesia for intra-abdominal surgery

Khaldoun Faris and Faraz Syed

Intra-abdominal surgery is a broad term that includes various operations within the abdominal cavity that involve the gastrointestinal (GI) system, genitourinary system, gynecologic system, and endocrine system. This chapter, however, focuses mainly on surgical procedures involving the GI tract and addresses a general approach that may be applicable to many procedures within the abdominal cavity and specific GI disorders.

General principles

Risk of aspiration

Aspiration, with its associated morbidity, is a potential risk in major abdominal surgery, whether elective (bariatric surgery, fundoplication) or emergent (acute abdomen, bowel obstruction) procedures. The incidence of pulmonary aspiration in the perioperative period is rare (<5/10,000 general anesthetic). Measures to prevent pulmonary aspiration of gastric contents are listed in [Table 100.1](#). Perioperative pulmonary aspiration prophylaxis is discussed in [Chapter 40](#). Additional considerations include the following:

- The gastroesophageal sphincter (GES) plays an important role in preventing the aspiration of gastric contents. The GES tone is altered or impaired in clinical conditions such as morbid obesity and hiatal hernia, and during anesthesia. Most anesthetics and analgesics alter the GES tone.
- Impaired gastric emptying due to obesity, bowel obstruction, or other disorders will lead to increased volume and acidity of the gastric contents.

Fluid management

Abdominal surgery may be associated with significant fluid loss as well as significant fluid shifts. These fluid changes may occur preoperatively as well as intraoperatively. Preoperative factors include bowel preparation (elective surgery) and vomiting, gastric decompression and/or drainage, sequestration of fluid, diarrhea, and bleeding (urgent surgery). Intraoperative, factors include insensible losses (traditionally assumed to amount up to 4–8 ml/kg/h for major abdominal surgery, a number that appears grossly overestimated in experimental models, which

show a modest increase from 0.5 ml/kg/h at baseline to approximately 1 ml/kg/h even with extensive surgical exposure of the gut), intraoperative bleeding, gastric drainage, and drainage of ascites. Thus, large-bore peripheral intravenous (IV) access may be necessary. Arterial and central lines may also be chosen to better manage hemodynamic changes associated with fluid shifts even though central venous pressure (CVP) and/or pulmonary capillary wedge pressure (PCWP) measurements do not predict fluid responsiveness and therefore are unable to guide the clinician in optimizing cardiac preload and tissue oxygenation.

Preoperative assessment of fluid status and careful monitoring of volume administration and fluid output during the procedure lead to better assessment of hemodynamic status and prevent complications of under- (as well as over-) resuscitation. The choice of fluid, whether crystalloid or colloid, is left to the judgment of the anesthesiologist and to the clinical condition of the patient. Frequent blood sampling to evaluate hemoglobin concentration, coagulation status, electrolytes, and

Table 100.1. Strategies to prevent pulmonary aspiration

Measure	Comments
NPO for elective surgery	8 h for solid food, 2 h for clear liquids
Decreased gastric acidity	H ₂ blockers (e.g., ranitidine 50 mg IV or famotidine 20 mg IV), Proton pump inhibitors (e.g., pantoprazole 40 mg IV or esomeprazole 20 mg IV)
Enhancement of gastric emptying	Metoclopramide: 10 mg IV 20–30 min before induction (inject over 1–2 min) Contraindicated in patients with obstruction or perforation
Nasogastric decompression	Nasogastric tube itself could impair the GES and would not assure an empty stomach
Rapid sequence induction +/- cricoid pressure	Cricoid pressure should be avoided in cases of active vomiting or if the cervical spine is unstable
Cuffed endotracheal tube	Uncuffed tube or supraglottic airway device such as laryngeal mask airway (LMA) may not prevent aspiration
Awake intubation	Awake intubation should be considered in cases of high risk of aspiration coupled with difficult airway, although topical anesthesia can ablate airway reflexes

arterial blood gases may be needed in prolonged procedures associated with significant blood loss.

Anesthetic technique

General anesthesia continues to be the mainstay of anesthetic management for major abdominal surgery. Although regional anesthesia (continuous epidural or spinal) could be the sole anesthetic in high-risk patients with significant pulmonary disease, this approach is rarely used in modern practice. Low thoracic epidurals are frequently used as adjuncts for intraoperative maintenance of anesthesia and for postoperative pain control. The use of thoracic epidural techniques as adjuncts to general anesthesia for major abdominal surgery has been shown to improve postoperative analgesia, decrease respiratory failure, and enhance ileus resolution, but not to decrease mortality. The risk of epidural hematoma and abscess, with a potential for permanent paralysis, albeit rare, should be kept in mind when deciding to place an epidural for elective abdominal surgery.

A balanced general anesthetic technique with an inhalational agent and an opioid or total IV anesthesia are both suitable anesthetic techniques for abdominal surgery. Muscle relaxation is often needed to improve surgical exposure and to facilitate abdominal closure. The use of nitrous oxide (N₂O) has been debated for years due to its ability to diffuse into gas-containing body cavities, thus theoretically distending the bowel and impairing surgical exposure. Therefore, some anesthesiologists avoid N₂O in major abdominal surgery reasoning that additional bowel distention could be harmful. Data supporting higher inspiratory oxygen concentration combined with mild hypercapnia as a means to improve outcome by reducing anastomotic leaks and wound infections should render obsolete the question as to whether to use N₂O in these cases.

Most patients undergoing abdominal surgery will be extubated successfully in the operating room (OR), but patients who require large amounts of fluid and blood products and who exhibit facial and airway edema and those with hemodynamic or respiratory instability should be kept intubated and ventilated in the intensive care unit (ICU). Extubation should be performed when the edema has resolved and hemodynamic and respiratory stability are achieved.

Intraoperative considerations

Heat loss

Abdominal surgery is associated with significant heat loss; therefore, the patient's temperature should be measured routinely. Items used to prevent hypothermia and associated complications include forced-air warming blankets and humidifiers. The intraoperative use of warming blankets can reduce convective heat loss, has been shown to improve operative outcome, and should be considered in every patient undergoing abdominal surgery. Fluid warmers should be used when large volumes of fluid are to be administered. For certain surgeries with

significant heat loss and in children, the ambient temperature of the OR should be raised.

Pulmonary complications

Significant retraction, carbon dioxide (CO₂) insufflation for laparoscopic surgery, and Trendelenburg position will elevate the diaphragm and decrease the functional residual capacity (FRC), potentially leading to hypoxia and hypoventilation. Adding positive end-expiratory pressure (PEEP) increases FRC and may help improve oxygenation and ventilation. The difficulty with ventilation may stem from the causative disorder itself. For example, high peak pressures and difficulty in maintaining adequate tidal volumes may be associated with intra-abdominal processes, such as abdominal compartment syndrome.

Unwanted diaphragmatic movement (hiccup)

Intermittent spasms of the diaphragm due to diaphragmatic irritation and visceral stimulation may be troublesome to the surgeon. They can also interfere with effective mechanical ventilation. If the diaphragmatic movements are significant and immobility is needed, the anesthesia may be deepened or an additional dose of muscle relaxant may be given.

Mesenteric traction syndrome

This syndrome involves sudden onset of tachycardia, hypotension, and flushing associated with excessive traction on the mesentery. Although the exact pathophysiology is unknown, the release of prostacyclin and possibly histamine may play a role in the etiology. Cyclooxygenase (COX) inhibitors such as IV ketorolac may be used to prevent the syndrome, although their use should be discussed with the surgeon, as their platelet-inhibiting effects may be undesirable during surgery. H₁- and H₂-antihistamines also play a role in the prevention of this syndrome.

Postoperative ileus

Ileus is a major complication of abdominal surgery. The etiology involves pain, surgical stress, electrolyte and fluid imbalance, and the use of opioids. Opioids bind to μ -opioid receptors, depressing GI motility and worsening the ileus. Therapeutic options to minimize ileus are mostly supportive and include limiting the use of parenteral opioids, using thoracic epidural analgesia, instituting early feeding and mobility, and using laparoscopic surgery. Epidural analgesia in any location sufficient to provide analgesia for abdominal surgery has a protective role against postoperative ileus by decreasing sympathetic autonomic activity. This decrease in sympathetic autonomic activity leaves parasympathetic autonomic outflow relatively unopposed. Alvimopan and methylnaltrexone, peripherally acting selective μ -opioid receptor antagonists, have been recently shown to accelerate GI tract recovery after bowel resection.

Postoperative infection

Abdominal surgery is an independent risk factor for surgical site infection (SSI). Although many factors contribute to the risk of SSI, several could be manipulated intraoperatively by the anesthesiologist. These factors include hypoxia, hypothermia, hyperglycemia, and blood transfusion. Thus, measures to minimize the likelihood of postoperative infection should be undertaken, including the use of a hyperoxic gas mixture, avoidance of hypothermia, tight glycemic control, and minimizing blood transfusion, and timely administration of appropriate antibiotics.

Specific GI disorders

Bowel surgery

Surgery of the bowel (Table 100.2) is indicated for a variety of disorders including obstruction, perforation, tumor resection, and inflammatory bowel disease. General anesthesia supplemented with a thoracic epidural is often the preferred technique. Postoperative ileus is the most common complication (approximately 7.5%). The mechanism may be multifactorial, but the choice of anesthetic seemingly does not play a role in the development of this complication.

- Bowel obstruction involving the small bowel, the large bowel, or both is associated with volume derangements secondary to severe vomiting and fluid sequestration. Patients with bowel obstruction are treated as having a full stomach, and measures to prevent aspiration should be taken as outlined previously. If time permits, fluid and electrolyte abnormalities should be corrected prior to induction of general anesthesia.
- Patients with bowel perforation may be septic and susceptible to severe hemodynamic changes upon induction. These patients must also be treated as having a full stomach, and fluid and electrolyte abnormalities must be corrected. Invasive monitoring to facilitate tight blood pressure control should be considered.
- Patients with inflammatory bowel disease are often placed on glucocorticoid therapy for flare-ups, and the need for stress dose glucocorticoids must be determined. These patients may also be severely volume depleted secondary to persistent diarrhea. Furthermore, those patients presenting with toxic megacolon may be severely septic and critically ill.

Splenectomy

Patients may undergo elective splenectomy for hematologic disorders (i.e., idiopathic thrombocytopenic purpura) or may require a splenectomy as part of a staging procedure for their malignancy. Patients with hematologic disorders may present with anemia, thrombocytopenia, and/or other coagulopathies. Patients with a prior history of malignancy may be on

Table 100.2. Anesthetic management of GI disorders

GI disorders	Anesthetic management
Bowel obstruction	Correction of fluid imbalance and electrolytes Aspiration precautions Metoclopramide is contraindicated
Bowel perforation	Correction of fluid imbalance and electrolytes if possible, but should not delay surgery Aspiration precautions Metoclopramide is contraindicated Anticipate sepsis and hemodynamic instability
Crohn's/ulcerative colitis	Correction of fluid imbalance and electrolytes Consider glucocorticoids Toxic megacolon may be present
Splenectomy for ITP and malignancies	Anticipate anemia and thrombocytopenia Consider stress dose glucocorticoids Large-bore IV access Transfusing platelets after the splenic vessels are ligated minimizes platelet sequestration
Emergent splenectomy for ruptured spleen	Anticipate multiple injuries with significant blood loss and hemodynamic instability Large-bore IV access Blood products should be available Aspiration precautions
Pancreatitis	Correction of fluid imbalance and electrolytes Anticipate SIRS and organ dysfunction
Whipple procedure for pancreatic tumor	Significant fluid loss, bleeding, hypothermia, and prolonged operative time are all possible Large-bore IV access Consider invasive monitoring Consider thoracic epidural
Carcinoid syndrome	Evaluate for cardiomyopathy Avoid drugs causing histamine release Anticipate need for fluid resuscitation May need central access for potent vasopressors Octreotide blunts much of the carcinoid response
Abdominal compartment syndrome	Large-bore IV access Invasive monitoring Vasopressors Consider an ICU ventilator Anticipate sudden hemodynamic changes following the decompression of the abdomen

ITP, idiopathic thrombocytopenic purpura; SIRS, systemic inflammatory response syndrome.

long-standing glucocorticoid therapy and may have systemic effects from their chemotherapeutic regimens.

Non-elective splenectomy may take place in patients with traumatic ruptured spleen and in those with a spontaneous rupture. These patients may have other considerations, such as difficult airway, multiple severe injuries, hemodynamic instability, and/or full stomach. Large-bore IV access is necessary, as major blood loss is possible. When considering platelet transfusion in thrombocytopenic patients, the patients should be transfused after the splenic vessels are ligated, as the platelets will otherwise be sequestered in the soon-to-be-removed spleen.

Pancreatic surgery

Patients for pancreatic surgery usually have acute pancreatitis, pancreatic cancer, a neuroendocrine pancreatic tumor, or complications of chronic pancreatitis (pseudocyst or abscess).

- Patients with acute pancreatitis are usually managed medically. If surgical intervention is necessary, severe electrolyte abnormalities including hypocalcemia and hyperglycemia may be present and should be corrected preoperatively. Intravascular volume depletion, due to third spacing of fluids and bleeding, systemic inflammatory response syndrome, and organ dysfunction, may be present and should be anticipated.
- The Whipple procedure is usually performed for cystadenocarcinoma of the head of the pancreas, and it consists of partial pancreatectomy, pancreatojejunostomy, gastrojejunostomy, and choledochojejunostomy. The Whipple procedure is historically associated with major intraoperative fluid loss, bleeding, hypothermia, and prolonged operative time, although improved surgical techniques have mitigated these problems. Large-bore IV access and invasive monitoring are usually required for fluid replacement, hemodynamic monitoring, and frequent arterial blood sampling. Epidural analgesia can supplement general anesthesia and provides postoperative analgesia. The epidural infusion of local anesthetic and opioids may be started intraoperatively if the patient is stable hemodynamically. The decision for extubation in the OR should be based on the level of hemodynamic and homeostatic stability. Infusion of large volume loads and the presence of facial edema should temper enthusiasm for immediate extubation.

Carcinoid syndrome

This is a rare syndrome caused by carcinoid tumors that release various hormones, including serotonin. It is characterized by cutaneous flushing, tachycardia, hypotension or hypertension, bronchospasm, and diarrhea. Surgical excision may produce a life-threatening carcinoid crisis but remains the treatment of choice. Patients with untreated carcinoid may develop cardiomyopathy (carcinoid heart disease). Retrospective analyses showed that patients who experienced perioperative mortality had a higher frequency of carcinoid heart disease and had higher urinary 5-hydroxyindoleacetic acid (5-HIAA) levels. Patients who received intraoperative octreotide experienced fewer intraoperative complications than those who did not. There appears to be no role for preoperative octreotide. Intraoperative management involves fluid resuscitation, vasopressors, correction of electrolyte imbalance, octreotide administration, and avoidance of drugs that cause histamine release (morphine, succinylcholine, atracurium, mivacurium). Every patient presenting to the OR with carcinoid tumors should undergo preoperative cardiac imaging (echocardiography) and cardiac function testing to assess cardiac function, particularly

function of the right side of the heart. A thorough cardiac assessment is important because 50% of patients with carcinoid tumors develop the typical endocardial plaques of fibrous tissue involving the tricuspid valve, pulmonary valve, the vena cava, and the pulmonary artery and are therefore at risk for right heart failure. Left heart involvement is rare, but if present should raise the suspicion for extensive liver metastasis, bronchial carcinoid, or a patent foramen ovale.

Abdominal compartment syndrome

The abdominal compartment syndrome is defined as intra-abdominal hypertension in association with worsening organ dysfunction. It is caused by a variety of disorders that lead to the elevation of intra-abdominal pressure and consequently hemodynamic instability, decreased lung compliance, and renal impairment. Causes include blunt and penetrating trauma, burns, major abdominal surgery, large fluid resuscitation, and refractory ascites. In addition to the hemodynamic and ventilatory support, prompt surgical decompression is required (see [Chapter 172](#)).

The anesthesiologist should be prepared to deal with hemodynamic instability, acute renal failure, and poor ventilation and oxygenation. Large-bore IV access is useful, and a central venous pressure catheter allows measurement of CVP and administration of potent vasoactive agents. In the case of significant ventilatory support requirements, a sophisticated ICU ventilator may be needed in the OR. Fortunately, many modern anesthesia machines feature such capabilities. Blood products should be available if bleeding is anticipated. The hemodynamic status usually improves with restoration of venous return. Sudden hypotension occasionally occurs upon decompression of the abdomen and should be treated promptly with fluid boluses and vasopressors.

Laparoscopic surgery

Kai Matthes and Bhavani S. Kodali

Minimally invasive surgical procedures, when compared to conventional open procedures, are associated with significantly less trauma and the potential advantages of reduced postoperative pain, shorter length of hospitalization, rapid recovery, and decreased health care costs. Laparoscopy produces significant physiologic changes associated with peritoneal carbon dioxide (CO₂) insufflation and alteration in patient position that can have a major impact on cardiopulmonary function, particularly in patients with significant comorbidities.

Physiologic effects of laparoscopic procedures

The physiologic effects of laparoscopy are related to the combined effects of creation of a pneumoperitoneum, alteration of patient position, and effects of systemic absorption of CO₂.

Hemodynamic effects

During laparoscopy, cardiac output decreases to a variable extent depending on intra-abdominal pressure (IAP) and patient position, despite an increase in systemic blood pressure (Fig. 101.1). A characteristic response during the initiation of the pneumoperitoneum is an initial fall of the cardiac index with a subsequent partial recovery. Left ventricular end-diastolic volume is reduced during laparoscopy. Intrathoracic pressure is increased, and that commonly results in increased right atrial and pulmonary artery occlusion pressures.

The heart rate is minimally increased or unchanged. Increased circulating concentrations of catecholamines, renin, angiotensin II, and vasopressin cause an increase in systemic and pulmonary vascular resistance. Compression of arterial vasculature contributes to the increase in afterload. The reduction in splanchnic circulation is an effect of the pneumoperitoneum that may be counterbalanced by the direct splanchnic vasodilating effects of CO₂. Mesenteric ischemia, however, has been reported following laparoscopy.

Effects of CO₂ absorption

CO₂ is used for abdominal insufflation, as it is noncombustible and is more soluble in blood than is O₂, nitrous oxide (N₂O), or air. The absorption of insufflated CO₂, however, may lead to hypercapnia and respiratory acidosis that cause a decrease in myocardial contractility, lowered arrhythmia threshold,

arteriolar dilatation, and decreased systemic vascular resistance. These responses are modulated by mechanical and neurohumoral responses resulting in catecholamine release. The PaCO₂ increases progressively to reach a plateau 15 to 30 minutes after insufflation of CO₂ is initiated. This extent of increase in PaCO₂ is unpredictable, particularly in patients with severe pulmonary disease. The increase in PaCO₂ results in significant decreases in pH and the requirement for an increase in minute ventilation. CO₂ absorption is greater during extraperitoneal (pelvic) insufflation than during intraperitoneal insufflation.

Respiratory effects

During laparoscopy, lung volumes are reduced due to a cephalad shift of the diaphragm caused by abdominal insufflation. The pulmonary compliance is decreased, resulting in increased peak airway pressures and a reduction in functional residual capacity (FRC). There is ventilation-perfusion mismatch that may cause hypoxemia. There is an increase in intrathoracic pressure that adds to the decrease in lung compliance.

Hemodynamic effects of pneumoperitoneum

There is a biphasic cardiovascular response to increases in IAP. At an IAP of less than 10 mm Hg, there is an increase in venous return, probably from reduction in splanchnic sequestration of blood, with a subsequent increase in cardiac output and arterial pressure. This response, however, is blunted by hypovolemia. At an IAP of more than 20 mm Hg, compression of the inferior vena cava leads to a decreased venous return from the lower body and consequent decreased cardiac output. Increased renal vascular resistance at an IAP of more than 20 mm Hg decreases renal blood flow and glomerular filtration rate (GFR).

Urine output during pneumoperitoneum is diminished, but it increases following deflation of the abdomen. An increase in cerebral blood flow velocity and intracranial pressure is observed, which may complicate the anesthetic management of patients with intracranial mass lesions.

Effects of patient positioning

Patient position during laparoscopy varies depending on the procedure performed. For laparoscopic cholecystectomy,

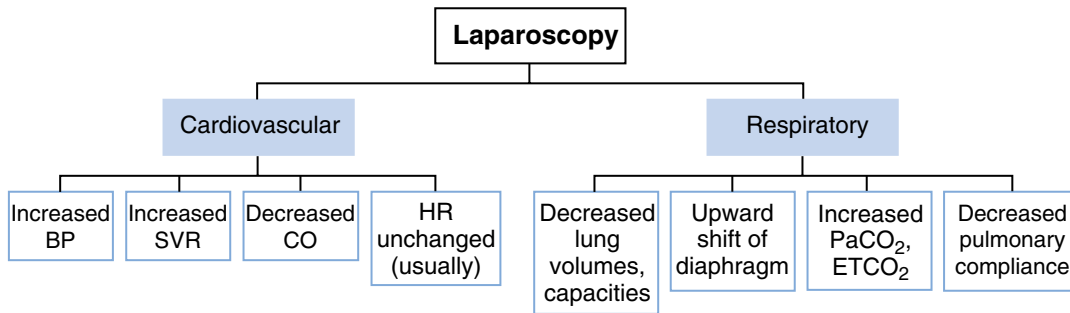

Figure 101.1. Physiologic effects of laparoscopy.

reverse Trendelenburg position with left lateral tilt is chosen to facilitate retraction of the gall bladder fundus and to minimize diaphragmatic dysfunction. This position improves pulmonary dynamics but may result in decreased venous return with a reduction in left ventricular end-diastolic volume. Increased IAP and the head-up position predispose to thromboembolism due to decreased femoral vein blood flow and lower limb venous stasis. The Trendelenburg position (for gynecologic procedures), in contrast, increases central blood volume, decreases diaphragmatic excursion, and causes pulmonary congestion. The ventilation–perfusion mismatch may result in hypoxemia, particularly in obese patients or in patients with pulmonary disease. Care should be taken so that the endotracheal tube does not slip into a mainstem bronchus during position changes.

Capnography during laparoscopic surgery

Capnography has three important applications during laparoscopic surgery. First, it serves as a noninvasive monitor of PaCO₂ during CO₂ insufflation and, therefore, can be used to adjust ventilation. Second, it may help in the detection of accidental intravascular CO₂ insufflation. Third, it may also help in the detection of other complications of CO₂ insufflation, such as pneumothorax or pneumomediastinum.

Prolonged intra-abdominal insufflation with CO₂ during upper abdominal laparoscopic surgery does not significantly affect the reliability of partial end-tidal CO₂ (PETCO₂) monitoring in predicting PaCO₂ in healthy American Society of Anesthesiologists (ASA) I and II subjects and elderly patients. In ASA III and IV patients, however, PETCO₂ may not reflect changes in PaCO₂ during insufflation due to changes in alveolar dead space consequent to reduced cardiac output or ventilation–perfusion mismatch. Therefore, direct arterial PaCO₂ monitoring is recommended in patients with significant cardiorespiratory diseases. An arterial line is reasonable to monitor PaCO₂ in ASA III and IV patients for three important reasons:

- (1) The end-tidal PCO₂ is not a reliable index of PaCO₂;
- (2) The normal gradient of 3 to 5 mm Hg between PaCO₂ and PETCO₂ is increased; and
- (3) Even with normal PETCO₂, achieved by increasing minute volume, PaCO₂ may be as high as 50 mm Hg, resulting in respiratory acidosis.

Occasionally during the course of laparoscopic surgery the arterial-end tidal (a-ET)PCO₂ gradient may be negative in adults, in which case PETCO₂ overestimates PaCO₂. The incidence of negative gradients is higher in infants and children undergoing laparoscopic surgery. Low frequency, high tidal volume ventilation will open hitherto closed alveoli, the CO₂ from which will now be seen as an increase in the slope of phase III of the capnogram. A low FRC coupled with increased CO₂ delivery to the alveoli can exacerbate this response, thereby increasing the frequency of occurrences of negative (a-ET)PCO₂ values during laparoscopic surgery.

Anesthetic considerations

Choice of anesthetic technique

Although reports about laparoscopic procedures performed under spinal or epidural anesthesia have been documented, the requirement of a pneumoperitoneum and change in patient position commonly limits these procedures to general anesthesia. Endotracheal intubation and controlled mechanical ventilation are required to reduce the increase in PaCO₂ and counterbalance the respiratory side effects of the Trendelenburg position. For alternative viewpoints, see [Chapter 103](#).

Recent studies demonstrate the feasibility and safety of using a ProSeal™ laryngeal mask airway (LMA) for laparoscopic procedures with the advantage of a decreased postoperative analgesia requirement and a lower incidence of postoperative nausea and vomiting (PONV). There is supporting evidence that LMAs may be used successfully with positive pressure ventilation, but many anesthesiologists are still reluctant to choose an LMA when positive pressure ventilation is needed. Even though the risk appears to be low, the increased IAP during laparoscopy may predispose to regurgitation and aspiration of gastric contents.

Monitoring

All patients should have ASA standard monitoring. Invasive monitoring may be indicated in ASA III and IV patients to evaluate the cardiovascular response to pneumoperitoneum and during position changes. ETCO₂ monitoring as a surrogate for PaCO₂ is recommended to adjust minute ventilation. (An increase of approximately 50% in tidal volume and respiratory

rate is required to maintain PETCO₂ closer to preinsufflation values). Pressure–volume loop monitoring may be helpful in identifying airway complications. PaCO₂ monitoring by intermittent blood gas analysis is recommended for patients with severe pulmonary disease.

Maintenance

A balanced anesthetic technique consisting of opioids (fentanyl on induction, and morphine or hydromorphone for long-acting pain control), muscle relaxants, and volatile anesthetic is used. The use of N₂O is controversial because it may theoretically diffuse into air-filled spaces and cause distention of the bowel. The diffusion coefficients of N₂O and CO₂ are similar enough so that there would be no clinically relevant diffusion of N₂O into CO₂-filled spaces. In addition, the use of N₂O may increase the incidence of PONV.

An orogastric tube is inserted to decompress the stomach. A urinary catheter may be inserted to decompress the bladder. The patient is hyperventilated to decrease the ETCO₂ to approximately 30 mm Hg prior to abdominal insufflation of CO₂. The patient's muscles should be adequately relaxed prior to the initial trocar insertion since it is inserted blindly. Perforation of the inferior vena cava and aorta have been reported to occur during trocar insertion. A vagal response may also occur during trocar insertion.

Intraoperative hypertension should be treated with adequate pain control, deepening of the anesthesia, and administration of an antihypertensive such as labetalol or metoprolol, if indicated. Control of pain may be achieved via a multimodal analgesic regimen combining opioids, COX inhibitors, and local anesthetic infiltration. The nonselective COX inhibitor ketorolac (30 mg) is being increasingly administered near the end of procedures.

Laparoscopic procedures are frequently associated with an increased risk of PONV. Serotonin receptor antagonists (ondansetron, granisetron, dolasetron, and palonosetron), compared with traditional antiemetics, are highly efficacious for PONV. It is likely that combined antiemetics with different sites and mechanisms of action would be more effective than one drug alone for the prophylaxis against PONV, especially in high-risk patients. Adding dexamethasone to ondansetron or granisetron improves antiemetic efficacy in PONV. Dexamethasone should be given early during the surgery, preferably before any emetogens.

Laparoscopy in pregnant patients

The current evidence suggests that laparoscopic surgery is safer than laparotomy during pregnancy and does not have a significant impact on the course of pregnancy or fetus. Contrary to studies in a model using pregnant sheep, maternal PaCO₂ can be maintained within reasonable limits during peritoneal insufflations in pregnant patients. Increasing ventilation by about 50% from the baseline during insufflation and maintaining PETCO₂ at approximately 32–34 mm Hg assures that the

maternal PaCO₂ is in a similar range. Monitoring arterial blood gases is not necessary unless there are accompanying respiratory and cardiac comorbidities. Cardiac output decreases from baseline values during peritoneal insufflations. Therefore, it is essential to maintain blood pressure within 20% of baseline values with boluses of ephedrine. It is also imperative to place a wedge under the right side of the patient to ensure left uterine displacement to maintain near-normal uterine perfusion during surgery. Our study has demonstrated that the maximum PaCO₂ occurs during the immediate postoperative period. Opioids should be administered with caution, since an overdose can depress ventilatory drive, contributing to a further increase in PaCO₂.

Laparoscopy in infants and children

Capnography has been proven to be an excellent guide in adjusting ventilation during CO₂ insufflation in infants and children. Monitoring PETCO₂, however, may overestimate PaCO₂ and consequently can result in hyperventilation during laparoscopic surgery in children. PETCO₂ often overestimates PaCO₂ during laparoscopy in children; thus, arterial blood gas analysis should be performed during long procedures to avoid hyperventilation.

Laparoscopy in obese patients

Laparoscopic procedures usually take longer in obese patients than in patients with a normal body weight and result in a prolonged exposure to the general anesthetic. In overweight patients, the pneumoperitoneum and the Trendelenburg position impair arterial oxygenation, leading to an increased alveolar–arterial oxygen tension difference (AaDO₂). Hemodynamic parameters are less affected by body weight.

Cephalad displacement of the diaphragm due to the increased weight of the abdominal wall in obese patients may cause increased airway pressure due to decreased compliance of the lung. Difficulties in ventilation of obese patients undergoing laparoscopic procedures may lead to hypercarbia and hypoxemia due to ventilation–perfusion mismatch. Due to the cephalad shift of the diaphragm, a firmly secured endotracheal tube may be displaced into the bronchial mainstem. Incidence of pulmonary atelectasis in morbidly obese patients is higher than that in nonobese patients.

Complications of laparoscopic procedures

Intraoperative complications during laparoscopic procedures can be a consequence of creation and maintenance of pneumoperitoneum and vascular injuries during surgical instrumentation (Table 101.1).

Postoperative considerations

Laparoscopic procedures have been suggested to reduce the incidence of postoperative pulmonary complications compared to open abdominal procedures. Diaphragmatic dysfunction

Table 101.1. Intraoperative complications during laparoscopy

Traumatic injuries associated with blind trocar or Veress needle insertion	<ul style="list-style-type: none"> • Injury of vascular structures: aorta, inferior vena cava, iliac vessels, retroperitoneal hematoma • Injury of gastrointestinal structures: small and large bowel, liver, spleen, and mesentery • Minimization of the risk of accidental organ injury by mini-laparotomy insertion of Veress needle
Venous CO ₂ embolism	<ul style="list-style-type: none"> • Inadvertent intravenous placement of the Veress needle • Passage of CO₂ into the abdominal wall or peritoneal vessels during insufflation • Passage of CO₂ into open vessels of the liver surface during laparoscopic cholecystectomy • Symptoms include hypotension with cardiovascular collapse, hypoxemia, mill-wheel murmur, decrease in ETCO₂ because of a reduction of pulmonary blood flow • Cerebral CO₂ embolism may result from a patent foramen ovale or atrial septum defect • The incidence of undetected CO₂ embolism may be as high as 79% of patients during laparoscopic cholecystectomy
Pneumothorax, pneumomediastinum, pneumopericardium	<ul style="list-style-type: none"> • Tracking of insufflated CO₂ around aortic or esophageal hiatus of the diaphragm into the mediastinum with subsequent rupture into the pleural space • Passage of gas through embryogenic defects of the diaphragm • Pleural tears • Rupture of emphysematous bullae • Inadvertent placement of needle in extraperitoneal spaces
Surgical emphysema	<ul style="list-style-type: none"> • Intentional extraperitoneal insufflation of CO₂ during inguinal hernia repair • Accidental extraperitoneal insufflation of CO₂: subcutaneous emphysema of abdomen, chest, neck, and groin
Vascular injury	<ul style="list-style-type: none"> • Instrument insertion may cause concealed bleeding, particularly in the retroperitoneal space; may result in delayed diagnosis of vascular injury
Cardiac arrhythmias	<ul style="list-style-type: none"> • Due to hypercarbia or increased vagal tone; due to peritoneal stretch (bradycardia, asystole)

following laparoscopic cholecystectomy may last for up to 24 hours postoperatively. The increased IAP during the pneumoperitoneum has been reported to cause venous stasis and an increased risk of deep venous thrombosis and pulmonary embolism. Bile duct injuries are more common after laparoscopic cholecystectomy than following an open procedure. Patients with this condition present with pain and jaundice. Same-day laparoscopic cholecystectomy imposes the risk of delayed diagnosis of postoperative complications. Patients who are discharged the same day after their surgery should be selected with care. In addition, it is important to adequately control the pain and any nausea before discharging the patient.

Anesthesia for esophageal and gastric surgery

Amy L. Kim and Warren S. Sandberg

Introduction

This chapter covers anesthesia for surgery of the upper alimentary tract, namely, the esophagus and the stomach. Anesthesia for esophageal surgery involves many of the specialized techniques of anesthesia for thoracic surgery, and the reader is referred to those chapters for more detailed information (Part 15). Similarly, when considering anesthesia for gastric surgery and many esophageal procedures, the reader will benefit from reviewing the chapter on intra-abdominal surgery (Chapter 100) for more general information. Finally, much gastric reduction surgery is performed laparoscopically, so a review of the chapter on laparoscopy (Chapter 101) as well as the chapter on obesity (Chapter 6) will be useful.

Esophageal surgery

Patients may present for esophageal surgery for numerous reasons. Some of these reasons are reflux disease, esophageal cancer, strictures, motility disorders, and perforation.

Esophagogastrectomy

Multiple surgical techniques are used for the treatment of esophageal carcinoma, depending on the location of the tumor. For tumors of the lower third of the esophagus, a left thoracoabdominal incision is made. An esophagogastrectomy is then performed followed by anastomosis of the jejunum to the proximal esophagus. For lesions of the middle third of the esophagus, an Ivor Lewis approach is generally used. In this approach, the stomach is first mobilized via an abdominal incision with the patient supine. The patient then is repositioned left side down after endobronchial intubation, and a right thoracotomy is performed for esophageal tumor resection. The stomach is then pulled up into the chest and anastomosed to the proximal esophagus. Lesions of the upper third of the esophagus may be managed by combined laparotomy with cervical incision (“blind esophagectomy”). For those lesions in the upper third of the esophagus, when there is insufficient stomach length or the presence of gastric disease, an esophagogastrectomy with colon interposition can be performed in two stages. During the first stage, a midline laparotomy and right thoracotomy are done for the esophagogastrectomy. The patient is then placed supine, and a cervical esophagostomy is performed. In the second stage, at a

second operative sitting, either the right or left colon is used and passed into the retrosternal space where it is anastomosed to the cervical esophagus above and to the stomach remnant below.

Preoperative assessment

The preoperative evaluation of patients with esophageal disease should be a multisystem approach, with focus on the nutritional, hematologic, and cardiopulmonary systems.

Patients with esophageal disease often present with malnourishment, dehydration, and poor synthetic nutritional status (represented by hypoalbuminemia but affecting many synthetic pathways) due to dysphagia. It has been shown that improvement in nutritional status preoperatively has decreased the incidence of wound infections, sepsis, and perioperative morbidity and mortality.

Based on the patient’s history and physical examination, additional tests may be necessary to evaluate the cardiopulmonary system. Preoperative tests of pulmonary function or arterial blood gases (ABG) may be helpful. They can predict the likelihood of perioperative pulmonary complications and the need for postoperative mechanical ventilation. Patients should also receive a thorough cardiac evaluation due to the possibility of intraoperative hemodynamic instability and ongoing inflammatory and stress responses due to the surgery. The evaluation may include an electrocardiogram (ECG), echocardiogram, or functional cardiac stress testing.

Laboratory tests are indicated based on the patient’s history and physical examination; however, a complete blood count (CBC) may be helpful given the ubiquity of anemia with these patients. A blood bank sample should be obtained given the presence of anemia and the possibility of perioperative blood transfusions.

A thorough airway evaluation should be performed preoperatively, with a focus on the presence of mediastinal lymphadenopathy, which may result in airway compression.

The preoperative evaluation should also focus on whether chemotherapy and/or radiation was used in patients with esophageal cancer because they can impact intraoperative patient management. Chemotherapeutic agents such as doxorubicin and bleomycin are commonly used in the management of esophageal cancer. These agents may result in the development of anemia, leukopenia, and thrombocytopenia. Doxorubicin,

in addition, may lead to a dose-related cardiomyopathy that can be either acute or slowly progressive and results in heart failure. Thus patients who have been treated with doxorubicin should have a preoperative echocardiogram or nuclear scan to evaluate cardiac function. Bleomycin is another antineoplastic agent that is used to treat esophageal squamous cell carcinoma. It causes minimal myelosuppression but has a high incidence of pulmonary toxicity. With severe toxicity, patients may have resting hypoxemia and interstitial pneumonia and fibrosis. These patients are at increased risk for developing adult respiratory distress syndrome (ARDS) postoperatively possibly due to increased FiO₂ resulting in free radicals.

Radiation is another treatment option that is more effective for squamous cell carcinoma than for adenocarcinoma. Complications of radiation include pneumonitis, pericarditis, bleeding, and tracheoesophageal fistula.

Intraoperative management

Preoperative management focuses on the establishment of adequate intravenous (IV) access, appropriate monitoring, and suitable avenues for effective postoperative analgesia. Sedation and IV analgesia for procedures are also important.

Depending on the patient's anxiety level, premedication with benzodiazepines may be necessary. A large-bore IV (14–16 gauge) catheter should be inserted for volume replacement as needed. Standard monitors including pulse oximeter, temperature, ECG, and blood pressure (BP) cuff are indicated. Additionally, an arterial line may be used for tight BP control and for frequent laboratory sampling. Either central venous or pulmonary artery catheters should be used based on the patient's cardiopulmonary status and the anticipated surgical severity. A Foley catheter is inserted to monitor intraoperative urine output (in this case, as a functional indicator of adequate circulating intravascular volume).

Preoperative placement of a thoracic epidural catheter may be helpful for postoperative pain management and to facilitate early extubation. Chandrashekar and colleagues have shown that patients with good analgesia from a thoracic epidural after a two-stage esophagectomy have been extubated safely postoperatively in the operating room (OR) due to blunting of the stress response from pain. Additionally, postoperative morbidity and mortality secondary to cardiopulmonary complications are reduced when there is adequate analgesia from a thoracic epidural catheter.

Because of the location of surgery, general endotracheal anesthesia (GETA) is the obligatory anesthetic technique, although this may be supplemented by an epidural catheter. Because patients with esophageal disease are often at risk for pulmonary aspiration, patients should be intubated either awake (blind nasal or fiber-optic techniques) with topical anesthesia or after rapid-sequence IV induction with cricoid pressure. A nasogastric tube is typically passed to empty the esophagus and stomach. Maintenance of anesthesia generally uses combinations of volatile anesthetics and local anesthetics

± opioids via the epidural catheter. Nitrous oxide is avoided by some anesthetists, with the goal to minimize bowel distension, thus optimizing surgical exposure. Anesthesia is generally supplemented with nondepolarizing muscle relaxants. The combination of general and epidural anesthesia can dramatically decrease the inhalational anesthetic and muscle relaxant requirements. Pressors and fluids may be needed to treat hypotension.

Depending on the surgical approach, one-lung ventilation with double-lumen endobronchial tubes may be needed to facilitate surgical exposure.

Positioning of the patient is important to prevent pressure injuries, peripheral nerve compression, or stretch injury. If the lateral decubitus position is used, an axillary roll and airplane arm holder should be used. Pressure points, especially of the upper extremities, should be checked to avoid brachial plexus injuries. Radial pulses should be checked to ensure correct placement of the axillary roll. Placement of the oximeter probe on the dependent arm may assist in monitoring the adequacy of perfusion. In addition, eyes and ears should be checked for compression, and the eyes should be taped closed.

Attention to the patient's temperature during long operations is crucial. To prevent hypothermia, consider the use of a forced-air warming blanket, a fluid warmer, and keeping the room temperature warm. Of these options, the forced-air blanket is by far the most effective, and its use obviates the need for any other intervention.

Intraoperative complications of esophageal surgery can include hypotension, bradycardia, dysrhythmias, tracheal damage, hypoxia, and hemorrhage.

The decision to extubate at the end of the surgery is multifactorial, depending on the extent of the surgical procedure and the patient's tolerance of surgery and anesthesia. Patients should be alert, cooperative, hemodynamically stable, and warm, and neuromuscular blockade should be fully antagonized. Those patients who require postoperative ventilation should have the DLT changed to a single-lumen endotracheal tube prior to leaving the OR. Patients can then be weaned from mechanical ventilation and extubated in the intensive care unit (ICU) postoperatively.

Postoperative management

Patients are usually managed postoperatively in an ICU setting, although this depends in part on the degree of surgical insult. In the early postoperative period, patients may have increased fluid requirements. Adequate postoperative pain control is essential to facilitate deep breathing, cough, mobilization of secretions, participation in chest physiotherapy, and early ambulation.

Postoperative complications from esophageal surgery include aspiration, atelectasis, acute lung injury, hemorrhage, pneumothorax, hemothorax, hypoxemia, hypoventilation, recurrent laryngeal nerve injury, deep vein thrombosis (DVT), and esophageal anastomotic leak.

Respiratory problems after esophagectomy are common. ARDS is a major contributor to respiratory morbidity and mortality after esophagectomy. Tandon and colleagues noted that acute lung injury after elective esophagectomy is associated with intraoperative cardiorespiratory instability. They also noted that the longer the one-lung ventilation time and operative time, the greater the incidence of acute lung injury. This may be attributed to the fact that both lungs are subjected to injury during the thoracic phase of the procedure. The dependent lung is exposed to microbarotrauma, whereas the collapsed lung suffers ischemia–reperfusion injury.

Another serious complication is the development of anastomotic leakage. Michelet and colleagues have noted that thoracic epidural analgesia is associated with a decrease in anastomotic leakage. This association may be due to thoracic epidural analgesia allowing intensive chest physiotherapy that helps preserve postoperative pulmonary function and prevent hypoxemia. It has also been shown that thoracic epidural analgesia use during major abdominal surgery increases tissue oxygen, thus improving oxygenation at the wound surfaces.

Nissen fundoplication

Esophageal fundoplication is an operation that increases lower esophageal sphincter pressure to prevent esophageal reflux by wrapping the fundus of the stomach around a 3- to 4-cm segment of the lower esophagus. (See Fig. 102.1.) This operation can be done transabdominally, transthoracically, or laparoscopically. The most commonly used technique is the open or laparoscopic Nissen fundoplication that uses both the anterior and posterior walls of the stomach. Indications for esophageal fundoplication include stricture, respiratory problems, esophageal ulcerations, and Barrett's esophagus, as well as failure of medical management or a patient's unwillingness to submit to a lifetime of medication.

Anesthetic management for open Nissen fundoplication is similar to that for esophageal surgery. Laparoscopic Nissen fundoplication is managed like a typical intra-abdominal laparoscopic case. The potential for carbon dioxide insufflation along the esophagus above the diaphragm is quite high, however, and

it can complicate ventilation management. Surgeons are concerned about the impact of postoperative retching on the viability of the fundoplication. Thus, aggressive postoperative nausea and vomiting prophylaxis is warranted in these patients.

Bariatric surgery

Morbidly obese patients are defined as those who are greater than 100 pounds over ideal body weight or 2 times ideal body weight. Body mass index (BMI) is defined by weight in kilograms divided by height in meters squared. Patients with a BMI greater than 28 are considered obese. Patients with a BMI greater than 35 are considered morbidly obese.

A variety of surgical procedures are used to treat morbid obesity. These procedures can be divided into malabsorptive versus restrictive procedures. Malabsorptive procedures include jejunioileal bypass and biliopancreatic bypass, in which most of the small bowel is bypassed, thus creating a state of chronic malabsorption.

Restrictive procedures include vertical banded gastroplasty and adjustable gastric banding. These procedures work by decreasing the size of the gastric pouch, thus limiting the amount of food that can be consumed at one time. Gastroplasty creates a small upper pouch (15–30 ml) in the stomach, which restricts food intake. The pouch communicates with the remainder of the stomach through a narrow channel, or stoma. Adjustable gastric banding is done by a minimally invasive laparoscopic approach. An adjustable inflatable band is placed around the proximal stomach to limit stomach capacity. The band can be made tighter or less so by adding or removing saline. Roux-en-Y gastric bypass (RYGB) combines gastric restriction with a minimal degree of malabsorption. Restrictive procedures can be performed laparoscopically or via laparotomy.

RYGB is the most commonly performed bariatric procedure in the United States. It is the most effective bariatric procedure to produce safe short- and long-term weight loss in severely obese patients. This procedure involves anastomosis of the proximal gastric pouch to a segment of the proximal jejunum that bypasses most of the stomach and entire

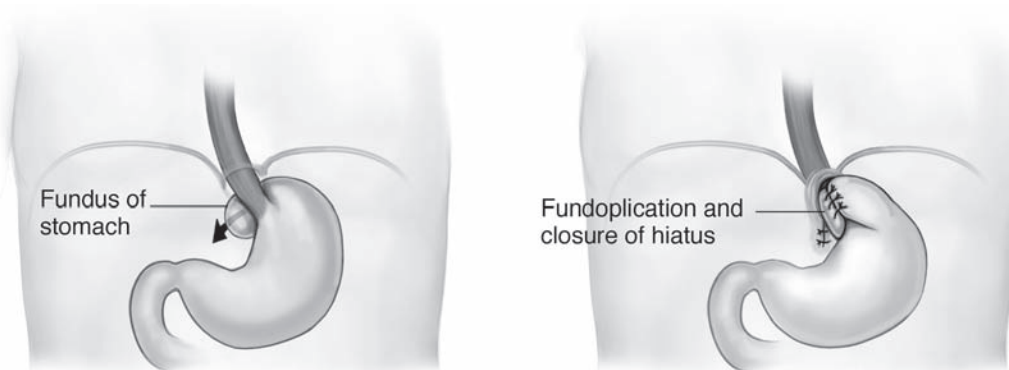

Figure 102.1. Illustration of the key anatomic step in Nissen fundoplication.

Figure 102.2. Illustration of the RYGB anatomy.

duodenum (see Fig. 102.2). With RYGB, patients lose an average of 50% to 60% of excess body weight and show a BMI decrease of approximately 10 kg/m² during the first 12 to 24 postoperative months. Type 2 diabetes resolves in the majority of patients.

Laparoscopic bariatric surgery is minimally invasive and is associated with less postoperative pain, lower morbidity, and faster recovery. Operative trauma is reduced when compared to open procedures due to smaller surgical incisions and the elimination of mechanical retraction of the abdominal wall. In addition, accumulation of third space fluid is significantly lower after laparoscopic RYGB than after open RYGB. A reduced incidence of wound infection and an early return to daily activities is seen in laparoscopic RYGB patients. Rhabdomyolysis is more common in morbidly obese patients undergoing laparoscopic procedures than open procedures, however. Unexplained elevations in serum creatinine and creatine phosphokinase levels or complaints of buttock, hip, or shoulder pain in the postoperative period should raise suspicion of rhabdomyolysis.

Preoperative assessment

The preoperative evaluation of morbidly obese patients again involves a multisystem approach with focus on the cardiopulmonary status and airway. The incidence of difficult mask ventilation and intubation is high in obese patients. Flexion of the neck in the obese patient could result in difficult intubation due to excessive soft tissue. The presence of submental fat may also limit mouth opening. A large tongue, redundant palate, and pharyngeal tissue may narrow the airway. It has been identified that neck circumference is the single best predictor of problematic intubation in morbidly obese patients. Thus careful airway examination is paramount.

Patients should also be evaluated for systemic hypertension, obstructive sleep apnea with coexisting pulmonary hypertension, signs of right and/or left ventricular failure, and ischemic heart disease. Obesity has serious cardiopulmonary consequences, as outlined in Fig. 102.3. Preoperative tests, such as echocardiogram, ECG, chest radiography, and baseline ABG, may provide useful information for the management of these patients intraoperatively.

This patient population is at risk for pulmonary aspiration of gastric contents due to increased intra-abdominal pressure, gastric volume, and acidity, as well as the increased incidence of hiatal hernia.

Laboratory tests are indicated based on the patient's history and physical examination. A CBC is useful because polycythemia may be present due to chronic hypoxemia. A measurement of fasting blood glucose may be necessary due to the frequent occurrence of glucose intolerance and diabetes mellitus in this patient population. Liver function is often abnormal and drug metabolism may be significantly affected.

Patients' usual medications (with the possible exception of insulin and oral hypoglycemics) should be continued until the time of surgery.

Intraoperative management

Premedication with oral or IV benzodiazepines is reliable for anxiolysis in this patient population, as modest sedative doses cause little or no respiratory depression. However, patients with a history of obstructive sleep apnea may be especially sensitive to sedatives and opioids. H₂-receptor antagonists, proton pump inhibitors, and nonparticulate antacids like sodium citrate may be useful preoperatively for reducing gastric volume and acidity, thus reducing the risk and complications of aspiration.

DVT prophylaxis with subcutaneous unfractionated or low-molecular-weight heparin, in addition to pneumatic compression devices, should also be used given the risk for sudden death from acute postoperative pulmonary embolism. Antibiotic prophylaxis is also important because of the increased risk of postoperative wound infection after gastric operations for obesity.

A large-bore (14–16 gauge) IV catheter should be inserted with the anticipation of potential large fluid loss mainly due to fluid shifts. Standard monitors such as pulse oximeter, temperature, ECG, and appropriately sized BP cuff are used for patient monitoring. An arterial catheter may be necessary in those patients with severe cardiopulmonary disease or for those with poor fit of the noninvasive BP cuff. Central venous catheterization may be performed in those in whom peripheral IV access cannot be obtained. Otherwise, central venous cannulation for monitoring and central drug administration is selected on a case-by-case basis, depending on the patient's medical condition and the expected impact of surgery. A urinary catheter is also placed to monitor urine output to guide in fluid management.

Again, the site of surgery necessitates GETA as the anesthetic technique, with or without an epidural catheter for

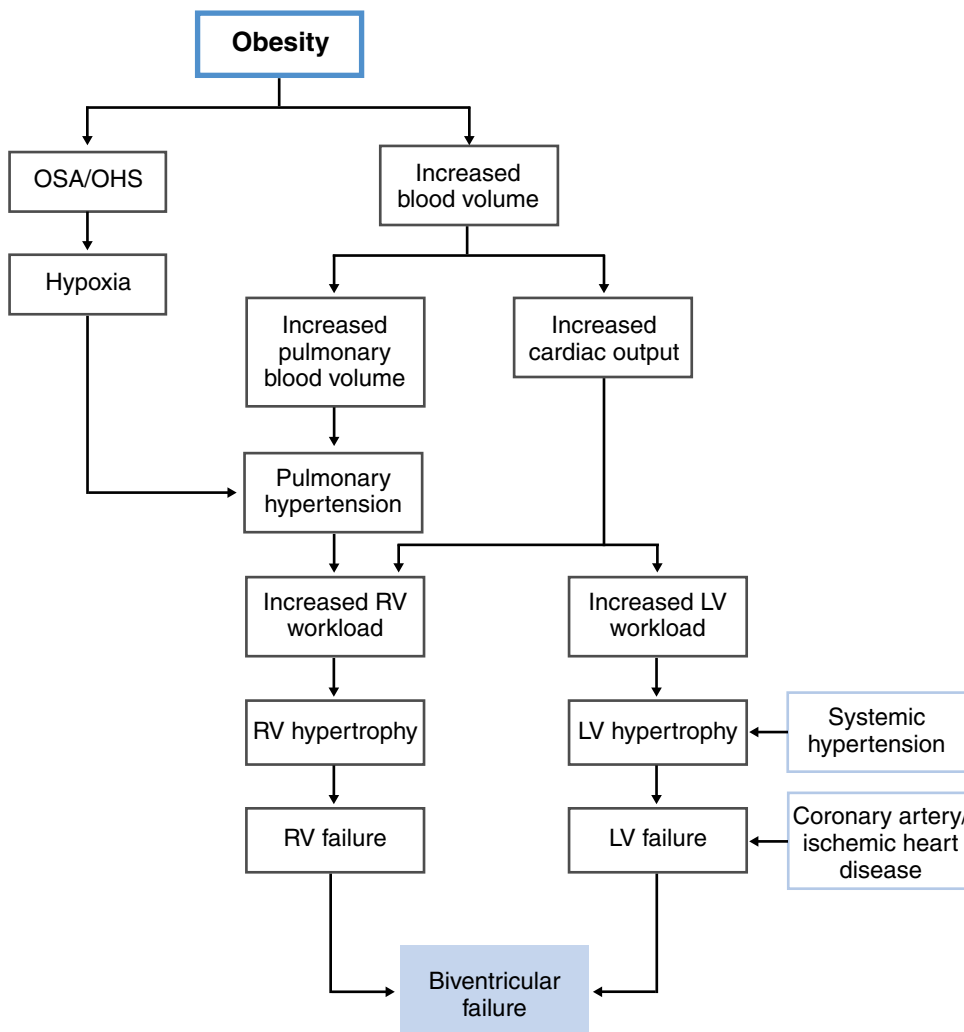

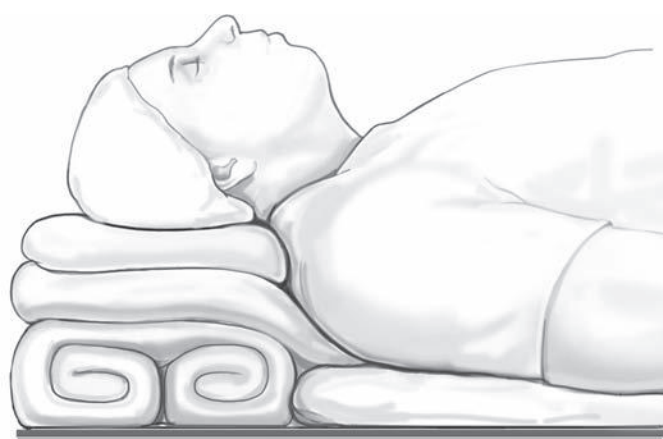

Figure 102.3. Flow diagram of the interrelationships between obesity and cardiopulmonary complications. RV, right ventricle; LV, left ventricle; OSA, obstructive sleep apnea; OHA, obesity hypoventilation syndrome. Redrawn from Figure 36-2, *Clinical Anesthesia*, Barash PG, ed. Philadelphia: Lippincott Williams & Wilkins; 2006.

postoperative analgesia. Preparation should be made for difficult mask ventilation, laryngoscopy, or intubation. Thus, positioning the patient prior to induction by elevating the shoulders and occiput so that the head is in the “sniffing” position greatly facilitates airway access. This can be done by placing towels or folded blankets under the shoulders and head so that the tip of the chin is higher than the chest. Another positioning maneuver known as the head-elevated laryngoscopy position (HELP) can improve laryngoscopic view (see Fig. 102.4). HELP elevates the obese patient’s head, upper body, and shoulders above the chest to the extent that an imaginary horizontal line connects the sternal notch to the external auditory meatus. During induction of anesthesia, patients should be positioned in a head-up reverse Trendelenburg position, providing the longest safe apnea period. Adequate preoxygenation is vital in obese patients because of rapid desaturation after loss of consciousness, attributed increased tissue oxygen consumption, and decreased functional residual capacity (FRC).

Because these patients are at risk for aspiration, they should be intubated either awake or after rapid-sequence induction with cricoid pressure. Following successful intubation, a nasogastric (NG) tube should be placed and the stomach contents suctioned. The NG tube may be used later in the surgery to check anastomotic integrity with the injection of saline or methylene blue. The NG tube should also be removed before gastric division to avoid unplanned stapling or transection of the tube.

Anesthesia is generally maintained with inhalational anesthetics. Some providers prefer desflurane due to its rapid recovery profile. Juvin and colleagues have noted that immediate recovery from anesthesia occurred faster with desflurane than with isoflurane or propofol. In addition, postanesthesia care unit (PACU) admission oxygen saturation of hemoglobin (SpO₂) values were significantly higher and patient mobility was significantly better after desflurane. At 30 and 120 minutes postoperatively, sedation was also significantly less pronounced

A

B

Figure 102.4. Preformed head elevation pillow and its use.

with desflurane. If an epidural catheter is present, it may be used in combination with an inhalational anesthetic. Nitrous oxide is generally avoided to minimize bowel distention as well as due to the high oxygen demand in obese patients. Nondepolarizing muscle relaxants are also used to facilitate adequate ventilation and surgical exposure. Dexmedetomidine infusions can be used to decrease anesthetic and opioid requirements. Infusion of remifentanyl, an ultra-short-acting opioid, has been used to supplement a total intravenous anesthesia (TIVA) or an inhalational anesthetic.

Proper positioning is crucial in this patient population. The appropriately sized OR table should be available, and patients should be well secured to the table to prevent falls and injury. Bean bags to help position a patient may also be useful. Protecting pressure areas is important in this patient population given the common occurrence of pressure sores and nerve injuries.

An association exists between ulnar neuropathy and increasing BMI. The supine position, as well as the Trendelenburg position, are generally not well tolerated by the obese patient. The development of ventilation–perfusion abnormalities, left-to-right shunting, and decrease in FRC may result in hypoxemia. Hypotension may also result from supine positioning due to occlusion of the inferior vena cava (IVC), which compromises venous return to the heart.

The decision to extubate at the end of the surgery depends on the patient's underlying cardiopulmonary status and the extent of the surgical procedure. Patients should be hemodynamically stable, warm, alert, cooperative, and fully reversed from any muscle relaxants prior to extubation. The patient should be preferably extubated in the semirecumbent position, which has less adverse effect on respiration. Supplemental oxygen should be administered after extubation.

Postoperative management

These patients – especially those with coexisting diseases – may require ICU admission for postoperative care. There is an increased incidence of atelectasis, which persists into the postoperative period, in morbidly obese patients after general anesthesia. Patients may need continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) postoperatively to reduce atelectasis and combat airway obstruction. Postoperative CPAP does not increase the incidence of major anastomotic leakage after gastric bypass surgery despite a theoretical risk.

Pain may cause patients to avoid taking deep breaths and ambulating. Thus adequate pain control is crucial as well as the use of a properly fitted elastic binder for abdominal support in improving pulmonary toilet. Epidural analgesia with local anesthetics, opioids, or both is an effective form of analgesia. Potential advantages of epidural analgesia include DVT prevention, improved analgesia, and earlier recovery of intestinal motility. Patients should be observed, however, for delayed respiratory depression with the use of central neuraxial opioids. Patient-controlled anesthesia (PCA) morphine is equivalent to low thoracic/high lumbar epidural analgesia with continuous infusions of bupivacaine/fentanyl in morbidly obese patients undergoing gastric bypass surgery with regard to the quality of pain control at rest, the frequency of nausea and pruritus, the time to ambulation, time to return of gastrointestinal (GI) function, and the length of hospital stay.

Complications postoperatively include anastomotic leak, gastric pouch outlet obstruction, jejunostomy obstruction, DVT, PE, respiratory failure, GI bleeding, and wound infection. RYGB may also cause a “dumping syndrome” resulting in diarrhea and abdominal cramps secondary to a high-sugar liquid diet.

Anesthesia for gynecologic and breast surgery

Bronwyn Cooper

Introduction

There is a wide range of breast and gynecologic procedures that require anesthesia. This chapter provides an overview of different gynecologic and breast surgeries and their anesthetic requirements that range from local to general anesthesia. In addition, major surgeries often require postoperative hospital admission and regional anesthesia for postoperative pain.

Breast surgery

Breast tumor surgery

The most common breast surgeries are lumpectomy, an enlarged excisional biopsy, and modified radical mastectomy for breast cancer. With axillary dissection, it is often wise to avoid muscle relaxants so that the surgeon may stimulate the long thoracic and thoracodorsal nerves to aid in their identification. Whereas breast biopsy and lumpectomy can be done with local anesthesia (such as bupivacaine or lidocaine) and sedation according to patient preference, major breast cancer surgery is usually done under general anesthesia for patient comfort and surgical ease. Breast surgery, in general, is a low-risk surgery, and perioperative risk is mainly dependent on the presence and severity of comorbidities and the age of the patient.

Nearly 60% of women experience severe pain following breast cancer surgery. One study showed that risk factors associated with pain at 1 month after surgery include non-white race, obesity, and high postanesthesia care unit (PACU) opioid use. It has been suggested by many authors that patients undergoing major surgery for breast cancer experience fewer postoperative side effects if they receive regional rather than general anesthesia for procedures such as mastectomy, lumpectomy, and reconstructive surgery. Lynch and colleagues studied outcomes of thoracic epidural anesthesia after oncologic breast surgery and reconstructive procedures. The conclusion of their retrospective analysis was that lower postoperative nausea and vomiting (PONV) was associated with statistically significant earlier hospital discharge and that thoracic epidural anesthesia is a safe technique not associated with neurologic or respiratory complications that improves patients' recovery while reducing the cost of these procedures. Thoracic epidural anesthesia and analgesia have been described for modified radical mastectomy, breast augmentation, and mastectomy with transverse rectus

abdominus myocutaneous (TRAM) flap reconstruction. It is usually initiated at the T3–T4 interspace (high thoracic), and breast tissue (i.e., augmentation) requires a blockade from T1 through T7. Procedures including the anterior chest wall (i.e., modified radical mastectomy) may require blockade up to C5 to include pectoral nerves. A thoracic paravertebral nerve block can be used to augment, or as an alternative to, general anesthesia in high-risk patients undergoing major breast surgery. Single-injection techniques are limited to the duration of the local anesthetic and are discussed elsewhere in the text. The introduction of disposable infusion pumps has facilitated the use of ambulatory perineural infusions. Preliminary retrospective data suggest a possible advantage of regional techniques in breast cancer surgery beyond decreased postoperative pain and PONV rates. Some retrospective data suggest that the use of regional analgesia and the avoidance of systemic opioids result in lower cancer recurrence rates, possibly due to inhibition of cellular and humoral immune function in humans. Larger prospective studies are under way.

Augmentation mammoplasty

Augmentation mammoplasty is often performed for cosmetic reasons or in patients who have undergone breast cancer surgery. A prosthesis is inserted under or above the pectoralis muscle. The most commonly used anesthetic is general anesthesia, although some patients prefer local with intravenous (IV) sedation. Regional anesthesia choices include epidural, thoracic paravertebral block, or a continuous paravertebral catheter. Local anesthesia includes several techniques, such as subcutaneous injection, intercostal nerve blocks, pump infusions, and “splashing” local anesthetic into the submuscular pocket. Patients who have already undergone breast surgery and chemotherapy may have difficult IV access and a history of exposure to chemotherapeutic agents that can have long-lasting effects on cardiac, pulmonary, and other systems. Commonly used chemotherapeutic agents and their side effects are summarized in [Table 103.1](#).

Gynecological surgery

Since the 1970s there has been a significant increase in gynecologic procedures performed in the ambulatory setting.

Table 103.1. Common chemotherapeutic drugs used in breast cancer

Drug	Significant side effect
Doxorubicin	Cardiomyopathy, nephrotoxicity, hepatotoxicity
Cyclophosphamide	Pseudocholinesterase inhibition, thrombocytopenia, decreased threshold for PONV
Methotrexate	Pulmonary infiltrates, hepatotoxicity, inhibition of folate metabolism
Tamoxifen	Hepatotoxicity
Cisplatin	Peripheral neuropathy, nephrotoxicity
Gemcitabine	Nephrotoxicity, lung toxicity, hepatotoxicity

Table 103.2 shows the different types of anesthesia suitable for common gynecologic procedures. Today, surgeons use improved techniques, such as minimally invasive surgery with small incisions, and new smaller, more flexible scopes and laparoscopic techniques. By the late 1990s, more than 80% of gynecologic surgery for benign pathology was done on an ambulatory basis.

Table 103.3 demonstrates the four major approaches to gynecologic surgery – laparoscopy, hysteroscopy, vaginal, and abdominal – and the different procedures associated with each. Hysteroscopy involves a visual examination of the uterine cavity through a flexible hysteroscope. The uterine cavity is distended with saline, glycine, dextran, or carbon dioxide (CO₂) to inspect the interior of the uterus. IV sedation or paracervical block is adequate for anesthesia as long as prolonged manipulation is not required. Applications include evaluation of abnormal uterine bleeding and polyp or intrauterine device (IUD) removal. Resection of submucosal leiomyomas and endometrial ablation usually require regional or general anesthesia. Often hysteroscopy is done in conjunction with curettage and laparoscopy. The most common complications include uterine perforation, bleeding, and infection. Intravascular extravasation of fluid or gas can become clinically significant only later with onset of hyponatremia, air embolism, cerebral edema, and even death.

The loop electrosurgical excision procedure (LEEP) is therapy for vulvar and cervical lesions, such as vulvar condylomata and cervical dysplasias. Low-voltage, high-frequency alternating current is used to limit thermal damage yet allow good

Table 103.2. Anesthetic options for common gynecologic procedures

Gynecologic procedure	Common anesthetic options
Transabdominal or transvaginal hysterectomy	GA or regional
Diagnostic laparoscopy	GA
LEEP, cervical biopsy	MAC or GA
Dilation & curettage	MAC or GA
Tubal ligation	GA or Regional

GA, general anesthesia; MAC, monitored anesthesia care.

Table 103.3. Major approaches to gynecologic surgeries

Laparoscopy	Hysteroscopy
Endometriosis	Myomectomy
Ectopic pregnancy	Septum resection
Hysteroscopy	Endometrial ablation
Myomectomy	Polypectomy
Tubal sterilization	Adhesions/Asherman's
Oophorectomy	Proximal tubal cannulation
Ovarian cystectomy	Hysterosalpingogram
Adnexal mass removal	
Salpingostomy/salpingectomy	
Bladder neck suspension	
Infertility	
Sling/Burch procedures	
Vaginal	Abdominal
Hysterectomy	Hysterectomy
Myomectomy (rare)	Myomectomy (low transverse incision)
Dilation & curettage	Tumor debulking
Dilation & evacuation	Urinary stress incontinence surgery
Laser therapy	

hemostasis. These lesions can also be excised either with a sharp knife or laser, and this procedure can be performed under local anesthesia with IV sedation or general anesthesia.

Tubal ligation is most commonly performed via laparoscopy under general anesthesia. Complications of general anesthesia have been the leading cause of death attributed to sterilization in the United States. The risks of general anesthesia are known to increase during the postpartum period. The use of local anesthesia alone has increased only from 4% to 8% in the United States. Worldwide, more than 75% of tubal ligation procedures are performed under local anesthesia because a mini-laparotomy can be done safely under local anesthesia. The disadvantages, however, can be anxiety and discomfort, both for the patient and the surgeon. It is unknown whether local anesthesia for tubal ligation has a better safety profile than general anesthesia.

Gynecological laparoscopy

Laparoscopy can be either diagnostic or operative. In recent years, the use of laparoscopy in gynecology has expanded dramatically from its use in diagnosis to tubal sterilization, treatment of ectopic pregnancy, and hysterectomy. Compared with laparotomy, laparoscopy offers a shorter hospitalization, less postoperative pain, less morbidity, and a shorter recovery period. The physiologic aspects associated with gynecologic laparoscopy are discussed in detail in the chapter on anesthesia for laparoscopy, [Chapter 101](#).

Anesthetic techniques for laparoscopy

Table 103.4 gives an overview of the different types of anesthetic options for laparoscopic gynecologic procedures. Because more laparoscopic procedures are performed on an outpatient

Table 103.4. Possible anesthetic techniques used for laparoscopic gynecologic surgery

GA with ETT
 GA/LMA with mechanical ventilation (either classic or ProSeal)
 GA with spontaneous ventilation
 Regional (spinal, epidural, or CSE)
 Local +/- IV sedation
 Combined GA/regional

basis, general and regional anesthesia have been successfully and safely used with great emphasis on short-duration drugs, cardiovascular stability, rapid recovery and fast-tracking, mobility, and prevention and treatment of PONV and pain. Most commonly, general anesthesia is used because it allows for controlled ventilation (to counteract the CO₂ absorption), good surgical conditions, and patient comfort. Shorter-acting drugs such as sevoflurane, desflurane, and continuous infusions of propofol are the maintenance agents of choice. An early recovery has been attained with any of these agents. Remifentanyl is often used in fast-tracking due to its lack of accumulation with continuous infusion.

Regional anesthesia provides some advantages but can be controversial during laparoscopy. The advantages include decreased PONV, reduced postoperative pain, shorter stay, cost effectiveness, improved satisfaction, fewer hemodynamic changes, and earlier diagnosis of complications. Requirements include a relaxed, cooperative patient, low intra-abdominal pressure, reduced Trendelenburg requirements, and a precise surgical technique. The combined effects of pneumoperitoneum and sedation can lead to hypoventilation and arterial oxygen desaturation. Advances in microlaparoscopy allow these procedures to be performed with local anesthesia alone or supplemented by sedation. Longer laparoscopic procedures may be more suitable for epidural anesthesia, and, if onset time is an issue, a combined spinal–epidural (CSE) anesthetic can be utilized. With the development of gasless laparoscopy and microlaparoscopy, spinal anesthesia will probably take on a greater role in the near future.

Robotic-assisted gynecologic surgery

Robotic-assisted gynecologic surgery is a relatively new technique that is gaining popularity. Fallopian tube anastomosis, hysterectomy, and myomectomy have been successfully performed with this technique. After induction of anesthesia, the abdomen is insufflated with CO₂, and the patient is placed in modified dorsal lithotomy with steep Trendelenburg position. General anesthesia is most commonly used, and continuous muscle paralysis is recommended. It is also advisable to use limited volumes of IV fluids while the patient is in the Trendelenburg position.

Preoperative considerations for gynecologic laparoscopy

Choosing the appropriate patient for laparoscopy and then scheduling an outpatient procedure require careful preoperative assessment to identify increased risk for the individual patient on a case-by-case basis. Most patients will be young and healthy, but, more recently, older, more complex patients have been arriving to the operating room for laparoscopic procedures. In many settings, the surgeon performs such screening, and the anesthesiologist first encounters the patient on the day of surgery.

Induction and maintenance of anesthesia

Induction of general anesthesia is most easily accomplished with an intravenous agent such as propofol, although inhaled agents may also be used. Gynecologic laparoscopy can be performed using a laryngeal mask airway (LMA) in lieu of tracheal intubation, although many anesthesiologists prefer intubation. In gynecologic laparoscopy, devices such as the ProSeal (LMA; San Diego, CA) and its analogs may be useful because they can allow higher airway pressure without leaking. Most studies examining the value of the ProSeal LMA as opposed to tracheal intubation have enrolled healthy American Society of Anesthesiologists (ASA) I-II patients who were not obese and had no airway issues. The choice of an endotracheal tube may also be dictated by the duration of surgery, excess Trendelenburg position, or high intra-abdominal insufflation pressures.

The choice of maintenance technique includes shorter-acting inhalational agents or total IV anesthesia (TIVA). Nitrous oxide (N₂O) is sometimes used to reduce the requirements of inhaled or IV anesthetics, although some studies show an increase in PONV. Muscle relaxants with longer half-lives can still be used, although diagnostic laparoscopy may be brief in duration.

Local anesthesia

In skilled surgical hands, laparoscopic surgery can be accomplished under local anesthesia. Drives toward more office-based procedures may increase the use of local anesthesia for laparoscopy because of its inherent simplicity. The transverse abdominis plane (TAP) block using a “double-pop” technique or ultrasound guidance to advance the needle into the proper neurofascial plane has been reported to provide excellent analgesia after abdominal surgery.

Postoperative analgesia

The multimodal anesthesia model is quickly becoming popular especially in the ambulatory setting, because postoperative pain is one of the most common factors leading to delays in discharge and an increase in hospital admissions. Table 103.5 shows

Table 103.5. Analgesic modalities for laparoscopic surgery

Modality	Clinical
Nonselective COX or selective COX-2 inhibitors	Multimodal approach to pain management, unless contraindicated
Intraperitoneal local anesthesia	More effective for pelvic procedures
Wound infiltration with local anesthesia	Better in combination with above
Removal of gas (and gasless surgery)	Possible decrease in shoulder pain
Intraperitoneal NS irrigation	Need large volumes (25–30 ml/kg) +/- local
Low intra-abdominal pressure	Decrease in analgesic requirements up to a week postoperatively
N ₂ O pneumoperitoneum	Pain reduction up to 24 h
Heated, humidified CO ₂	Less pain and earlier return to activities
Phrenic nerve block	Decrease in the incidence of shoulder pain, but not analgesic requirements
Mesosalpinx/tubal block	Significant decrease in pain post tubal ligation
Rectus sheath block	Earlier discharge and decreased analgesic requirements
Pouch of Douglas block	+/- catheter, especially helpful post bilateral tubal ligation

NSAIDs, nonsteroidal anti-inflammatory drugs; COX-2, cyclooxygenase-2; NS, normal saline.

various analgesic modalities currently being used for laparoscopic procedures.

Prolapse repair

Genital prolapse (i.e., pelvic organ prolapse) includes cystocele, urethrocele, enterocele, and rectocele as well as uterine prolapse. The laparotomy approach has a fairly high risk of operative hemorrhage usually from the laceration of the sacral veins. Bleeding can be difficult to control if the veins retract into the bone. The majority of gynecologists prefer the use of local anesthesia with epinephrine to obtain hydrodissection between the vaginal mucosa and the bladder and rectum that also diminishes bleeding.

Obliterative vaginal operations such as LeFort's procedure and colpocleisis can be performed under local or regional anesthesia. Most patients are elderly or chronically ill and usually present with severe prolapse. There are at least 130 operative procedures described for the treatment of female urinary stress incontinence. The latest modification is the midurethral sling procedure, either retropubic or transobturator with tension-free vaginal tape (TVT). These procedures have been successfully performed under local anesthesia, sedation, or general anesthesia.

Laparoscopic hysterectomy and myomectomy

Ellstrom and colleagues performed a prospective randomized study to evaluate pain with respect to pulmonary function in the first 48 hours after abdominal versus laparoscopic surgery. Pain scores were lower after laparoscopic hysterectomy on both the first and second postoperative days. Although lung function measured as peak expiratory flow, forced vital capacity, and forced expiratory volume in the first second of expiration was impaired in both groups, the patients who had laparoscopic hysterectomy had less impairment in pulmonary function. The influence on pulmonary function is more pronounced in patients having upper abdominal surgery than in those having lower abdominal surgery. For laparoscopic myomectomy, the potential for blood loss due to myometrial vascularity exists

and needs to be monitored. Surgical techniques to minimize blood loss and the need for blood transfusion include applying a tourniquet around the lower uterine segment to compress the uterine arteries, injecting vasopressin intramyometrially, using intraoperative blood-scrubbing devices, correcting anemia preoperatively, donating autologous blood, mild overhydration, and requiring (rarely) a simultaneous hysterectomy.

Anesthesia for liver transplantation

Jason C. Brookman and Warren S. Sandberg

Introduction

The first successful orthotopic liver transplant in a human occurred in 1967. Since then, transplant complexity and survival rates have improved significantly due to enhanced surgical techniques and immunosuppressive drugs. Liver transplant anesthetics are still some of the most complex currently performed because of the surgical and medical criticality of the patients and because of the complexity of the equipment required. Liver transplantation consumes tremendous resources. At least two anesthesiology personnel and at least two additional professional personnel (i.e., perfusionist, monitoring nurse, auto-transfusion nurse) are assigned to each case in most centers. Many of the considerations for liver transplantation anesthesia apply equally to liver resection. Liver resection surgery has tracked with transplantation – trending toward increasing complexity and magnitude of resection, in increasingly sicker patients, while at the same time reducing morbidity and mortality. Accordingly, this chapter is written largely from the transplantation anesthetic perspective, but most of the material is directly applicable to anesthesia for liver resection.

Pretransplant assessments

Indications, contraindications, patient selection

The indications for orthotopic liver transplantation are numerous (Table 104.1). The most common indication is chronic hepatocellular disease due to alcohol and/or hepatitis. Hepatitis B and C both predispose patients to hepatocellular carcinoma. As the prevalence of hepatitis C in the population increases, so does the incidence of hepatocellular carcinoma, which is becoming an increasingly common indication for liver transplantation. Patients with fulminant hepatic failure are relatively rare but require particular attention, as they may develop daily (or even hourly) contraindications to transplantation.

As surgical techniques, risk stratification of potential recipients, and the management of intercurrent diseases all improve, the contraindications to liver transplantation are becoming more nuanced.

Liver transplantation is a grueling process before, during, and after the operation. To be listed as recipients, patients must be screened by a liver transplant listing committee – made up of surgeons, hepatologists, anesthesiologists, psychiatrists,

addiction specialists, social services specialists, family therapists, and financial assistance experts – that will assist in the patients' continued care before, during, and after the transplant has occurred.

Liver transplant candidates must be willing to accept (potentially) massive blood transfusion during and after surgery, although some centers are able to reliably perform liver transplantation with little or no transfusion. Postoperative intubation, mechanical ventilation, and intensive care unit (ICU) admission are likely, and the patient should be aware of these possibilities. Obese patients with a body mass index (BMI) > 30, considered to be a relative contraindication to

Table 104.1. Indications for liver transplantation (not exhaustive)

End-stage liver disease (chronic)
Hepatocellular disease
Chronic viral hepatitis (mostly hepatitis C)
Alcoholic liver disease
"Cryptogenic" cirrhosis
Chronic drug-induced liver disease
Cholestatic disease
Primary sclerosing cholangitis
Primary biliary cirrhosis
Biliary atresia (mostly children)
Other familial cholestatic syndromes
Vascular disease
Budd–Chiari syndrome
Veno-occlusive disease
Polycystic liver disease
Hepatic malignancies not amenable to other therapy
Hepatocellular carcinoma (often in setting of hepatitis C)
Cholangiocarcinoma
Carcinoid tumor
Other cancers (e.g., insulinoma)
Fulminant hepatic failure
Drug induced hepatic failure
Acute viral hepatitis (A, B, C, delta)
Metabolic diseases
Wilson's disease, organic acidurias, others
Metabolic diseases affecting the liver
Alpha-1 antitrypsin deficiency
Hemochromatosis
Other rare diseases (e.g., Alagille syndrome, glycogen storage diseases, urea cycle deficiencies)

Table 104.2. Additional preanesthetic history for the patient with liver disease

1. For the patient with known or suspected liver disease, presenting for surgery
 - a. Potential inciting agents/events: blood transfusion, infectious diarrhea, travel, jaundice, hepatitis, tattoos, IV drug use, high-risk sexual activities, medication history, alcohol use history, or contact with other jaundiced patients
 - b. Signs and symptoms of aggravation of liver disease: worsening fatigue, malaise, or pruritus; hematemesis, abdominal distention
 - c. Neurologic manifestations: altered sleep patterns – especially day/night reversal, or behavioral changes – confusion, excitation, lethargy – indicating encephalopathy
2. For the patient presenting for unscheduled surgery, including liver transplantation
 - a. Quality and quantity of recent oral intake
 - b. Vascular access and history of previous central venous and/or arterial catheter placement
 - c. Cardiovascular risk, focusing on recent screening tests of cardiac function and ischemic risk, recent changes in exercise tolerance (although it may be difficult to differentiate between cardiac dysfunction and worsening liver disease), and especially signs or symptoms of angina
 - d. Assessment hepatic synthetic function
 - i. Changes in abdominal girth or peripheral edema, indicating insufficient albumin and other plasma protein synthesis to maintain plasma oncotic pressure
 - ii. History of easy bruising or prolonged bleeding, indicating insufficient hepatic synthetic function of clotting factors
 - e. Assessment of neurologic status, including worsening encephalopathy, as well as focal neurologic deficits, as positioning injuries with consequent neurologic deficits are not uncommon

transplantation, are encouraged to lose weight because obesity is associated with increased perioperative mortality.

Preanesthetic evaluation

The prescreening process to place a patient on the liver transplant list is rigorous. Most patients have had an extensive diagnostic and risk stratification assessment in preparation for liver transplant. Patients for hepatic surgery should be evaluated as indicated by their health status and the surgical severity, with the surgery itself being considered “high-risk” or “major” surgery. The immediate preoperative anesthetic evaluation on the day of surgery should be focused on the history and physical examination relevant to the case immediately at hand (Table 104.2).

The physical examination should be tailored for the patient undergoing major intra-abdominal surgery. Special attention should be paid to the assessment of ascites, as it potentiates the possibility of gastric regurgitation and aspiration, and may compromise pulmonary performance, manifesting as dyspnea and atelectasis secondary to ascites, which further reduces the functional residual capacity [FRC]. Attention should also be paid to sites for vascular access. Landmarks for internal and external jugular cannulation, as well as subclavian access, should be examined, as well as peripheral venous and arterial sites on both arms.

Laboratory tests and diagnostic studies should focus on cardiac performance, pulmonary function, hepatic synthetic and excretory function, coagulation status, hemoglobin, and renal function. Table 104.3 summarizes the most pertinent studies.

For liver transplant recipients, cardiac functional testing proximate to the date of surgery is important, as orthotopic liver transplantation is still, physiologically, a highly stressful operation with potential for sudden, massive, and ongoing blood loss complicated by extreme electrolyte derangements. Untreated significant coronary disease is potentially lethal in the setting of liver transplantation. In one study, half of all patients with coronary artery disease who underwent liver transplantation died in the perioperative period, and the morbidity rate was 81%.

Patients should be able to, hypothetically, tolerate variable periods with heart rates greater than 110 bpm, mean arterial pressure (MAP) < 50 mm Hg, hemoglobin of 7 gm/dl, and pH < 7.2. Most transplant programs use a cardiac risk stratification schema similar to that devised by Plevak. The version used by our program, for example, is shown in Fig. 104.1.

Portopulmonary hypertension is an important contributor to morbidity and mortality in liver transplantation. Half of the patients with mean pulmonary pressures between 35 and 50 mm Hg died in the peritransplant period, and mortality was 100% in those with mean pulmonary artery pressure > 50 mm Hg. Because of this result, patients with moderate to severe portopulmonary hypertension are typically refused transplantation.

Perioperative management

Timing of surgery- and anesthesia-related events must be well coordinated, as one donor typically supplies organs to many

Table 104.3. Preoperative laboratory tests and diagnostic studies for liver transplant patients

- All patients-
- Serum albumin and bilirubin (hepatic synthetic function)
 - Coagulation studies (prothrombin time, partial thromboplastin time, fibrinogen, and platelet count)
 - Hemoglobin/hematocrit
 - Blood type and antibody screen
 - Serum electrolytes (Na⁺, K⁺, Cl⁻, Ca²⁺, Mg²⁺, PO₄⁻)
 - BUN and creatinine
 - Electrocardiogram
- Liver transplant recipients (and patients for hepatectomy, as indicated)
- ABG measurement (for both pulmonary and renal function)
 - Dobutamine stress echocardiogram (or, possibly, exercise stress thallium imaging test)
 - Transthoracic echocardiogram (to exclude structural cardiac disease and portopulmonary hypertension)
 - Preoperative chest radiograph
 - Pulmonary function testing

BUN, blood urea nitrogen; ABG, arterial blood gas.

Diagnostic Approach to Inducible Myocardial Ischemia

Figure 104.1. Suggested algorithm for assessment of inducible myocardial ischemia. OLT, orthotopic liver transplantation. Modified from Sandberg WS, Raines DE. Anesthesia for liver surgery and transplantation. In: Longnecker D, Brown D, Newman M, Zapol W. *Anesthesiology*. New York: McGraw-Hill; 2008, with permission.

*Clinical predictors

- History of coronary disease or congestive heart failure
- Signs and symptoms of coronary disease or congestive heart failure
- Abnormal ECG
- Diabetes
- Current or prior smoking
- Hypertension
- Hyperlipidemia
- Obesity
- Age > 50 for males, > 55 for females
even in absence of any above

hospitals, and procedural delays can ripple widely. Liver transplant recipients are usually brought to the operating room (OR) area and undergo several preparatory procedures in advance of knowing whether the donor liver is actually suitable for transplantation. After the harvested organ is deemed suitable, the patient will undergo induction of anesthesia and placement of several invasive monitoring catheters. Concerns and activities during anesthesia for liver transplantation mirror the major phases of the surgery (Table 104.4).

Monitoring and vascular access

Again, many considerations about monitoring apply equally to liver transplant and hepatic resection. Typical monitoring

consists of American Society of Anesthesiologists (ASA) standard monitors and selected invasive monitors.

- Blood pressure monitoring is accomplished by an arterial catheter, which is useful for early recognition of hypotension and for obtaining frequent blood samples.
- Central venous pressure (CVP) measurement is useful to guide intravascular volume replacement and to assess right heart pressures when the dissection is expected to be bloody. Central venous access has the added benefit of providing a conduit for potent vasopressor administration.
- A pulmonary artery catheter is sometimes used for measuring pulmonary artery pressures (especially for assessing pulmonary hypertension); assessing left heart

Table 104.4. Liver transplant anesthetic phases

Anesthetic phase	Surgical correlate
• Preinduction	• Beginning of harvest procedure, evaluation of donor organ
• Induction, preparation for surgery, and maintenance	• Donor organ harvest and transport to recipient hospital
• Preanhepatic phase	• Recipient hepatectomy is performed; donor liver is prepared for implantation
• Anhepatic phase	• Vascular anastomoses between the donor liver and recipient's vessels are constructed
• Venous reperfusion of the graft	• Venous clamps removed; surgeon may limit flow of blood through organ to smooth hemodynamic insult
• Neohepatic phase	• Hepatic arterial and biliary anastomoses are constructed; wound is closed
• Emergence/transport to ICU	• Assumption of homeostatic control from the anesthesia team

filling pressures via pulmonary artery occlusion pressure (i.e., wedge pressures); following cardiac output, which is usually elevated to 10 L/min (\pm 2 L/min) in the setting of a hyperdynamic circulation; and guiding pharmacologic therapy in the setting of hypovolemia from dystonic peripheral vasculature.

- Transesophageal echocardiography can also provide information regarding both intravascular volume status and cardiac performance, especially early detection of large embolic events (i.e., air embolus or thrombus).
- Many teams use some form of level-of-consciousness monitoring, often with the goal of minimizing exposure to anesthetic agents and their negative inotropic effects. The interpretation of these data are not straightforward, however, as hepatic encephalopathy itself depresses the bispectral index.

Peripheral vascular access with multiple large intravenous (IV) catheters (i.e., 16 gauge or larger), above the diaphragm, is usually sufficient – this is often the only vascular access placed prior to anesthetic induction. One helpful device is called the rapid infusion catheter (RIC; Arrow International, Reading, PA), an 8.5 French peripherally inserted catheter useful for rapid infusion of large volumes with a high-flow infusion pump. It can be placed in any large peripheral vein. Antecubital or cephalic veins are commonly chosen, but even distal veins on the forearm and hand can be used if they are large enough. The RIC alleviates the need for multiple central lines that might be required to pass a pulmonary artery catheter, run multiple infusions, and accommodate high-flow administration of large volumes.

Another development in the intraoperative management of liver transplant surgery is the use of venovenous bypass (VVB) to decompress the inferior venous systemic and/or portal

circulations. This modality, first described in 1984, maintains venous return to the heart by bypassing the portal circulation after the hepatic vessels have been cross-clamped. VVB is accomplished by actively pumping blood (with flow rates of 1.5–5 L/min) in a circuit usually from the left femoral vein via a percutaneous catheter (inserted by the surgical team), to a large venous vessel that drains into the superior vena cava (SVC) above the liver (i.e., internal jugular vein, subclavian vein, or axillary vein). The anesthesia or surgical team performs the return line cannulation via cutdown to the left axillary vein (by the surgical team) or percutaneously. The portal vein, if accessed, is cannulated intraoperatively via the surgical field. It is important to make sure there is no air in the circuit prior to starting bypass and that all the connections are connected tightly, as any air in the system would be catastrophic.

Induction and maintenance of anesthesia

Liver transplantation produces at least transient hepatic dysfunction, so it may be preferable to choose drugs for which elimination is not completely dependent on hepatic metabolism. In practice, the dose-to-effect mode of administration is almost always sufficient to minimize the interaction between choice of anesthetic and the effect of liver transplantation.

Induction of anesthesia is typically accomplished using standard methods. Careful attention should be directed to adequate denitrogenation, as ascites significantly reduces FRC. Furthermore, patients with ascites should be considered to have a full stomach and receive a rapid-sequence induction with cricoid pressure, if not otherwise contraindicated. Doses of hypnotic drugs, such as propofol or pentothal, should be reduced. Alternately, etomidate may be used to avoid the hemodynamic consequences of propofol. Skeletal muscle paralysis may be achieved either using succinylcholine followed by a nondepolarizing agent (e.g., vecuronium, cisatracurium) or by a rapid-sequence induction dose of rocuronium. Antibiotics directed against skin flora (e.g., cefazolin) should be given no more than 60 minutes before incision and redosed appropriately to account for pharmacologic elimination or loss due to hemorrhage.

Anesthesia is maintained by standard methods. Any commonly used halogenated inhalational agent (e.g., isoflurane, sevoflurane) may be used for maintenance. Many anesthesiologists avoid nitrous oxide, as it can contribute to bowel distension. Intermediate-acting opioids, such as morphine, hydromorphone, or fentanyl, are titrated to meet the patient's needs for analgesia. Paralysis is maintained to facilitate surgical exposure. Like that of antibiotics, readministration of IV drugs must be adjusted to account for losses due to hemorrhage.

Positioning the patient on the operating table is important. The patient is supine, and the right arm is usually tucked to allow for better surgical access. No critical monitors or

Table 104.5. Major foci of intraoperative management during anesthesia for orthotopic liver transplantation

Major focus (problem or organ system)	Subtopics	Related and modifying factors
Cardiac	Ischemic potential Dysrhythmias Right ventricular performance	Hemorrhage (demand and carrying capacity) Acid–base and electrolyte disturbances Emboli, hepatic washout
Portal-to-central venous gradient	Graft perfusion is tenuous	Need to keep CVP adequate to provide cardiac preload during vena cava cross-clamping Need to prevent venous air embolism Sudden hemorrhage
Renal performance	Urine output	Hypovolemia and hypotension Preexisting renal disease Need for intraoperative renal replacement therapy
Anesthesia	Hypnosis Analgesia Muscle relaxation	Patients may not tolerate cardiovascular depression from deep anesthesia
Brain protection	Acute brain herniation can happen, especially in fulminant hepatic failure	Intracranial pressure monitoring risky but helpful Barbiturates and mild hypothermia (34°C) may be helpful
Immunosuppression	Different regimens depending on indication for OLT	
Prophylaxis	Temperature management DVT prophylaxis Preemptive antibiotics	Large incision, large prepped area Dilution due to massive hemorrhage
Glucose management	Coexisting diabetes	Steroid administration Absent gluconeogenesis during anhepatic phase
Coagulation	Hypocoagulable state due to liver failure Platelet sequestration Platelet dysfunction due to uremia	Massive hemorrhage Acute fibrinolysis at graft reperfusion
Electrolytes	Potassium Sodium Calcium	Elevated by K load in blood products Hyponatremic patients at risk for CPM with massive infusions of sodium-rich fluids Citrate in blood products chelates Ca ²⁺
Pulmonary performance	Ventilation Oxygenation Pulmonary vascular resistance	May be impaired by pleural effusions May be impaired by intrapulmonary shunts Acutely elevates in the face of acid load at graft reperfusion
Hemodynamics	Vasodilated hyperdynamic circulation Massive hemorrhage Vena cava compression Possible VVB	

OLT, orthotopic liver transplantation; DVT, deep vein thrombosis; CPM, central pontine myelinolysis.

Modified from Sandberg WS, Raines DE. Anesthesia for liver surgery and transplantation. In: Longnecker D, Brown D, Newman M, Zapol W. *Anesthesiology*. New York: McGraw-Hill; 2008, with permission.

vascular access catheters should be placed in this extremity. The procedure time is long so there is great risk of positioning injuries from many potential pressure points. All pressure points should be supported and padded with viscoelastic gel or soft, compressible foam. The operation is performed through a right-sided subcostal incision extended across the midline to the left subcostal area and sometimes upward along the midline toward the xiphoid.

The surgical preparation for a liver transplant covers the entire abdomen and lower chest, left groin, and, sometimes, the left axilla. This large preparation area makes it initially difficult to maintain satisfactory body temperature. With such a large area exposed, patient warming is important and needed to maintain good clotting performance and to minimize the risk

of surgical site infection. Forced-air warming blankets applied to (1) the lower limbs and (2) the upper chest, left arm, and head and a full under-body unit, all together, are highly effective at maintaining normothermia after the drapes have been applied. IV fluids must be actively warmed during infusion, given the high volume of cooled blood products that are transfused. Warming is usually accomplished by a high-flow warming device which, ideally, has a reservoir for blood products, a debris filter, an air-removal system downstream from the warmer, a pump, and air detectors. Flow capacities are dependent on either the device's pump or the gauge of catheter used.

A summary of the variety of homeostatic goals to which the anesthesia team attends throughout a liver transplant can be found in [Table 104.5](#).

Preanhepatic phase

The preanhepatic phase of the surgery is the point at which a total hepatectomy is being performed.

Surgical approach

After surgical exposure of the hepatic vasculature, the hepatic artery, portal vein, and the common bile duct are clamped and divided in one of two different techniques:

- (1) An en bloc technique in which the inferior vena cava (IVC) is clamped above and below the liver, and part of it is resected and replaced with a section of the donor vena cava. This technique causes potentially massive loss of venous return and profound hemodynamic instability. VVB bypass (see Monitoring and Vascular Access above) may be used to minimize these insults.
- (2) A “piggyback” technique in which the recipient IVC is preserved and clamped with a side-biting clamp and an end-to-side anastomosis is constructed to the donor liver venous outflow. This method preserves vena cava flow, except for a few minutes during the anastomosis, and may significantly reduce severity of physiologic problems.

While the hepatectomy is being performed, a separate surgical team prepares the graft vessels on the donor liver.

Anesthetic concerns

Clamping the portal triad reduces venous return, although cardiac output and blood pressure do not necessarily decrease. In contrast, cross-clamping the IVC reduces systemic blood pressure and cardiac output secondary to the large reduction in venous return. While moderate decreases in cardiac output and blood pressure can be treated by vasopressor administration, preferably an agent with some inotropic activity (e.g., norepinephrine), and judicious intravascular volume expansion, severe cardiovascular compromise may require institution of VVB. Targeting for CVP between 7 and 10 mm Hg also reduces the incidence of postoperative renal failure and 30-day mortality.

The goals of hemodynamic management (see Table 104.6) are to provide sufficient circulating volume, vascular resistance,

Table 104.6. Major contributors to hemodynamic changes during liver transplantation

- Episodic alterations in venous return
- Hemorrhage
- Sepsis
- Acidemia
- Hypocalcemia due to citrate toxicity
- Embolism (air or thrombotic)
- Acute right ventricular failure
- Graft reperfusion (due to sudden acid load and temperature decrease)

Fluid and blood component replacement strategy

Figure 104.2. High-level overview of one volume and blood component replacement strategy for liver transplantation requiring massive transfusion. All fluids are warmed. The thickness of the bars represents the approximate relative proportions of each fluid in the replacement infusions. Modified from Sandberg WS, Raines DE. Anesthesia for liver surgery and transplantation. In: Longnecker D, Brown D, Newman M, Zapol W. *Anesthesiology*. New York: McGraw-Hill; 2008, with permission.

and cardiac output to perfuse the vital organs. This management is guided by urine output, CVP, and minimal vasopressor requirements, except during periods of inadequate venous return.

The goal of volume management and transfusion is to maintain adequate volume to support good circulation. Large-volume hemorrhage requires direct intervention to control the composition of the circulating intravascular volume and coexistent coagulopathy.

Figure 104.2 gives an overview of volume and transfusion management strategies as a function of blood loss during transplantation. Volume replacement therapy should attend to preserving or moving clotting potential toward a normal state as part of the effort to reduce blood loss (see Tables 104.7 and 104.8).

Table 104.7. Intraoperative transfusion therapies

To maintain intravascular volume

- 5% Albumin
- FFP (when coagulopathic)
- PRBCs

- Good surgical technique

To maintain coagulation capacity

- FFP
- Platelets
- Epsilon aminocaproic acid (AMICAR; Wyeth-Ayerst, Madison, NJ) – antifibrinolytic
- Cryoprecipitate (concentrated source of fibrinogen)

Table 104.8. Serial intraoperative laboratory studies^a

Parameter	Purpose
Hemoglobin/hematocrit	Gauge volume of blood loss/red cell mass, manage transfusion with RBCs
PT/INR, PTT, platelet count, D-dimer, fibrinogen thromboelastography	Determine coagulation performance (clot initiation, formation, lysis)
ABG	Follow acid–base status, assess/correct acidemia/metabolic acidosis
Electrolytes (Na ⁺ , K ⁺ , Cl ⁻ , Ca ²⁺ , Mg ²⁺ , PO ₄ ⁻)	Help assess potentially hemodynamically destabilizing blood levels (i.e., hypocalcemia from chelation by sodium citrate in transfused RBCs and FFP)
Blood glucose	Treat hypoglycemia (or hyperglycemia) during anhepatic phase

^a Drawn every 30 minutes after the beginning of surgery.

PT, prothrombin time; INR, international normalized ratio; PTT, partial thromboplastin time; ABG, arterial blood gas.

Anhepatic phase

The anhepatic phase of liver transplantation occurs from the point at which the native liver is sufficiently compromised to no longer function (i.e., hepatic artery clamping) until the new liver is reperfused. This is a relatively quiet time, hemodynamically speaking, especially if a piggyback technique or VVB (en bloc resection) is used. Vasopressors may be needed if there is no venous return conduit because of IVC clamping.

The donor liver is brought over from the separate worktable to the surgical field and kept on ice while the vascular anastomoses are completed. It is during the early part of this phase that immunosuppressive drugs are given, usually 100 mg of IV methylprednisolone, to supplement the induction dose of mycophenolate mofetil (CellCept, Roche Pharmaceuticals) given prior to surgery.

Metabolic acidosis may develop in the anhepatic phase due to portal cross-clamping, and partial or complete IVC cross-clamping, in addition to the loss of residual ability to clear organic acids. Ongoing transfusion of low-pH, citrated blood products also contributes to the acidemia, as does a release of an acid load and metabolic waste products during reperfusion. The latter is corrected by hyperventilation and IV sodium bicarbonate.

During the anhepatic phase of liver transplantation, there may be significant changes in potassium balance which favor hyperkalemia. Factors that influence this include infusion of large-volume blood products (e.g., packed red blood cells [PRBCs], fresh frozen plasma [FFP]) with high potassium concentrations, splanchnic ischemia, metabolic acidosis, compromised renal function, and the potassium-rich preservative solution used for the donor liver. Hyperkalemia must be treated to avoid myocardial irritability and cardiac dysrhythmias. Various treatment modalities include potassium-wasting diuretics, bicarbonate, glucose and insulin, and/or continuous venovenous hemofiltration or conventional dialysis in patients with compromised renal function.

Renal failure requiring renal replacement therapy (e.g., dialysis or continuous venovenous hemofiltration) is common after liver transplantation, but is associated with higher mortality rates than in patients who have preserved renal function. Maintaining an adequate circulating volume or a selective medical therapy facilitates preservation of renal function. A commonly used clinical adjunct for assessing renal function is measuring urine output, with a target of 1 ml/kg/h.

Use of large amounts of citrated blood products causes a concomitant reduction in ionized calcium due to chelation. Consequences of hypocalcemia include depressed inotropy and vascular tone and abnormal clotting. Calcium is replaced with calcium gluconate or calcium chloride to achieve the lowest ionized calcium concentration necessary for adequate cardiac performance and coagulation (~0.9–1.0 mmol/L). After the donor liver is functioning, it readily metabolizes the citrate chelator and may lead to a rebound postoperative hypercalcemia.

Glucose management during liver transplant is usually fairly straightforward. Because the liver is the major site of gluconeogenesis, complete hepatectomy creates the possibility of intraoperative hypoglycemia, although this is rarely a problem in clinical practice.

Neohepatic phase

Graft reperfusion

The neohepatic phase begins with the initial reperfusion of the liver. Volume status and hemodynamic performance must be optimized prior to this event. The perireperfusion period is chaotic, and all potential anesthesia-related distractions (e.g., medication redosing, IV bag/syringe changes, sending laboratory studies) should be addressed prior to this time. Furthermore, abnormalities in pH, K⁺, and/or Ca²⁺ should be corrected, and sodium bicarbonate, glucose and insulin, and calcium chloride should be prepared and ready for use.

Immediately prior to reperfusion, the donor liver is flushed antegrade from portal vein to hepatic vein with crystalloid, colloid (e.g., 5% albumin) or blood to wash out the potassium- and heparin-rich preservative solution. The venous anastomoses are then sutured closed, and the hepatic vein and portal vein clamps are removed.

Graft reperfusion, with release of residual preservative solution, air, clot, debris, and acidemic blood, is a major insult on cardiovascular performance. Possible consequences include acute pulmonary hypertension causing acute right heart dysfunction with resultant elevation in right heart pressures and CVP, reduced systemic pressure and coronary perfusion pressure due to inadequate left ventricular preload, and, finally, if the multiple insults are significant enough, cardiovascular collapse and cardiac arrest. In preparation for this insult, the patient is often hyperventilated to lower end-tidal carbon dioxide (CO₂) and blood pH is increased to induce pulmonary vasodilation. Infusions of vasopressors such as epinephrine, dopamine, and/or norepinephrine should be available and ready for use to support the heart and circulation. Some

anesthesiologists also use small prophylactic doses of a vasoconstrictor, such as epinephrine (10- μ g boluses), at the time of reperfusion. Selective pulmonary vasodilators, such as inhaled nitric oxide, may be useful at this point. If cardiac arrest occurs, Advanced Cardiac Life Support (ACLS) protocols should be followed, with treatment directed at the presumptive major problem. If necessary, percutaneous venoarterial cardiopulmonary bypass may also be used.

Postgraft reperfusion

After the venous anastomoses are complete and venous reperfusion of the liver has occurred, the hepatic artery anastomosis is constructed to deliver oxygenated blood to the new liver, followed by construction of the bile duct connection, either directly or with a Roux-en-Y anastomosis.

Clotting activity is often deranged during the immediate reperfusion period, as fibrinolysis is increased from reduced clearance of tissue plasminogen activator (t-PA) during the anhepatic phase (see Table 104.9). The anesthesiologist's main goal at this point in the transplant is to stop clot lysis and provide adequate levels of platelets and clotting factors (by way of FFP) to support clotting.

Although controversial in liver transplantation due to concerns of unwanted thrombosis (e.g., clinically significant pulmonary embolism, stroke, myocardial infarction, graft thrombosis), antifibrinolytic agents including aprotinin, tranexamic acid, and epsilon aminocaproic acid have been

used to reduce fibrinolysis and transfusion requirements. Use of these agents during liver transplant should be reserved for patients with a high risk of severe hemorrhage. Aprotinin is now of largely historical interest because of an excess morbidity and mortality when used in cardiac surgery.

Postoperative preparations

During the neohepatic phase, the anesthesia team prepares for the postoperative disposition of the patient (see Table 104.10). Most liver transplant recipients are discharged from the OR to an ICU bed. The patient should be transported on an ICU bed, with all necessary infusions running and the patient fully monitored. Although early extubation (i.e., in the OR) is possible and desirable, most patients are left intubated for pulmonary support in the early postoperative period and gradually prepared for extubation within one to two days. Furthermore, although positive end-expiratory pressure (PEEP) may decrease cardiac output, it does not have a major effect on graft function and may be needed to counteract the pulmonary consequences of postoperative intra-abdominal hypertension.

Postoperative pain management is usually relatively straightforward and done with potent opioids (e.g., morphine, hydromorphone). Epidural analgesia is avoided because of the profound perioperative coagulopathy in end-stage liver disease. For some unknown reason, liver transplant patients tend to have less postoperative pain than do hepatectomy patients, although some studies have suggested that immunosuppressive steroids used may have some analgesic effects.

Anesthesia for Endocrine Diseases

Balachundhar Subramaniam, editor

Thyroid disorders

Emily A. Singer and Pankaj K. Sikka

Anatomy

The thyroid gland is located in the neck, anterior to the trachea, and between the cricoid cartilage and the suprasternal notch. It consists of a right and left lobe, joined in the middle by the isthmus (see Fig. 105.1). It is a highly vascular organ, fed by the superior and inferior thyroid arteries. It is important to note that the superior thyroid artery is a branch of the external carotid artery and that the inferior thyroid artery is a branch of the thyrocervical trunk, which arises from the subclavian artery. Superior, middle, and inferior thyroid veins are responsible for drainage. It is bordered laterally by the recurrent laryngeal nerves (RLNs), arising from the vagus nerve. In addition, the external branch of the superior laryngeal nerve runs lateral to the upper pole of each lobe. The four parathyroid glands lie posterior to the upper and lower poles of each thyroid lobe.

Physiology

The follicular cells of the thyroid gland produce two circulating hormones, T_3 and T_4 . Approximately 80% of circulating thyroid hormone is T_4 ; however, T_3 is the more active thyroid hormone. The hormones circulate in the blood mainly bound to thyroid binding globulin (TBG) and, to a lesser extent, to albumin. In the periphery, T_4 is converted to T_3 and reverse T_3 (rT_3), which is inactive. T_3 acts on nuclear receptors to influence metabolism. Thyroid hormones increase carbohydrate and fat metabolism, thereby affecting growth and metabolic rate. As a result of their effect on metabolism, they are partially responsible for changes in oxygen consumption, carbon dioxide production, and minute ventilation. They also affect heart rate (HR) and contractility, and therefore, cardiac output.

Thyroid hormone production is dependent on a dietary source of iodine. Lack of iodine produces goiter, and with more severe deficiency, produces hypothyroidism and cretinism. In the gastrointestinal (GI) tract, dietary iodine is reduced to iodide and released into the circulation. Iodide is taken up by the follicular cells of the thyroid gland, where tyrosine is iodinated to form monoiodotyrosine (MIT) and diiodotyrosine (DIT), which are then coupled by an oxidation reaction inside the follicular cells to form T_3 and T_4 . This reaction is stimulated by the thyroid-stimulating hormone (TSH) secreted from

the anterior pituitary, the production and secretion of which is in turn stimulated by the thyroid-releasing hormone (TRH) secreted from the hypothalamus. Circulating T_3 and T_4 negatively feed back on TSH secretion (Fig. 105.2).

Hyperthyroidism

Hyperthyroidism is a syndrome caused by excessive secretion of thyroid hormones, occurring more commonly in women. The diagnosis is generally made by the presence of a high free T_4 or free T_3 and a low TSH level. Hyperthyroidism is most threatening to the cardiovascular system and can lead to tachycardia, arrhythmias, atrial fibrillation, and congestive heart failure (Table 105.1).

Causes

The most common cause of hyperthyroidism is Graves' disease (multinodular diffuse goiter). The disease is caused by thyroid-stimulating antibody (TSAb), an IgG antibody directed against the TSH receptors of the thyroid follicular cells. Because the TSAb operates outside the normal T_3/T_4 -TSH feedback loop, it stimulates the excess production of T_3 and T_4 , causing progressive hyperthyroidism that may lead to thyrotoxicosis. Other causes of hyperthyroidism include toxic thyroid adenoma, a functioning thyroid carcinoma, thyroiditis, pregnancy, amiodarone, and radiation therapy.

Treatment

Hyperthyroidism can be treated medically or surgically. Non-emergency surgery, including thyroidectomy, on the hyperthyroid patient should be avoided until the patient is clinically euthyroid. Even after a patient has been rendered euthyroid, antithyroid medications and β -blockers should be given on the morning of surgery.

Medical therapy includes the usage of propylthiouracil (PTU) and methimazole, both of which interfere with thyroid hormone synthesis by inhibiting oxidation and coupling of inorganic iodide. PTU, in addition to its action within the thyroid gland, also inhibits the peripheral conversion of T_4 to T_3 . Side effects of antithyroid drugs include agranulocytosis, thrombocytopenia, and hypoprothrombinemia. β -blockers, such as propranolol or atenolol, are effective in controlling the

Figure 105.1. Anatomy of the thyroid gland and its relation to the parathyroid glands and the larynx.

adrenergic symptoms of hyperthyroidism. β -blockers decrease tachycardia (goal of HR < 90 bpm), tremor, and anxiety. In addition, they inhibit the peripheral conversion of T_4 to T_3 . Nonselective β -blockers should be used cautiously in patients with asthma or congestive heart failure (CHF). Also, glucocorticoids (dexamethasone) may be useful as they inhibit thyroid hormone secretion as well as peripheral conversion of T_4 to T_3 .

Medical therapy can be used alone or as a pretreatment to radioiodine thyroid ablation or surgery. Patients should be

pretreated with PTU or methimazole prior to radioiodine ablation, in order to diminish the risk of mobilizing the stores of thyroid hormones and therefore worsening the thyrotoxicosis. These medications will need to be stopped approximately 3 days prior to ablation therapy to achieve optimal results. Many patients become hypothyroid after radioiodine ablation and require treatment with levothyroxine (T_4). Subtotal or total thyroidectomy may be used for hyperthyroid patients who have very large goiters, who fail medical or radioiodine therapy, or who are pregnant. Surgery is treatment of choice for thyroid cancer, toxic adenomas, and enlarging thyroid nodules. If a total thyroidectomy is performed, the patient will require levothyroxine therapy postoperatively.

Anesthetic considerations

Patients with goiter should be carefully evaluated for airway difficulties and tracheal deviation. Usually surgery is conducted with endotracheal intubation; however, the use of the laryngeal mask airway (LMA) is becoming increasingly popular. The use of LMA allows the visualization of vocal cords in a spontaneously breathing patient. For induction of anesthesia, thiopental, because of its slight antithyroid effect, may be a better choice than other induction agents. Hyperthyroid patients are frequently hypovolemic, and close attention to fluid balance is necessary. In addition, hypovolemia and vasodilation may cause an extreme hypotensive response during induction.

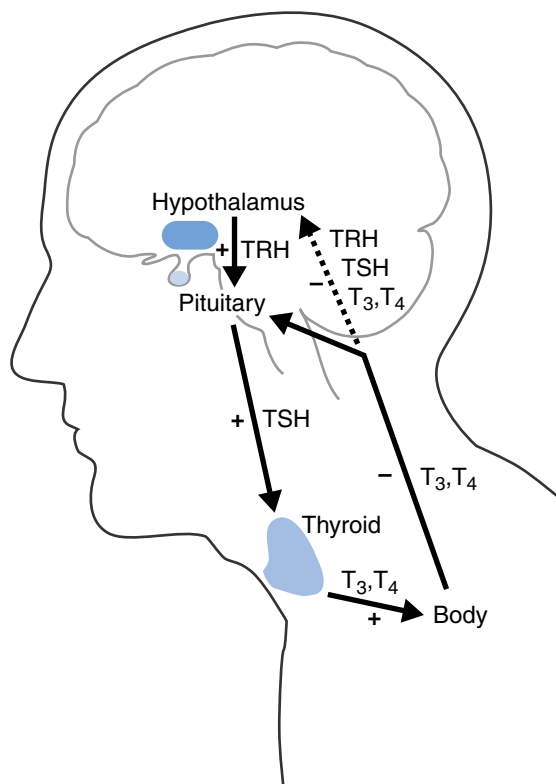

Figure 105.2. Hypothalamus-pituitary-thyroid axis.

Table 105.1. Symptoms and signs of hyperthyroidism

Cardiovascular	– Palpitations, tachycardia, elevated systolic blood pressure, CHF, atrial fibrillation, arrhythmias, increased ventricular contractility
Central nervous system	– Fine tremor, rapid speech, irritability, restlessness, nervousness, sweating, heat intolerance, hyperactivity, muscle weakness, fatigue
Ophthalmic	– Eyelid lag or retraction, proptosis, or exophthalmos
Other	– Weight loss, hair loss, diarrhea, oligomenorrhea, leg swelling, pretibial myxedema

If emergency surgery is required for a patient who is currently hyperthyroid, extremely close monitoring of HR, cardiac function, body temperature, and fluid status is critical. Tachycardia, which may induce CHF, can be treated with esmolol (100–300 µg/kg/min IV), titrated to HR, pulmonary artery wedge pressure, and clinical evidence of heart failure. Sympathomimetic drugs (ketamine, pancuronium) should be avoided, as they may cause exaggerated hypertensive and tachycardic responses. Cooling blankets may be necessary for the hyperthermic patient.

Muscle relaxation should be guided by a “twitch monitor” as myopathy and myasthenia gravis are more common in the thyrotoxic patient. Intravenous (IV) steroid administration is recommended to prevent complications from coexisting adrenal suppression. Patients with exophthalmos should have their eyes carefully taped closed to avoid inadvertent corneal abrasion. Although the increased cardiac output may increase the uptake of inhaled volatile anesthetics, MAC (minimum alveolar concentration) is not increased. In addition, the sympathetic blockade provided by regional anesthesia may be beneficial for nonthyroid surgeries in hyperthyroid patients.

Additional anesthetic implications

Because of the intimate physical relationship among the thyroid gland, RLN, and the parathyroid glands, surgical complications can have a direct effect on anesthetic management.

Nerve damage

Damage to only one RLN causes hoarseness, as the paralyzed nerve causes the vocal cord on that side to assume an intermediate position. Damage to both RLNs, a risk associated with total thyroidectomy, causes aphonia and total airway obstruction as the vocal cords fall toward the midline. Damage to the superior laryngeal nerves, which are responsible for sensation above the larynx, causes hoarseness and an increased risk of pulmonary aspiration.

Prevention and early recognition of nerve damage can be pursued through a variety of mechanisms. During surgical dissection, the RLN is identified with the goal of preservation; however, identification can be difficult in a patient with an altered neck anatomy. Endotracheal tubes with external wires to detect electromyographic (EMG) activity from electrical stimulation of the RLN are commercially available. In addition, several studies have shown that the use of a fiber-optic bronchoscope through an LMA can be used by the anesthetist to confirm vocal cord response to electrical stimulation of the RLN by the surgeon. This technique can be used intraoperatively, when working near the RLN territory as well as prior to extubation to confirm patency of the airway. Whether an LMA or endotracheal tube is used, the patient should be asked to phonate (say “e”) after extubation. Evidence of bilateral RLN injury should be followed by immediate reintubation, which is often followed by tracheostomy.

Airway issues

Other airway issues may arise from a large goiter, which may cause tracheal compression on induction of anesthesia. These patients should be handled as any other patient with a potential for airway compromise. Sedation should not be excessive, and awake intubation should be considered. A firm endotracheal tube should be used, and should extend past the point of airway compression. Extubation should occur when the patient is fully awake, and the anesthetist should be prepared for reintubation in case the large thyroid gland has caused weakening of the tracheal rings (tracheomalacia) that might lead to airway collapse. Postoperatively, a hematoma at the surgical site can cause airway compromise. Treatment involves opening the wound and evacuating the clot, as well as preparing for intubation or a surgical airway. In addition, extensive neck exploration may lead to an inadvertent pneumothorax, especially in patients with lung disease.

Hypocalcemia

Total thyroidectomy increases the risk of inadvertent parathyroidectomy and resulting hypocalcemia. Hypocalcemia can develop as soon as 1 hour after surgery, but more commonly develops 1 to 3 days postoperatively. Tetany is perhaps the most concerning manifestation of hypocalcemia. The laryngeal muscles are sensitive to hypocalcemia, and inspiratory stridor leading to laryngospasm may be the first sign of hypocalcemia. Treatment includes prompt administration of calcium.

Thyroid storm

Thyroid storm, a life-threatening exacerbation of hyperthyroidism, may occur due to sudden and massive release of thyroid hormones into the circulation. It usually occurs 6 to 24 hours postoperatively, but may occur intraoperatively mimicking malignant hyperthermia. Thyroid storm can also be precipitated by an acute illness or infection, trauma, stroke, surgery, or radioiodine therapy. It is a hypermetabolic state presenting as tachycardia, hyperthermia, and/or arrhythmias and even causes myocardial ischemia or CHF. It is managed (Table 105.2) by administration of PTU (250–500 mg every 6–8 hours) and potassium iodide (250 mg every 6 hours) and by supportive management, including IV fluids, oxygen, and cooling blankets. β-blockers should be used to control the HR, as tachycardia can lead to a high-output heart failure. Steroid administration should be considered: An IV bolus of 10 mg of dexamethasone followed by 2 mg IV every 6 hours decreases peripheral conversion of T₄ to T₃ and treats the relative adrenal insufficiency caused by the hypermetabolic state. The trigger of the thyroid storm should be identified and treated.

Hypothyroidism

Hypothyroidism is a disorder of the thyroid gland associated with a decreased circulation of the thyroid hormones. Diagnosis is made on the basis of an elevated TSH (secreted by the

pituitary) plus clinical symptoms and signs, which are usually slow to develop (Table 105.3). Thyroid hormone levels may be normal or low. Hypothyroidism often presents in a subacute manner, and its diagnosis is often delayed until symptoms have existed for some time. Often, patients are not aware of their symptoms until after treatment has begun.

Causes

Common causes of hypothyroidism in the United States include autoimmune disease, Hashimoto's (chronic) thyroiditis, and can also be the result of the treatment for hyperthyroidism (drugs, radioiodine, or surgery). Worldwide, iodine deficiency is the most common cause of hypothyroidism. Less common causes include lithium, amyloidosis, sarcoidosis, scleroderma, thyroiditis (postpartum, infectious), pituitary disorders, and hypothalamic disorders.

Table 105.3. Symptoms and signs of hypothyroidism

Slow metabolism – sensitive to drugs
Cardiovascular system – bradycardia, decreased cardiac output and cardiac contractility, pericardial effusion, vasoconstriction, decreased intravascular volume, blunted baroreceptor reflexes, peripheral edema
Central nervous system – lethargy, tiredness, weakness, delayed tendon reflexes, difficulty in concentration, sensitivity to cold, hoarseness of voice, hair loss
Respiratory system – goiter (autoimmune thyroiditis), dyspnea secondary to pleural effusion, sleep apnea, decreased ventilatory drive, weakened diaphragm, decreased production of surfactant
Other – Weight gain but poor appetite, constipation, oligomenorrhea or amenorrhea, carpal tunnel syndrome, decreased cortisol production

Treatment

Hypothyroidism is treated with oral replacement of thyroid hormone (T_4 , levothyroxine). An IV preparation is available if oral therapy is not possible or if there is concern that enteral absorption is impaired. The half-life of T_4 is approximately 7 days, and that of T_3 (faster acting than T_4) is approximately 1.5 days. Up to 6 months of replacement therapy may be necessary for full resolution of symptoms. Treatment is guided to a normal TSH value. Angina pectoris may worsen during thyroid hormone replacement, for which the patient may need a cardiac evaluation. Patients with coexisting coronary artery disease are at risk of myocardial ischemia with administration of IV levothyroxine; therefore, emergency coronary revascularization should be considered for those patients with severe hypothyroidism and severe coronary disease.

Anesthetic considerations

As with patients with hyperthyroidism, those with severe hypothyroidism or myxedema coma should not undergo elective surgery until they have achieved a euthyroid state, although mild to moderate hypothyroidism is not an absolute contraindication to surgery. Patients requiring emergency surgery should be treated with IV levothyroxine (100–500 μ g IV). Patients with hypothyroidism are sensitive to drug-induced respiratory depression and have decreased response to hypoxia. Therefore, premedication with respiratory depressants, such as benzodiazepines, should be done with caution, and narcotic doses should be minimized in favor of nonopioids, such as ketorolac. Anesthetic requirements (such as minimum alveolar

concentration) are not decreased in hypothyroid patients. However, gastric emptying may be delayed in hypothyroid patients; H₂-antagonists and promotility agents, such as metoclopramide, may prove beneficial.

Because hypothyroid patients have decreased cardiac output, decreased intravascular volume, and blunted baroreceptor reflexes, profound hypotension on induction should be prevented. This goal can be achieved by induction with ketamine or by the use of a traditional induction agent (such as thiopental or propofol) with ephedrine (or other vasoactive medications). If hypotension is refractory, steroid administration should be considered, as coexisting adrenal insufficiency is not uncommon. Fluid and electrolyte balance should be monitored carefully and treated with appropriate IV solutions. Because body temperature regulation is altered in hypothyroidism, intraoperatively the patient's temperature should be monitored and maintained in the normal range. As with hyperthyroidism, there is an increased incidence of myasthenia gravis in patients with hypothyroidism. Therefore, neuromuscular blockade should be used with caution. Because recovery from general anesthesia may be prolonged, extubation should be done when the patient is normothermic, awake, and breathing adequately. Regional anesthesia may be a reasonable choice for anesthesia as long as intravascular volume is maintained.

Myxedema coma is a severe form of hypothyroidism and is a medical emergency. It presents with the features of hypothyroidism (Table 105.3) as well as a depressed level of consciousness (stupor, coma), profound hypothermia, hypoventilation, hypotension, hyponatremia, and occasionally seizure activity. The disease is most common in the elderly population and is usually precipitated by sepsis or illness that cause impaired ventilation, such as pneumonia, CHF, stroke, myocardial infarction, or GI bleeding. Sedatives, anesthetics, and antidepressants may also be the precipitating factors. Treatment involves IV levothyroxine and supportive care, which includes ventilatory support, external rewarming, and electrolyte and fluid

management. Steroids (hydrocortisone) may be administered, as severe hypothyroidism is associated with impaired adrenal function. Any precipitating illnesses should be aggressively managed.

Parathyroid disorders

David R. Moss

Anatomy and physiology

The parathyroid glands are responsible for the tight regulation of plasma calcium concentration. They are small (35–50 mg), paired structures located posterior to the thyroid gland, although anatomic variation is not uncommon. The inferior glands, derived from the third pharyngeal pouch, can be found undescended at the carotid bulb, under the thyroid capsule, intrathyroidal, or in the anterior mediastinum within the thymus. The superior glands, derived from the fourth pharyngeal pouch, are more consistent in their location but may migrate down the tracheoesophageal groove into the middle mediastinum or may be retropharyngeal. In addition, some individuals may have fewer or more than four glands.

Parathyroid hormone (PTH) is an 84-amino-acid peptide, the principal effector sites of which are the bone and kidney. Although the interaction of PTH with bone is complex and incompletely understood, PTH has both anabolic and catabolic actions that allow for early rapid mobilization of calcium stores followed by a slow sustained release. In the kidney, PTH acts at multiple sites to increase both calcium reabsorption and phosphate excretion. In addition, it up-regulates the renal enzyme that converts inactive 25-hydroxyvitamin D₃ to the active 1,25 dihydroxyl form, facilitating calcium absorption in the gastrointestinal tract.

The vast majority of the body's calcium stores are found in bone as insoluble hydroxyapatite. Soluble extracellular calcium exists either as a non-ionized albumin-bound form or as a free ion in close to a 1:1 ratio. It is the ionized form that is physiologically active and maintained within a narrow concentration in the plasma (1.0–1.3 mM). Ionized calcium [Ca²⁺] is sensed by the parathyroids via direct stimulation of a cell-surface, G-protein-coupled receptor. A drop in [Ca²⁺] is met with a rapid increase in PTH secretion from preformed granules in chief cells. If [Ca²⁺] is not promptly restored, the hypocalcemic signaling mechanism sequentially works to increase PTH synthesis, PTH mRNA, and ultimately cellular hypertrophy and proliferation. Conversely, when [Ca²⁺] increases, PTH secretion is suppressed.

Hyperparathyroidism and hypercalcemia

Primary hyperparathyroidism

Primary hyperparathyroidism is the most common cause of hypercalcemia in outpatients. In 80% to 90% of cases a solitary parathyroid adenoma is the culprit. Multiglandular hyperplasia accounts for most of the remaining cases. Parathyroid carcinoma is an uncommon etiology (<1%). Primary hyperparathyroidism is frequently silent or subtle. Early symptoms are nonspecific and may include muscle weakness, fatigue, and vomiting. Early detection and treatment have decreased the incidence of other organ system involvement, which may be widespread and frequently correlates with the degree of hypercalcemia (Table 106.1). Hypercalcemic crisis is a life-threatening condition characterized by profound dehydration, nausea and vomiting, weakness, and mental status changes. If untreated, it will lead to oliguric renal failure, cardiac arrhythmias, and death. Treatment of hypercalcemia is outlined in Table 106.2.

Surgery is the only definitive treatment for primary hyperparathyroidism and has a 95% cure rate. Some controversy remains over which patients should undergo surgery, particularly older asymptomatic individuals. Although treatment options must always be individualized, there is a trend toward recommendation of parathyroidectomy for all patients with a definitive diagnosis of primary hyperparathyroidism.

Table 106.1. Manifestations of hypercalcemia

Cardiac	Hypertension, LVH, arrhythmias, shortened QT interval
Renal	Nephrolithiasis, renal tubular acidosis, polyuria, polydipsia
Gastrointestinal	Nausea and vomiting, anorexia, constipation, peptic ulcer, pancreatitis
Neurologic	Fatigue, confusion, psychosis, decreased pain sensation
Neuromuscular	Muscle weakness, hyporeflexia
Skeletal	Osteopenia, vertebral body fractures, aches and pains

LVH, left ventricular hypertrophy.

Table 106.2. Treatment of hypercalcemia

Rehydration:
1/2 NS or NS at 250–500 ml/h ± furosemide, 20–100 mg q2h
Avoid thiazide diuretics
Vigilant electrolyte monitoring
Bisphosphonates:
Pamidronate 30–90 mg over 2–4 h
Zoledronate 2–4 mg over 15 minutes

NS, normal saline.

Secondary hyperparathyroidism

Secondary hyperparathyroidism occurs when chronic hypocalcemia stimulates PTH secretion and parathyroid hyperplasia ensues without intrinsic parathyroid disease. The most common cause is chronic renal failure, owing to deficient vitamin D synthesis and hyperphosphatemia. Deficiency or malabsorption of vitamin D (rickets, osteomalacia) is another possible etiology. Medical treatment is the mainstay of therapy and consists of calcium and vitamin D supplementation as well as phosphate restriction. Surgery is sometimes necessary when conservative measures are inadequate and symptoms are severe (particularly bone manifestations and pruritus). Parathyroidectomy, performed as either a subtotal procedure in which a portion of one gland is left in situ, or rarely as a total parathyroidectomy with autograft placement (typically in the forearm), improves symptoms in 80% of patients.

Tertiary hyperparathyroidism

Tertiary hyperparathyroidism occurs when autonomous oversecretion of PTH persists despite correction of the underlying disease (i.e., after renal transplantation) due to a failure of the hyperactive glands to adapt to a normal renal handling of calcium and phosphate. These glands usually return to normal size and function within 12 months; parathyroidectomy is rarely necessary.

Multiple endocrine neoplasia (MEN) types I or II and non-MEN-related familial hyperparathyroidism may also warrant parathyroidectomy under certain circumstances.

Anesthesia for parathyroidectomy

Conventional parathyroidectomy comprises a bilateral neck exploration, identification of all four parathyroids, and resection of enlarged glands. Adequacy of resection can be assessed using intraoperative PTH monitoring. A decline in PTH by more than 60% 15 minutes after resection of an enlarged gland is highly specific in predicting a cure. Frozen section is useful only to confirm that parathyroid tissue has been resected but is unreliable in distinguishing a normal from a hyperplastic gland.

General anesthesia with endotracheal intubation is most commonly employed, although an LMA could be considered in select patients, acknowledging the potential risk of laryngeal edema with airway compromise. Anesthetic considerations for the hypercalcemic patient include maintaining adequate hydration and urine output and vigilantly monitoring

electrocardiography (ECG). Hypercalcemia can enhance the toxicity of digoxin. Response to nondepolarizing muscle relaxants may be variable as patients with skeletal muscle weakness may have decreased requirements, and hypercalcemia itself may antagonize the drug's effect. Osteoporosis warrants special care in positioning. Given the risk of recurrent laryngeal nerve (RLN) injury, some surgeons advocate evaluating the position of the vocal cords during extubation. Whereas complete paralysis of the nerve leaves the vocal cord in a half abducted position, a partial lesion of the RLN renders the vocal cord in an adducted position, and a bilateral partial RLN injury may be life-threatening. Emergence from anesthesia should be as smooth as possible as hypertension, coughing, and bucking can increase the risk of postoperative hematoma formation.

Given that the majority of cases of primary hyperparathyroidism are due to a solitary adenoma, there has been debate in the surgical literature about the need for a bilateral neck exploration. If a unilateral exploration or minimally invasive parathyroidectomy (MIP) is considered, patients must first undergo preoperative localization with technetium (^{99m}Tc) sestamibi scintigraphy. Ultrasound is also frequently used to delineate anatomy. The approach may be open or video-assisted with an endoscope. Randomized controlled trials comparing the techniques have shown that cure rates and complications were no different than the conventional approach, but patients undergoing the unilateral approach had a lower incidence of postoperative hypocalcemia (symptomatic and biochemical) and shorter operating times.

Anesthesia for MIP may be general or regional, using a superficial or deep cervical plexus block, although a block necessitates a considerable degree of patient cooperation. In studies comparing general versus regional anesthesia, patients who underwent MIP with a block had better pain control and less postoperative nausea and vomiting. Length of stay, cure rate, and complications were similar. Furthermore, assessment of the RLN may be performed intraoperatively under regional anesthesia.

Complications of parathyroidectomy

Transient hypocalcemia following parathyroidectomy is common, and symptoms, if present, are usually mild and may include paresthesias of the lips and fingertips. Oral calcium supplementation begun the night of surgery minimizes the incidence and severity of this complication, which is generally self-limiting, resolving in a few weeks. Symptoms of acute hypoparathyroidism and hypocalcemia (tetany, fatigue, seizures) are of particular concern and warrant immediate evaluation and ionized calcium (or albumin-corrected serum calcium) determination. Patients undergoing subtotal parathyroidectomy for secondary or tertiary hyperparathyroidism are at higher risk of developing severe symptoms. Treatment for symptomatic patients consists of an initial bolus followed by a continuous intravenous (IV) infusion of calcium gluconate titrated to resolve symptoms, and possibly oral or IV calcitriol (1,25-OH-vitamin D). Magnesium levels must also be monitored as

Table 106.3. Symptoms and treatment of hypocalcemia

Symptoms of hypocalcemia	Neurologic: Paresthesias (Chvostek, Trousseau signs), tetany, hyperactive reflexes, muscle cramps/weakness, seizures Respiratory: Laryngospasm, bronchospasm Cardiac: Arrhythmias, hypotension, bradycardia, QT prolongation
Treatment of hypocalcemia	[Ca ²⁺] > 0.8 mM – Usually asymptomatic [Ca ²⁺] 0.5–0.8 mM – May have mild symptoms; calcium replacement [Ca ²⁺] < 0.5 mM – Potentially life-threatening <ul style="list-style-type: none"> • Ensure an adequate airway is present • IV calcium supplementation required: 100–200 mg of elemental calcium over 10 minutes followed by maintenance 1–2 mg/kg/h until levels normalize (usually 6–12 h), then continue at 0.3–0.5 mg/kg/h • Oral calcium supplementation should be given as soon as possible to supply 1–4 g daily. • Calcitriol, start with 0.25 µg daily, and titrate up to maintain normocalcemia • Vigilant electrolyte monitoring and magnesium repletion
Chemical conversions	1 g of calcium gluconate = 93 mg of elemental calcium 1 g of calcium chloride = 272 mg of elemental calcium

hypomagnesemia aggravates hypocalcemia, rendering the latter refractory to treatment. Treatment of hypocalcemia is outlined in Table 106.3.

Postoperative inspiratory stridor may occur following parathyroidectomy for several reasons that must be considered in the differential diagnosis: laryngeal edema, hematoma, hypocalcemia, and bilateral RLN palsy (Table 106.4). The most common etiology is laryngeal edema. Treatment with inhaled racemic epinephrine is most effective, although corticosteroids may be necessary for refractory cases. Hematoma complicates 0.3% of parathyroid explorations. The diagnosis is made by inspection of the surgical site for neck swelling, pain, pressure, or discoloration. Re-exploration is mandatory and, in the case of severe airway compromise, may need to be performed at the bedside. Acute hypocalcemia after parathyroidectomy must be ruled out, but administration of IV calcium should not be delayed while the ionized calcium level is pending. RLN injury is uncommon (0%–0.8% for unilateral injury), and the use of RLN monitoring is not routinely necessary. Prevention of injury is best accomplished by avoidance of electrocautery, vigorous dissection, or ultrasonic devices near the nerve. Most patients who develop this complication will improve over the course of months, although patients in whom re-exploration was undertaken are at higher risk for permanent paralysis. Bilateral RLN

injury is even rarer but, if present, requires intubation and systemic steroid administration.

Last, operative failure and persistent hyperparathyroidism may complicate up to 5% of initial explorations. Surgical expertise is a significant factor, and surgeons who perform fewer than 10 parathyroidectomies per year had a lower rate of cure than did more experienced surgeons. Failed surgery is nearly always preventable, and patients who require re-exploration have a greater frequency of complications.

Pheochromocytoma

Deborah S. Pederson

Pheochromocytoma is a rare neuroendocrine tumor that can manifest in severe hypertension, cardiac arrhythmias, heart failure, stroke, renal failure, and (rarely) death. Ideally, the diagnosis will be known preoperatively if the patient is scheduled for surgery to remove the tumor, or it may be previously unrecognized. Therefore, it is important that anesthesiologists be familiar with the disease, its presentation, and its management (see Fig. 107.1).

Etiology

Pheochromocytomas are a heterogeneous group of neuroendocrine-secreting tumors that arise from chromaffin cells. Although they are most known for secreting catecholamines, the tumors may secrete a variety of other substances, including neuropeptide Y, dopa, vasoactive intestinal polypeptide (VIP), serotonin, calcitonin, and adrenocorticotropic hormone (ACTH). They are primarily found in the adrenal glands (90%); however, they may occur in extra-adrenal sites along the sympathetic nervous system, where they are referred to as *paragangliomas*.

The annual incidence of pheochromocytoma is two to eight per million per year. The disease may occur at any age, with the peak incidence in the third to sixth decades. Men and women are equally affected. Ten percent of pheochromocytomas are bilateral and 10% are malignant, as defined by distant metastasis. Approximately 25% of pheochromocytomas occur as part of a hereditary disorder, with associated syndromes such as multiple endocrine neoplasia (MEN 2A and MEN 2B), von Hippel-Lindau disease, neurofibromatosis type 1, tuberous sclerosis, and familial paraganglioma (PGL1 and PGL4).

Pathophysiology

The manifestations of pheochromocytoma are the result of elevated levels of plasma catecholamines combined with an up-regulated sympathetic nervous system. These factors lead to increased afterload and decreased capacitance, with subsequent effects on end organs. These effects may include left heart strain with hypertrophy or (rarely) dilated cardiomyopathy, cardiac irritability, pulmonary edema, renal impairment, and stroke. The presentation is variable (see Table 107.1) but can range

from asymptomatic with detection only at autopsy to severe life-threatening disease.

The mechanism of hypertension in pheochromocytoma is not completely understood. Elevated levels of plasma catecholamines are considered the hallmark of pheochromocytoma. This is unlikely the sole mechanism, however. Bravo and Tagle observed a poor correlation between circulating catecholamine levels and the presence of elevated blood pressure. In a series of 34 patients with known pheochromocytoma, they found increased levels of catecholamines in patients with elevated mean arterial pressure; however, the degree of hypertension did not correlate with the plasma catecholamine concentration. Additionally, Bravo published a case report

Figure 107.1. Anatomic distribution of pheochromocytomas and paragangliomas.

Table 107.1. Signs and symptoms of pheochromocytoma

Signs	Symptoms
Hypertension – may be paroxysmal Weight loss	Headache Palpitations Diaphoresis Syncope

demonstrating the lack of temporal relationship between catecholamine levels and hypertension. These data suggest that hypertension associated with pheochromocytoma is multifactorial.

Diagnosis

The prevalence of pheochromocytoma is 0.2% to 0.4% among hypertensive patients. Although it must be considered in the differential diagnosis of hypertension, not all patients with pheochromocytoma are hypertensive. In fact, only 50% to 60% of patients with pheochromocytoma have hypertension, and half of these people have paroxysmal episodes. The classic triad of headache, diaphoresis, and palpitations is present in 15% to 25% of patients. Thus, the absence of hypertension or the common clinical symptoms does not exclude the disease.

Traditionally, 24-hour urinalysis with high-performance liquid chromatography (HPLC) for metanephrines and vanillylmandelic acid (VMA) have constituted the laboratory test for pheochromocytoma. More recently, analysis of plasma free metanephrines has proven superior for pheochromocytoma detection with a sensitivity of >95% and a specificity of >80%. Imaging is becoming increasingly useful, particularly in diagnosing metastatic disease. CT, MRI, MIBG (metaiodobenzylguanidine; a functional scan using a guanethidine analogue), and PET scans have all been used to aid in the diagnosis.

The clonidine suppression test can be used to diagnose pheochromocytoma when traditional tests are inconclusive. Studies have suggested that the sympathetic nervous system plays a significant role in producing hypertension. In a study of patients with either essential hypertension or known pheochromocytoma, the administration of clonidine lowered blood pressure in both groups. In the essential hypertensive patients, clonidine lowered catecholamine levels; however, it had no

effect on plasma catecholamines in the pheochromocytoma group. This finding suggests that the sympathetic nervous system has a direct role in mediating hypertension in pheochromocytoma. When the sympathetic nervous system is blocked by a centrally acting α_2 -agonist agent, the patients are normotensive despite elevated plasma catecholamine levels. This is the basis for the clonidine suppression test to diagnose pheochromocytoma.

Preoperative management

The two issues that must be addressed preoperatively are control of blood pressure and replacement of intravascular volume. The state of chronically increased vascular tone leads to hypovolemia, which is manifest clinically by orthostatic hypotension and elevated hematocrit. Patients with known pheochromocytoma must be evaluated for end organ dysfunction. An elevated serum creatinine level may reveal renal disease and an electrocardiogram arrhythmias, myocardial infarction, or ventricular hypertrophy. Occasionally the presentation can be severe and involve cardiomyopathy. If symptoms of left heart failure, such as dyspnea, orthopnea, or decreased exercise tolerance, are present, an echocardiogram to further assess cardiac function is warranted.

Preoperative antihypertensives (see Table 107.2) combined with volume replacement (either oral or intravenous [IV]) are indicated prior to elective surgery. Traditionally α -blockade was used to decrease peripheral vascular resistance; however, case reports with calcium channel blockers and combined α - and β -blockade have proven to be effective. Given the low incidence of the disease, it is unlikely that randomized controlled trials will ever establish a preferred regimen.

α -Blockers

Historically, nonspecific α -blockade with phenoxybenzamine to achieve preoperative blood pressure control was associated with a decrease in surgical mortality from 40% to 0% to 1%. The drawback of this drug is its long half-life, which may result in hypotension when the tumor is removed. Selective α_1 -blockade (prazosin, doxazosin, and terazosin) has the benefit of sparing the presynaptic α_2 -receptors; therefore, these drugs do not enhance norepinephrine release and do not lead to reflex

Table 107.2. Medications used preoperatively to control hypertension in pheochromocytoma

Drug	Site of action	Properties
Phenoxybenzamine	Noncompetitive, nonselective α -blocker	Long-acting, risk of hypotension post-tumor excision, reflex tachycardia (due to inhibition of presynaptic α_2 -receptors)
Prazosin	Selective α_1 -blocker	Decreased incidence of reflex tachycardia due to sparing of α_2 -receptors
Labetalol	α - and β -blocker (1:7)	Works predominantly at β -receptors
Propranolol	Nonselective β -blocker	Give only after initiation of α -blockade to avoid unopposed α effects
Atenolol	β_1 -blocker	Long-acting selective β_1 -antagonist
Nifedipine	Calcium channel blocker	Less likely to produce orthostatic hypotension

Table 107.3. Medications used intraoperatively to control hypertension in pheochromocytoma

Drug	Site of action	Initial dose IV	Properties
Nitroprusside	Direct arteriovenous vasodilator	0.5–2 µg/kg/min; titrate to effect up to 10 µg/kg/min	Short and rapid acting; potent vasodilator
Esmolol	Selective β ₁ -antagonist	250–500 µg/kg/min IV load followed by infusion (50–300 µg/kg/min)	Short acting; can be used to treat tachydysrhythmias
Phentolamine	Nonselective α-antagonist	Bolus 2–5 mg IV, infusion- 0.5–1 mg/min	Short acting; can result in tachycardia and tachyphylaxis
Magnesium sulfate	Anti-adrenergic and direct vasodilator	Bolus 40 mg/kg, infusion 1–2 g/h, goal 2–4 mmol/L plasma concentration	May prolong nondepolarizing neuromuscular blockade

tachycardia. Additionally, they are shorter acting and therefore less likely to result in postoperative hypotension.

β-Blockers

β-blockade is contraindicated without pre-existing α-blockade to prevent unopposed α₁-mediated vasoconstriction. Nonselective β-blockade is most useful in patients with arrhythmias, but may also be used for blood pressure control. It should be avoided in patients with catecholamine-induced cardiomyopathy as it may lead to heart failure.

Calcium channel blockers

Calcium channel blockers inhibit the norepinephrine-mediated release of intracellular calcium in vascular smooth muscle cells leading to a decrease in peripheral vascular resistance. The primary advantage of using calcium channel blockers is the absence of orthostatic and perioperative hypotension.

When the patient is normovolemic and normotensive for >24 hours and is without significant arrhythmias, it is safe to proceed with elective surgery.

Intraoperative management

The goal of intraoperative management is to maintain normal hemodynamics despite stimulating events such as laryngoscopy, surgical incision, and tumor manipulation. This goal is achieved using a multimodal approach largely based on blockade of the sympathetic nervous system. Regional and general anesthesia techniques have been used, with general anesthesia being most common. Drugs that are known to stimulate the sympathetic system, such as pancuronium or ephedrine, should be avoided.

The surgical approach can be laparoscopic or open. In the case of laparoscopic surgery, the introduction of pneumoperitoneum may stimulate the release of catecholamines and should be anticipated. Studies comparing laparoscopic resection versus open resection of pheochromocytoma have demonstrated equivalent intraoperative hemodynamic control. Laparoscopic resection, however, results in decreased length of stay, decreased intensive care unit (ICU) admission, and decreased postoperative pain. Additionally, laparoscopy allows for superior visualization of the adrenal vein, facilitating ligation. Regardless of

the technique, fluctuations in blood pressure are highly dependent on surgical manipulation. Communication with the surgical team will allow for anticipation of hypertension, as is likely to occur with tumor handling, as well as hypotension, which can be dramatic after ligation of the tumor's venous drainage.

IV access, standard monitors, and invasive blood pressure monitoring are necessary prior to induction. Central venous access may be useful to assess volume status and deliver potent vasoconstrictors. Pulmonary artery catheterization or transesophageal echocardiography is indicated only if it will impact intraoperative management in patients with severely compromised cardiac function.

Preoperative pharmacologic regimens are generally not effective in blunting the hemodynamic response during tumor manipulation and surgical stimulation. Intraoperative blood pressure control is achieved by the use of short-acting modulators of the cardiovascular system as indicated in Table 107.3.

Postoperative management

Postoperatively, the major concern is continued hemodynamic instability; therefore, it is recommended the patient be monitored for hemodynamic lability at least 24 hours postoperatively. Persistent hypertension can result from the release of increased stores of catecholamines. Fluid resuscitation as well as vasopressors are used to treat hypotension. Blood glucose levels should be checked to rule out hyper- or hypoglycemia.

SIADH, diabetes insipidus, and transsphenoidal pituitary surgery

John Summers and Balachundhar Subramaniam

Antidiuretic hormone (ADH), also known as vasopressin, is a nonapeptide neurohormone synthesized in the hypothalamus and released by the posterior pituitary in response to increases in serum osmolarity and decreased extracellular volume. Osmoreceptors in the hypothalamus can detect changes in serum osmolarity of as little as 1% (normal is 285 mOsm/L), whereas stretch receptors in the left atrium sense changes in blood volume. Many other factors, such as pain, nausea, sympathetic stimulation, positive pressure ventilation, and hyperthermia, also affect ADH release.

One of the most important functions of ADH is to conserve body water. In the absence of ADH, the collecting ducts of the kidney are almost impermeable to water allowing it to flow out as urine. In the presence of ADH, however, aquaporins (water channels) are inserted into the principal cells of the collecting ducts allowing free water to be reabsorbed into the hypertonic renal medulla.

ADH also has other physiologic functions. The term *vasopressin* was coined from the observation that high concentrations of ADH results in widespread constriction of arterioles – primarily in the splanchnic, renal, and coronary vessels. ADH has also been found to play a role in hemostasis by increasing levels of factor VIII and von Willebrand factor. Disruptions in this process from either too much (syndrome of inappropriate ADH secretion [SIADH]), too little (central diabetes insipidus [DI]), or abnormal responses to ADH (nephrogenic DI) will be the subject of this chapter.

SIADH

Too much ADH results in water intoxication. Although there are numerous etiologies of SIADH (Table 108.1), the clinical manifestations remain the same: oliguria, concentrated urine, and signs of hyponatremia. As serum sodium concentrations drop below 125 mEq/L, osmotic fluid shifts lead to cerebral edema and increased intracranial pressure resulting in nausea and anorexia (early signs), followed by confusion, weakness, agitation, muscle cramps, obtundation, seizures, and ultimately coma. As the condition worsens, cardiac and other life-threatening complications may occur when serum sodium concentrations drop below 105 mEq/L. The severity of the symptoms also depends on how quickly hyponatremia develops. Chronic hyponatremic patients with sodium of 120 mEq/L

may show no clinical symptoms. Of note, it has been shown that premenopausal women are more susceptible to the effects of hyponatremia than are men.

Laboratory studies to aid in the diagnosis of SIADH include measuring the osmolarity and sodium levels in both the urine and serum. The presence of hyponatremia and a urine osmolarity higher than maximal dilution (generally >200 mOsm/L) confirm the diagnosis. Other pertinent laboratory test results include a decreased (dilutional) serum uric acid, $FeNa >1\%$, urinary sodium >30 mEq/L, normal potassium (hyperkalemia, hyponatremia, and acidosis may be from adrenal insufficiency rather than SIADH), and normal glucose (serum sodium is decreased by 1.6 mEq/L for every 100 mg/dl increase in glucose). Hyponatremia in the setting of polyuria may indicate cerebral salt-wasting syndrome. Pseudohyponatremia occurs with severe hyperlipidemia and hyperproteinemia (as in multiple myeloma).

Treatment of SIADH is primarily water restriction. Three percent hypertonic saline and furosemide may be needed, however, in symptomatic hyponatremia or when fluid restriction is not possible. Lithium and demeclocycline interfere with the renal tubules' ability to concentrate urine and may be used for chronic hyponatremia. In the event of SIADH from subarachnoid hemorrhage, fluid restriction may worsen the condition as it may promote cerebral vasospasm and infarction secondary to hypotension. The rate of sodium correction should not exceed 12 mEq/L in the first 24 hours so as to minimize the risk of central pontine myelinolysis. Calculations for corrections are shown in Table 108.2.

Table 108.1. Causes of SIADH

Paraneoplastic syndromes	Small cell lung cancer
CNS processes	Multiple sclerosis, tumors, head trauma, delirium tremens, Guillain-Barré syndrome, infection
Pulmonary processes	Pneumonia, tuberculosis, positive-pressure ventilation
Drugs	TCAs, chlorpropamide, clofibrate, NSAIDs, nicotine
Endocrine	Hypothyroidism
Sympathetic activation	Postoperative pain

CNS, central nervous system; TCAs, tricyclic antidepressants; NSAIDs, nonsteroidal anti-inflammatory drugs.

Table 108.2. Replacement of sodium**Sodium deficit:**

$$\text{Na deficit} = (\text{Desired Na} - \text{Measured Na}) \times 0.6 \times (\text{Weight in Kg})$$

Volume of hypertonic saline needed for correction:

$$\text{Volume of 3\% saline} = (\text{Na Deficit}) / 513 \text{ mEq Na/L}$$

$$\text{Time needed for correction} = (\text{Desired Na} - \text{Measured Na}) /$$

$$0.5 \text{ mEq/L per hour}$$

$$\text{Rate of infusion} = (\text{Volume of 3\% saline}) / (\text{Time needed for correction})$$

Anesthetic considerations for SIADH include identifying and correcting any underlying disorder as well as optimizing the patient for surgery. In general, elective surgeries should be postponed until the patient's sodium level is corrected to >130 mEq/L, even if he or she is asymptomatic. Lower sodium concentrations may result in cerebral edema, especially in surgeries with large potential fluid shifts, such as in transurethral resection of the prostate.

Diabetes insipidus

Inadequate ADH activity results in water wasting. DI is divided into central and nephrogenic etiologies. Central DI results from decreased production or release of ADH. Nephrogenic DI is caused by the inability of ADH to act normally on the kidneys. Causes of DI are listed in Table 108.3. Clinically, DI is characterized by polydipsia and polyuria, which may be accompanied by hypovolemia and hypernatremia (dehydration) if access to free water is restricted. Laboratory studies include serum sodium and osmolarity along with urine sodium and osmolarity.

Treatment depends on both the cause of DI (central vs. nephrogenic) and the extent of the ADH deficiency. For central DI, serum osmolarity and serum levels should be measured on a regular basis and be treated accordingly. Options for treatment include intravenous (IV) administration of aqueous ADH (100–200 mU/h), intramuscular (IM) vasopressin, and intranasal desmopressin, which has a low incidence of pressor effects. If the patient does not have complete DI, the stress of surgery alone may induce enough ADH secretion to compensate. If plasma osmolarity is less than 290 mOsm/L in a patient with incomplete DI, treatment is usually not necessary during a procedure. On an outpatient basis, clofibrate and

chlorpropamide (an oral hypoglycemic) have been used for incomplete central DI. The best treatment for nephrogenic DI is to treat the underlying disorder (Table 108.3). Thiazide diuretics, however, are known to have a paradoxical antidiuretic action in nephrogenic DI by effecting increased sodium losses.

Anesthetic considerations mainly involve correcting any fluid deficits or existing hypernatremia. Elective cases should be delayed until sodium levels are less than 150 mEq/L.

Anesthetic considerations of transsphenoidal surgery: pituitary tumors

Pituitary tumors are often hypersecretory, and medical therapy is not curative. As a result, surgery for these tumors is commonly performed. These tumors are common in the fifth to seventh decade of life. Tumors more than 10 mm in diameter are called *macroadenomas*. Nonfunctioning tumors tend to present as larger tumors as they are nonsecretory and are detected later. Craniopharyngioma and Rathke cleft cyst are some examples of nonfunctioning tumors. The common functioning tumors are *microadenomas* and can be Cushing disease (hypersecretion of adrenocorticotropic hormone [ACTH]), acromegaly (growth hormone–secreting adenoma), prolactinoma (prolactin hypersecretion), and hyperthyroidism (thyrotrophic hormone oversecretion). These individual diseases have been dealt with elsewhere in this section. The anesthetic considerations of transsphenoidal surgery for pituitary tumor resection will be discussed here.

Anesthetic considerations

The anesthetic considerations include managing the

- hypersecretory endocrine systemic effects;
- local mass effects, such as increased intracranial pressure, headache, and vision loss;
- hypopituitarism due to tumor compression of the anterior pituitary gland; and
- understanding of surgical approach, such as endonasal or older sublabial transseptal approach. The endonasal approach has a lower incidence of postoperative DI and a shorter recovery period.

Table 108.3. Causes of diabetes insipidus

Central	Idiopathic (up to 50% of cases)	Autoimmune process with destruction of cells of the hypothalamus
	Surgery	Transsphenoidal resection of an adenoma may result in DI in up to 60% of patients with large tumors
	Trauma	Severe head injury, basal skull fracture, subarachnoid hemorrhage
Nephrogenic	Tumors	Craniopharyngioma, pineal tumors
	Other	Hypoxic encephalopathy, anorexia nervosa, sarcoidosis, arteriovenous malformations
	Drugs	Lithium, demeclocycline, foscarnet, glyburide, methoxyflurane, amphotericin B
	Familial (rare)	Autosomal dominant
	Collecting system insults	Medullary cystic disease, ureteral obstruction

Preoperative evaluation should include:

- (a) complete hematological assessment;
- (b) airway assessment, especially in patients with acromegaly;
- (c) metabolic panel to look for electrolyte and glucose derangements; and
- (d) specific endocrine disorders, such as hyperthyroidism, and their systemic effects.

Intraoperative management

The transsphenoidal approach is performed with a mild head-up position to favor venous drainage. Venous air embolism is a possible risk with such a patient positioning. The mucosal surfaces are infiltrated with lidocaine and epinephrine to decrease bleeding and improve surgical dissection. This infiltration has the potential for arrhythmogenicity and hypertension. Hypertensive episodes are common with this type of surgery and should be treated to bring the patient's blood pressure closer to baseline blood pressure. The potential for blood loss is usually limited; however, the proximity of major vessels can lead to massive hemorrhages. There is a potential for cerebrospinal fluid (CSF) leak, and a Valsalva maneuver may be used to check these leaks. The potential for obstructive sleep apnea will mean careful extubation and may be an oral airway left in situ. The nares are packed postoperatively and make the nasal breathing difficult.

Postoperative complications

The postoperative complications are listed below:

- Cranial nerve dysfunction
- CSF leakage
- Nausea and vomiting
- Pain
- DI
- SIADH
- Hypopituitarism

Managing pituitary tumors requires a multidisciplinary approach for successful outcome following surgery.

Disorders of the adrenal cortex

John Summers and Balachundhar Subramaniam

The adrenal cortex synthesizes three distinct classes of hormones: glucocorticoid, mineralocorticoids, and androgens. Our main focus will be on disorders of cortisol – the principal glucocorticoid (produced by the zona fasciculata) – and aldosterone – the most important mineralocorticoid (produced in the zona glomerulosa). Androgens, made in the zona reticularis, are less relevant to our anesthetic evaluations and therefore will not be discussed further in this chapter.

Glucocorticoids

Cortisol has many physiologic effects, such as gluconeogenesis, inhibition of glucose uptake in muscle and adipose tissue, mobilization of amino acids from extrahepatic tissues, and stimulation of fat breakdown in adipose tissue. It also has anti-inflammatory and immunosuppressive properties. These effects are mediated by an intracellular glucocorticoid receptor that controls transcription from a number of genes, leading to changes in the cell's phenotype. Therefore, the effects of cortisol last longer than its plasma half-life of 80 to 110 minutes. In the plasma, only approximately 10% of cortisol is free, with the rest bound to plasma proteins – mostly to corticosterone-binding globulin (CBG). CBG is thought to both prolong the life of plasma cortisol and act as a buffer to swings in plasma cortisol levels by serving as a depot. Only free cortisol is available to enter cells and mediate the physiologic effects and therefore is the best marker for cortisol activity. The kidneys excrete unbound cortisol; therefore, a urinary cortisol is the most accurate way to measure its activity.

Regulation of cortisol is mediated via a negative feedback loop (Fig. 109.1). Corticotropin-releasing factor (CRF) from the hypothalamus stimulates the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which in turn directly controls cortisol secretion. CRF and ACTH release are stimulated by stress (psychological or physical), inhibited by cortisol, and affected by the sleep–wake cycle. In the absence of stress, ACTH release follows a diurnal pattern with the highest levels just after awakening followed by another lesser peak later in the day. For hospitalized patients, cortisol is dosed twice daily, with a higher dose in the morning so as to follow these natural fluctuations. Glucocorticoids may also exert mild mineralocorticoid effects at high levels.

Cushing syndrome

Cushing syndrome is the result of an excess of glucocorticoid activity. The many causes of Cushing syndrome may be broadly divided between ACTH-dependent and ACTH-independent etiologies. The vast majority of ACTH-independent Cushing syndrome cases are caused by exogenous administration of glucocorticoids. Other causes include adrenocortical adenomas and carcinomas. Cushing disease occurs from an ACTH-secreting pituitary tumor and accounts for 70% of ACTH-dependent Cushing syndrome. The remainder of ACTH-dependent Cushing syndrome cases is due to ectopic secretion of ACTH – usually from tumors of the lung (small-cell), pancreas, or thymus (carcinoid tumors from neuroendocrine cells in those tissues). Only approximately 1% arises from ectopic corticotropin-releasing hormone (CRH) secretion. Signs and symptoms of Cushing syndrome include central obesity, moon facies, muscle wasting and weakness, glucose intolerance, hypertension, and mental status changes. Glucocorticoids may exert some mineralocorticoid effects as well, resulting in hypervolemia and a hypokalemic metabolic alkalosis.

Figure 109.1. Negative feedback loop for cortisol secretion.

Figure 109.2. Renin–angiotensin system.

Anesthetic considerations

Anesthetic considerations include:

- correcting any electrolyte abnormalities, such as hypokalemia;
- administering spironolactone (a potassium-sparing diuretic) to deal with volume overload;
- potentially difficult airway due to moon facies; mask ventilation may be particularly difficult; and
- difficult IV placement due to fragile veins.

Easy bruising may lead to difficulty in positioning these patients. In addition, stress dose steroids should be administered in patients with exogenous steroid use as outlined later in the section “Perioperative steroid use.”

Mineralocorticoids

The principal mineralocorticoid is aldosterone, which maintains volume and electrolyte homeostasis by increasing sodium reabsorption and increasing potassium and hydrogen ion excretion. Regulation of aldosterone is primarily influenced by the renin–angiotensin system. Hyperkalemia, prostaglandin E, and ACTH also stimulate aldosterone release. The juxtaglomerular cells surrounding the afferent arterioles release renin in response to decreased renal perfusion pressure and sympathetic stimulation (β_1 -adrenoceptors). Renin then cleaves angiotensinogen into the decapeptide angiotensin I, which is then enzymatically cleaved to the octapeptide angiotensin II in the lungs by angiotensin-converting enzyme (ACE).

Angiotensin II is a potent vasoconstrictor and also stimulates the release of aldosterone by the adrenal cortex (see Fig. 109.2). The macula densa adjacent to the juxtaglomerular apparatus inhibits renin release when it senses elevated levels of sodium and chloride in tubular fluid.

Addison disease

Adrenal insufficiency may result from a defect anywhere in the hypothalamic–pituitary–adrenal (HPA) axis. Primary adrenal insufficiency occurs from the destruction of the adrenal cortex and results in depletion of both mineralocorticoids and glucocorticoids. Autoimmune destruction of the adrenal gland is the most common cause of Addison disease in the United States, whereas tuberculosis is the most common cause in developing countries. Other possible etiologies of adrenal gland destruction include infectious (e.g., fungal, HIV, bacterial), neoplastic, traumatic, vascular (e.g., hemorrhage, emboli, thrombus), metabolic (amyloidosis), and iatrogenic (exogenous steroids) events. Patients may remain asymptomatic until 90% of the adrenal gland has been destroyed. Clinical signs of Addison disease include chronic fatigue, muscle weakness, anorexia, weight loss, nausea, vomiting, diarrhea, and hyperpigmentation. Decreased levels of adrenal cortex hormones interrupt the feedback inhibition of the HPA axis and result in elevated levels of corticotropin and melanocyte-stimulating hormone (MSH). MSH is formed when corticotropin is cleaved from its prohormone. Elevated levels of MSH result in the characteristic bronze appearance. Hyperkalemia, hypovolemia, hyponatremia, and metabolic acidosis

result from mineralocorticoid deficiency and may lead to associated clinical manifestations, such as cardiac dysrhythmias. Secondary adrenal insufficiency as a result of inadequate ACTH production by the pituitary is not associated with cutaneous hyperpigmentation or mineralocorticoid deficiency. Acute Addisonian crisis presents as refractory hypotension, shock, abdominal pain, severe vomiting, and diarrhea. In critically ill patients, Addisonian crisis may resemble sepsis without a source of infection.

Treatment involves replacement of mineralocorticoids and glucocorticoids. Normal daily endogenous production of cortisol is approximately 20 mg with maximal output at 150 to 400 mg in a day. Usually patients are placed on fludrocortisone and prednisone or hydrocortisone for prolonged therapy.

Anesthetic considerations

Anesthetic concerns involve avoiding acute adrenal insufficiency, which is an emergency and is managed with

- an IV bolus of 100 mg of hydrocortisone, followed by an additional 100 mg every 6 hours for 24 hours;
- IV isotonic crystalloid fluids; and
- correction of any electrolyte abnormalities, such as hyperkalemia and hyponatremia.

The use of stress dose steroids is covered in the section on perioperative steroid use.

Primary hyperaldosteronism

Increased secretion of aldosterone from the adrenal cortex is usually caused by an adrenal adenoma (Conn syndrome) or adrenal hyperplasia. Increased levels of aldosterone result in

- hypertension,
- hypervolemia (without edema),
- suppressed renin activity, and
- hypokalemic metabolic alkalosis.

Primary hyperaldosteronism is now thought to be the most common form of secondary hypertension.

Anesthetic considerations

Anesthetic considerations include

- correcting any electrolyte abnormalities. This usually involves potassium supplements and spironolactone (an aldosterone antagonist) and
- correcting any volume overload.

Patients may also have glucose intolerance from hypokalemia and low ionized calcium secondary to alkalosis.

Hypoaldosteronism

Decreased secretion of aldosterone from the adrenal cortex may be congenital, result from prolonged heparin use, or be caused by certain medical problems, such as renal failure or diabetes. Low levels of aldosterone may result in a hyponatremic, hyperkalemic metabolic acidosis if left untreated. These patients should be treated with 0.05 to 0.1 mg of fludrocortisone preoperatively to correct any electrolyte abnormalities followed by close electrolyte monitoring throughout the surgery.

Perioperative steroid use

In 1952 Fraser and colleagues first described cardiovascular collapse attributed to iatrogenic adrenal insufficiency in the setting of surgical stress. Since that time, many studies have tried to form a consensus on the proper perioperative administration of steroids. Most anesthesiologists have used the recommendations described by Kehlet, Symreng and colleagues, and Salem and colleagues. These state, “New recommendations are proposed which suggest that the amount and duration of glucocorticoid coverage should be determined by: (a) the preoperative dose of glucocorticoid taken by the patient, (b) the preoperative duration of glucocorticoid

Table 109.1. Glucocorticoid treatment regimens

Patients currently taking glucocorticoids	Prednisone 5 mg/d or dexamethasone 1 mg/d or equivalent	Minor surgery (e.g., herniorrhaphy)	Hydrocortisone 25 mg at induction
		Moderate surgery (e.g., TAH)	Usual daily glucocorticoid dose + hydrocortisone 25 mg at induction + 100 mg/d for 24 h
		Major surgery (e.g., CABG)	Usual daily glucocorticoid dose + hydrocortisone 25 mg at induction + 100 mg/d for 48–72 h
Patients who have taken glucocorticoids within the last year	High-dose immunosuppression	Any surgery	Give usual immunosuppressive doses During perioperative period Hydrocortisone 25 mg at induction
		Minor surgery (e.g., herniorrhaphy)	Hydrocortisone 25 mg at induction + 100 mg/d for 24 h
		Moderate surgery (e.g., TAH)	Hydrocortisone 25 mg at induction + 100 mg/d for 24 h
	Major surgery (e.g., CABG)	Hydrocortisone 25 mg at induction + 100 mg/d for 48–72 h	

TAH, total abdominal hysterectomy; CABG, coronary artery bypass graft; HPA, Hypothalamic Pituitary Axis.

Table 109.2. Relative potencies of common glucocorticoids

Steroid	Relative glucocorticoid potency	Relative mineralocorticoid potency	Equivalent glucocorticoid dose, mg
<i>Short acting</i>			
Cortisol (hydrocortisone)	1.0	1.0	20.0
Cortisone	0.8	0.8	25.0
Prednisone	4.0	0.8	5.0
Prednisolone	4.0	0.8	5.0
Methylprednisolone	5.0	0.5	4.0
<i>Intermediate acting</i>			
Triamcinolone	5.0	0	4.0
<i>Long acting</i>			
Dexamethasone	30.0	0	0.75

Note: Synthetic glucocorticoid varies in both their potencies and mineralocorticoid effects.

administration, and (c) the nature and anticipated duration of surgery.” Suggested steroid treatment regimens are outlined in Table 109.1. Current literature states that hypotension in patients previously treated with glucocorticoids is caused by a loss of the permissive effect of glucocorticoids on vascular tone, which may be related in turn to enhanced prostaglandin I₂ (PGI₂) production in the absence of glucocorticoids. It is not caused by mineralocorticoid deficiency. Therefore, if the mineralocorticoid effects are not needed, it seems reasonable to administer the equivalent dose of dexamethasone (Table 109.2) to reap the added benefit of its antiemetic properties.

Physiologic adrenal response to surgery is blunted by anesthesia and will be delayed until the postoperative period. Patients who have taken supplemental steroids greater than 5 mg of prednisone a day for more than a week are theoretically at risk for HPA suppression for up to 1 year. Recovery from short courses of treatment (e.g., 5 days) occurs much more rapidly. Other sources suggest that stress dose steroids are appropriate for a year after a patient takes lower doses (e.g., 5 mg of prednisone) by any route for longer than 2 weeks. Of note, etomidate suppresses adrenal function for at least 24 hours and is affected by both (a) the dose administered and (b) if there is coadministration of an opioid. Long-term use of etomidate may cause severe glucocorticoid deficiency.

Possible side effects of intraoperative steroid use include impaired wound healing, psychiatric disturbances, and glucose intolerance. Topical vitamin A has been shown to decrease the effect of steroids on wound healing by stabilizing lysosomes. All things considered, although the probability of acute adrenal insufficiency is quite small, it is a potentially life-threatening

conditioning and therefore skews the risk–benefit curve in favor of providing stress steroids.

Anesthesia for Neuromuscular and Collagen Diseases

Paul D. Allen, editor

Malignant hyperthermia

Matthew C. Martinez and John D. Mitchell

Malignant hyperthermia (MH) is a rare, inherited disease involving two or more transmembrane proteins in skeletal muscle that is induced by specific anesthetic agents in almost all cases. The incidence of MH ranges from 1:5000 to 1:50,000–100,000 anesthetics. It affects humans, but can also affect pigs, dogs, cats, horses, and (most likely) other animals. The disease is characterized by hypermetabolism of muscle cells following the administration of a triggering agent, and is thought by some to be associated with heat intolerance.

Etiology

MH was first described by Denborough and Lovell in 1960. They encountered a patient who had 10 of his close relatives die while either under general anesthesia or immediately following a procedure. An investigation into the genetics of this patient's family revealed an inborn error of metabolism that seemed to be inherited as a dominant trait.

Mutations in the skeletal sarcoplasmic reticulum (SR) calcium release channel (ryanodine receptor, RyR1), which is responsible for excitation–contraction (EC) coupling, are the source of the majority of MH cases. EC coupling is the event that translates an action potential into a mechanical event. The action potential depolarizes a muscle cell and allows a conformational change and a small initial influx of calcium via slow voltage-gated calcium channels (dihydropyridine receptors, DHPRs). In skeletal muscle, the conformational change in the DHPR then triggers a large release of calcium stored in the SR through direct signaling to RyR1, and unlike the case in heart and skeletal muscle, this Ca^{2+} release does not require Ca^{2+} entry through the DHPR. The calcium then binds troponin and initiates the interaction of actin and myosin that are translated into a muscle contraction. In cases of MH, one or more of these calcium channels are affected, and large amounts of calcium are released from the SR.

The inheritance pattern in families with MH is thought to be autosomal dominant with variable penetrance. There have been multiple genes linked to MH, with specific mutations found in two of them. The RyR gene, which is found on chromosome 19 and plays a part in EC coupling, is the most studied of these genes. The DHPR gene, which encodes a voltage-gated Ca^{2+} channel, is another gene known to have mutations in MH-susceptible patients. Mutations in these genes can lead

to altered function of the calcium release channels, which leads to increased calcium release from the SR. Mutations in the RyR gene were the first to be considered as the cause of MH, but they have been shown to account for just 50% to 80% of the studied cases.

Triggering agents

The two types of drugs known to trigger MH in humans are all depolarizing muscle relaxants (e.g., succinylcholine) and all volatile general anesthetics (Table 110.1). Even in a susceptible patient, however, these drugs will not always cause MH. In at least half of MH cases, the patient has had a previous uneventful exposure to a triggering agent. When MH does occur, there is a rapid release of calcium from the SR in skeletal muscle. This release causes a sudden increase in muscle metabolism, which can cause a contracture when the mechanical threshold is reached. Adenosine triphosphate (ATP) is rapidly consumed, causing an increase in both aerobic and anaerobic metabolism. These hypermetabolic pathways increase oxygen and glucose utilization, leading to an increased carbon dioxide (CO_2) production. This is soon followed by respiratory and metabolic acidosis, hyperkalemia, and dysrhythmias and may result in death.

Presentation

Masseter muscle rigidity

Although a syndrome by itself, one of the first signs of MH can be masseter muscle rigidity (MMR) after the administration of sodium thiopental or halothane (in children) and succinylcholine. MMR is characterized by rigidity of the jaw

muscles that prevents the mouth from being opened. Normally, only the jaw is affected, and the remainder of the patient's muscles will be flaccid. The incidence of MH as diagnosed by arterial blood gas abnormalities following MMR is roughly 15%. If the anesthetic is stopped following MMR, there are usually no sequelae. It is uncommon for fulminant MH to occur immediately following MMR, but if the anesthetic is continued with triggering agents, signs of fulminant MH can occur within 20 minutes in susceptible individuals.

Most often the surgery is rescheduled after MMR, but if there are no other signs of MH, some anesthesiologists may elect to continue the case, (particularly if emergent), with non-triggering agents as long as fulminant MH treatment and proper monitoring are immediately available. If MMR is associated with rigid limb muscles, treatment with dantrolene is indicated immediately. Urine should be observed for color change; if cola colored, testing for myoglobin should be undertaken; creatine kinase (CK) studies may also be warranted. Postanesthesia care unit (PACU) observation for at least 12 hours following MMR is also prudent.

Fulminant MH

Unexplained tachycardia and tachypnea may be the first noticeable signs in the operating room that a patient is susceptible to triggering agents. These symptoms are the result of a hyperactive sympathetic nervous system and a sign of the body's increased metabolic state. If the patient has received a muscle relaxant or is mechanically ventilated, tachypnea may not be recognized; however, in its place will be an increase in end-tidal CO₂, even in the face of aggressive hyperventilation. Whole-body muscle rigidity and an increase in body temperature are late signs. At its peak, body temperature can increase as much as 1°C to 2°C every 5 minutes. Other signs include cyanosis, mottling, sweating, and a warm and quickly discharged CO₂ absorber (Table 110.2).

An arterial blood gas analysis will reveal hypercarbia and a mixed respiratory and metabolic acidosis. Other laboratory findings can include lactic acidemia and, late in the crisis, marked hyperkalemia and hypercalcemia. Serum myoglobin

and CK levels increase quickly in the hours following the event. Ventricular fibrillation can occur quickly following the initial presentation of MH, and is the most common cause of death. Later sequelae of a fulminant crisis include renal failure induced by myoglobinuria, congestive heart failure (CHF), acute cerebral edema, and disseminated intravascular coagulopathy (DIC).

Treatment

The mortality rate from a case of MH has dropped from approximately 70% in the 1970s to 5% today. This decrease is a direct result of the availability of dantrolene to treat acute episodes of MH and an increased awareness of the signs and symptoms. Dantrolene is the only available agent that is specifically used for treating MH. It was first synthesized in 1967 and was found to have muscle relaxant properties in animals. Its mechanism of action is unknown, but the end result of its use is a decrease in the resting calcium levels in susceptible muscle to near normal levels, followed by a return to baseline metabolism.

Dantrolene is a hydantoin derivative that is lipophilic and, therefore, has poor water solubility. Dantrolene is available in 20-mg vials that need to be dissolved in 60 ml of water. The dose of dantrolene is 2 to 2.5 mg/kg every 5 minutes up to a total dose of 10 mg/kg, if needed. The half-life of intravenous (IV) dantrolene is approximately 12 hours, but the therapeutic level lasts approximately 4 to 6 hours. Therefore, dantrolene (recommended dose 1 mg/kg) needs to be given at least every 6 hours for the first 24 hours following an event. Recrudescence, or a return of MH symptoms, has been shown to occur in approximately 20% of patients. Dantrolene has few side effects, with muscle weakness (100%), phlebitis (10%), respiratory failure (3%), and gastrointestinal discomfort (3%) being reported.

Treatment for an acute episode of MH is summarized as follows.

- All triggering agents should be discontinued immediately.
- Hyperventilate with 100% oxygen at flows >10 L/min to remove residual anesthetic gases and additional CO₂.
- Call for help, notify surgeons, and obtain dantrolene.
- Administer dantrolene therapy 2.5 mg/kg every 5 minutes up to a total of 10 mg/kg, or until cessation of signs and symptoms of MH.
- Administer sodium bicarbonate (2–4 mEq/kg) for treatment of metabolic acidosis.
- Control fever with surface ice packs, iced gastric and rectal lavage; stop cooling at 38°C to avoid hypothermia.
- Manage hyperkalemia with glucose, insulin, and bicarbonate.
- Follow serial blood gases and laboratory tests and treat as needed.

The patient needs to be followed closely for signs of recrudescence, DIC, and renal failure and should be admitted to an

intensive care unit. As noted earlier, dantrolene may require redosing every 4 to 6 hours over the first 24 hours. Therapy may need to be initiated to treat rhabdomyolysis and myoglobinuria, including maintenance of high urine output and alkalization of urine.

Differential diagnosis

There are several disorders that cause hyperthermia in the operating room and may therefore be mistaken for MH (Table 110.3). Thyroid storm presents with similar changes in vital signs, but usually occurs postoperatively and is most often associated with hypokalemia instead of hyperkalemia. It is also not associated with respiratory acidosis or muscle rigidity. Sepsis can be confused with MH, but muscle rigidity is rarely seen in sepsis. Unlike with MH, the signs of sepsis can be treated with antibiotics and nonsteroidal anti-inflammatory drugs (NSAIDs). Pheochromocytoma is another disease associated with marked increases in heart rate and blood pressure, but increased end-tidal CO₂ is not a common finding.

Neuroleptic malignant syndrome (NMS) is clinically similar to MH. It presents with tachycardia, hypertension, fever, muscle rigidity, and acidosis. The difference is that it is not triggered by anesthetic agents, but rather after exposure to certain antipsychotic drugs. These drugs cause a decrease in dopaminergic activity in the central nervous system. The onset of symptoms varies from hours to days after the drug is administered. Bromocriptine, a dopamine agonist, may be useful in the treatment of NMS. Dantrolene also seems to be an effective therapy in some cases of NMS but is associated with a higher death rate in some studies.

MH diagnosis

The gold standard test for diagnosis of MH in the United States is the caffeine halothane contracture test (CHCT). The analogous test in Europe is referred to as the in vitro contracture test (IVCT). A muscle biopsy is required to perform this test and is usually taken from the vastus lateralis or the quadriceps. Portions of the biopsy sample are exposed to 0.5 to 10 mM caffeine, 3% halothane, and both in combination. MH susceptible muscle is more sensitive to caffeine and more likely to have a contracture when exposed to halothane than is normal muscle.

The classifications given as a result of the CHCT (US protocol) are either MH susceptible (MHS) or MH normal (MHN). MH susceptibility is diagnosed by an abnormal response to caffeine, halothane, or both in combination. Under the IVCT, three designations are given. MH susceptible (MHS) refers to patients who have abnormal responses to both the caffeine and halothane baths. MH equivocal (MHE) is designated for an abnormal response to either caffeine or halothane, but not to both. MH normal or nonresponders (MHN) have no abnormal response to either caffeine or halothane.

The CHCT (US protocol) has a sensitivity of 97% and a specificity of 78%, whereas the IVCT (European protocol) has been suggested to have a sensitivity of 99% and a specificity of 94%. These rates, however, are highly skewed as the comparison groups are derived only from patients with abnormal responses to anesthesia that resemble MH and not from the general population or a population that includes other muscle disease groups. Despite invasive and expensive testing, patients who have been fully evaluated are often not managed appropriately following a suspected MH crisis. MH normal patients are commonly still given nontriggering anesthetics or subjected to delays in care despite the availability of normal test results, which has made some practitioners question the usefulness of testing, beyond academic interests.

Genetic testing has been proposed as a screening tool, but proves difficult because MH has such a heterogeneous genetic basis. Multiple different mutations have been shown to occur in the RyR gene of some patients. Furthermore, markers may also be present on other chromosomes, making routine screening even more difficult. Finally, discordance has been shown in some patients who have negative genetic screening and a positive IVCT.

Follow-up after presumed MH event

The patient and family should be alerted to the risks and familial nature of MH and referred to the Malignant Hyperthermia Association of the United States (MHAUS). Arrangements should be made for follow-up and, if desired by the patient, a muscle biopsy can be performed for definitive diagnosis. An Adverse Metabolic Reaction to Anesthesia (AMRA; available at www.mhreg.org) report should be completed, and the patient's primary care provider should also be contacted. MHAUS has been operating since 1981 and provides an invaluable resource for physicians and patients. They can be reached at www.mhaus.org, info@mhaus.org, or 1-800-644-9737 (1-315-464-7079 outside the United States).

Myasthenia gravis

Tomas Cvrk

Myasthenia gravis (MG) is an autoimmune disease caused by the presence of autoantibodies against the proteins (most often acetylcholine receptor [AChR] of the postsynaptic cell in the neuromuscular junction [NMJ]). It is characterized by the varying degrees of weakness in the muscles of the body. The prevalence of the disease in the general population is 5 to 12.5 per 100,000.

The result of antibody binding to the AChR is a decrease in effective concentration of the receptor in the postsynaptic cell membrane. At least three different mechanisms have been proposed for this to occur: (1) binding and activation of complement at the NMJ; (2) accelerated degradation of AChR molecules by internalization of the antibody-labeled receptor; and (3) functional AChR block that prevents functional binding of ACh.

ACh binding to the AChRs causes an allosteric (conformational) change that increases the AChR channel permeability for Na^+ and K^+ , which in turn results in membrane depolarization. This current flowing across the membrane, if sufficient, allows for firing of the action potential and potentially muscular contraction. The reduction in the number of AChRs in MG lowers the generated endplate potential and thus increases the threshold for the number of remaining AChRs that must be activated for triggering an action potential. It is estimated that the presence of the antibody results in an approximately 70% reduction of AChR number, with remaining receptor molecules probably occupied by the antibody. The anti-AChR antibody is present in 85% of tested MG patients. The remaining 15% patients are called *seronegative*. It has been found that the majority of these seronegative patients have antibody against another protein present at the postsynaptic membrane, MuSK, which plays an important role in the process of clustering AChRs during the development of the NMJ.

The cause of MG is still not clear. The majority of patients have an abnormality of the thymus gland, either hyperplasia or thymoma. Several different types of MG have been recognized and are summarized in Fig. 111.1.

Clinical features

MG has a bimodal presentation, affecting women more than men in the third through the fourth decade of life, but there is a higher prevalence in men in the fifth decade onward. The

characteristic presentation of MG is fatigability of skeletal muscles with repetitive use. Interestingly, the first muscles that are usually affected by the disease are eyelids and extraocular muscles. As the disease progresses, patients may have difficulty chewing and swallowing. Most of the patients (85%) will develop generalized weakness if not treated. The most serious complication is respiratory failure, either from exacerbation of the stable disease (myasthenia crisis) or from progression of the disease without effective treatment. Patients with anti-MuSK IgG present with bulbar and respiratory weakness rather than limb involvement.

Diagnosis

Initial diagnosis is usually based on a high level of clinical suspicion. The edrophonium (Tensilon) test consists of administration of up to 10 mg of edrophonium with the expectation of a reduction of symptoms in MG patients. The mechanism of action behind this test is that edrophonium is a short-acting acetylcholinesterase (AChE) inhibitor that increases the concentration of ACh at the NMJ, which leads to improvement of the signal transduction and, clinically, increased muscle

Figure 111.1. Types of MG.

strength within 45 seconds. Although diagnostic, this test has a low sensitivity and specificity.

Another diagnostic modality used for diagnosis is electromyography (EMG). One looks for a >10% decrease in muscle action potential during a 2- to 3-Hz stimulation. Here, single-fiber EMG is more sensitive than compound muscle measurements. The abnormalities that are seen with EMG in MG patients, however, can be caused by other NMJ disorders, such as myopathies or Lambert–Eaton myasthenic syndrome (LEMS). The most specific test is the detection of the circulating autoantibodies.

There is an association between MG and other autoimmune processes like thyroiditis, rheumatoid arthritis, polymyositis, celiac disease, and sarcoidosis. Approximately 75% of MG patients have thymic abnormalities, and 10% of those have thymoma. Thymomas are usually surgically removed because of the risk of invasion.

Treatment

There are two treatment modalities for patients with MG: medical and surgical. AChE inhibitors are usually recommended as the first line of treatment. Pyridostigmine is the most commonly prescribed medication. The dose is slowly titrated up by the effect to avoid overdosing and developing a cholinergic crisis. The disease often can be controlled reasonably well by using drugs, but waxing and waning of symptoms is common with AChE inhibitor treatment.

Steroids are the drugs used most frequently in patients with insufficient control on AChE inhibitors only. Steroid dose is titrated up slowly because a high dose of corticosteroids could cause exacerbation of the disease. After several months of high-dose steroids, dose is reduced for chronic administration. The shortcoming of steroids is a high frequency of side effects associated with their use.

Azathioprine is an immunosuppressant used commonly for MG treatment. As a purine analogue, it interferes with T- and B-cell proliferation. It is as effective as steroids and is often used as a steroid-sparing therapy in patients who do not tolerate high-dose corticosteroids. The disadvantage of its use is that there may be a delay of up to 15 months before the clinical benefit is apparent. Cyclophosphamide is another effective immunosuppressant. It is usually only used in patients who do not respond to other immunosuppressants because it has an undesirable adverse effect profile (hair loss, delayed effect, anorexia, skin discoloration, nausea, vomiting). Less frequently used immunosuppressants are cyclosporine, tacrolimus (FK506), and mycophenolate mofetil, which are usually used as steroid-sparing agents.

Surgical treatment involves thymectomy in patients post puberty. Although the remission of the disease after the surgery has been documented, the clinical efficacy of thymectomy has been questioned because of the lack of solid evidence supporting its use. Moreover, the therapeutic effect can be delayed until

months to years after the surgery. One of the reasons why it has been so difficult to establish the benefit of thymectomy is that a lot of patients are treated with corticosteroids and other immunosuppressive medications at the same time, making it impossible to know which treatment is responsible for the remission.

Other treatment modalities that are usually reserved for myasthenia crisis or acute disease exacerbation are plasma exchange and intravenous immunoglobulin (IVIG) therapy. The former directly decreases the titer of the antibodies against AChR by replacing a patient's plasma with albumin, saline, and plasma protein fraction. The mechanism of IVIG is not fully understood, but it involves administration of pooled human IgG for 5 days leading to complex immunomodulatory effects and a decrease in native antibody production. In several randomized clinical trials, neither of these modalities has been shown to have any benefit as a chronic therapy. Thymectomy is a surgical treatment option that involves removal of the thymus gland. This procedure can be quite effective, although it may take time for clinical symptoms to improve.

Anesthetic management of the patient with MG

Preoperative evaluation

Patients with a history of MG present with several preoperative considerations. The history of the disease and its severity should be obtained as well as the current and past therapeutic regimen. Special consideration should be given to assessment of any muscle strength compromise, especially weakness of the respiratory or bulbar muscles. The patient's inability to generate a strong cough to clear secretions is important because it can be a marker for increased risk of aspiration as well as postoperative atelectasis. The baseline preoperative pulmonary function tests should be obtained to identify patients with low forced vital capacity and negative inspiratory pressures that may be at increased risk for postoperative mechanical or noninvasive ventilation.

Most MG patients are managed on AChE inhibitors. The presence of these medications in the body reduces the effect of neuromuscular blockade intraoperatively and diminishes the muscle relaxation effect of inhalational agents in non-muscle-relaxant anesthesia. Therefore, AChE inhibitors are usually discontinued on the day of surgery and resumed postoperatively.

Patients with significant preoperative muscle weakness on AChE inhibitor or other therapy may benefit from a preoperative course of plasmapheresis or IVIG therapy, both of which have been found to result in short-term improvement of functional status.

In patients with MG associated with thymoma, the location, size of the mass, and potential compromise of adjacent structures (airway/vascular) should be evaluated with imaging as well as by pulmonary function flow–volume loops.

Neuromuscular blockade

Succinylcholine

Due to a reduced number of receptors in the postsynaptic membrane, patients with MG usually have an increased requirement for depolarizing agents. A higher concentration of succinylcholine at the NMJ is required to block a sufficient number of receptors that would block the signal transmission. The measured dose response to succinylcholine in MG patients showed that their 95% effective dose (ED₉₅) was 0.8 mg/kg, or 2.6 times higher than that in patients without MG. An administered total dose of 2.0 mg/kg should be sufficient for rapid sequence induction in most MG patients. The duration of action of succinylcholine, however, can be prolonged because of the presence of AChE inhibitors used for treatment. The anesthetist must remember that the high first dose of succinylcholine and/or multiple doses required for intubation put MG patients at increased risk for development of the phase II block.

Nondepolarizing neuromuscular blockers

In general, MG results in increased sensitivity to nondepolarizing neuromuscular blockers (NMBs) because of the lower number of receptors that need to be blocked in the NMJ. It is recommended that the baseline neuromuscular block be tested before inducing anesthesia and again before administration of nondepolarizing NMBs. The train-of-four can be used for that purpose for routine use in the operating room. Other monitoring modalities (electromyography [EMG], mechanomyography) that can be used for neuromuscular monitoring provide more objective data, thus allowing for more precise quantification of the neuromuscular blockade. The set up of these monitoring modalities is more elaborate, however, and therefore often impractical for routine use in the operating room. Patients with a decreased T1/T4 ratio before anesthesia is administered are at increased risk for postoperative weakness and the possibility of prolonged mechanical ventilation.

Because sensitivity to all nondepolarizing NMJ blockers is increased, long-acting NMJ blockers should be avoided. The dose of the agent should be reduced and titrated to effect by giving small increments. A reasonable starting dose of cisatracurium, vecuronium, atracurium, and even rocuronium and mivacurium is approximately 40% of the dose recommended for the normal population given the fact that the ED₉₅ for most of these drugs is in the 40% to 60% range of that for normal controls. However, significant variability exists among patients, depending on the natural course of the disease, severity, and treatment.

Choice of anesthesia modality

General anesthesia, regional anesthesia (including peripheral nerve blocks), and the combination of regional with general anesthesia have been used successfully in patients with MG.

Induction

To avoid postoperative complications, some anesthesiologists prefer to avoid use of muscle relaxants all together and use inhalational or IV agents to facilitate muscle relaxation for tracheal intubation as well as surgical relaxation. To avoid using succinylcholine, a rapid sequence technique using propofol and remifentanyl for induction has been successfully used in patients with MG who needed emergent surgery. Inhalational induction can be used in patients without indication of rapid sequence induction.

Maintenance

Anesthesia is usually maintained with nitrous oxide and/or volatile gases. The advantage of volatile gases is their ability to provide muscle relaxation in MG patients for many surgical procedures, which may eliminate the need for additional NMBs. The fast elimination of current inhalational agents ensures minimal residual blockade and facilitates prompt extubation. Successful use of total intravenous anesthesia (TIVA) has been reported. Remifentanyl has been described as providing great analgesia and hemodynamic stability, especially in older patients, in addition to its rapid and predictable elimination.

Regional anesthesia

Regional anesthesia can provide an excellent level of anesthesia without the need for NMJ blockade. However, it is important to avoid a high level of anesthesia when neuraxial blockade is used, in order to prevent a respiratory muscle compromise. There is a theoretical potentiation of neuromuscular block with the use of local anesthetic; therefore, a reduced dose of local anesthetics for regional anesthesia is recommended. The combination of general anesthesia and epidural anesthesia has been reported for abdominal surgery and thymoma resections. Epidural anesthesia in this case provides analgesia intraoperatively and postoperatively and, in addition, provides muscle relaxation during the surgery.

Postoperative considerations

The majority of patients with MG can be safely extubated at the end of the procedure. Patients with severe, long-standing disease, respiratory compromise (peak inspiratory pressure < -25 cm H₂O; vital capacity < 4 ml/kg), and those on high dose pyridostigmine (>750 mg) are predicted to be at higher risk for need of postoperative ventilatory support. All patients with MG need careful monitoring in the postoperative period for signs of muscle weakness and respiratory failure and for the possible need for reintubation. Adequate analgesia should be provided; however, oversedation from narcotic drugs is undesirable.

Any medications that can exacerbate muscle weakness should be avoided intraoperatively and in the postoperative period. These medications include glucocorticoids, lithium,

Table 111.1. Comparison of MG and LEMS

Effect	LEMS	MG
Muscles	Proximal limb weakness (legs > arms) Exercise improves strength Muscle pain common Reflexes absent or decrease	Extraocular, bulbar, and facial muscle weakness Fatigue with exercise Muscle pain uncommon Reflexes normal

Coexisting pathology	Small cell carcinoma of the lung	Thymoma
Succinylcholine	Sensitive	Resistant
Nondepolarizing muscle relaxants	Sensitive	Sensitive
AChE agents	Decreased (poor) response	Good response

phenytoin, aminoglycoside antibiotics, clindamycin, ciprofloxacin, propranolol, magnesium, and procainamide. AChE inhibitor therapy should be restarted in the immediate postoperative period. Exacerbation of muscle weakness should be evaluated at once, and any possible residual anesthetic effect should be differentiated from possible myasthenia crisis or cholinergic crisis.

Neonatal myasthenia

Transient neonatal MG occurs in 10% to 20% of infants born to mothers with MG. Maternal AChR antibodies cross the placenta and are responsible for transient MG symptoms in the neonate. The main clinical manifestation of neonatal MG is generalized weakness, and these infants are at increased risk for respiratory insufficiency. AChE therapy is required for 3 to 4 weeks after birth.

Myasthenic crisis versus cholinergic crisis

Both myasthenic crisis and cholinergic crisis can present as respiratory failure. Triggers for myasthenia crisis include disease exacerbations, noncompliance with cholinesterase inhibitor medication, adverse effects of other medications, fever, and emotional stress. Cholinergic crises develop secondarily to an overdose of cholinesterase inhibitor medication. In these cases, excessive ACh stimulation of striated muscles at the NMJ produces a flaccid muscle paralysis that can be clinically indistinguishable from weakness due to myasthenia crisis. Respiratory failure may be present without other cholinergic symptoms (miosis, diarrhea, urinary incontinence, bradycardia, emesis, lacrimation, or salivation).

The edrophonium test can be used to distinguish between cholinergic and myasthenic crises. The initial dose of edrophonium should be 2 mg IV, administered slowly. Atropine is the drug of choice for bradycardia or atrioventricular (AV) block, if encountered. If there is no response or there are no adverse cholinergic effects, another 8 mg IV of edrophonium can be slowly administered, for a total dose of 10 mg. Improved muscle strength after the dose of edrophonium implies myasthenic crisis; increased weakness indicates that it is cholinergic crisis. A myasthenic crisis should be treated with a cautious

administration of appropriate longer acting cholinesterase inhibitors. Treatment for cholinergic crisis is respiratory support, discontinuation of all anticholinesterase drugs, and symptomatic treatment of any associated autonomic dysfunction.

Lambert-Eaton myasthenic syndrome

LEMS is another autoimmune disorder that affects neurotransmitter signaling in the NMJ. In contrast to MG, the autoantibodies are directed toward presynaptic ending, more specifically against voltage-gated Ca^{2+} channels. ACh is released from intracellular vesicles as a result of calcium influx via these channels. The presence of LEMS antibody results in a decrease of ACh release toward the postsynaptic membrane.

In a majority of LEMS patients, the antibody is produced as a part of paraneoplastic syndrome due to underlying malignancy; most commonly it is associated with small cell cancer of the lung (up to 60%). LEMS, however, can exist as a standalone autoimmune disorder. The disease is characterized by lower and upper extremity weakness of variable progressivity, associated with autonomic dysfunction and occasional oculobulbar palsy. The muscle weakness improves with repetitive contraction as more ACh is being released to the endplate.

Diagnosis is usually made based on clinical presentation with increased suspicion in patients with small cell carcinoma and concomitant dysautonomia. A positive calcium voltage-gated channel antibody test confirms the diagnosis. Muscle biopsy most frequently demonstrates a reduction of type 1 muscle fibers. Often the diagnosis of LEMS leads to the diagnosis of previously unrecognized small cell carcinoma.

The only effective medications currently used for treatment of LEMS are guanidine hydrochloride and 3,4-diaminopyridine. The latter increases time of calcium influx into the cells via blockade of potassium. The former inhibits the binding and uptake of calcium into subcellular organelles such as mitochondria, thereby increasing the free intracellular calcium level and facilitating ACh release. Guanidine hydrochloride is hepatotoxic, which limits its use. Plasmapheresis and immunosuppression also have been found to be effective at improving symptoms. A comparison of the clinical symptoms of LEMS and MG is summarized in Table 111.1.

Anesthetic implications

In contrast to MG patients, LEMS patients are characterized by increased sensitivity to both depolarizing and nondepolarizing muscle relaxants. The sensitivity to nondepolarizing agents is more pronounced in LEMS than in MG. An anesthetic strategy that would involve avoidance of muscle relaxants should be strongly considered in patients with known LEMS. When nondepolarizing NMBs are used, the reversal of muscle relaxation in these patients is often incomplete or transient, posing an increased risk for the need for postoperative ventilatory support. As discussed earlier in this chapter regarding MG, volatile anesthetics and/or IV anesthetics are often sufficient in providing muscle relaxation for intubation and maintenance of anesthesia. LEMS should be on the list of differential diagnoses in patients with prolonged paralysis without any evidence of pseudocholinesterase deficiency.

Muscular dystrophy and myotonic dystrophy

Jason M. Erlich and Sugantha Sundar

Neuromuscular diseases are a group of diseases that include muscular and myotonic dystrophies (Tables 112.1 and 112.2) as well as additional disease states. Many, although not all of the diseases are clinically characterized by the progressive loss of skeletal and cardiac muscle function due to abnormal or insufficient quantities of muscle cell proteins, which affect the integrity of the muscle membrane. As genetic diagnosis of disease becomes more pervasive, new classifications may become the standard. It is possible that neuromuscular disease has been underdiagnosed as clinically mild cases may not arouse suspicion.

The goals of this chapter are to

- (1) discuss the different types of muscular dystrophies and their anesthetic implications, and
- (2) discuss the anesthetic implications of ion channel myotonias.

Discussion of myasthenia gravis (MG), myasthenic syndromes, multiple sclerosis, motor neuron disease, Guillain-Barré syndrome, mitochondrial disease, and Charcot-Marie-Tooth disease is beyond the scope of this chapter.

Muscular dystrophies

The muscle cell is made up of a variety of proteins, such as dystrophin, merosin, utrophin, syntrophin, dystrobrevin, and sarcoglycans. Errors in production of these proteins lead to abnormalities in the muscle membrane. These are disorders of usually genetic etiology characterized by skeletal muscle necrosis and hence progressive muscle weakness. In some cases, the cardiac muscle is also involved. Muscular dystrophies are often described by their clinical presentation; however the current classification is based on molecular, genetic, and protein biochemistry.

Duchenne muscular dystrophy

Duchenne muscular dystrophy (DMD) is the most common type of childhood muscular dystrophy, occurring at a rate of 1 in 3300 live male births. It primarily affects males via X-linked recessive transmission; however, a milder phenotype can be observed in female carriers. DMD is characterized by a lack of

dystrophin and an imbalance between muscle cell necrosis and regeneration. A mouse model exists and has been scrutinized since the mid-1990s, but a comprehensive mechanism explaining the disease has not been elucidated. There are a number of hypotheses that attempt to explain the mechanism by which absent dystrophin leads to muscle degeneration. The mechanical hypothesis relates the weakened muscle membrane to the fragility of muscle fibers themselves, especially after sustained contraction. This hypothesis has led to the notion that, although physical therapy is still useful in treatment, overexertion may be harmful. The calcium hypothesis states that the poorly controlled calcium influx observed through voltage-independent channels may result in high cytosol calcium levels and destabilization of the cell membrane, which in turn leads to more calcium influx. By age 12, many affected individuals are confined to a wheelchair. Death by age 30 is frequent and is usually secondary to congestive heart failure (CHF) or pneumonia. Cognitive dysfunction is related to the lack of dystrophin in neuronal membranes.

Because there is no curative treatment for DMD, medical management has focused on decreasing the rate of decline of muscle function. Chronic steroid use has an impact on the rate at which DMD progresses and has been shown to slow the progression of disease, improve peripheral muscle function, preserve pulmonary function, and delay wheelchair use by 3 years. Corticosteroids are thought to increase muscle mass via increasing insulin-like growth factor I and promoting skeletal muscle repair and regeneration.

Becker muscular dystrophy

Becker muscular dystrophy (BMD) results from a dystrophin deficiency. The disease course is milder than DMD because the dystrophin protein is present but in insufficient quantity. It is

Table 112.2. Overview of types of muscular dystrophies

Name	Incidence	Inheritance	Clinical	Treatment	Notes
Duchenne	1:3300 males	X-linked recessive	Progressive proximal muscle weakness beginning in childhood; death possible before 30 y due to cardiac or pulmonary complications	Steroids	Avoid succinylcholine; response to mivacurium is normal
Becker	1:30,000 males	X-linked recessive	Milder form of above; cardiac abnormalities in 75% of 40+ year olds	None	Avoid succinylcholine
Emery–Dreifuss	1:33,000	AD or X-linked recessive	Early contracture of elbows and Achilles tendons, humeropectoral muscle wasting, life-threatening cardiac conduction abnormalities	Implantable defibrillator	Avoid succinylcholine
Limb-girdle	1:20,000	AR > AD	Slowly progressing, relatively benign course; onset 20s–50s; shoulder and pelvic girdle weakness		Avoid succinylcholine; most common in families of North African descent
Oculopharyngeal	Rare		Presents after 30 y; slowly progressive dysphagia; ptosis		Highly sensitive to muscle relaxants; weakness not helped by anticholinesterase agents
Congenital	0.7–1.2:10,000 (Fukuyama form Japan)	AR	Poor prognosis; hypotonia at birth; respiratory difficulty; swallowing abnormalities; CNS involvement; seizures in 50%; death by 10 y; common 10		Avoid succinylcholine; rarely seen outside Japan
Facioscapulohumeral	10–20 per million	AD	Facial, scapulohumeral, anterior tibial, and pelvic girdle muscle weakness beginning in adolescence; cardiac conduction defects, deafness, and retinal disease are also associated		Avoid succinylcholine
Myotonic dystrophy (MD1 and MD2)		AD	Myotonia, insulin resistance, cardiac conduction defects, cataracts, testicular atrophy, frontal balding (males)		Avoid succinylcholine

AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system.

also caused by an X-linked recessive mutation in the dystrophin gene. Onset is in childhood but may be as late as 16 years.

Emery–Dreifuss muscular dystrophy

Patients with Emery–Dreifuss muscular dystrophy often have implantable defibrillators, as cardiac conduction defects associated with the disease can be fatal. Skeletal muscle manifestations are milder, associated with contractures of the elbows, ankles, and spine. There are two types of Emery–Dreifuss muscular dystrophy associated with defective nuclear proteins: an autosomal dominant type associated with defective lamin and an X-linked recessive type associated with defective emerin.

Limb-girdle muscular dystrophy

Limb-girdle muscular dystrophy is exemplified by shoulder- and pelvic-girdle weakness. It is most common in families of

North African descent. It is associated with a sarcoglycan protein abnormality and is usually inherited as an autosomal dominant or recessive trait.

Facioscapulohumeral muscular dystrophy

Facioscapulohumeral muscular dystrophy is associated with weakness of facial, scapulohumeral, anterior tibial, and pelvic girdle muscles; cardiac conduction defects, deafness, and retinal disease are also associated. It has an autosomal dominant inheritance pattern.

Oculopharyngeal muscular dystrophy

Oculopharyngeal muscular dystrophy is associated with ptosis and dysphagia with onset in late adulthood. The dysphagia is secondary to esophageal smooth muscle dysfunction and pharyngeal skeletal muscle weakness.

Congenital muscular dystrophy

Congenital muscular dystrophy is associated with muscle weakness, mental retardation, feeding difficulties, and respiratory dysfunction with an onset during infancy.

Myotonic dystrophy

This is the most common form of muscular dystrophy in adults. It results from the mutation on either chromosome 19q13 (type 1) or chromosome 3q21 (type 2). Patients present with myotonia, progressive myopathy, testicular atrophy, insulin resistance, defects in cardiac conduction, cataracts, neuropsychiatric illness, as well as frontal balding. Death is usually from cardiac and respiratory complications.

Anesthetic considerations

- (1) Patients with DMD frequently require surgical intervention with general anesthesia to correct scoliosis caused by unopposed antagonism of dystrophic muscles. As some diseases such as DMD become multisystemic over time, preoperative testing includes electrocardiography (ECG), echocardiography, chest radiograph, pulmonary function tests and, more recently, cardiac MRI. Postoperatively, patients should be closely monitored for evidence of cardiac and pulmonary dysfunction.
- (2) During the administration of general anesthesia, succinylcholine should be avoided in patients with diagnosed or suspected neuromuscular disease, as hyperactive muscle membranes have been associated with rhabdomyolysis, hyperkalemia, and cardiac arrest due to the release of intracellular contents. In addition, there are case reports of both previously unrecognized as well as correctly diagnosed instances of DMD resulting in postoperative rhabdomyolysis, hyperkalemia, and cardiac arrest despite avoiding succinylcholine but using inhalational agents. This has created a debate about the use of inhalational agents previously thought to be acceptable in patients with DMD. Sevoflurane may be the preferred inhalational anesthetic as it may have less of a tendency to release calcium from the sarcoplasmic reticulum. Inhalational anesthetics are better avoided, however, and total intravenous (IV) anesthesia may be indicated in this patient population.
- (3) DMD and BMD produce variable cardiac manifestations, such as cardiomyopathy, arrhythmias, and CHF, which generally become clinically significant after skeletal muscle disease develops. Cardiomyopathy can be hypertrophic with potential systolic and diastolic dysfunction. Valvular dysfunction may develop as a result of dilatation. A preoperative echocardiogram is helpful in the intraoperative hemodynamic management of these patients.
- (4) Other considerations (not specific to DMD) include intestinal hypomotility and gastroparesis associated with degeneration of alimentary smooth muscle, which increase the risk of aspiration.
- (5) Resistance to the effect of nondepolarizing muscle relaxants is due to the reduced sensitivity of the nicotinic acetylcholine receptors. Nondepolarizing muscular relaxants have been noted, however, to have a prolonged effect due to their reduced ability to produce a contractile force from muscle wasting. The response to mivacurium is normal.
- (6) Anticholinesterases to reverse nondepolarizing neuromuscular blockers are better avoided because of the variable response noted to these medications.
- (7) Notably, blood loss during scoliosis surgery has been shown to be high, possibly due to impaired vasoconstriction from lack of dystrophin as well as reduced neuronal nitric oxide synthase and platelet dysfunction.
- (8) Hyperglycemia should be controlled preoperatively as these patients have an insulin resistance syndrome possibly linked to lack of insulin receptors in the muscle fiber membrane.
- (9) The patient should be positioned with attention to avoid injury.
- (10) When reviewing laboratory test results, it is important to note that persistently elevated serum creatine kinase (CK) is associated with neuromuscular disease states and that it may be the presenting symptom in a mildly symptomatic or asymptomatic patient.

Ion channel myotonias

The ion channel myotonias are a diverse collection of disorders characterized by abnormal sodium, calcium, and chloride channels in muscle. Clinically, myotonia is the result of a prolonged depolarization with a delay in muscle relaxation. Muscle relaxants, general anesthesia, and regional anesthesia do not usually prevent myotonia from occurring.

They are broadly classified as:

- (1) Channelopathies: myotonia congenita, paramyotonia, hyperkalemic periodic paralysis, potassium-aggravated myotonia, hypokalemic periodic paralysis, and acquired neuromyotonia
- (2) Myotonic dystrophy: type 1 and type 2 (which is classified under muscular dystrophy)

Myotonia congenita

There are two types:

- (1) Autosomal dominant: Thomsen
- (2) Autosomal recessive: Becker

Both Thomsen and Becker forms of the disease result from mutations in chloride ion channels that decrease Cl^-

Table 112.3. Types of ion channel myotonias

conductance into the cell. The result is a hyperexcitable muscle membrane that contributes to muscle stiffness. Patients have difficulty initiating muscle movement, which is followed by impaired relaxation of the muscle. When there is sustained activity, the condition improves. Muscle stiffness can be precipitated by the conditions listed in Table 112.4.

Similar to muscular dystrophy considerations, anesthetic considerations in patients with myotonic dystrophy include impaired pulmonary function, cardiomyopathy, delayed gastric emptying, glossal hypertrophy, contractures, and spinal deformity. As the response to nondepolarizing agents is normal to prolonged, using short-acting nondepolarizing neuromuscular blockers such as mivacurium and cisatracurium with close monitoring may be beneficial. Succinylcholine may exaggerate myotonic contracture, and neostigmine may provoke a myotonic episode. Association with MH is uncertain.

Successful anesthetics have included low-dose propofol infusions (high-dose infusions have been associated with prolonged recovery and exaggerated ventilatory depression). Regional techniques have been used with success in both children and adults. Epidural anesthesia has been successful in parturients, although the condition may be exacerbated by pregnancy.

Periodic paralyses

These are of two types:

- (1) Hyperkalemic periodic paralysis (paramyotonia congenita) and potassium-aggravated myotonia (mutations of skeletal muscle voltage-gated sodium channel gene)
- (2) Hypokalemic periodic paralysis (mutation of skeletal muscle voltage-gated calcium channel gene)

Hyperkalemic periodic paralysis/paramyotonia congenita and potassium-aggravated myotonia

- (1) Potassium levels should be reduced before surgery; potassium-free IV solutions are used.
- (2) Maintain blood sugar levels with dextrose-rich solutions.

Table 112.4. Conditions that precipitate muscle stiffness with myotonia congenita

1. Cold and shivering
 2. Diathermy
 3. Succinylcholine
 4. Anticholinesterases

- (3) Plasma potassium level as well as acid–base status should be monitored.
- (4) Short-acting nondepolarizing muscle relaxants are preferred, and succinylcholine is to be avoided.
- (5) ECG monitoring for arrhythmia is standard.
- (6) Potassium-wasting diuretics may have a role in the preoperative preparation of these patients.
- (7) Propofol may be beneficial because it blocks normal and mutant voltage-gated sodium channels.
- (8) Spinal anesthesia seems relatively safe in this patient population.
- (9) Successful emergency treatment of hyperkalemia includes calcium chloride.

Hypokalemic periodic paralysis

- (1) Attacks are triggered by hypothermia, carbohydrate-rich foods, insulin, and vigorous exercise.
- (2) Potassium-sparing diuretics may be beneficial in the preoperative setting.
- (3) Anxiolytics to avoid preoperative stress should be considered.
- (4) Intraoperative K⁺ levels should be checked.
- (5) Short-acting nondepolarizing muscle relaxants are preferred, and succinylcholine is to be avoided.
- (6) Spinal and epidural anesthesia seem relatively safe in this patient population.

Acquired neuromyotonia

- (1) Autoantibodies that target the presynaptic voltage-gated potassium channels lead to inhibition of repolarization and hence a hyperexcitable state (i.e., the opposite of MG, although neuromyotonia can coexist with MG).
- (2) Symptomatology includes muscle twitching at rest (myokymia); muscle cramps, stiffness, insomnia, mood changes, and hallucinations may be present.
- (3) Drugs like phenytoin that increase the sodium pumping action on the nerve may be beneficial.
- (4) There is no contraindication to succinylcholine, and no association with MH.
- (5) Spinal and epidural anesthesia but not peripheral nerve blocks have been successful in blocking the spontaneous discharges that cause muscle twitching.
- (6) Some patients may exhibit resistance to nondepolarizing muscle relaxants, although they are useful in providing muscle relaxation.

Other neuromuscular diseases and malignant hyperthermia

Links between MH and King–Denborough syndrome (KDS) have been made after clinical suspicion was followed up with contracture testing in patients. The inheritance pattern of KDS

is not completely understood, and a genetic link has not been made. Contracture testing in some but not all DMD patients has indicated a link to MH as well.

Central core disease (CCD), not usually classified with the myotonic muscular dystrophies, has been shown to be strongly linked to MH with clinical and laboratory evidence. CCD is a distinct disease of the muscle fiber in which “cores” are noted in a significant number of fibers on oxidative enzyme histochemical analysis of skeletal muscle. The clinical presentation of CCD varies between being asymptomatic to being severely disabled due to skeletal muscle weakness. The association between CCD and MH has been made by analyzing several families with large pedigrees and through genetic analysis. Genetic proof linking CCD to MH comes from the close proximity of the CCD gene to the ryanodine receptor gene (a gene suspected as a cause of MH), both on chromosome 19. Based on this proof, all patients with CCD should be treated as if they are MH susceptible. Hyperkalemic periodic paralysis has also been linked to MH.

Conclusion

Patients with neuromuscular disease are not uncommon, and some of them need repeated surgery for management of complications. Hence adequate knowledge of these clinical situations is vital as there are multiple anesthetic implications. Team collaboration among the neurologist, surgeon, intensivist, and anesthesiologist can lead to better patient outcome.

Anesthesia for Ocular, Ear, and Throat Diseases

D. John Doyle, editor

Ophthalmic procedures

J. Victor Ryckman and D. John Doyle

Anatomy and physiology

The globe of the eye averages 24 mm in diameter. Its wall has three layers: the inner retina, the middle vascular choroid, and the tough white outer sclera. The iris, ciliary body, and the choroids are referred to collectively as the uveal tract (Fig. 113.1).

Light takes the following path through the eye to the retina:

- **Cornea:** Moistened by tears, this clear membrane is the outermost surface of the eye. The cornea joins the sclera at the limbus.
- **Anterior chamber:** Filled with clear aqueous humor, this chamber forms an angle anteriorly where the cornea meets the iris. It is at this location that the trabecular network drains the aqueous humor into Schlemm's canal.
- **Pupil:** This is the opening in the center of the iris. The muscles of the iris control the pupillary size or aperture of the eye by constricting one of two muscle groups. Radial fibers are sympathetically innervated and dilate the pupil when stimulated (mydriasis). Sphincter fibers are circular and parasympathetic innervated; the pupil constricts (miosis) when they are stimulated.
- **Posterior chamber:** Bathed in the aqueous humor, it is in this chamber that the clear lens is suspended by the zonular fibers to the ciliary body. The ciliary body adjusts the lens shape and acts to focus light on the retina. The ciliary body also secretes aqueous humor.
- **Vitreous:** This is the transparent, gelatinous material that fills the space between the lens and the retina.
- **Retina:** It is the retina that converts light to electrical nerve impulses that run via the optic nerve and subsequently radiate to the visual cortex.

Extraocular muscles

The eye is powered by six extraocular muscles. They insert into the anterior sclera 6 mm posterior to the limbus. The inferior oblique's origin is on the nasal side of the maxilla. The superior oblique passes through the trochlea before inserting

into the sclera. The superior, inferior, lateral, and medial rectus muscles form a cone that originates at the apex of the orbit where they form the annulus through which the optic nerve leaves the orbit and where the ophthalmic artery, the first branch of the internal carotid artery, enters.

Sympathetic and parasympathetic nerves converge on the ciliary ganglion within this intraconal space prior to innervating the eye. Three cranial nerves innervate these extraocular muscles: III (oculomotor), IV (trochlear), and VI (abducens). Most of the sensory innervations to the eye and orbit are via the ophthalmic branch of the trigeminal nerve, which divides shortly after entering the orbit through the superior orbital fissure into the frontal, lacrimal, and nasociliary nerves.

Intraocular pressure

Because the blood supply to the retina and the optic nerve is related to the intraocular perfusion pressure (defined as the difference between the mean arterial pressure and the intraocular pressure [IOP]), IOP is important in eye surgery. High IOP levels not only impair blood flow but can contribute to loss of eye contents after the globe has been opened. A number of physical factors and drugs will affect IOP. Normal IOP is between 10 and 20 mm Hg; physical factors, such as coughing, vomiting, or even a lid squeeze, can raise IOP to 30 to 40 mm Hg or more.

Similarly, a poorly placed anesthesia mask putting pressure on the eye and even ordinary tracheal intubation can raise IOP. Increases in central venous pressure (CVP) and arterial carbon dioxide tension will also increase IOP and vice versa. To a lesser degree, increases in arterial blood pressure and large decreases in arterial oxygen tension will also increase IOP (and vice versa for arterial blood pressure).

Drugs can also have important effects on IOP. Inhalational agents, barbiturates, and benzodiazepines (and to a lesser extent, opioids) all tend to reduce IOP. Succinylcholine can cause a moderate (6–8 mm Hg) increase in IOP lasting for a few minutes. Consequently, its use in “full stomach” patients with open-globe injuries to facilitate rapid-sequence intubation remains controversial (vide infra). Glaucoma is a condition with increased IOP that is often treated using IOP-lowering drugs, such as timolol (a β -blocker), echothiophate

Figure 113.1. Anatomy of the eye.

(an anticholinesterase), acetazolamide (a carbonic anhydrase inhibitor), as well as other drugs (discussed later).

Oculocardiac reflex

A particularly important consideration in eye surgery (and in a number of other procedures) is the oculocardiac reflex. This is a trigeminovagal reflex whose afferent limb extends from the orbital contents to the sensory nucleus of the trigeminal nerve in the brainstem and whose efferent limb is via the vagus nerve to the sinoatrial (SA) node of the heart. The reflex is usually activated by traction on the extraocular muscles (as with strabismus surgery) or with pressure on the eyeball. Although the usual result is bradycardia, more dangerous rhythm disturbances, even asystole, can occur. Should significant bradycardia persist despite the surgeon stopping the eye manipulation, treatment with intravenous atropine or glycopyrrolate can be used. The reflex is accentuated with concomitant hypercarbia and is most predominant in children. Fortunately, the reflex tends to disappear with repeated stimulation.

Clinical issues

Ophthalmic procedures, particularly surgery for cataracts, are commonly carried out. Providing anesthesia for these patients involves a number of special issues. For example, the patients are usually elderly and frequently have comorbidities such as diabetes, hypertension, or coronary disease. In contrast, ophthalmic surgery is low risk, usually involving minimal physiologic trespass, so that mortality after eye procedures is much lower than for the general surgical population. These two conflicting considerations have led to differing philosophies about how ophthalmic patients should be evaluated prior to eye surgery, with one group advocating minimal evaluation beyond a good history and physical examination and another group advocating a more complete evaluation process so that the patient will be fully optimized and be exposed to the lowest risk possible. Regardless, most clinicians would hold that if an untreated reversible condition would be expected to lead to a perioperative complication, then a more complete workup is indicated. A detailed review of the preoperative assessment of the eye surgery patient has been provided by Gordon.

Ophthalmologic drugs

Ophthalmic patients often take eyedrops, some of which have important systemic effects and may interact with anesthetics. Eye drops made with echothiophate, an irreversible inhibitor of cholinesterase used to provide miosis in glaucoma patients, may decrease plasma butyryl- and cholinesterase and consequently may prolong the duration of action of succinylcholine and mivacurium. Phenylephrine, an α -agonist, is often applied topically to dilate the pupil but may also cause severe hypertension with the 10% preparation. Timolol is a topical β -blocker used in glaucoma treatment that may cause systemic β -blockade. Acetazolamide, a carbonic anhydrase inhibitor, is another drug used to lower IOP. It may cause hypokalemia. Mannitol, sometimes given to lower IOP, may distend the urinary bladder from the ensuing osmotic diuresis. Toxicity from atropine drops can result in tachycardia, dry skin, fever, and even agitation. Systemic administration of atropine has fewer mydriatic effects than does that of scopolamine and is not

associated with an acute increase in ocular pressure, even in glaucoma patients. Glycopyrrolate, with its quaternary ammonium structure, might be a better choice if anticholinergics are required (i.e., for reversal of neuromuscular blockade).

Nitrous oxide in ophthalmic surgery

In some vitreoretinal procedures the surgeon injects an intra-vitreous gas bubble (usually sulfur hexafluoride or perfluoropropane) to maintain apposition of the neuroretina to the retinal pigment epithelium. Use of nitrous oxide during or after such cases will cause bubble expansion as nitrous oxide diffuses into the bubble, causing IOP to increase to dangerous levels. Consequently, nitrous oxide should be avoided in future cases until the bubble is resorbed, a period that can be longer than a month for perfluoroethane and 1 to 2 weeks for sulfur hexafluoride (Fig. 113.2). Should you find yourself using nitrous oxide and subsequently end up surprised by a change in surgical plan that now includes the addition of a gas bubble, you must insist

Figure 113.2. Sample warning information and warning bracelet for patients receiving intraocular gas bubbles.

on having 20 minutes (with a generous fresh gas flow of either 100% O₂ or O₂/air mix) to allow the nitrous oxide to dissipate before a gas bubble is placed.

Topical anesthesia

Cataract surgery and some other eye procedures can often be done using only topical anesthesia, such as tetracaine or lidocaine eye drops. The technique works best when the incision is small and the patients are cooperative, but does not provide akinesia. Consequently, topical anesthesia for cataract surgery has now become more the rule than the exception, as it offers both extreme simplicity as well as the avoidance of the risks associated with retrobulbar and peribulbar injection techniques. Topical eye anesthesia is sometimes supplemented by the surgeon injecting 0.1 ml of 1% preservative-free lidocaine into the anterior chamber (intracamerally). Topical anesthesia is a poor choice, however, for patients unable or unwilling to follow instructions. Also, there is more eye movement, which may be a disadvantage to the surgeon. Finally, note that the technique is often supplemented with mild to moderate intravenous sedation.

Conduction anesthesia for ophthalmic surgery

A variety of regional anesthetic techniques have been developed for eye surgery. These offer several advantages over general anesthesia: postoperative analgesia, a low frequency of nausea and vomiting, earlier ambulation, and earlier discharge. The primary goals of these blocks are eye anesthesia and eye akinesia (immobility). In addition, patient comfort and anxiolysis must be provided. The former usually involves placing pillows under the knees to keep them flexed, and the latter is usually achieved with judicious intravenous sedation (e.g., midazolam, fentanyl, and/or propofol). In all cases, standard monitors are applied, and oxygen is given via a nasal cannula.

The *retrobulbar* block (Fig. 113.3) provides both eye akinesia and eye anesthesia. As the name implies, it involves injecting local anesthesia behind the globe. The procedure is often done in conjunction with a block of the facial nerve. Retrobulbar hemorrhage is the most common complication of this block. Special care must be taken when performing this block in patients with high myopia because globe perforation is more likely to occur in this situation.

Concerns about retrobulbar hemorrhage with the retrobulbar block have led some ophthalmologists to champion the *posterior peribulbar* block. Disadvantages include a longer onset time and less complete eye akinesia. Another block, the *sub-Tenon* block, avoids sharp needles entirely. The technique uses a blunt cannula that is inserted between Tenon's fascia and the sclera under local anesthesia. Local anesthesia (1–2 ml) is then injected into the catheter. Although analgesia with this technique is excellent, and it is less painful than the retrobulbar block, conjunctival edema is a frequent occurrence.

For these blocks, a 1:1 ratio of preservative-free bupivacaine 0.75% and preservative-free lidocaine 2% (without epinephrine) is sometimes used. Hyaluronidase is sometimes added to increase the absorption and dispersion of the local anesthetic. It is not uncommon to “stun” the patient with a small dose of thiopental (50–100 mg) or propofol (30–50 mg) just prior to carrying out a retrobulbar block. Complications of these blocks are usually related to direct needle trauma or local anesthetic toxicity.

- Trauma: retrobulbar hematoma, puncture or perforation of the globe, intraneural injury, intramuscular injury resulting in postoperative strabismus
- Local anesthetic properties: seizures from intravascular (arterial) injection, loss of consciousness and respiratory arrest from local anesthesia entering the central nervous system (epidural, intrathecal) from injection into the sheath of the optic nerve, which is continuous with the dura and arachnoid

General anesthesia for ophthalmic surgery

In patients who are unsuitable for topical or regional anesthesia, general anesthesia is usually used. Unsuitable patients include some anxious patients, patients who are unable to lie still for surgery, mentally challenged patients, patients who are otherwise uncooperative, and much of the pediatric population. Other examples include patients with severe tremors (e.g., from Parkinson's disease), restless leg syndrome, chronic cough, and severe claustrophobia (a patient unable to ride in an elevator due to claustrophobia cannot be expected to tolerate the confinement of surgery while awake).

Strabismus surgery and emergency surgery for an open globe frequently require general anesthesia. It may be wise to use general anesthesia in young, healthy patients undergoing a sclera buckle or in those who may require enucleation of the eye. Other patients who should be considered for general anesthesia include those with high myopia and an intraocular axial length greater than 25 mm (making them at risk for injury to the globe for some eye blocks), monocular patients, patients who have suffered complications from previous regional anesthesia to the eye, anticoagulated patients, and patients with needle phobia.

General anesthesia can be accomplished by using inhalation anesthesia, total intravenous anesthesia, or a “balanced” technique. Muscle relaxants are often used. Use of the laryngeal mask airway (LMA) is popular in Europe for ophthalmologic surgery and is often favored because it is said to provide for a smoother, cough-free emergence. Because the airway is inaccessible during the surgery, however, the technique is shunned by many anesthesiologists in this setting, who are fearful of laryngospasm and other potential airway problems.

Postoperative nausea and vomiting (PONV) is always a concern when general anesthesia is used. Frequently in ophthalmic

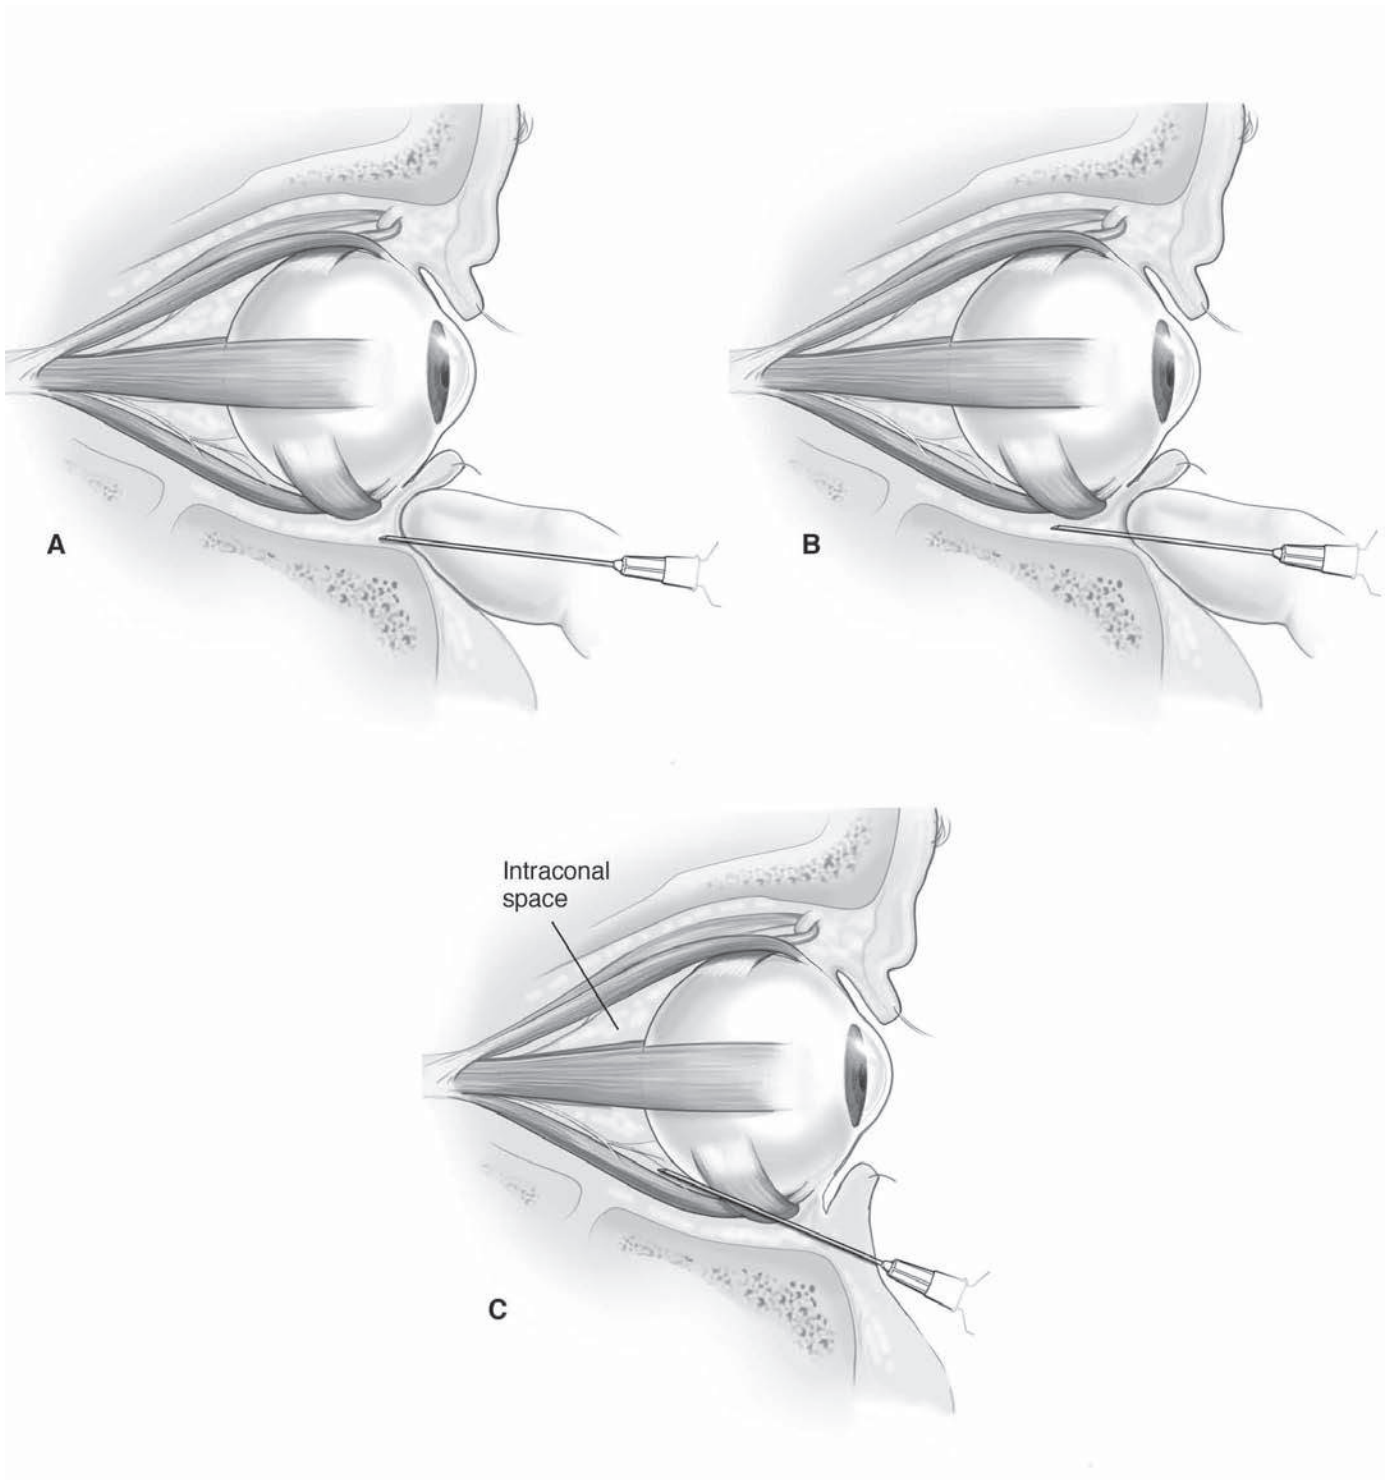

Figure 113.3. Retrobulbar block (inferotemporal intraconal block). **(A)** The needle tip enters at the lower temporal orbital rim slightly up from the orbital floor and passes very close to the bone. **(B)** At 10° elevation parallel to the orbital floor, the needle (e.g., 25 gauge Atkinson needle) passes backward until its mid-shaft is at the iris. The tip is then at the equator of the globe. **(C)** The needle does not pass the midsagittal plane of the globe. It enters the intraconal space after passing through the intermuscular septum. Any movement of the sclera is noted. After test aspiration, 4 ml of anesthetic solution is injected.

surgery prophylactic antiemetic agents, such as ondansetron or droperidol, are used to reduce the likelihood of this happening.

Open globe injury

Globe rupture following blunt injury and globe penetration after a penetrating injury are major emergencies that as a rule require surgery under general anesthesia. (Retrolbulbar blocks are contraindicated due to concerns that external pressure might result in extrusion of vitreous.) Unfortunately, these patients usually do not have empty stomachs, necessitating tracheal intubation via rapid-sequence induction if the surgeon is unwilling to delay the surgery until the stomach is empty. Special attention should be paid to the avoidance of applying external pressure to the eye, as with application of a face mask.

Because awake intubation can be associated with considerable coughing and bucking that would be expected to lead to loss of eye content, its use should be reserved to situations in which intubation by direct laryngoscopy would be expected to be difficult. In addition, the use of a supraglottic airway in this setting would usually be inappropriate, as it does not protect the airway against aspiration.

Further complicating matters is the fact that laryngoscopy and intubation are associated with increased IOP, as is the use of succinylcholine as compared to nondepolarizing muscle relaxants. These cases thus present a clinical dilemma that remains unanswered to this day: Is it better to secure the airway more rapidly using succinylcholine, with its typical 6 to 8 mm Hg increase in IOP, or is it better to use a nondepolarizing muscle relaxant that will take longer to work, even in large doses? After years of rigid teaching that the latter is the preferred approach, thinking is now shifting toward the former.

Common otolaryngology procedures

Naila Moghul and D. John Doyle

Otolaryngologic surgery encompasses a wide variety of procedures and an equally wide variety of patients, many with significant comorbidities. It is important to assess the anesthetic risk for the patient and note any history of congenital or acquired malformations, abscesses or other infections, tumors, a history of head and neck radiation, previous airway trauma, the presence of nasal polyps, proven or suspected obstructive sleep apnea (OSA), and a history of hoarseness, stridor, or hemoptysis.

In all cases, assessment of the airway is particularly vital. Before beginning any case, one must first establish whether problems with ventilation or intubation might be expected. The 11-point airway examination developed by the American Society of Anesthesiology (ASA) is recommended. Additional information may be available from the surgeon in cases in which nasopharyngoscopy has been performed. Many patients will also have recent CT and MRI scans of the head and neck that should be reviewed for possible airway compromise. If there is substantial concern about the airway, an awake intubation (for instance, using a flexible fiberoptic bronchoscope [FOB]) or even a tracheotomy under local anesthesia should be considered.

After induction of anesthesia, it is common that the operating room table be rotated 90° or 180° from the anesthesia setup, necessitating extensions to the patient's breathing circuit. A lower-body or under-body forced-air heating blanket is often placed (e.g., Bair Hugger; Arizant, Eden Prairie, MN), although in long cases body temperature can sometimes become excessive from retained heat from drape use. Inspiratory gases should be humidified. Low-flow anesthesia, over a long period, can help preserve airway heat and humidity. Pressure points must be padded well and frequently checked, and a Foley catheter placed in prolonged cases.

Ear surgery

A number of ear procedures require either general anesthesia or sedation in conjunction with local anesthesia. Myringotomy with tube insertion is an especially common pediatric procedure that is often performed under simple local anesthesia in adults and in older children, although general anesthesia is usually required in younger patients. Ear procedures that usually

require anesthesia include acoustic neuroma removal, cochlear implant surgery, otoplasty, tympanoplasty, and stapedectomy.

Use of nitrous oxide

Under normal physiologic conditions, any gas pressure buildup within the middle ear is relieved through an open eustachian tube. This pathway may be partially or completely obstructed in conditions, such as otitis media, upper respiratory tract infection, or sinusitis, preventing the release of gas from the middle ear cavity. This potentiality explains why nitrous oxide can be a problem in ear surgery. Specifically, nitrous oxide diffuses into air-filled cavities more rapidly than the nitrogen present in air is absorbed into the bloodstream. This property results in gas expansion within the middle ear cavity, leading to increased middle ear pressure, possible rupture of the tympanic membrane (eardrum), and even hearing loss. Even in tympanoplasty procedures, during which the middle ear pressure is the same as atmospheric pressure, placement of the tympanic membrane graft converts the middle ear into a closed cavity. If nitrous oxide is either introduced at this point or is discontinued, a change in air pressure in either direction risks dislodgement of the graft. It is therefore recommended that nitrous oxide be avoided entirely during middle ear surgery, or at least discontinued 20 minutes prior to tympanoplasty.

Hemostasis

One of the requirements of microsurgery is that the surgical field be kept clear of blood and secretions to allow good visualization. What may appear to be mere tiny droplets of blood to the naked eye may obscure the operating field when a microscope is in use. Controlled (deliberate) hypotension is one technique occasionally used to counter this problem. The surgical benefits, however, may not always outweigh the inherent risks to the patient.

Nerve injury

In some types of ear operations, nerve stimulators are used to identify nerves. Consequently, intraoperative use of neuromuscular blockade may sometimes predispose to misidentification of anatomic structures and even result in dissection injury to

structures such as the facial nerve. In contrast, even the slightest movement under a surgical microscope is magnified. These two aspects must be resolved by a discussion with the surgeon prior to the induction of anesthesia. Not infrequently, an infusion of remifentanyl is used as an anesthetic adjunct in such cases.

Postoperative nausea and vomiting

Ear surgery, especially middle ear operations, commonly result in postoperative nausea and vomiting (PONV). PONV prophylaxis is usually employed in such cases, and an anesthetic technique that eliminates or deemphasizes the use of potent inhalational agents and opioids should be considered. Although PONV prophylaxis is detailed elsewhere in this book, commonly used antiemetics include a scopolamine patch, ondansetron, and dexamethasone.

Extubation

Smooth extubation without straining or coughing on the endotracheal tube (ETT) is always desirable, but is particularly important in many ENT cases. Topicalization of the glottic structures with lidocaine at the time of intubation and the intravenous (IV) administration of lidocaine (1–1.5 mg/kg) around the time of extubation may be used to blunt the patient's response to the ETT. Small doses of remifentanyl are sometimes also used for this purpose (e.g., 0.2–0.5 µg/kg).

Specific ear operations

Acoustic neuroma surgery

These tend to be long-duration procedures that are often done by a neurosurgical team. A variety of surgical approaches are commonly used (middle cranial fossa approach, retrosigmoid suboccipital approach, translabyrinthine approach), and the function of the facial nerve is often monitored.

Cochlear implant surgery

Cochlear implantation is a common surgical procedure used to treat severe hearing loss, often done in the pediatric population. The procedure usually includes placing an electrode array into the cochlea and inserting the matching signal receiver into the mastoid bone behind the ear.

Mastoidectomy

This surgical procedure is designed to remove pathology, such as a pocket of infection or a cholesteatoma from the mastoid bone. Its purpose is to prevent eventual damage to the hearing apparatus. In a radical mastoidectomy, usually performed to combat extensive spread of a cholesteatoma, the eardrum and middle ear structures may be removed, although the stapes is often spared. The procedure begins with an incision behind the ear. The mastoid bone is then exposed and opened with a drill. The pathology is then removed, followed by closure with

stitches. A drain may be placed. Facial nerve injury is a rare complication.

Myringotomy

Myringotomy is commonly a pediatric procedure and is discussed elsewhere (see Part 24 on pediatric anesthesia).

Tympanoplasty

Tympanic membrane microsurgical repair using homografts is a common otologic procedure. Tissue materials located near the operative field are used to make the graft. Temporalis fascia and perichondrium are two of the more commonly used materials, although artificial materials (e.g., AlloDerm; LifeCell Corporation, Branchburg, NJ) are sometimes used in repeat procedures. Nitrous oxide should be avoided.

Tracheostomy

A tracheostomy creates a surgical airway in the cervical trachea, usually with the intent to place a tracheostomy tube (Fig. 114.1). The procedure is most commonly carried out in patients who could not be weaned off a ventilator, although it is also used for trauma patients, patients who have experienced severe neurologic injury, and patients with head and neck cancers. Although the procedure is often carried out between the second and third tracheal rings, in dire emergencies it is sometimes carried out through the more easily entered but higher positioned cricothyroid membrane (cricothyrotomy).

Some key points to note are as follows:

After the trachea is secured with an ETT, the trachea and the hypopharynx are suctioned, the patient is ventilated with 100% oxygen, and the surgeon dissects down to the trachea. Care must be taken to avoid the use of cautery while 100% oxygen is being administered to prevent an airway fire. The

Figure 114.1. Tracheostomy tube assembly. Courtesy Klaus D. Peter, Wiehl, Germany.

Figure 114.2. Harvesting of a free flap from the upper extremity in a head and neck cancer operation.

ETT cuff is temporarily deflated before the surgeon cuts between the tracheal rings with the scalpel, to avoid cuff perforation. After the tracheal wall is transected and the tracheostomy tube is ready to be placed, the cuff is deflated and the ETT withdrawn until the tip is just cephalad to the incision while the cuff remains distal to the vocal cords.

At this point, the breathing circuit is disconnected from the ETT and handed over to the surgeon, using utmost caution to keep the ETT firmly in place. Only after placement of the tracheostomy tube is confirmed through capnography, chest-rise, and auscultation is the ETT cuff finally deflated and the ETT removed. A reinforced tracheal tube or laryngectomy tube may be temporarily placed when the tracheostomy is part of a cancer operation; otherwise, a regular tracheostomy tube is used (Fig. 114.2).

Possible complications include bleeding (e.g., from a divided thyroid isthmus or other nearby vessels), pneumothorax, subcutaneous emphysema, and tube obstruction from impingement on the posterior tracheal wall, blood clot, or mucus plugging. Inadvertent early decannulation and subsequent difficulty in correctly replacing the tube carry significant mortality. Late complications include tracheal stenosis, tracheoesophageal fistula, and tracheal necrosis. Massive hemorrhage from erosion of the innominate artery can also occur, and is often fatal.

Some individuals favor using a percutaneous tracheostomy technique (e.g., Ciaglia Blue Rhino kit; Cook Medical, Bloomington, IN), especially in some surgical intensive care unit (ICU) wards. In experienced hands this may be a safe and effective alternative to traditional surgical techniques. Regardless of the technique used, it should be emphasized that changing a tracheostomy tube following a fresh tracheostomy is especially perilous as the new tube may enter a false passage. Thus, if a fresh tracheostomy tube is inadvertently removed, a direct laryngoscopy and intubation with an ETT may be necessary to salvage the airway.

For the first 5 to 10 days postoperatively, all tube changes should ideally be carried out in the operating room. After the surgical site has had time to mature, it is no longer necessary to carry out tube changes in an operating room, but a full set of tracheostomy instruments (especially cricoid hooks) should still be available. Changing the tube using a tube exchanger or using an FOB to confirm tracheal placement of a tracheostomy tube prior to attempting positive pressure ventilation may also be useful. Finally, patients should be preoxygenated with 100% oxygen prior to the tube change.

Head and neck cancer surgery, laryngeal surgery, and endoscopy

General considerations

Integrity of the airway is a key concern when evaluating any patient with a neoplastic growth in the head and neck region. Many tumors may enlarge considerably without causing airway compromise, whereas others, due to their location, may lead to problems, such as stridor and aspiration. Highly vascular tumors can hemorrhage with minimal manipulation. Radiation therapy may cause fibrosis of the temporomandibular joint (TMJ) and other structures, adding to difficulty with mouth opening or making it difficult to identify anatomic structures during laryngoscopy.

Surgical treatment of head and neck cancer can include such diverse procedures as laryngectomy, pharyngectomy, hemimandibulectomy, parotidectomy, or radical neck dissection. Because of the extensive nature of these operations and possible complicated postoperative sequelae, most of these patients will have been extensively evaluated prior to presenting for surgery. This patient population tends to be elderly and have various comorbidities, such as hypertension, cardiovascular disease, chronic obstructive pulmonary disease (COPD) from chronic smoking, and heavy alcohol use. Chronic malnutrition, dehydration, and weight loss are also common. The patient's medical history and the anticipated extent and duration of surgery will influence choices of inhalational, opioid, and paralytic agents.

Large-bore IV access is appropriate for most cases. A central venous catheter may also be appropriate if existing IV access is suboptimal. Arterial cannulation for closer monitoring of blood pressure or for frequent blood sampling may be indicated in patients with significant cardiovascular, pulmonary, hepatic, or endocrine disease or in surgeries during which there is a possibility of substantial blood loss or when carotid manipulation may lead to cardiac rhythm disturbances or variations in blood pressure. Manipulation of carotid bodies, sinuses, and the stellate ganglion during radical neck dissection may cause wide swings in blood pressure, arrhythmias, QT abnormalities in the electrocardiogram, and even sinus arrest. In such cases the surgeon must be immediately notified and the procedure must be paused. Infiltration of the carotid sheath with local anesthetic usually produces resolution of these side effects. The denervation of carotid bodies and sinuses, especially in bilateral neck

dissection, may result in wide blood pressure variation (hypertension or hypotension) in the postoperative period. Hypoxic drive may be affected as well. The postoperative course may require a stay in the ICU, and the patient is sometimes left intubated due to laryngeal and pharyngeal edema following surgical manipulation.

Radical neck dissection or parotidectomy requires careful surgical dissection of tissues to preserve peripheral nerves, such as the facial and the spinal accessory. Consequently, the anesthesiologist is often asked to withhold neuromuscular blockade after the initial intubating dose. Intubation of trachea may be carried out with succinylcholine or other short-acting agents, after which it is important to document return of neuromuscular function. The planned anesthetic would entail a deeper plane of anesthesia, with the inhalational agents often supplemented by a remifentanyl infusion to ensure absence of motor response to surgical stimuli.

In head and neck cases involving free flaps harvested from upper or lower extremities, special attention should be directed at providing adequate flap perfusion. There is substantial uncertainty on how to best achieve this goal. The use of vasopressors, such as phenylephrine, has been questioned because they elicit vasoconstriction. In animal experiments, however, flap blood flow was not altered when phenylephrine was given at low or moderate doses. Maintaining mean arterial pressure solely by means of large amounts of fluid administration can increase tissue edema, jeopardize the integrity of the anastomosis, and ultimately impair tissue oxygenation. Maintaining normothermia and modulating the perioperative inflammation might offer additional means to optimize surgical outcome. Close communication with the surgical team will help to provide appropriate care for every individual case.

Whether a hematocrit at or around 30 provides optimized rheologic properties within the capillaries remains unclear. The negative impact of the transfusion of stored allogenic red blood cells might mitigate this presumed effect.

Airway management

General anesthesia with endotracheal intubation is most commonly used. Distortion of the oropharynx from tumor or tumor-related respiratory compromise may necessitate securing the airway by awake fiber-optic intubation or even awake tracheotomy. Upper airway tissues may be friable following radiation and may be prone to bleeding upon manipulation. Alternatively, radiation therapy may lead to tissue fibrosis or spondylosis of the TMJ, resulting in reduced mouth opening.

In cases where there are serious airway concerns, the surgeon should be present in the operating room during induction should emergent cricothyrotomy or tracheostomy become necessary. An inhalation induction with sevoflurane with the goal of maintaining spontaneous ventilation is sometimes a useful alternative to an IV induction or awake intubation.

If an awake fiber-optic intubation is chosen because of significant airway compromise, the oropharynx should be

Figure 114.3. An oral RAE ETT. Image used with permission from Nellcor Puritan Bennett LLC, Boulder, Colorado, part of Covidien.

topicalized with lidocaine or benzocaine. In addition, some practitioners will sedate the patient with midazolam, fentanyl, or dexmedetomidine.

As noted earlier, some head and neck procedures, depending on intraoperative requirements and postoperative airway logistics, will require a tracheostomy. If so, the tracheostomy is usually done following the induction of anesthesia, either at the beginning or the end of the main procedure itself. RAE ETTs are popular in ENT surgery as they are designed for secure fixation and easy access. They are available in oral (Fig. 114.3) and nasal (Fig. 114.4) styles.

Airway management issues also arise in laryngoscopy, bronchoscopy, esophagoscopy, and phonosurgery procedures. In head and neck cancer, the first three of these procedures are often carried out in a single session. Intubation is usually accomplished with a small diameter (5.0–6.0 mm) ETT. Another option is to use a microlaryngeal type ETT (MLT).

Figure 114.4. A nasal RAE ETT. Image used with permission from Nellcor Puritan Bennett LLC, Boulder, Colorado, part of Covidien.

These ETTs have a narrow shaft (e.g., 4, 5, or 6 mm ID) but are the same length as the adult tube and have a large, high-volume, low-pressure cuff. Naturally, they offer higher resistance to breathing than a regular ETT, and ventilating pressures may need to be higher for a given tidal volume. Phonosurgery involves surgery to the vocal cords and related structures and can be done under sedation to allow the patient to phonate, although it is also commonly done under general anesthesia with an MLT in place.

A mixture of helium and oxygen (heliox) is sometimes used to substantially decrease the pressures needed to ventilate patients with small-diameter endotracheal tubes. Commonly used mixtures include 80%/20% or 70%/30% helium to oxygen. Heliox also offers a potential advantage in patient upper airway obstruction resulting from edema, tumors, or foreign objects. It is the low density of helium that allows it to be useful in such cases.

In some ENT procedures, jet ventilation is used in conjunction with total intravenous anesthesia (TIVA). Typically, the surgeon inserts a special laryngoscope (e.g., Dedo; KARL STORZ Endoscopy-America, Inc., El Segundo, CA) to which a jet ventilation attachment is placed. The patient is ventilated intermittently with bursts of 100% oxygen at 10 to 40 PSI, with special attention to watching the chest rise and fall. (Recall that 1 PSI = 51.71 mm Hg.) Jet ventilation should be done only when the vocal cords are visible through the laryngoscope; consequently, continuous communication with the surgeon is essential. Because barotrauma resulting in pneumothorax is a potential complication, the minimum effective driving pressure should be chosen.

An apneic oxygenation technique can also be used for some short endoscopic procedures, such as tracheal dilatation procedures for tracheal stenosis. The patient is ventilated by mask (or via an ETT) until oxygenation is maximal. The mask is then removed and the surgery performed under apnea until the arterial saturation decreases, and ventilation must again be started.

Nasal and sinus surgery

Common procedures include septoplasty, polypectomy, endoscopic sinus surgery, and maxillary sinusotomy (Caldwell–Luc procedure). Most of these procedures are performed under general anesthesia. These procedures, however, can be tolerated with sedation and local anesthesia in a cooperative patient. Preoperatively, patients should be asked about possible signs of OSA, recent infections, and antibiotic, antihistamine, or aspirin use.

Patients should be assessed for audible or mouth breathing, diminished speech quality, inspiratory stridor, expiratory wheezes, or a prolonged expiration, which may signal partial airway obstruction. Nasal polyps can be associated with allergic disorders and reactive airway disease, such as asthma, or with cystic fibrosis. Aspirin or nonsteroidal anti-inflammatory drug use in association with nasal polyps is of a particular concern.

Premedication may include an antisialogogue, an anxiolytic, and/or antiemetic prophylaxis. Anesthetic induction should always take into account the possibility of existing partial airway obstruction.

Many surgeons like to treat the nose with cotton-tipped pledgets soaked with local anesthetic (e.g., cocaine 4% or 10% to a maximum dose of 3 mg/kg), thereby blocking the sphenopalatine and anterior ethmoidal nerves that provide sensation to the nasal septum and lateral walls. This anesthetic also shrinks the nasal mucosa and reduces blood loss. Intranasal cocaine must be used cautiously in patients with hypertension or with a history of coronary artery disease. Many surgeons also prefer the use of RAE style or reinforced type ETTs. A posterior pharyngeal pack is sometimes used to help prevent blood from trickling down to the trachea. Special care must be taken to tape the patient's eyes because of the proximity of the surgical equipment to the face. These cases are often conducted with the assistance of special surgical navigation equipment.

Coughing, bucking, or straining at the time of extubation can cause increased vascular pressure, thereby risking postoperative bleeding. It is desirable to carry out extubation in as smooth a manner as possible, with the patient having regained consciousness and airway protection reflexes. Smooth extubation is sometimes facilitated using small doses of remifentanyl to blunt the patient's reaction to awakening with the ETT in place.

Some anesthesiologists like to employ “deep extubation”: The trachea is extubated after establishing spontaneous respiration but before the return of airway reflexes, while the patient is still in a deep plane of anesthesia. This technique is considered to be hazardous by some practitioners because it places the patient at risk for laryngospasm as well as aspiration of gastric contents or bloody secretions. This option may be less attractive for patients who are at high risk for aspiration or who have a history of a difficult intubation. Care must be taken to assist the patient's respiration until all airway reflexes return and full consciousness is regained.

Obstructive sleep apnea

OSA disorder is characterized by the obstruction of the airway during sleep by the oropharyngeal soft tissue. Both anatomic factors (e.g., redundant folds of oropharyngeal tissue, tonsillar hypertrophy, macroglossia, or anomalous positioning of the maxilla and mandible) and neuromuscular factors (e.g., reduced oropharyngeal muscle tone with reduced ventilatory motor output to upper airway muscles during sleep) may be contributing factors. If undetected, OSA can lead to serious health problems and result in important perioperative complications. Patients with OSA may complain of snoring, daytime sleepiness, repeated morning headaches, intellectual impairment, and other symptoms. OSA is also associated with obesity.

The perioperative concerns in patients with OSA are primarily respiratory in nature, and include airway obstruction, the potential for difficult intubation, and an increased sensitivity to opioids. In addition, potential nonrespiratory

concerns include a link between OSA and heart failure, ventricular hypertrophy (right-sided first, then left-sided), systemic and pulmonary hypertension, cardiac rhythm disturbances, and vascular disease.

Physiologically, the patency of the upper airway during inspiration requires active muscle tone. When this tone is reduced as a result of sleep, neuromuscular disease, anesthesia, or residual neuromuscular blockade, upper airway obstruction may occur. The velopharynx, a particularly narrow segment of the upper airway, is especially predisposed to obstruction in such settings. Obese patients with large necks often have a more collapsible velopharynx that predisposes to upper airway obstruction. Not surprisingly, OSA apnea events are associated with intermittent hypoxemia, and a potential long-term consequence is pulmonary hypertension and cor pulmonale due to pulmonary vasoconstriction. Heart failure and other complications may follow.

Polysomnography, usually involving an overnight sleep study, is required to formally diagnose OSA. The study is usually performed in a specialized sleep center, where numerous body functions are monitored and scored (e.g., respiratory pattern, pulse oximetry, electroencephalogram [EEG], electrooculogram [EOG], and chin electromyogram [EMG]). In the absence of polysomnography, some specific clinical findings may be helpful in identifying potential OSA patients. In particular, the ASA has recently published guidelines for the perioperative care of OSA patients.

It has been established that the presence of OSA may lead to difficulties in tracheal intubation. Although this does not imply that awake intubation is necessary in OSA patients, clinicians should have immediately available various alternate means to secure the airway should difficulties with intubation be encountered using conventional equipment.

A number of ENT procedures are sometimes used to treat OSA. These may include a uvulopalatopharyngoplasty (UPPP) procedure, tonsillectomy, hyoid myotomy surgery, or other surgical interventions. Postoperative complications such as hypoxemia, hypercapnia, delirium, unplanned ICU days, reintubation, and cardiac events occur disproportionately. It should also be noted that there is a propensity for sedatives to increase the frequency of sleep-related apneic episodes in OSA patients. Although this problem is often highlighted from the perspective of postoperative opioid administration, it should be noted that agents such as benzodiazepines and barbiturates increase the chance of upper airway obstruction by decreasing upper airway muscle tone. In any event, the lowest effective dose of analgesic or sedating drugs should be used, with antagonists such as naloxone and flumazenil being readily available.

Experts surveyed to develop the *ASA Practice Guidelines for the Perioperative Management of Patients with Obstructive Sleep Apnea* suggested that OSA patients be monitored for (a median of) three hours longer than their non-OSA counterparts before discharge from an outpatient facility. In addition, monitoring should continue for (a median of) 7 hours after the last episode of airway obstruction or hypoxemia while the patient is

breathing room air in a quiet, unstimulated environment. It is also important that the patient's postdischarge instructions emphasize the continued use of home continuous positive airway pressure (CPAP) in patients who use CPAP preoperatively.

Special situations

Laryngospasm

Laryngospasm is a reflex involving spasm of the glottic musculature. It is triggered to protect the upper airway from exposure to foreign material. Laryngospasm is associated with light anesthesia, is caused by blood or secretions irritating the vocal cords, and may occur after septoplasty and rhinoplasty surgery. This form of airway obstruction is common in children and can occasionally result in profound hypoxia. Although laryngospasm can often be broken using a sustained positive pressure breath or by increasing the depth of anesthesia with propofol or an inhalational agent, muscle relaxation (e.g., succinylcholine 10–20 mg IV) is sometimes needed to break the spasm. Attempts by the patient to breathe in against the glottic obstruction may occasionally produce “negative-pressure” pulmonary edema.

Retropharyngeal abscess

Retropharyngeal abscess formation may occur from a bacterial infection of the retropharyngeal space, which usually results from tonsillar or dental infections. If untreated, the posterior pharyngeal wall may advance anteriorly into the oropharynx, resulting in dyspnea, painful swallowing, trismus, and (eventually) airway obstruction. As abscess rupture can lead to tracheal soiling, contact with the abscess during laryngoscopy and intubation should be minimized. Incision and drainage is the usual treatment, and a temporary tracheostomy is sometimes required.

Ludwig's angina

Ludwig's angina is an infection of the floor of the mouth. The tongue may become elevated and displaced posteriorly, with a resulting concern about loss of the airway. Awake fiber-optic intubation or awake tracheotomy are commonly used to secure the airway in this condition.

Using supraglottic airways

Although the use of an ETT remains customary in most ENT cases, it should be emphasized that there exist a number of reports on the use of supraglottic airways, such as the laryngeal mask airway (LMA), during ENT cases. One advantage of using LMAs and other supraglottic airways is that they can be inserted blindly without the need for paralysis, making them helpful in many cases of difficult intubation. After securing the airway with the LMA, an FOB jacketed with an Aintree intubation catheter (Cook Medical) can be passed through the LMA when there is a need to intubate the trachea. Alternately, one can use supraglottic airways, such as the LMA FastTrac

(The Laryngeal Mask Company, Limited, San Diego, CA), which is specifically designed to aid in tracheal intubation.

Supraglottic airway devices are not only used to facilitate intubation, but can also be used as an alternative to ETTs in some ENT cases. For instance, Webster and colleagues compared use of the flexible reinforced LMA for intranasal surgery to use of an ETT and found that the LMA provided safe conditions with smoother emergence from anesthesia. Use of the flexible reinforced LMA for tonsillectomy procedures has also been reported, and remains popular in some centers.

Lasers, airway surgery, and operating room fires

Alvaro A. Macias, Naila Moghul, and D. John Doyle

Laser surgery

It has been several decades since lasers were first introduced into clinical practice (LASER = Light Amplification by Stimulated Emission of Radiation). Since that time, the laser has become an important tool for surgeons in many specialties, but especially for the ENT surgeon performing laryngeal or tracheobronchial surgery. The use of lasers allows surgeons to concentrate high levels of energy onto a small area, allowing for precise resection of tissue and with the added advantage of providing excellent hemostasis. Different laser types with differing energy properties produce different effects on tissue (Fig. 115.1). With the advent of laser surgery, however, the risk of airway fires as well as fires at other surgical locations has become an important safety issue.

A number of laser technologies are in clinical use. The carbon dioxide (CO₂) laser produces a long-wavelength (10,600 nm) infrared beam that causes instantaneous vaporization of tissue following energy absorption and subsequent internal boiling of the water in cells. Because the beam is not directly visible, a low-energy red targeting laser usually accompanies the beam. In addition, the beam cannot be transmitted via a fiber-optic bundle, a requirement for use in conjunction with a flexible fiber-optic bronchoscope. The CO₂ laser can be used either as a precision cutting instrument or as a tissue vaporizer, depending on the extent to which the beam is focused.

Other popular lasers for clinical use are the Nd-Yag (neodymium-yttrium aluminum garnet) laser, with a beam in the near infrared region at a wavelength of 1064 nm; the KTP-Nd-Yag laser, green colored at a 532-nm wavelength; and the argon laser. All these have beams that can be transmitted fiberoptically. Associated with each laser type is special protective eyewear (goggles) designed to absorb electromagnetic radiation at the wavelength of the laser in use. For example, goggles absorbing radiation at a 532-nm wavelength typically have an orange appearance and would be ineffective in protecting against a laser emitting energy at 1064 nm (Fig. 115.2). CO₂ laser protection eyewear consists of clear glass or plastic lenses that are opaque to far infrared wavelengths. KTP laser protection eyewear distorts color perception significantly in contrast to CO₂ or Nd-Yag laser protection lenses. Glass lenses in general are heavier and more expensive, but provide better protection (higher optical density) and visibility. Note that the

energy of the photons making up a laser beam depend on their wavelength; shorter-wavelength photons (toward the ultraviolet region) have more energy than do longer-wavelength photons (toward the infrared region).

A misdirected laser beam can injure both the patient and the caregiver. Ocular injuries are a special concern, as CO₂ lasers can cause corneal injuries whereas Nd-Yag lasers place the retina at risk. Consequently, the eyes of the patient are protected by taping the eyelids and then applying wet dressings on top, while caregivers wear protective goggles. In addition, laser warning signs should be placed on the outside of any doors leading to the operating room. It should also be emphasized that misdirected laser beams can ignite surgical drapes and other materials. American National Standards Institute (ANSI) standard Z136.3 (Safe Use of Lasers in Health Care Facilities) provides additional information on this and related matters. EN 207 is the European standard for laser safety eyewear.

Anesthesia providers should also be aware that when a laser beam hits tissue, a plume of smoke containing fine particulates is often produced. Because this material has mutagenic and

Figure 115.1. Different wavelengths of laser light cause different patterns of tissue destruction. The destructive effect of laser light on tissue depends on laser parameters and tissue factors.

Figure 115.2. Example of three types of laser safety eyewear. Source: http://en.wikipedia.org/wiki/Image:Laser_goggles.jpg. Reproduced with permission.

teratogenic potential, or may serve as a vector for viral infection, inhalation of the smoke is best avoided by using a smoke evacuator (Fig. 115.3).

Laser-resistant endotracheal tubes

The risk of an airway fire during ENT laser surgery in an oxygen-enriched environment can be reduced by using specially designed laser-resistant ETTs that are less likely to ignite when exposed to intense heat. The traditional polyvinyl chloride tubes, as well as red rubber and silicone tubes, are combustible and potentially toxic. Whereas in earlier years such tubes were often fashioned on the spot using commercially available metallic tape wrapped in a spiral manner to protect standard ETTs, a number of specialized ETTs are now available, such as the Lasertubus tube (Teleflex, Durham, NC). Another example is the Laser-Flex tube (Cardinal Health, Dublin, OH)

(Fig. 115.4). Only metal ETTs, however, will not ignite when struck by a laser.

Vocal cord polyps and cysts

Vocal cord polyps and cysts can occur in a variety of shapes and sizes but typically occur only on one side. Depending on the characteristics of the lesion, its effects can range from merely causing a voice disturbance to complete airway obstruction. In some cases, awake intubation is the most prudent course. Laser evaporation of these lesions is commonly done, although other techniques are available. A suspension laryngoscope is usually used to expose the glottis.

Frequently a laser-resistant ETT is employed, although some surgeons prefer to avoid using an ETT entirely; in the later case, jet ventilation in conjunction with a total intravenous anesthetic (TIVA) with propofol and remifentanyl infusions is useful. The pharmacologic effects of the remifentanyl will help to counter the hemodynamic effects (hypertension and tachycardia) from the suspension laryngoscopy. Muscle relaxation is usually achieved using rocuronium and a neuromuscular blockade monitor to guide administration. In addition, IV dexamethasone is sometimes given to help reduce glottic edema.

Airway fires

An airway fire is a potentially deadly complication that may occur during tracheotomy surgery, laser surgery, or a number of other procedures. Several principles apply to reduce the chance of fires in such settings.

- The surgeon should never enter the trachea by using electrocautery.

Figure 115.3. Concerns that infectious human papilloma virus (HPV) may be present in the plume of laser-treated recurrent respiratory papillomatosis have led some clinicians to use battery-operated air-purifying hoods, such as those shown here. Such systems typically include a blower, battery, headpiece, and breathing tube, creating a decidedly eerie effect.

Figure 115.4. Laser-Flex laser-resistant ETT from Cardinal Health. Note the special double cuff arrangement. Some clinicians like to fill the cuffs with dilute methylene blue; in this way, an ETT cuff rupture from a misdirected laser beam can be readily detected.

- The anesthesiologist must maintain special vigilance at the moment of entry into the trachea.
- The anesthesiologist should keep the FiO_2 used to the minimum needed when a significant potential for an airway fire is present.
- Nitrous oxide should not be used during airway surgery, because it supports combustion just like oxygen.

As an example of an airway fire, consider the case described by Chee and Benumof:

A 28-yr-old, 100-kg man was scheduled for elective tracheostomy. The patient's lungs had been ventilated in the intensive care unit for 35 days after emergency craniotomy for a closed head injury. During the course of intensive care unit stay the patient remained comatose and adult respiratory distress syndrome developed, which was now resolving. The airway evaluation revealed an in situ 8.0-mm ID polyvinylchloride ETT, swollen lips, an edematous tongue protruding out of the mouth and an oropharynx filled with secretions.

General anesthesia was induced with 300 mg intravenous propofol and maintained with 0.4% inspired isoflurane and a 35% oxygen/air mixture. The vital signs remained stable within 10% of the baseline values. Electrocautery was used for coagulation by the surgeons. The patient was administered 100% oxygen immediately before insertion of the tracheostomy tube. Suddenly, the surgeons reported a blue flame shooting up vertically from the patient's neck. The breathing circuit was disconnected immediately from the ETT; 20 ml saline, 0.9%, was flushed into the ETT. The fire extinguished promptly.

This case illustrates the kind of situation for which anesthesiologists should always be prepared: a fire in the operating room. Operating room fires are best divided into airway fires and non-airway fires. A recent report by the American Society of

Anesthesiologists provides specific guidance for both these scenarios (Fig. 115.5). In addition, Table 115.1 provides specific guidance in the case of airway fires. Note that the prevailing conventional wisdom, at least until recently, holds that cases of airway fire call for immediate removal of the endotracheal tube (ETT). Although this is a reasonable rule of thumb, it should also be noted that there are some patients in whom removal of the ETT would in all likelihood result in irreversible loss of the airway.

Clinicians in such a setting face a particularly difficult choice: leave the ETT in place and risk injury to the patient, or remove the ETT and risk losing the airway entirely. Both

Table 115.1. Airway fire protocol

1. Prevention: Inform the surgical team working on the airway of any situation in which high concentrations of oxygen are being used.
2. Construct an improvised fire extinguisher by filling a 60-ml syringe with saline.
3. In the case of an airway fire:
 - a. Inform the surgical team and anesthesia coordinator (control desk).
 - b. Stop ventilation.
 - c. Discontinue nitrous oxide (which supports combustion) and lower the fraction of delivered oxygen to as little as possible.
 - d. Remove ETT.
 - e. Put out the fire with your improvised fire extinguisher.
4. When the fire is extinguished:
 - a. Ventilate the patient with 100% oxygen via face mask (or supraglottic airway if appropriate).
 - b. Assess the extent of any airway damage via laryngoscopy/bronchoscopy.
 - c. Reintubate the patient if significant airway damage is found.
 - d. Where appropriate, arrange for admission to an intensive care unit.

Note: Removing the ETT may be inappropriate in some cases (see text).

Figure 115.5. American Society of Anesthesiologists operating room fires algorithm.

¹ Ignition sources include but are not limited to electrosurgery or electrocautery units and lasers.

² An oxidizer-enriched atmosphere occurs when there is any increase in oxygen concentration above room air level, and/or the presence of any concentration of nitrous oxide.

³ After minimizing delivered oxygen, wait a period of time (e.g., 1-3 min) before using an ignition source. For oxygen dependent patients, *reduce* supplemental oxygen delivery to the minimum required to avoid hypoxia. Monitor oxygenation with pulse oximetry, and if feasible, inspired, exhaled, and/or delivered oxygen concentration.

⁴ After stopping the delivery of nitrous oxide, wait a period of time (e.g., 1-3 min) before using an ignition source.

⁵ Unexpected flash, flame, smoke or heat, unusual sounds (e.g., a “pop,” snap or “foomp”) or odors, unexpected movement of drapes, discoloration of drapes or breathing circuit, unexpected patient movement or complaint.

⁶ In this algorithm, airway fire refers to a fire in the airway or breathing circuit.

⁷ A CO₂ fire extinguisher may be used on the patient if necessary.

CO₂ = carbon dioxide. OR = operating room.

Chee and Benumoff and Ng and Hartigan provide examples where leaving the ETT in place was probably the best strategy. Chee and Benumoff offer the following commentary: “In certain circumstances, the benefits of leaving the ETT in may outweigh the risks after the airway fire is extinguished. The ETT may still allow acceptable ventilation of the lungs with oxygen, especially when the airway is edematous enough to provide a reasonable seal around the perforated cuff. In addition, the ETT can serve as a conduit for a tube exchanger; this consideration may be extremely important if the airway is difficult to reestablish.”

Anesthesia for Orthopedic and Trauma Surgery

Abdel-Kader Mehio and Kamen V. Vlassakov, editors

Anesthesia for common orthopedic procedures

Patricio Leyton, Gian Paolo Volpato, and Kamen V. Vlassakov

Introduction

Providing optimal anesthesia and perioperative care for orthopedic surgery patients may be quite challenging for the anesthesiologist due to surgical procedure diversity and various coexisting diseases. Most common orthopedic procedures can be performed under regional anesthesia (in the absence of specific contraindications), but because of discomfort in the unanesthetized areas or long surgical duration, a combination of regional and general anesthesia may sometimes be a better choice than regional anesthesia alone. Many orthopedic surgery patients are elderly and present with multiple comorbidities. In addition, the orthopedic procedures themselves predispose to several common complications, such as venous thromboembolism, fat embolism, pneumatic tourniquet- or bone cement-associated hemodynamic instability, and patient positioning injuries. Finally, specific complications could also be related to neuraxial and other regional anesthetic techniques.

General considerations

Anticoagulation

Concomitant thromboprophylaxis presents a unique challenge when planning the optimal anesthetic, especially when neuraxial anesthesia is considered. Careful risk/benefit analysis is warranted when trying to balance possible advantages of the different regional anesthesia techniques against the odds of potentially devastating complications (e.g., epidural or spinal hematoma). The American Society of Regional Anesthesia and Pain Medicine (ASRA) has published a consensus statement addressing patient safety when regional anesthesia is performed in the presence of anticoagulant or antiplatelet drugs. These guidelines are summarized and discussed in [Chapter 57](#).

Management of blood loss

Perioperative blood loss in orthopedic surgery can be high, especially in joint replacements, occasionally exceeding several liters in cases such as complex revision of total hip arthroplasty (THA). Risks and costs associated with blood transfusion are discussed in [Chapters 67](#) and [68](#).

The term *bloodless surgery* refers to a series of perioperative patient care measures aiming to reduce or avoid the need

for allogeneic blood transfusion. Patient assessment and optimization, including accurate history and physical examination, are focused on personal and family history of bleeding disorders and medications that may impair coagulation. Pre-admission testing should be done in advance (e.g., 1 month) to allow time for adequate identification, evaluation, and treatment of any coagulation defect or anemia. Possible corrective measures include the administration of iron, folate, vitamin B₁₂, and recombinant erythropoietin. It is important to plan the intraoperative availability of all equipment necessary to facilitate blood conservation strategies (e.g., cell salvage apparatus).

Surgeons practicing careful hemostasis may help minimize intraoperative blood loss. The use of electrocautery during surgery, a harmonic scalpel, and local hemostatic aids may also help reduce bleeding. Various techniques can also be used to reduce transfusion requirements, including controlled hypotension, acute normovolemic hemodilution, and autologous blood cell salvage. These techniques are discussed in detail in [Chapter 69](#).

Multiple pharmacologic agents are also used to decrease bleeding in high-risk patients. These agents include recombinant activated factor VII, the lysine analogues (ϵ -aminocaproic acid and tranexamic acid) that inhibit plasmin-mediated fibrinolysis, and desmopressin that stimulates the endothelial release of factor VIII and von Willebrand factor, thereby enhancing platelet aggregation.

Tourniquets

Tourniquets are used frequently in distal extremity procedures to reduce blood loss and provide a bloodless operating field. They may cause systemic effects due to ischemia and reperfusion, as well as local effects from the pressure applied to the tissues. Tourniquet injury has been implicated as a main cause for peroneal and tibial nerve palsies after total knee arthroplasty (TKA), ranging from mild neuropraxia to permanent neurologic deficits. The incidence of tourniquet-induced paralysis is approximately 1 in 8000 operations. Pressurization of the tourniquet above 400 mm Hg is associated with increased risk of transient nerve injury. A retrospective study suggests that patients with mean total tourniquet time of 145 ± 25 minutes have a 7.7% incidence of nerve injury, recovering completely in 89% of the cases. This finding suggests that tourniquet time

should not exceed 90 to 120 minutes and tourniquet pressure should not be higher than 150 mm Hg above systolic blood pressure. Controversially, the use of epidural analgesia has been reported to increase the frequency and/or severity of peroneal palsy after tourniquet use. Nevertheless, no explanation other than local anesthetic effects masking sensory and/or motor deficits has been postulated. Similarly, it has been suggested that long-acting sciatic nerve block may also delay the diagnosis of nerve injuries and should be avoided in patients at risk, such as those with preoperative flexion contracture $>20^\circ$ or a valgus deformity, as well as for anticipated complex or prolonged surgeries.

Anesthesia for hip fracture

Hip fracture refers to a femur fracture in the region immediately distal to the articular cartilage of the femoral head to approximately 5 cm below the lower border of the lesser trochanter. An estimated 1.7 million hip fractures occurred worldwide in 1990. In the United States, the incidence is approximately 80 per 100,000 and is increasing each year. Because the majority of these cases are treated surgically, hip fracture surgery has become one of the most commonly performed urgent orthopedic procedures. There is agreement that a delay (more than 24 hours) of surgical management increases the risk of morbidity and mortality.

Preoperative assessment

Most patients presenting with hip fractures are elderly, and many of them have significant coexisting diseases, such as coronary artery disease, arterial hypertension, diabetes, chronic obstructive pulmonary disease, cerebral vascular disease, and/or dementia, all of which may affect the choice of optimal anesthetic and monitoring strategies. Conditions that adversely affect mental status, sensory perception, visual impairment, balance, and locomotion are associated with an increased risk of hip fracture. It is important to evaluate the cause of the fracture because although approximately 90% of hip fractures in both sexes result from a simple “mechanical” fall, sometimes these “falls” can also be the result of syncope due to comorbidities such as dysrhythmias, severe aortic stenosis, cardiovascular collapse, stroke, and so forth. These patients are usually volume-depleted because of low oral intake; in addition, the intravascular volume can be compromised due to occult, but sometimes significant, blood loss.

Another common finding in these patients is the presence of perioperative hypoxia that is usually multifactorial. Possible etiologies include atelectasis due to long periods of bed rest, and pulmonary congestion secondary to heart failure, pneumonia, and rarely fat embolism. Obtaining a thorough medical history, including a review of the tolerated level of preinjury physical activity and medications, as well as a careful physical examination, are also important in assessing the perioperative pulmonary and cardiovascular risk. While patients await surgery, pharmacologic and mechanical

(e.g., pneumatic intermittent compression devices) thromboprophylaxis is strongly indicated for every patient presenting with hip fracture because of the high venous thrombosis risk. Venous thrombosis–associated pulmonary embolism (PE) is the third most common cause of death in hip fracture patients, accounting for 18% of perioperative deaths. As discussed earlier in this chapter, the anesthetic technique choice is influenced significantly by the presence of concomitant pharmacologic thromboprophylactic therapy.

Antimicrobial prophylaxis is usually used for orthopedic surgeries, especially when foreign material is implanted. Prophylactic antibiotics have lowered the incidence of superficial and deep wound infection after hip fracture surgery. Most failures of antibiotic prophylaxis occur because of inappropriate timing (antibiotic blood concentration must be near peak at the time of surgical incision). The Surgical Infection Prevention Guideline Writers Workgroup recommends that infusion of the first antimicrobial dose should begin within 1 hour before the incision. When vancomycin or a fluoroquinolone is used, the infusion may begin 2 hours before incision. If a proximal tourniquet is required, the entire dose should be infused before the inflation of the tourniquet. First-generation cephalosporins have been the agents most commonly used in prophylaxis (e.g., cefazolin 1–2 g). Other methods used to decrease surgical site infection include ultraviolet lights over the field (which require patient and provider skin and cornea protection) or positive pressure laminar flow ventilation systems.

Laboratory testing

Complete blood count, electrolytes, blood urea nitrogen and creatinine values, electrocardiogram, and chest radiography are obtained per standard preoperative protocol. Arterial blood gas analysis may be considered in patients with a history of severe pulmonary disorders or clinical manifestations of fat embolism syndrome. Preoperative cardiac evaluation should be performed in patients with known heart disease, multiple risk factors, and in cases where the mechanism of injury suggests a cardiac event. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines for perioperative cardiovascular evaluation for noncardiac surgery should be followed to stratify the risk in these patients.

Anesthetic management

No consensus exists regarding the best anesthetic technique for hip fracture. Because of insufficient evidence from randomized trials comparing regional versus general anesthesia, clinically important long-term outcomes cannot be confirmed. Differences in protocol and small sample size of many studies limit the validity and power of the conclusions to be drawn. Epidural anesthesia is associated with less acute postoperative confusion, but no definite conclusions can be obtained regarding mortality or other life-threatening postoperative complications, such as PE, myocardial infarction, or pneumonia. Based on existing

evidence, epidural analgesia may be superior to systemic opioid analgesia during the first 4 to 6 hours of the postoperative period, but the difference is no longer significant at 18 or 24 hours. To obtain good analgesia and anesthesia of the hip, it is necessary to block the T10 to S2 dermatomes (preferably extending to T8), easily accomplished with spinal or epidural anesthesia. When spinal anesthesia is planned, hypobaric local anesthetic solution might offer some advantages because it permits placing the patient in the lateral decubitus position over the nonfractured side and thus avoids repositioning after the blockade. Isobaric solutions also reliably block the operative side irrespective of patient position. Alternatively, hyperbaric spinal anesthesia is easier to be influenced by position change. The brief repositioning to supine, necessary to obtain adequate anesthesia coverage, is usually used for bladder catheter placement. Some hip fracture operations (transfemoral nail, dynamic hip screw, hip “pinning”) are also performed with the patient in the supine position on a traction table.

In addition to standard intraoperative monitoring, arterial pressure monitoring should be considered in patients with a high risk of coronary events or with poorly controlled hypertension. Significant blood loss and potential hemodynamic instability should be anticipated, especially with hip hemiarthroplasty and THA. Large-bore intravenous lines are recommended in preparation for blood transfusion and rapid fluid resuscitation. Patients with hip fracture are at an increased risk for perioperative pulmonary thromboembolism, as well as fat (Table 116.1), air, or methyl methacrylate monomer embolism, resulting in right heart strain, acute ventilation–perfusion mismatch, and decreased oxygen saturation. The presentation may vary, ranging from subclinical to a catastrophe presenting as sudden cardiac arrest, resistant to resuscitation and often necessitating open heart surgical embolectomy. Early transesophageal echocardiography may be useful to confirm or support the diagnosis, and guide the treatment.

Anesthesia for hip arthroplasty

THA is a common orthopedic procedure. In 2002, approximately 343,000 patients underwent 345,000 hip replacement

procedures in the United States. Most of these patients suffered from osteoarthritis, rheumatoid arthritis (RA), congenital dislocation, or aseptic/avascular necrosis of the hip.

Preoperative assessment

This group of patients usually presents with limited functional capacity resulting from decreased joint mobility and pain, which potentially masks underlying coronary artery disease and pulmonary dysfunction. These patients should undergo a careful preoperative evaluation to assess their cardiovascular status. RA affects multiple organs, and these patients need to be carefully evaluated prior to surgery (see Chapter 118). Airway management can be difficult and may require awake fiber-optic intubation. If the patient is taking glucocorticoids, a “stress dose” should be given to avoid acute adrenal insufficiency. Moderate to large blood loss, necessitating blood transfusion, is common; therefore, availability of autologous and/or cross-matched homologous blood should be ensured. Thromboprophylaxis and antibiotic prophylaxis recommendations used in hip fracture surgery apply to THA surgery as well.

Laboratory testing

Similar tests as for hip fracture should be obtained. Additionally, dynamic flexion and extension cervical spine radiographs are recommended in patients with RA, as up to 50% have radiographic evidence of cervical spine subluxation. When the atlantoaxial subluxation exceeds 5 mm, neck stabilization and awake fiber-optic intubation reduce the trauma associated with airway management.

Anesthetic management

Patients undergoing THA pose challenges to the anesthesiologist similar to those in patients with hip fracture, such as hemodynamic instability, transfusion requirements, deep vein thrombosis (DVT), or PE (including fat or cement embolism). THA is usually performed with the patient in a lateral decubitus position. The patient’s head must be positioned on the side and the cervical spine aligned with the rest of the body. The dependent arm is resting on a padded arm board; an axillary roll should be positioned just caudal to the axilla to relieve pressure on the shoulder and prevent compression of the brachial plexus and vascular structures. The upper arm should be supported on a padded overarm rest. It is important to protect all pressure points in the lower extremities (e.g., inner legs, dependent greater trochanter) to prevent traction or pressure injuries of nerves and skin surfaces. Standard intraoperative monitoring must be used, and invasive arterial blood pressure monitoring should be considered if the patient’s comorbidities warrant it, if a hypotensive anesthesia technique is planned, or if the procedure is a revision THA. Large-bore intravenous access for rapid fluid resuscitation and/or blood transfusion is recommended.

Despite the frequency of THA surgery, debates continue regarding which anesthetic technique is best. A recent

Table 116.1. Diagnostic criteria for fat embolism (Two major or one major and four minor criteria are necessary for diagnosis.)

Major criteria	Minor criteria
Petechial rash	Fever
Cerebral involvement	Tachycardia (>120 bpm)
Respiratory distress	Retinal changes (fat or petechiae)
Arterial blood gas abnormalities	Renal changes
PaO ₂ < 60 mm Hg breathing room air	Jaundice
PaCO ₂ > 55 or a pH < 7.3	Fat macroglobulinemia
	Hemolytic anemia (a drop of more than 20% of the admission hemoglobin value)

Adapted from Gurd AR, Wilson RI. The fat embolism syndrome. *J Bone Joint Surg Br* 1974; 56B:408–416.

meta-analysis comparing central neuraxial blockade and general anesthesia for elective THA showed statistically significant reductions in the intraoperative blood loss and the number of patients requiring blood transfusions with neuraxial anesthesia. Decreased mean arterial pressure, redistribution of blood flow, and locally reduced venous pressure could all be responsible for this favorable effect. Evidence also suggests that neuraxial blockade might diminish the incidence of DVT when pharmacologic prophylaxis is not used; however, it is not clear if these beneficial effects are still present with the improved pharmacologic DVT prophylaxis today.

Various regional anesthetic techniques have been used for THA. Central neuraxial blockade provides excellent surgical anesthesia. Spinal anesthesia provides rapid and intense anesthesia, with drugs such as bupivacaine and tetracaine providing long surgical block and extended analgesia. When larger doses (particularly of hyperbaric local anesthetic) and higher sensory levels are obtained, deliberate hypotension can be achieved, providing hypotensive anesthesia. Combined spinal–epidural anesthesia offers both the rapid onset and solid block of spinal anesthesia and the extended postoperative analgesia via an epidural catheter.

Lumbar plexus block (single-dose or continuous) is another option. This block can be performed by using different approaches, but the lumbar paravertebral or psoas compartment block is the most reliable in blocking all major lumbar plexus branches (femoral, lateral femoral cutaneous, and obturator nerves). When used for postoperative analgesia after hip replacement surgery, continuous psoas compartment block has shown efficacy similar to epidural analgesia. This technique can be quite challenging, however, and reported complication rates are relatively high; therefore, it is recommended that only anesthesiologists with advanced regional anesthesia training and experience perform it.

Regional anesthetic techniques can be used in combination with general anesthesia. After placement of the epidural catheter or peripheral nerve block, general anesthesia can be induced. This combination of techniques may improve the comfort of the patient in long procedures. When performing a combination of general and neuraxial anesthesia, the amount and concentration of local anesthetics have to be reviewed carefully to lessen hemodynamic derangements.

Complications

Bone cement, polymethyl methacrylate, is frequently used to implant THA prostheses and has been associated with adverse pulmonary and cardiovascular events. Typical clinical signs and symptoms (also described as bone cement implantation syndrome) are similar to those of pulmonary or fat embolism and include tachycardia, hypotension, hypoxemia, tachypnea, dyspnea, bronchoconstriction, pulmonary hypertension (sometimes progressing to heart failure), severe systemic hypotension, and cardiac arrest. In addition, the manipulation, the reaming, and the high pressures reached inside the femoral

canal during the insertion of the cemented (or even uncemented) femoral component, with measured peak pressures as high as 680 mm Hg, cause fat particles and other debris to reach the bloodstream. Eventually, such particles reach the lungs through the medullary venous plexus, resulting in ventilation–perfusion mismatch, pulmonary hypertension, and right ventricular failure, usually manifesting as sudden oxygen desaturation and acute systemic hypotension that may be more dramatic in hypovolemic patients. Strategies to prevent or minimize these complications include increasing the inspired oxygen concentration, optimizing the intravascular volume and proactively treating hypovolemia prior to cementing and using vasoconstrictor drugs to treat hypotension. In addition, drilling a vent hole in the distal femur to relieve intramedullary pressure and removing the debris prior to high-pressure lavage of the femoral canal can help minimize embolism. Treatment of such complications includes timely oxygen administration, ventilation support, and cardiovascular resuscitation, including fluids, inotropic and vasopressor therapy.

Anesthesia for knee surgery

Arthroscopy and partial or total joint replacements are the most frequent knee operations today. Knee arthroscopy is often performed on an ambulatory basis and in mostly younger, active patients. It is used as a diagnostic tool, for removal of loose intra-articular bodies, and to repair ligament and meniscus lesions and/or defects. In contrast, patients who need a total or partial knee replacement are often older and may have significant coexisting disease.

Knee arthroscopy

A routine preoperative visit, history and physical examination, as well as standard testing (as required per protocol) modified by medical conditions and age, are recommended in these usually American Society of Anesthesiologists (ASA) physical status I or II ambulatory patients. In the operating room, the patient is in the supine position, or occasionally with both legs bent at right angles and placed on leg holders. Surgery begins with the intra-articular insertion of two or more ports close to the patellar tendon. An irrigation system is then connected to the portals to improve intra-articular visualization and to wash debris and blood. To provide a bloodless field, surgeons use a pneumatic tourniquet on the thigh and/or arthroscopic pump systems that fluid-distend and pressurize the joint without causing thigh compression. Surgery usually lasts less than 1 hour and is accompanied by little hemodynamic impact and fluid requirements.

Several anesthetic techniques are suitable for knee arthroscopic surgery. Although uncommon, intra-articular injections of local anesthetics have been successfully used for short and purely diagnostic procedures, usually in association with intravenous sedation. Spinal anesthesia is one of the common anesthesia techniques for knee arthroscopy. It provides quick,

reliable, and profound anesthesia and short-term postoperative analgesia. With careful choice of local anesthetics and their dose, it does not significantly delay recovery and home discharge. Potential disadvantages of spinal anesthesia include delay in ambulation, urinary retention and pruritus, as well as risk of postdural puncture headache and transient neurologic syndrome (TNS). Faster resolution of the spinal block can be usually achieved by using very low doses of long-acting local anesthetics (bupivacaine or ropivacaine, 4–9 mg) with or without opioids (fentanyl ≤ 10 μg) or short-acting local anesthetics, such as lidocaine (see [Chapter 57](#)). The incidence of TNS is very low with bupivacaine. Peripheral nerve blocks can also be used alone or in combination with spinal anesthesia. Femoral nerve and lumbar plexus blocks are both suitable techniques for knee arthroscopy (for details, see [Chapter 61](#)). To achieve functional recovery of the blocked nerves before discharge, short-acting local anesthetics could be used, but this also limits analgesia duration. Finally, general anesthesia with low-solubility inhaled anesthetics (sevoflurane or desflurane) or propofol, often in association with an LMA, is broadly used in ambulatory centers because it is easily accomplished, allows rapid initiation of surgery, and has similar (and often shorter) time-to-home discharge when compared to regional techniques. General anesthesia, however, prolongs emergence time (time from the end of surgery until exit from the operating room), in most cases requires a postanesthesia care unit (PACU) stay, and is associated with higher incidence of nausea and vomiting and lower overall patient satisfaction. With better antiemetic prophylaxis, and especially in combination with preemptive analgesia techniques, general anesthesia is quickly becoming the norm for ambulatory knee arthroscopy.

Pain after knee arthroscopy is usually moderate but can be intense during the first postoperative day. Tourniquet use, type of arthroscopic procedure, and duration of surgery and anesthesia appear to have no significant impact on postoperative pain. Preemptive analgesia confers a better and smoother transition from anesthesia to adequate analgesia, and may permit a faster patient discharge accompanied with better patient satisfaction. A variety of preemptive analgesic techniques have been investigated (including COX inhibitors, intra-articular ketamine, oral or intra-articular opioids, intra-articular local anesthetics, and peripheral nerve blocks). Most of these techniques, to some extent, have been shown to improve postoperative analgesia.

Arthroscopic anterior cruciate ligament repair is a more extensive surgery than knee arthroscopy and causes moderate to severe postoperative pain. Preemptive techniques include oral COX inhibitors, intra-articular local anesthetics, and femoral and sciatic blockade. Postoperative pain is better controlled with peripheral nerve blocks. Postoperative analgesia with continuous peripheral nerve blockades (CPNB) has been used, particularly continuous femoral nerve block (CFNB). A protocol of 2-day home CFNB infusion has shown to maintain pain scores below the moderate range without rebound pain. Careful patient selection and infrastructure, providing support

and potential complication management, are critical for the safety and success of CPNB.

Anesthesia for total knee arthroplasty

Total knee arthroplasty (TKA) is indicated most frequently for patients with osteoarthritis, RA, and hemophilic arthropathy of the knee. Notably, TKA is associated with the highest DVT and PE incidence of all orthopedic procedures (approximately 80% and 20%, respectively). Furthermore, mortality associated with TKA, approximately 0.4% at 1 month and 1.8% at 1 year, is largely attributed to infection and DVT. Therefore, numerous antibiotic and DVT prophylaxis protocols have been used to prevent these complications, presenting the anesthesiologist with specific challenges when choosing the optimal anesthesia and postoperative analgesia approach.

Preoperative assessment

The preoperative evaluation of these patients is similar to what is required for patients undergoing hip arthroplasty. TKA is considered an intermediate risk procedure. Similarly, emphasis should be placed on the cardiovascular and respiratory state, and appropriate tests must be ordered if the clinical condition of the patient warrants it. For RA patients, special focus on airway and cervical spine evaluation is advised.

Anesthetic management

TKA can be performed with general or regional anesthesia. Several studies have suggested lower mortality and morbidity after regional anesthesia; however, recent long-term outcome data for patients undergoing TKA receiving up-to-date medical care do not support this advantage. Nevertheless, regional anesthesia confers superior analgesia and higher patient satisfaction and may improve short-term functional results. In this surgery, associated with significant postoperative pain and need for early and extensive postoperative physical therapy, lumbar epidural anesthesia remains one of the preferred anesthetic choices. Combined spinal–epidural anesthesia is also common, providing fast onset, adequate intraoperative anesthesia including profound motor block, and excellent postoperative analgesia. Aggressive antithrombotic prophylaxis, however, limits the use of postoperative neuraxial techniques in favor of peripheral nerve blocks. General and spinal anesthesia can be used in combination with continuous femoral blockade (with or without sciatic nerve blockade) to provide preemptive analgesia. Peripheral blocks alone (lumbar plexus block combined with sciatic nerve block) are an alternative but a challenging choice, requiring a motivated patient and an expert in regional anesthesia.

TKA takes approximately 1 to 3 hours, and patients are positioned supine. A thigh tourniquet is generally used, and intraoperative blood transfusion is rarely needed. Routine antibiotic prophylaxis is ideally completed 20 to 40 minutes prior to tourniquet inflation and incision. Standard monitoring is complemented in patients with moderate to severe coexisting

Table 116.2. Effects of tourniquet deflation

Hemodynamic	↓ MAP, SVR ↑ Venous capacitance ↑ PVR ↓ CO
Metabolic	Mixed acidosis Hypoxemia/hypoxia ↑ CO ₂ production
Embolism	Thrombus Fat Air Cement (methacrylate) Bone marrow debris

MAP, mean arterial pressure; SVR, systemic vascular resistance; PVR, pulmonary vascular resistance; CO, cardiac output; CO₂, carbon dioxide.

cardiovascular and respiratory disease by invasive arterial pressure monitoring. The patients are usually stable during surgery and before deflation of the tourniquet. After cuff deflation, hemodynamic instability, bleeding, and hypoxia may occur (Table 116.2).

Embolism can occur at any time during surgery. It is sometimes observed after inflation of the tourniquet, at the beginning of the surgery, or during cementing of the femur, tibia, or patella. Transesophageal echocardiogram (TEE) detects embolism after release of the tourniquet in most patients. Fortunately, the amount of emboli is usually not clinically significant because PE signs and symptoms are relatively rare. The use of an extramedullary fixed prosthesis is not associated with less visible echogenic embolic material, suggesting that emboli are usually thrombi, not cement or bone marrow. Hemodynamic measurements have demonstrated that mean pulmonary artery pressure (MPAP) and pulmonary vascular resistance (PVR) increase in patients who have large-particle emboli observed by TEE. PVR remains elevated long after mixed venous oxygen saturation (SvO₂) returns to normal values, suggesting that the main cause of the increase in PVR is embolism rather than a drop in SvO₂. Finally, some studies have related the stasis caused by the tourniquet itself to the development of thrombi.

Postoperative analgesia

Most patients experience moderate to severe pain after TKA and may significantly benefit from regional analgesia. Single-injection femoral block has been recognized for more than a decade to provide better analgesia than opioids and COX inhibitors, but it is insufficient in duration (less than 24 hours) and extent (it does not provide analgesia to the posterior part of the knee). Therefore, continuous analgesic techniques have been preferred over single-shot peripheral nerve blockades. Although epidural analgesia provides better coverage of the entire leg, compared to continuous femoral perineural analgesia, it also presents disadvantages, such as urinary retention, pruritus, delayed mobilization, and the inherent risk of

neuraxial hematoma in the aggressively anticoagulated patient. Continuous lumbar plexus or femoral blockades are appealing postoperative analgesia options, offering adequate analgesia with an acceptably low incidence of side effects and complications and allowing for earlier rehabilitation. With these techniques, a supplemental single-injection sciatic nerve blockade can be indicated to complete the analgesia of the knee. It is important to remember, however, that TKA is associated with a significant incidence of surgically induced peroneal nerve palsy that might be masked by a routine use of sciatic nerve blocks. COX inhibitors can be used to supplement postoperative analgesia by reducing opioid consumption and side effects. Selective COX-2 inhibitors such as celecoxib have been shown not to increase blood loss.

Anesthesia for shoulder surgery

Shoulder surgery is frequently performed in patients with osteoarthritis, or in healthy individuals following shoulder trauma. Common shoulder surgeries include diagnostic and therapeutic arthroscopy, acromioplasty, rotator cuff repair, and shoulder arthroplasty.

Preoperative assessment

Routine preoperative evaluation should be performed. Preexisting neurologic deficits must be recognized and documented.

Intraoperative management

Regional anesthesia alone is well suited for most patients undergoing short procedures, as it provides good intraoperative anesthesia, muscle relaxation, and superior postoperative analgesia. Regional anesthesia also allows for faster recovery time and discharge. To block the brachial plexus, one can select among several regional techniques, but to achieve anesthesia of the entire shoulder, it is necessary to perform an interscalene block or a cervical paravertebral block (see Chapter 60). General anesthesia is often considered when prolonged surgery is expected, as well as in patients who refuse regional anesthesia or present other contraindications. Because airway access during shoulder surgery is restricted, one should secure the airway when performing general anesthesia. A laryngeal mask airway can be used easily and safely in individuals breathing spontaneously in association with regional anesthesia. Conversely, endotracheal intubation, which better controls and protects the airway, is recommended in patients undergoing surgery exclusively with general anesthesia, when long procedures are expected, when muscle relaxation is required, and in patients with coexisting respiratory problems.

Patient positioning is an important consideration during shoulder surgery. Almost invariably, surgery is performed with the patient in a modified sitting position, also called the “beach chair position.” Typically, the affected shoulder is moved beyond the side of the table and is sometimes elevated with a

pad under the scapula. The head and neck are stabilized in a neutral position, avoiding hyperextension of the neck and/or excessive rotation of the head, thus decreasing the risk of injury to the brachial plexus that is already subject to surgical traction. The unaffected arm is secured over a padded arm holder in elbow flexion and slight shoulder abduction to prevent brachial plexus stretch and peripheral nerve injury. The thorax is stabilized with a padded brace or side supports; the legs are slightly flexed at the knees. Elastic compressive stockings and pneumatic compressive devices are used for DVT prophylaxis. Some operating room beds, specially designed for shoulder surgery, have features that improve patient comfort, safety, and surgical accessibility.

Complications

Shoulder surgery is associated with several rare complications. Many complications occur more commonly in the sitting position, including cardiac arrest, stroke, blindness, ophthalmoplegia, and air embolism. Cardiac arrest is rare, but may occur when a hypovolemic patient (especially under general anesthesia) is abruptly moved from the supine to a steep sitting position. Sudden emptying of the ventricles is probably responsible for the extreme bradycardia and hypotension, sometimes progressing to pulseless electrical activity or asystole. Immediate reversal of the sitting position to the Trendelenburg position, rapid fluid resuscitation, and pressor and inotrope support usually quickly reverse the acute circulatory failure spiral.

Stroke in the sitting position can be attributed to postural hypotension, unrecognized decrease in cerebral perfusion pressure, as well as head and neck manipulation that may produce regional changes in cerebral blood flow. Loss of vision and ophthalmoplegia have also been attributed to ischemic events due to low blood pressure. These ischemic events could be related to failure to recognize the perfusion pressure differences, resulting from the sitting position and erroneous choice of blood pressure monitoring reference points. The cerebral blood pressure will differ from the measured pressure by approximately 1 mm Hg for each 1.3-cm difference in height between the brain and the reference point (transducer position for invasive pressure monitor or the blood pressure cuff site for a noninvasive pressure monitor). For example, in an adult patient in the sitting position, the cerebral arterial pressure will be approximately 25 to 30 mm Hg lower than the pressure measured at the arm. Furthermore, the compensatory mechanisms regulating and maintaining cerebral blood flow are affected by general anesthesia. Therefore, blood pressure should be monitored with extreme caution. A noninvasive blood pressure cuff should not be placed routinely at the calf. For invasive blood pressure measurements, the transducer can be positioned at the level of the external auditory meatus for the measured blood pressure to best reflect the cerebral arterial pressure. These considerations are particularly important in patients with a history of cerebrovascular disease and/or chronic hypertension.

Postoperative analgesia

Pain and neurologic complications are important considerations during the postoperative period. Postoperative pain after shoulder surgery ranges from moderate to severe, correlating poorly with the type of surgery performed. In fact, some arthroscopic procedures do not differ from open surgery in postoperative pain scores. Interscalene brachial plexus block provides analgesia superior to all other pain control modalities, reduces opioid use, allows for faster hospital discharge both in the inpatient and outpatient setting, and permits earlier rehabilitation therapy.

Rheumatoid arthritis and scoliosis

Kenji Butterfield, Abdel-Kader Mehio, and John D. Mitchell

Rheumatoid arthritis

Introduction

Rheumatoid arthritis is a chronic autoimmune inflammatory disease of unknown etiology, characterized by symmetric polyarthropathy and significant systemic involvement. It occurs in approximately 1% of the population and has a female predominance. Onset is typically seen in patients between 30 and 50 years of age. [Table 117.1](#) summarizes its effects on organ systems. As discussed below, rheumatoid arthritis causes a variety of systemic disturbances that may present serious perioperative challenges.

Vascular access

Peripheral veins are usually small, brittle and difficult to cannulate – a frequent association with glucocorticoid therapy. The distal arteries are often calcified and placement of a radial arterial catheter could be difficult due to flexion deformities of the wrist joints. Internal jugular venous access may also be challenging due to fusion of cervical vertebrae and/or limited extension.

Airway

Atlantoaxial (C1–C2) subluxation

Cervical spine flexion deformity may limit the degree of neck extension. The majority of subluxations are anterior, but can be in the posterior, lateral, or vertical positions. Anterior subluxation generally presents with flexion of the neck; consequently, great care must be taken with patient positioning to prevent cord compression or vertebral artery compression. Although the “sniffing” position is often recommended for endotracheal intubation, there have been case reports of subluxation associated with this position as well. Lateral neck radiographs or MRI studies revealing a greater than 3 mm gap between the anterior arch of the atlas and the odontoid process can confirm the presence of anterior subluxation ([Fig. 117.1](#)).

Temporomandibular joint

Severely limited movement of the temporomandibular joint (TMJ) may make visualization of the glottis by direct laryn-

goscopy extremely difficult. Such patients may present with micrognathia and obstructive sleep apnea. When challenges with direct laryngoscopy are predicted, the use of alternative options, such as video-assisted laryngoscopy, fiber-optic laryngoscopy, or use of the Fastrach LMA (LMA North America, Inc., San Diego, CA), should be considered.

Cricothyroiditis

This condition may be present in patients complaining of hoarseness, stridor, odynophagia, or pain when speaking or coughing. Direct laryngoscopy typically reveals bright red swelling over the arytenoids and narrowing of the glottic opening, but normal vocal cords. If the patient presents with mild symptoms, the use of a smaller endotracheal tube (ETT) is recommended. In the presence of severe symptoms, however, oral intubation is relatively contraindicated. Anesthetic alternatives to oral intubation include local anesthesia, regional anesthesia, or presurgical tracheotomy under local anesthesia. These options should be discussed with the patient and the surgeon in the preoperative setting. Due to the possibility of postextubation supraglottic obstruction in these patients, close postoperative observation is of paramount importance.

Neuraxial regional anesthesia

The lumbar spine usually remains unaffected by rheumatoid arthritis. Neuraxial regional anesthesia techniques involving the thoracic spine may be technically challenging. A thorough physical examination should be performed to assess for bony spinal deformities, which if found, may warrant radiographic evaluation. Performing neuraxial anesthesia techniques under fluoroscopic guidance should be strongly considered in such cases.

Scoliosis and spine surgery

Scoliosis is a complex lateral and rotational deformity of the thoracolumbar spine, also resulting in rib-cage deformity. Anterior or posterior deformities, such as kyphosis or lordosis, may also accompany this condition. Approximately 70% of all

cases are idiopathic, occurring with a male:female ratio of 1:4. The remaining 30% are secondary to an array of causes, including neuromuscular disease, mesenchymal disorders, infection, trauma, or congenital causes. Surgery is usually considered when the Cobb's angle (lateral curvature) exceeds 50° in the thoracic spine, or 40° in the lumbar spine (Fig.117.2). Surgical intervention aims at halting the disease progression and partially correcting the deformity, thereby improving the quality of life and facilitating care. If left untreated, scoliosis can lead to severe respiratory and cardiovascular compromise, including restrictive lung disease, pulmonary hypertension, and right heart failure.

In general, for patients undergoing cervical spine surgery, gentle neck manipulation is advised while intubating the airway. Direct laryngoscopy with in-line stabilization or awake fiber-optic intubation may be necessary in cases involving cervical spine instability. Thoracolumbar surgery generally involves degenerative disease in older patients who may also present with significant comorbidities.

Preoperative assessment

Scoliosis patients presenting for spinal surgery require a thorough preoperative assessment of their respiratory and cardiovascular systems. The anesthesiologist should be cognizant of the potential for a difficult airway. The possible need for post-operative ventilation and ICU admission should be discussed with the patient, the family, and the surgical team prior to the procedure. As with most spinal surgeries, the need for a wake-up test should be addressed and rehearsed with the patient in advance.

Figure 117.2. Scoliosis is a lateral deviation in the frontal plane associated with rotation. (With permission from *The Spine Society of Europe* at eurospine.org)

Respiratory

The restrictive pulmonary disease caused by scoliosis is related to the following factors:

- Extent of Cobb's angle
- Number of vertebrae involved
- Cephalad location of the curve
- Loss of normal thoracic kyphosis

Both vital capacity and total lung capacity are reduced, but generally the residual volume remains unchanged. In addition, patients often exhibit ventilation/perfusion mismatch due to hypoventilated areas. Physiotherapy and nebulized bronchodilators are the mainstay treatments for these pulmonary conditions.

Cardiovascular

Cardiac disease can occur as a direct result of scoliosis or be indirectly linked to its underlying causes. Distortion of the chest cavity can lead to chronic hypoxemia and pulmonary hypertension, resulting in cor pulmonale. Impaired cardiac contractility can be severely exacerbated by anesthesia and hypovolemia in patients with Duchenne's muscular dystrophy. [Table 117.2](#) summarizes the preoperative planning.

Intraoperative techniques

The most important intraoperative goals include a stable depth of anesthesia, an adequate level of neuromuscular blockade, and a tight control of the patient's hemodynamic parameters. The anesthesiologist can be faced with multiple challenges including (1) significant blood loss, (2) one-lung ventilation during thoracic spine surgery, (3) prone positioning, and (4) the wake-up test.

Hemodynamic management

Several techniques are used to minimize blood loss. The use of antifibrinolytics, such as aminocaproic acid or tranexamic acid, have proven helpful, albeit not risk-free. Intraoperative cell salvage could also be beneficial, yet is often insufficient alone because clotting factors and platelets are lost in the process. Transfusion of fresh-frozen plasma, platelets, and/or cryoprecipitate may be necessary. Controlled hypotension may also be used in some circumstances; although this intervention can play a valuable role, it is not appropriate for all patients. It is therefore important to evaluate each patient for comorbidities that could render controlled hypotension inappropriate and discuss the limitations with the surgical team.

Table 117.2. Summary of preoperative planning for scoliosis surgery

Airway	<ul style="list-style-type: none"> – Potentially difficult – C-spine movement may be limited
Respiratory	<ul style="list-style-type: none"> – Double-lumen ETT may be necessary – Chest radiograph – Arterial blood gas: usually low PaO₂ with normal PaCO₂
Cardiovascular	<ul style="list-style-type: none"> – Spirometry – ECG – Echocardiogram: LVEF and PA pressures – Dobutamine stress echocardiogram considered in patients with limited exercise tolerance
Laboratory Tests	<ul style="list-style-type: none"> – CBC – Electrolytes – Coagulation profile – Crossmatched blood
IV Access	<ul style="list-style-type: none"> – Large-bore IVs (possibly central line) – Arterial line
Planned Monitors	<ul style="list-style-type: none"> – Standard – Spinal cord monitoring – Wake-up test – Arterial line – TEE (preferable to CVP or PAC)

LVEF, left ventricular ejection fraction; PAC, pulmonary artery catheter.

Intraoperative invasive hemodynamic monitoring can be challenging in the prone position. For example, central venous pressure (CVP) and pulmonary artery (PA) pressure can often yield falsely elevated levels, and only trends can be useful. Transesophageal echocardiography (TEE) allows for better assessment of filling pressures and contractility; however, that modality may also be complicated in the prone position.

Ventilation

Ventilation in such patients can be very challenging due to the difficulties negotiating the specifics of restrictive lung disease management with the surgical positioning constraints. High peak airway pressures are common in these circumstances. Pressure-controlled ventilation may be helpful in managing allowable peak pressures. In some patients, one-lung ventilation with a double-lumen tube or a bronchial blocker is required. Each technique offers its own unique advantages: although a double-lumen tube provides the benefit of optional passive oxygenation to the nonventilated lung, its use often necessitates the eventual exchange to a single-lumen ETT at the end of the procedure. This procedure may be complicated due to postoperative facial and airway swelling from the prone position and major fluid shifts. The use of an endotracheal tube exchanger may be prudent to avoid loss of the airway in this setting. Ultimately, pulmonary function is unlikely to improve immediately after surgery. Indeed, months to years may elapse before improvement can be observed in the patient's respiratory status.

Positioning

Special consideration needs to be made for patients in the prone position, with particular attention to the head, neck, arms and face, especially the eyes. In particular, such patients are at greater risk of developing a postoperative visual deficit. Eye injuries can include corneal abrasion, ischemic optic neuropathy, central retinal artery occlusion, and cortical blindness. Risk factors include prolonged procedures, profound blood loss, anemia, hypotension, hypoxia, in addition to the prone and Trendelenburg positions.

Spinal cord monitoring

Spinal cord monitoring is vital in scoliosis patients undergoing spine surgery. The risk of postoperative neurologic deficits, including paraplegia, is significant. To minimize these risks, three monitoring techniques can be employed: somatosensory evoked potentials (SSEPs), motor evoked potentials (MEPs), and the wake-up test (see [Chapter 29](#)).

The monitoring of MEPs can reduce the incidence of neurologic complications, however, it does not completely prevent the risk. When MEPs are monitored, total intravenous anesthesia (e.g., with propofol and opioid infusions) is required with little or no volatile anesthetics. A low-dose infusion of muscle relaxants can also be used, though no muscle relaxation is preferable.

Table 117.3. Summary of intraoperative care for scoliosis surgery

Premedication	<ul style="list-style-type: none"> – Anxiolytics – Bronchodilators may be helpful
Induction	<ul style="list-style-type: none"> – Guided by patient's condition – Avoid succinylcholine in patients with muscular dystrophy
Intubation	<ul style="list-style-type: none"> – Direct versus fiber-optic laryngoscopy – Double-lumen ETT, depending on surgical approach
Maintenance	<ul style="list-style-type: none"> – Maintain stable depth so that spinal cord monitoring can be interpreted reliably – Isoflurane <0.5 MAC with 60% nitrous oxide is compatible with SSEPs – Total intravenous anesthesia (preferably with propofol and opioid infusions), especially when MEPs are monitored (avoidance of muscle relaxants preferred)
Positioning	<ul style="list-style-type: none"> – Often prone; slight reverse Trendelenburg if possible – Assess baseline neurologic deficits, including range of motion
Muscle relaxation	<ul style="list-style-type: none"> – Continuous IV infusion of muscle relaxant – Minimal or no muscle relaxants if MEPs monitored
Spinal cord monitoring	<ul style="list-style-type: none"> – Commonly recommended methods include SSEPs, MEPs, or a wake-up test – With wake-up test, use short-acting agents (e.g., remifentanyl, propofol, desflurane)
Blood preservation	<ul style="list-style-type: none"> – Antifibrinolytics – Cell salvage – Controlled hypotension

The wake-up test is still considered the most reliable evaluation of an intact spinal cord. This test should be planned well in advance. The patient should be warned about the possibility, the concept explained and the scenario rehearsed. Clear communication with the surgical and neurophysiological monitoring teams is vital not only to determine whether a wake-up test will be necessary, but also to allow for appropriate depth of anesthesia. Often, short-acting agents, such as nitrous oxide, propofol, and remifentanyl, are used for rapid emergence and resumption of anesthesia. [Table 117.3](#) summarizes the basics of intraoperative care.

Postoperative care

As discussed previously, patients undergoing surgery for scoliosis often have poor preoperative pulmonary function. The need for postoperative ventilation is dependent on a number of patient and surgical factors, including:

- Preoperative forced vital capacity (FVC) <35% of the predicted value
- Preexisting neurologic deficits
- Right heart failure
- Obesity
- Prolonged operative time
- Thoracic surgical involvement
- Blood loss >30 ml/kg

Table 117.4. Postoperative care for scoliosis surgery

Postoperative ventilation	– Risk factors as above – Preoperative discussion indicated
Postoperative analgesia	– IV PCA opioids, epidural (opioid-based), intrathecal morphine, intrapleural LA/opioids

PCA, patient-controlled anesthesia.

Patients exhibiting any one or more of these features can be described as the best candidates for postoperative ventilation. In addition, any signs of postoperative visual loss should prompt an urgent ophthalmologic consultation.

Postoperative analgesia is of great importance and is often challenging following scoliosis surgery because of the size of the incision and possible preexisting chronic pain. Moderate to severe pain can be expected for several days postoperatively. Patients who are cognitively impaired or very young may present special challenges in this regard as they are less able to communicate discomfort. If epidural analgesia is used, it should be primarily or entirely opioid-based, because neuraxial local anesthetics can compromise the ability to assess neurologic function. [Table 117.4](#) summarizes the basics of postoperative care.

Anesthetic management in spine surgery

Abdel-Kader Mehio and Swapneel K. Shah

Introduction

The spectrum of spine surgery is considerable. There is a significant increase in procedures performed each year, due to both improvements in surgical technique and an increase in patients deemed suitable for surgery.

Spine surgery patients often present with comorbidities, such as serious cardiovascular and respiratory disease. Airway management could be challenging, especially in patients with cervical spine pathology. Spine surgery is frequently associated with significant blood loss, prolonged anesthesia (often in the prone position), and problematic postoperative pain management. The anesthesiologist's role in the perioperative management of these patients is discussed, including techniques to monitor spinal cord function.

Preoperative assessment

When assessing patients before spine surgery, particular care should be given to the respiratory, cardiovascular, and neurologic systems; all may be affected by the pathology for which the spine surgery is proposed.

Airway assessment

The potential for a difficult airway should always be considered, particularly in those patients presenting for surgery of the upper thoracic or cervical spine. Previous intubation history and documentation should be reviewed, and careful assessment of neck flexion and extension should be performed. In addition, the stability of the cervical and thoracic spine should be determined and discussed preoperatively with the spine surgeon.

The cervical spine should be assessed clinically (presence of pain and/or neurologic deficits) and radiographically (lateral or flexion/extension plain films, computer-assisted tomography, or magnetic resonance imaging). The stability of the cervical spine is dependent on ligamentous and vertebral elements. Damage to these elements may not be detectable by plain radiographs alone. The adult cervical spine below C2 is unstable or on the brink of instability when one of the following conditions is met:

1. All the anterior or all the posterior elements are destroyed.
2. There is a >3.5-mm horizontal displacement of one vertebra in relation to an adjacent one on lateral radiograph.

3. There is more than 11° rotation of one vertebra relative to an adjacent one.

Above the level of C2, examples of unstable injuries include disruption of the transverse ligament of the atlas and Jefferson burst fracture of the atlas following axial loading that causes atlantoaxial instability. Disruption of the tectorial and alar ligaments and some occipital condylar fractures also cause atlanto-occipital instability.

Some inherited disorders such as Duchenne muscular dystrophy (DMD) may lead to glossal hypertrophy, and previous radiotherapy to tumors of the head and neck can cause difficulty in direct laryngoscopy. A decision must be made whether to intubate the patient awake or asleep.

Respiratory assessment

Patients presenting for spine surgery may have impaired respiratory function. Those who have sustained cervical or high thoracic trauma or who have multiple injuries may be mechanically ventilated preoperatively. Others can suffer from recurrent respiratory infections. Preoperatively, respiratory function should be assessed by a thorough history, focusing on functional impairment, physical examination, and appropriate testing. Scoliosis causes a restrictive pattern on pulmonary function tests (PFTs), with reduced vital capacity and reduced total lung capacity (TLC) (see Chapter 117). The residual volume is unchanged. The severity of functional impairment is related to the angle of the scoliosis, the number of vertebrae involved, cephalad location of the curve, and loss of the normal thoracic kyphosis. The extent of functional impairment cannot, therefore, be directly inferred from the angle of scoliosis alone. The most common blood gas abnormality is a reduced arterial oxygen tension with a normal arterial carbon dioxide tension that is a result of the mismatch between ventilation and perfusion in the hypoventilated lung units (increased shunt). Respiratory function should be optimized by treating any reversible cause of pulmonary dysfunction (including infection) with physiotherapy, nebulized bronchodilators, and antibiotics, as indicated. There is controversy over whether surgery for idiopathic scoliosis improves or worsens pulmonary function.

The type of surgery proposed has also been shown to have a significant effect on PFTs, and may explain some of the

contradictory findings in the previously mentioned studies. Spine surgery involving the thorax (anterior approach, combined approach, or rib resection) is associated with an initial decline in forced vital capacity (FVC 19% of baseline values), forced expiratory volume in 1 second (FEV₁ 13%), and TLC (11%) at 3 months. These declines are followed by subsequent improvement to preoperative baseline values at 2 years postoperatively. However, surgery involving the posterior approach only, is associated with an improvement in PFTs in 3 months (although not reaching statistical significance) and improvements that are statistically significant at 2-year follow-up: FVC (14% increase from baseline), FEV₁ (14%), and TLC (5%). Older studies have reported that if preoperative vital capacity is less than 30 ± 35% of predicted, postoperative ventilation is likely to be required.

Cardiovascular assessment

Cardiac compromise may be a direct result of the underlying pathology, such as a muscular dystrophy. Cardiac dysfunction may also occur secondary to scoliosis that causes distortion of the mediastinum, and cor pulmonale secondary to chronic hypoxemia and pulmonary hypertension. Assessment of functional cardiovascular impairment is difficult in patients who are wheelchair-bound. Minimum investigations should include electrocardiography and echocardiography to assess left and right ventricular function and pulmonary arterial pressures. Dobutamine stress echocardiography may be used to assess cardiac function in patients with limited exercise tolerance.

Neurologic assessment

A full neurologic assessment of the patient should be documented preoperatively for the following reasons:

1. In certain patients undergoing cervical spine surgery, the anesthesiologist must minimize neck movement to avoid further neurologic deterioration during airway instrumentation and patient positioning.
2. Muscular dystrophies may involve the bulbar muscles, increasing the risk of perioperative aspiration.
3. In case of spinal cord injury, its anatomical level and the time elapsed from the insult are predictors of possible perioperative cardiovascular and respiratory complications. If surgery is contemplated within the first 3 weeks after the injury, spinal shock may still be present. Later on, autonomic dysreflexia may develop, more likely in injuries above the mid-thoracic level.

Anesthetic techniques

Premedication

In patients with a high spinal cord lesion or those in whom fiber-optic intubation is to be undertaken, administration of anticholinergic agents, such as glycopyrrolate, may be considered to decrease airway secretions. Many patients will present with

factors contributing to increased risk of regurgitation and aspiration of gastric contents, such as recent opioid administration, high spinal cord injury, or recent traumatic injury. In these circumstances, it may be prudent to premedicate patients with a histamine H₂ receptor antagonist, or a proton pump inhibitor, and with a nonparticulate antacid, such as sodium citrate. Some patients may have nasogastric tubes in situ that decrease the competence of the lower esophageal sphincter.

Induction

The choice of an intravenous (IV) or inhalation induction is guided primarily by the patient's clinical condition and by the patient's airway assessment. Preoxygenation is advisable in all patients.

The use of succinylcholine in patients with muscular dystrophies may cause cardiac arrest secondary to hyperkalemia. In patients with denervation as a result of spinal cord lesions, the increased number of extrajunctional acetylcholine receptors on skeletal muscle can cause hyperkalemia after administration of succinylcholine. The amount of potassium released may possibly correlate with the extent of the patient's motor deficit. It is usually considered safe to administer succinylcholine within the first 24 hours of injury. The increase in serum potassium is maximal between 4 weeks and 5 months after spinal injury. Serum potassium levels may increase from normal to as high as 14 mEq/L, causing ventricular fibrillation and/or asystole. There are no specific contraindications to the use of nondepolarizing agents, while varying degrees of resistance could be observed.

Intubation

Awake or asleep?

Indications for awake intubation include the need for neurologic assessment following airway management, the risk of aspiration combined with a potentially difficult airway, or the presence of a neck stabilization device (such as halo traction) that prevents adequate access to the airway.

Direct or fiber-optic laryngoscopy?

There is controversy as to whether direct laryngoscopy is a major factor contributing to cord injury in patients with cervical spine instability. Other factors, such as hypotension and patient positioning, may be equally important. Direct laryngoscopy with manual in-line stabilization or a hard collar is an accepted means of intubation for many patients, provided this can be achieved with limited neck movement. Fixed flexion deformities of the upper thoracic and cervical spine may make direct laryngoscopy impossible, requiring a fiber-optic bronchoscope to facilitate intubation.

Anterior approaches to the thoracic spine may necessitate the use of a double-lumen endotracheal tube or a bronchial blocker, optimizing the surgical field by providing single-lung ventilation for portions of the procedure.

Maintenance

To avoid and/or appropriately interpret changes to somatosensory evoked potentials (SSEPs), a stable anesthetic depth is required. Although employing nitrous oxide and volatile anesthetics at combined levels of less than 0.5 minimum alveolar concentration (MAC) is compatible with SEP monitoring, IV techniques using propofol and an opioid are generally preferred due to their reduced effects on the amplitude and latency of evoked potentials.

Prevention of blood loss

Most of the blood loss in spinal instrumentation and fusion occurs with decortication and disruption of rich vascular networks, and is proportional to the number of vertebral levels involved. During more extensive spine surgery, it can be considerable, varying typically between 10 and 30 ml/kg. Blood loss and transfusion requirements may be reduced through proper positioning and the use of intraoperative blood salvage, induced hypotension, intraoperative hemodilution, and the administration of antifibrinolytic agents, such as tranexamic acid and aminocaproic acid. Induced hypotension is not without risk, and has been reported to cause cord ischemia and neurologic deficits, including blindness.

When patients are placed in the prone or knee–chest position, care must be taken to minimize intra-abdominal pressure. Positioning devices, such as the Relton–Hall frame, which allow the abdominal viscera to hang freely, reduce inferior vena cava (IVC) pressure by one third compared with conventional pads. Elevated IVC pressure is associated with lumbar venous engorgement and increased blood loss. Minor changes to patient positioning on the Wilson frame can reduce blood loss per vertebral level by approximately 50%.

Agents for maintaining deliberate hypotension include volatile anesthetics, calcium channel antagonists, sodium nitroprusside, nitroglycerin, and, in children, the dopamine D₁ receptor agonist, fenoldopam. Mean arterial pressure (MAP) is typically maintained at 60 mm Hg.

Caudal anesthesia has also been shown to reduce surgical bleeding by 50% in patients undergoing lumbar spine surgery. This reduction was thought to be a result of a reduction in sympathetic tone causing a measurable decrease in lumbar vertebral intraosseous pressure. This technique, however, is not as controllable as is continuous IV titration of a short-acting hypotensive agent, nor is it suitable for operations involving the thoracic and cervical spine. It may also hinder early postoperative neurologic assessment.

Thromboembolic prophylaxis

Patients undergoing spine surgery may be at increased risk for thromboembolic complications as a result of prolonged surgery, prone positioning, malignancy, and/or extended periods of postoperative immobilization. The use of compression stockings and/or pneumatic boots is recommended. Many

surgeons prefer not to administer anticoagulants because their use may be associated with hemorrhagic complications, including increased blood loss and epidural hematoma.

Muscle relaxation

When the spinal integrity monitoring plan involves motor evoked potentials (MEPs), neuromuscular blocking drugs are best avoided or used sparingly.

Intraoperative monitoring

Cardiovascular monitoring

Prolonged surgery, significant blood loss, the use of controlled hypotension in selected cases, and the hemodynamic and respiratory effects of thoracic spine operations are all indications for invasive arterial pressure monitoring.

In the prone position, central venous pressure (CVP) may be a misleading indicator of right and left ventricular end-diastolic volumes. A study of 12 pediatric patients undergoing surgery for scoliosis in the prone position compared CVP and transesophageal echocardiography (TEE) in the assessment of ventricular filling. Measurements were taken before and after positioning. The results demonstrated that there was no correlation between the measurement of cardiac volume indicators by TEE and CVP or pulmonary artery occlusion pressure (PAOP) in such conditions. High CVP values may be misleading indicators of adequate cardiac filling in the prone position. The changes are probably a result of raised intrathoracic pressure causing reduced ventricular compliance and compression of the inferior vena cava. The dependent position of the lower limbs results in reduced venous return to the heart.

Respiratory monitoring

Patients with severe respiratory dysfunction as a result of scoliosis may have an increased alveolar–arterial oxygen gradient that may be further increased during prolonged surgery because of regional hypoventilation. Serial measurements of arterial oxygen tension are usually recommended.

Temperature monitoring

Thermoregulation may already be impaired in patients with spinal cord lesions secondary to the sympathectomy distal to the lesion. In addition, prolonged surgery is associated with significant heat loss. The use of temperature monitoring, warming of IV fluids, and a warm air mattress device are recommended.

Spinal cord monitoring

When corrective forces are applied to the spinal column, osteotomies are performed, or instrumentation is applied onto the vertebral structures, the spinal cord is at risk of injury. The incidence of motor deficit or paraplegia after surgery to correct scoliosis in the absence of spinal cord monitoring has been quoted to vary between 3.7% and 6.9%. By using

intraoperative neurophysiological monitoring (IONM), this percentage can be reduced to 0.5%. The American Academy of Neurology has published guidelines on IONM, concluding that considerable evidence favors the use of neurological monitoring as a safe and efficacious tool in clinical situations in which a significant risk for nervous system injury exists. It is now considered mandatory to monitor spinal cord function during such procedures, while also recognizing the limitations of IONM. The IONM ideally detects perturbations in spinal cord function early, allowing the surgeon to take appropriate corrective steps before irreversible damage occurs. However, the time between a change in the electrophysiologic recordings from the cord after overdistraction and the onset of irreversible ischemic damage is in the order of only 5 to 6 minutes in animal studies. Spinal cord neurophysiological monitoring includes:

- Wake-up test
- SSEPs
- MEPs
- Electromyography

Acute alterations in neurophysiological monitoring (amplitude and/or latency) signify spinal cord compromise and may be the result of direct trauma, ischemia, compression, or hematoma.

Positioning

Patient positioning for spine surgery varies, depending on the level of the spine to be operated on and the type of surgery. Patients may be repositioned intraoperatively. It is important that venous pressure at the surgical site is kept low to reduce bleeding (reverse Trendelenburg tilt and a free abdomen). In addition, peripheral nerves, bony prominences, and the eyes should be protected (see [Chapter 51](#)). It is also important to avoid displacement of unstable fractures during patient positioning.

Lumbar surgery

Anterior approaches sometimes require a laparotomy. Minimally invasive surgery with lateral incision has become more popular recently. Posterior surgery requires prone patient position with a decompressed abdomen to keep the epidural venous pressure low (the patient supported on a Wilson frame, for example, or a raised mattress with a hole for the abdomen; see [Fig. 118.1](#)). For disc surgery, patients may be placed in the knee-

Figure 118.1. Prone position for lumbar surgery.

chest position with a well padded, secure support behind the upper thigh to support the patient's weight. This position results in a horizontal lumbar spine with vertical intervertebral discs.

Thoracic surgery

Anterior approaches to the thoracic spine are via a thoracotomy with the patient supported in a lateral position. One-lung ventilation with a double-lumen endotracheal tube or a bronchial blocker is often used to allow for better surgical retraction of the lung. The optimal tube placement should always be confirmed fiberoptically after the patient is repositioned. Posterior approaches to the thoracic spine require a prone patient with a decompressed abdomen.

Cervical spine surgery

Patients are sometimes positioned with their head away from the anesthesia machine to allow surgical access to the head and neck. Access to the upper extremities is limited and extensions are often needed for the breathing circuit, and arterial and IV lines. Tracheal tubes must be carefully secured without encroaching on the surgical field or the pathway of the C-arm fluoroscopy machine. For anterior surgery, a reinforced tracheal tube may be considered to reduce the risk of airway obstruction as tracheal retraction sometimes occurs during surgery. The head is supported on a padded head ring, or the Mayfield horseshoe headrest. Spine traction may be required by tongs and weights placed into the outer bone plate of the skull for some procedures. Reverse Trendelenburg positioning could minimize venous bleeding and provide counter-traction for the weight attached to the head. Venous pooling in the lower limbs and intraoperative retraction of the carotid artery make an arterial line advisable for some patients, and often practitioners will level the transducer to the level of the head, rather than to the right atrium, to better assess cerebral perfusion. For posterior approaches to the cervical spine, the head of the prone patient can be supported on the gel-padded Mayfield horseshoe headrest or placed in a skull clamp. The orbits, the superior orbital nerve, and the skin over the maxilla are at particular risk of ischemic injury if positioning is incorrect. These problems are avoided by using a skull clamp. The head height and degree of neck flexion may be adjusted intraoperatively, and pressure areas must be rechecked after such maneuvers.

Venous air embolism

Venous air embolism (VAE) is a catastrophic event that may occur during spine surgery. The large amount of exposed bone and the elevated location of the surgical incision relative to the heart predispose to VAE. Incidence of VAE in patients undergoing neurosurgical procedures in the sitting, supine, prone, and lateral positions are 25%, 18%, 10%, and 8%, respectively. The presenting sign in all cases was unexplained hypotension and an increase in the end-tidal nitrogen concentration. If VAE is suspected, the wound should be irrigated with saline, nitrous oxide discontinued, and vasopressors and fluid boluses initiated.

Vision loss after spine surgery: review of the literature and recommendations. *Neurosurg Focus* 2007; (5):15.

Postoperative visual loss

The devastating permanent impairment or loss of sight associated with spine surgery in the prone or lateral position under general anesthesia has led to the creation of a registry by the American Society of Anesthesiologists (ASA) in 1999. In 2006, a review of the first 131 postoperative visual loss cases reported to the registry, of which 93 patients had undergone spine surgery (Fig. 118.2), was completed. A practice advisory was formulated to enhance awareness of postoperative visual loss (POVL) and to reduce its frequency by assisting the clinicians in decision-making when caring for patients undergoing spine surgery under general anesthesia.

The most common causes for POVL associated with spine surgery are ischemic optic neuropathies (IONs), either anterior (AIONs) or (more frequently) posterior (PIONs). AION has been linked to degenerative vaso-occlusive disease involving small arteries, such as the posterior ciliary branches supplying the optic nerve. PION occurs between the optic foramen at the orbital apex and the central retinal artery's point of entry at the midportion of the optic nerve. The perfusion pressure in this section of the optic nerve might be particularly susceptible to increased venous pressure because the supplying arteries consist of small end vessels from the surrounding pia. POVL may also occur from direct trauma to the eye, cortical blindness secondary to hypoperfusion or thromboembolic events, central retinal artery occlusion (CRAO), secondary to direct pressure on the globe or thromboembolic event, or increased intraocular pressure (Fig. 118.3).

The occurrence of ophthalmic complications after spine surgery is reported to be less than 0.2%. There is evidence from one case-control study and several case reports that preoperative anemia and vascular risk factors, such as hypertension and carotid artery disease, as well as smoking, obesity, and diabetes, may be associated with POVL after spine surgery. Patients with these characteristics are referred to as high-risk patients. In

Figure 118.3. Distribution of 93 ophthalmic lesions associated with POVL after spine surgery from the ASA POVL Registry. Data were obtained from the study by Lee et al. The American Society of Anesthesiologists Postoperative Visual Loss Registry. *Anesthesiology* 2006; 105:652-9. Figure with permission from Baig M, Lubow M, Immesoete P, et al. Vision loss after spine surgery: review of the literature and recommendations. *Neurosurg Focus* 2007; (5):15.

addition, careful analysis shows that prolonged surgical procedures >6.5 hours and/or substantial blood loss of an average of 44.7% of estimated blood volume are patient independent risk factors.

The advisory recommends continuous monitoring of blood pressure in high-risk patients and maintaining MAP within 24% of baseline or with a minimum systolic blood pressure of 84 mm Hg. Intravascular volume should be maintained with adequate crystalloid or colloid formulations. Periodic blood sampling to diagnose anemia is advised. There is no recommended threshold for hemoglobin level that may prevent POVL. Therefore, current decision-making strategies for perioperative transfusion therapy apply. CVP monitoring may be considered in high-risk patients. Precautions should be taken when positioning the patient to avoid direct pressure on the eyes and, in high-risk patients, to maintain the head in neutral position above the level of the heart, if possible. Staged procedures could be advised. The advisory committee considers procedures as prolonged when they exceed an average of 6.5 hours (range 2–12 hours).

Postoperative management

Aside from worsened neurologic deficits and continued hemorrhage, airway patency should be a main focus, especially in patients undergoing cervical spine surgery. It is in these patients that a higher incidence of airway obstruction occurs if:

- Surgery involves multiple spinal levels
- Higher spinal levels are involved (C2–C4)
- There is prolonged surgical time
- There is excessive blood loss
- There is significant facial and/or airway edema
- A combined antero-posterior approach is used

Thus, if some of the above criteria are met or if the intubation was difficult, it is usually advised to keep the patient intubated and ventilated in the immediate postoperative period. The use of IV glucocorticoids and head elevation may help to decrease airway edema that could reach a peak on postoperative day 2 or 3. When planning for extubation, a member of the anesthesia team may be present, and the use of a tube-changing stylet may be considered.

Anesthesia for trauma

Bishr Haydar

Introduction

Trauma continues to be a leading cause of morbidity and mortality worldwide. Concerted efforts to prevent secondary injuries and development of algorithmic approaches have improved care and outcomes in patients suffering a wide array of traumatic injuries. The role of the anesthesiologist in the care of trauma patients varies worldwide, from preanesthetic assessment and intraoperative management alone in some regions of the world, to directing the entire continuum from the prehospital resuscitation to the critical care unit in others. This chapter will focus primarily on preanesthetic assessment and intraoperative management, with a brief overview of the overall management of trauma patients.

“Unintentional injuries” continue to be the leading cause of morbidity and mortality in the United States for people aged 1 to 44 years, with the majority of patient deaths due to motor vehicle accidents and other blunt trauma. Homicide, mostly via penetrating trauma, is the next most frequent cause of death in young adults. In adults older than 44 years, trauma continues to contribute significant morbidity and mortality, having been the fourth leading cause of mortality for more than a decade. In the elderly population, hip fractures carry a significant risk of death, and fatal outcomes attributed to other causes (such as pulmonary embolism or sepsis) may have been brought on by the antecedent trauma.

The guiding principles in the care of trauma patients are:

- To treat all potentially life-threatening conditions in order of severity,
- To prevent delay of an indicated treatment, prioritizing it above establishing a definitive diagnosis, and
- To prevent secondary injuries.

Introduction to advanced trauma life support

Advanced trauma life support (ATLS) was developed in the late 1970s to create an algorithmic approach to the resuscitation of the trauma victims. It has become the standard of care in the initial evaluation and treatment of the trauma patient, although it has never been subjected to a randomized trial. The ATLS protocol structures the way the patient is assessed, beginning with the ABCDE mnemonic (see next paragraph); it also gives clear roles and responsibilities to each member of the surgical

or emergency medicine team to maximize the efficiency of the initial approach. Life-threatening injuries are treated before the diagnosis is firmly and fully established, with the goal of minimizing any delay. Multiple animal and human studies have shown that, for injuries associated with massive and continuing blood loss, delaying operative treatment in order to further resuscitate or diagnose leads to worsened outcomes. Unstable patients with insufficient vital organ perfusion will suffer from any delay, and the more unstable the patient, the less necessary it is for a definitive diagnosis to be established prior to instituting treatment. Thorough examination, frequent reassessment, and continuous monitoring, however, are critical as these patients often have significant findings missed on initial assessment and can suffer rapid clinical status deterioration.

On arrival to the emergency department, patients may already have an airway device and/or an intravenous (IV) catheter in place and, depending on the perceived initial severity of the injury, may also have a cervical collar and backboard in place. ATLS begins with the primary survey, summarized in the mnemonic ABCDE – Airway, Breathing, Circulation (and hemorrhage control), Disability, and Exposure/Environmental control.

Airway

The need for securing the airway via endotracheal intubation or tracheostomy is determined by assessing both the current status of the patient and the treatment goals. For example, patients may be intubated for obstruction or impending obstruction of the airway due to swelling or hematoma, for mental status changes with failure to protect the airway or respiratory insufficiency, as well as to allow hyperventilation for severe closed-head injuries (see “Airway management” and [Table 119.1](#)). If an

Table 119.1. Indications for definitive airway

Airway protection, e.g., GCS < 8 (or vomitus)
Inadequate ventilation, e.g., apnea, hypoxia, hypercarbia, airway bleeding, severe carboxyhemoglobinemia
Severe maxillofacial injury
Impending airway obstruction, e.g., inhalational injury, pulsatile neck mass
Need for hyperventilation

GCS, Glasgow Coma Scale.

airway device is already in place, its correct position must be verified before proceeding further.

Breathing

Establishing, monitoring, and maintaining adequate ventilation are based on the respiratory rate, pulse oximetry, capnography, and physical examination of the thorax and abdomen, including observation, auscultation, palpation, and percussion (ultrasound is also being used increasingly). The goal of the examination is also to rule out tension pneumothorax, open pneumothorax, flail chest, and massive hemothorax. Initial management includes supplemental oxygen, ventilatory assistance with a bag-valve-mask device or endotracheal intubation, placement of a chest tube if necessary, or the decision to perform a thoracotomy emergently.

Circulation

The next goal is to assess for adequate perfusion of vital organs, including identifying sources of potentially exsanguinating hemorrhage. On examination, the level of consciousness, skin color, and pulse quality and rate are immediately assessed; for critically injured patients, mean arterial pressure of 60 to 65 mm Hg is thought to be adequate, although for patients with impaired autoregulation from poorly controlled hypertension or impaired cerebral or coronary vasculature, this value may be insufficient. Rapid circulatory deterioration during the primary survey can be caused by hemorrhage, massive hemothorax, tension pneumothorax, or cardiac tamponade. Until another diagnosis is made, the working assumption for hypotension must be exsanguinating hemorrhage, and resuscitation with lactated Ringer's solution should be immediately instituted. Exsanguinating hemorrhage may occur into five locations – the outside environment, the peritoneum, the retroperitoneal space, the thorax, and fractured long bones and their surrounding tissues. External bleeding is best controlled with direct pressure; internal compartments may require emergent surgical control. Large-bore IV access is established as soon as possible, and resuscitation is initiated with warmed lactated Ringer's solution.

Disability

Disability, or the neurologic status of the patient, is assessed next, by evaluating the patient's best prehospital mental status, Glasgow Coma Scale (GCS) score (see Table 119.2), the ability to move the four extremities, and pupil size and reactivity. Mental status changes may be due to insufficient cerebral oxygenation or perfusion, direct cerebral injury, metabolic derangements, or alcohol or drug intoxication.

Exposure and environmental control

This step is the final one of the primary survey. The patient is undressed and briefly examined from head to toe, and obvious exposures to ingested and environmental toxins are identified.

During the primary survey, monitoring is instituted including electrocardiogram (ECG), blood pressure, and pulse

Table 119.2. GCS

oximetry. Depending on the patient's status and injuries, a urinary catheter and gastric tube may be placed, and initial blood laboratory samples, often including an arterial blood gas, may be sent. Chest, cervical spine, and pelvic radiographs, along with a diagnostic peritoneal lavage or Focused Assessment with Sonography in Trauma (FAST) examination, are done as soon as possible. The FAST examination is meant to rapidly diagnose hemorrhage by using ultrasonography on four primary views – right upper quadrant, subxiphoid, left upper quadrant, and suprapubic.

The secondary survey begins when the primary survey is complete and resuscitation efforts are well established. This survey includes a head-to-toe evaluation, a complete history and physical examination, and any further laboratory tests and imaging studies. A useful mnemonic for the minimum history required is AMPLE – Allergies, Medications, Past illness/history, Last meal, and the Events and Environment that caused the injury. The patient's vital signs and status are continually reassessed, as yet-undiagnosed injuries may cause rapid deterioration.

During this initial resuscitation, the surgical team seeks to identify immediate threats to the patient's life; these threats define the surgical priorities. Indications for emergent surgery include airway compromise (cricothyroidotomy or emergency tracheostomy), exsanguinating hemorrhage (laparotomy or thoracotomy), or intracranial epidural or subdural hematoma with mass effect. Indications for urgent surgery include limb-threatening injuries, such as a vascular injury or compartment syndrome; sight-threatening globe injuries; or injuries with a high risk of sepsis, such as a bowel perforation.

Blunt trauma

For victims of blunt trauma, the primary ATLS survey should identify obvious severe injuries, such as flail chest or large open wounds. Life-threatening injuries that warrant immediate intervention include exsanguinating hemorrhage into the thorax or peritoneum, tension pneumothorax, and cardiac tamponade. Significant blunt thoracic injuries are common with

high-energy motor vehicle collisions but may even occur in falls from standing height in the elderly population. In motor vehicle collisions, blunt thoracic trauma is associated with high-speed, unrestrained collisions with steering wheel deformity or extensive vehicular damage. Fatalities at the scene of a motor vehicle collision, rollover accidents, intrusion into the vehicle, or the victim's ejection from the vehicle are risk factors for more severe injury and mortality. A pronounced initial clinical instability is more predictive of the severity of injury than the mechanism of injury itself. Prehospital death from blunt trauma is usually the result of direct cardiac, aortic, and/or tracheobronchial injury.

Blunt aortic injuries are thought to occur from torsion, deceleration with traction, or "osseous pinch," i.e., compression between bony structures. Predictors of an aortic injury include age greater than 60, high-energy collision with chest wall deformity, multiple rib fractures, pneumothorax, hemothorax, and radiographic chest abnormalities. Such findings should lead to further investigation via chest computed tomography (CT), transesophageal echocardiogram (TEE), or angiography. Suggestive chest radiographic findings include a widened mediastinum, abnormal aortic contour, large hemothorax, or rightward tracheal or esophageal deviation. Initial steps for blunt aortic injury include reducing wall stress by lowering the heart rate, usually below 100 bpm, and systolic blood pressure (SBP) to below 100 mm Hg; common agents for this indication include β -blockade and nitrates until definitive repair can be performed. Contained aortic ruptures are at significant risk of rebleeding within 24 hours.

Cardiac injuries from blunt trauma may include contusion, infarction, or myocardial rupture. Cardiac contusion may present with new bundle branch block, dysrhythmia, or unexplained persistent tachycardia, although hypovolemia must be ruled out first. Myocardial infarction (MI) due to direct trauma may occur due to coronary artery dissection and thrombosis, often in the left anterior descending artery. An MI may also be antecedent to the trauma, whether in a fall or a motor vehicle collision. Myocardial rupture has a significant prehospital mortality; overly aggressive fluid resuscitation may cause further rupture. Myocardial rupture has also been described as occurring several days after admission. Signs of cardiac tamponade physiology, such as hypotension, muffled heart sounds, distended neck veins, and equilibration of central venous and pulmonary artery pressures, may be present. These patients may require emergent thoracotomy, sometimes performed in the emergency department, presenting additional risks for significant injuries and a high mortality rate.

Pulmonary injuries may include pneumothorax, hemothorax, pulmonary contusion, tracheobronchial injuries, diaphragmatic rupture, and lung parenchymal injuries. Pulmonary contusions typically develop over the first 24 hours and may be complicated by pneumonia and acute respiratory distress syndrome. Tracheobronchial injuries in the setting of blunt trauma are highly associated with death in the field; for patients who survive, these injuries are often missed. Persistent pneumothorax despite thoracostomy tube may suggest such an injury. As

many as 25% of patients with laryngotracheal injuries have no clinical signs of injury on presentation; signs and symptoms include local contusion, subcutaneous or mediastinal emphysema, voice changes, stridor, and hemoptysis. Cricoid pressure or attempts at endotracheal intubation may dislodge fractured cricoid cartilage causing complete airway obstruction; for these patients, surgical airway backup preparedness is imperative. Although primary repair is most common, there are reports of nonoperative management. Diaphragmatic injuries are associated with hepatic or splenic injuries; herniation of abdominal visceral contents into the thorax is rare, especially after intubation and positive pressure ventilation are instituted. Rib fractures, especially of three or more ribs, and particularly in the elderly population, have been associated with pulmonary contusions and pneumonia. Several studies have demonstrated significant reduction in the incidence of pneumonia and ventilator times in such patients when epidural analgesia is provided. Esophageal rupture is rare in blunt trauma, and is usually associated with high-energy collisions and multiple other injuries; in that context, it could often be overlooked.

Blunt intra-abdominal trauma occurs via direct transmission of energy, such as crush injuries, or through sudden acceleration or deceleration, such as stretch injuries to vascular beds or hollow viscera. Injuries to solid organs are most common, with splenic injuries outnumbering hepatic. Nonoperative management of solid-organ injuries is increasingly favored, so urgent laparotomy for these reasons usually signifies a significant injury or hemorrhage. Urgent laparotomy may also be required when there is persistent hypotension or other signs of continuing internal blood loss, severe gastrointestinal bleeding, evidence of peritoneal irritation, pneumoperitoneum, or diaphragmatic rupture. Massive fluid resuscitation may result in abdominal compartment syndrome, manifesting as hypotension from decreased venous return, increased airway pressures, renal dysfunction, and acidemia.

Crush injuries to the extremities may also precipitate acidemia and renal dysfunction via compartment syndrome, rhabdomyolysis and myoglobinuria. Bone injuries, especially long bone and pelvic injuries, can result in fat embolism syndrome, with the classic triad of petechiae, hypoxia, and neurologic manifestations occurring up to 24 to 72 hours after the fracture. Mental status changes are typical, although focal neurologic findings and seizures have been described. These findings are typically self-limited, although crush injury syndrome is associated with a mortality rate of up to 15%. Treatment is supportive; in one study, prophylactic use of glucocorticoids was demonstrated to reduce the incidence of fat embolism syndrome, but no data exist supporting their use after the onset of symptoms.

Penetrating trauma

For patients with penetrating trauma, a brief history may help predict the degree of internal injury. First, there may be associated blunt trauma, including possible cervical spine injury, from

falling after the penetrating insult or blast injury. Second, identifying the mechanism of injury is very important. Stab wounds cause less indirect injury than missile injuries. The projectile characteristics, including the type and distance of the firearm from the patient, help to predict the amount of concussive internal injury associated with the missile, separate from the direct lacerating or cutting effect of the missile itself. A military rifle bullet fired at short range, for example, exerts a massive amount of kinetic and concussive energy when compared to a small-caliber pistol bullet or shotgun blast at a greater distance. For penetrating trauma victims with no obvious trauma to the neck, no history consistent with blunt trauma or loss of consciousness, and a normal physical examination of the cervical spine, the incidence of cervical spine injury secondary to this penetrating trauma is exceedingly low. For patients with a direct injury to the trachea, intubation through the airway defect has been described.

Blast injury

Explosions cause four distinct types of injury patterns. Primary blast injury is the direct interaction of the blast wave with the body tissue, whereas secondary blast injury is the interaction of debris energized by the blast with the victim. Tertiary blast injury is the injury sustained by the physical displacement of the body by the blast wind, including tumbling and crush injury, and quaternary injury includes all other types, including burn injuries. Blasts in enclosed spaces are often more severe, as the blast wave may reflect off the walls. Underwater blasts are similarly much more injurious, as water is a better energy transmission medium than is air.

Primary blast injury affects most severely the borders between substances of different densities, for example, at air-tissue junctions in the ear, or air-fluid surfaces in the colon. Blast injury to the thorax typically causes transient apnea, bradycardia lasting up to an hour, and more sustained hypotension. Blast injury to the lung may cause retrosternal chest pain, dyspnea, dry cough, or hemoptysis; hemothorax, pneumothorax, and/or alveolar hemorrhage may ensue. These injuries may, in fact, be more pronounced in victims wearing personal body armor, due to internal reflections of the blast wave. Myocardial ischemia or infarction and arrhythmia may result from coronary emboli, including air. Intestinal injury occurs at the air-tissue junctions and may cause immediate perforation or significant contusion requiring resection to prevent perforation; solid-organ injuries are caused by physical displacement of the body wall. Sensorineural deafness is common, with permanent hearing loss occurring in 55% of patients. Traumatic limb amputations usually occur through a long bone shaft and not through joints.

Secondary blast injuries are similar in character to other high-energy penetrating trauma; any debris in the victim's environment, including radiolucent materials, may be a potential missile. The "blast winds," or the initial wave of energy from the explosion, which may be as fast as 100 mph, can also energize

the trauma victim, causing tertiary blast injuries and significant blunt trauma. Quaternary injuries may be immediately identified, such as surface burns and inhalational injury, but may also be significantly delayed, as with acute stress disorder and post-traumatic stress disorder.

Airway management

Victims of severe trauma are often intubated in the field, whereas those with minor trauma may only require intubation with general anesthesia for surgical interventions. For all patients, the first resuscitation step is to confirm that a patent airway is present and that ventilation and oxygenation are adequate. Upper airway obstruction may occur as a direct result of trauma, such as pharyngeal swelling or bleeding, presence of foreign bodies in the airway, laryngeal injury, or hematoma; it may also be due to secondary causes, such as incorrectly applied oropharyngeal airways, unrecognized esophageal intubation, or vomitus in the airway. Inadequate ventilation can result from airway obstruction or other mechanical causes, such as pneumothorax or hemothorax, tracheobronchial injury, aspiration of gastric contents, or bronchospasm. It may also occur as the result of decreased respiratory drive from traumatic brain injury, intoxication, or administered medications (especially opioids and sedatives). Several trauma-specific indications for endotracheal intubation include the need for mechanical hyperventilation to decrease elevated intracranial pressure, to deliver 100% oxygen in patients with carbon monoxide poisoning, or to provide sedation for combative patients unable to comply with urgent diagnostic testing. Importantly, trauma patients should all be considered to be at high aspiration risk ("full stomach"), as the associated catecholamine surge causes significant delay in gastric emptying.

For patients with inadequate ventilation, the initial steps of airway management include application of supplemental oxygen, chin lift, and clearing of the upper airway, with placement of an oropharyngeal airway and/or assisted with bag-valve-mask ventilation. Jaw thrust and cricoid pressure may cause movement of the cervical spine and should be used with caution. Similarly, placement of a nasal airway, NG tube, or nasal intubation should be avoided in patients with suspicion of skull base fracture, as there are reports of intracranial tube placement. For patients who subsequently require a more definitive airway, reproducing operating room (OR) conditions for securing the airway can help minimize complications and number of attempts needed. Basic monitoring such as noninvasive blood pressure (cuff) measurement, 3- or 5-lead ECG and pulse oximetry, along with some form of capnometry, is sufficient. Suction and a functioning IV access are necessary, as well as a laryngoscope with a variety of blades, a backup device for difficult intubation such as laryngeal mask airway, and a bag-mask-valve ventilator with an oxygen source. If emergent intubation is needed, the patient's position should be optimized, with manual in-line stabilization applied if indicated (see [Chapters 17 and 18](#)). A succinct airway examination should always

Table 119.3. Causes of hypotension

Hypovolemia (e.g., hemorrhage, “third-space” losses from burns, neurogenic)
Loss of sympathetic tone (high spinal cord injury)
Impaired venous return (tension pneumothorax, pericardial tamponade)
Myocardial dysfunction (myocardial infarction, myocardial contusion, fat or air embolism)
Arrhythmia
Medications, including ingestions or environmental toxins

be performed prior to intubation with the goal of identifying the usual predictors of difficult mask ventilation or difficult intubation, along with trauma-specific considerations, such as facial fractures or markers of inhalational injuries. Surgical airway backup preparedness is vitally important. Please refer to Part 2 for specifics of airway management techniques, including the choice of awake versus anesthetized airway management, induction agents, and use of muscle relaxants.

In patients with facial fractures, the decision to perform an elective tracheostomy is dependent on the individual patient’s injury characteristics and surgical plan. In one retrospective review, approximately 12% of patients with facial fractures had a tracheostomy performed concomitantly with the facial fracture repair; tracheostomy was more common in patients with LeFort III fractures or comminuted mandibular fractures and in patients with lower GCS score on admission.

Circulation

In trauma victims, hypotension is most often the sign of significant hemorrhage and empiric treatment is rapidly begun. The list of differential diagnoses, however, must include disease states specific to trauma patients as well as those present in the general perioperative patient population (Table 119.3). Large-bore IV access should be established in the emergency department followed by infusion of 2 L of lactated Ringer’s solution, or 20 ml/kg in children; if the hypotension persists, transfusion of uncrossmatched type O blood should be considered.

In young, healthy patients, an acute hemorrhage of up to 40% of the patient’s blood volume may have no apparent hemodynamic effects other than tachycardia. In elderly patients or those who take β -blocking agents, a class III (30%–40%) hemorrhage (Table 119.4) may not initially present with any obvious hemodynamic signs either.

Table 119.4. Classes of hemorrhage

	Heart rate	Blood pressure	Pulse pressure	Respiratory rate
Class I: <15% blood volume	—	—/▲	—	—
Class II: 15%–30%	▲	—	▼	▲
Class III: 30%–40%	▲	▼	▼	▲
Class IV: >40%	▲	▼	▼	▲

The goals of resuscitation in the OR setting are to maintain adequate vital organ perfusion and to prevent the cycle of ischemia, capillary leak, acidosis, and immune system activation that leads to further organ dysfunction. To that end, monitoring blood pressure, cardiac output, mixed venous oxygen saturation, urine output, plasma lactate, and other surrogates of perfusion adequacy should permit optimal goal-directed therapy. Delaying definitive control of severe hemorrhage for further resuscitation has been associated with increased mortality. In animal models of uncontrolled hemorrhage, active reduction in blood pressure occurs to decrease the rate of hemorrhage and to allow the formation of a functional clot. In these same studies, resuscitation led to further bleeding and worse outcomes, possibly due to mechanical disruption from higher blood pressures or from dilution of clotting factors. So-called hypotensive resuscitation, or permitting hypotension until definitive hemorrhage control can be obtained, has been demonstrated to reduce mortality in animal models. Bickell demonstrated that, in young men with penetrating thoracic trauma, mortality was reduced by limiting resuscitation prior to the OR. Further studies have demonstrated the safety of hypotensive resuscitation in patients without head trauma. In patients with head trauma, hypotension is clearly associated with significantly increased mortality. Similarly, data on hypotensive resuscitation in patients with impaired autoregulation, such as uncontrolled hypertension, are lacking. After hemorrhage is controlled, prompt resuscitation and establishing adequate perfusion becomes the primary goal. This “under-resuscitation” approach may become more common, even though it is in conflict with the ATLS protocol, which, although never prospectively studied, remains the de facto standard of care.

Significant diffuse hemorrhage, due to trauma-associated coagulopathy, can still occur even after surgical control of bleeding is achieved. Heat loss via conduction, convection and radiation from exposed body areas, evaporation from visceral surfaces, and via cold fluid infusion often causes hypothermia, possibly potentiating platelet and coagulation factor dysfunction. The plasma factor dysfunction may persist after rewarming, due to denaturing of the proteins. Coagulation tests such as prothrombin time and partial thromboplastin time are performed on warmed samples that may overstate the patient’s actual ability to form clot. Acidosis can also significantly decrease coagulation factor activity, effects additive to these of hypothermia. Hemodilution and packed red blood cell administration reduce clotting factors, platelets, and fibrinogen. Finally, disseminated intravascular coagulopathy may develop, especially in patients suffering from traumatic brain injury, fat embolism, or multiorgan system failure. Prevention and reversal of worsening coagulopathy is of paramount importance for the survival of trauma victims.

Disability

Trauma to the central nervous system is associated with high morbidity and mortality. Patients with a single episode of

Table 119.5. Traumatic brain injury management goals

Maintain SBP > 90 mm Hg
Maintain O ₂ Sat > 90%
Mannitol 0.25–1 gm/kg
No evidence of benefit from hypothermia
ICP monitoring if GCS 3–8 and CT abnormalities
Maintain ICP < 20 mm Hg
Maintain CPP (MAP-ICP) 50–70 mm Hg
Use of barbiturates only for surgically refractory elevated ICP
Use of anticonvulsants to prevent early posttraumatic seizures (<7 d)
Avoidance of hyperventilation – used only as a temporizing measure
No evidence of benefit from glucocorticoids

ICP, intracranial pressure; CPP, cerebral perfusion pressure; MAP, mean arterial pressure.

hypotension, defined as SBP <90 mm Hg, in the setting of cerebral trauma have a 40% higher mortality; long-term neurologic deficits are often the primary concern. When brain or spinal cord trauma is suspected or confirmed, and after airway and exsanguinating hemorrhage are controlled, minimizing further neurologic injury becomes the primary critical care goal. For patients with traumatic brain injuries, guidelines are available from the Brain Trauma Foundation (management goals in Table 119.5).

For patients at risk of having spinal injuries, preventing secondary injury is the mainstay of therapy. Immobilization of patients with possible injury is the first priority; cervical collar placement, manual in-line stabilization during direct laryngoscopy, and logroll movement of the patient are necessary until the injuries can be definitively ruled out, both clinically and radiologically. The use of steroids for acute head trauma is not indicated. The use of steroids for acute spinal cord injury is controversial in the setting of incomplete blunt injury, and is

not indicated for penetrating spinal cord injuries. If steroids are used and initiated within 3 hours of injury, administer a methylprednisolone bolus (30mg/kg IV) over 15 min, and after a 45 minute pause initiate an infusion of 5.4 mg/kg/h for 23 hours. If steroid therapy is initiated within 3–8 hours of injury, continue infusion for a total of 47 hours. Although there is some evidence of improved sensory and motor scores in patients who were administered steroids within 8 hours of injury, the use of steroids may significantly increase the risk of infections, and therefore remains controversial.

Obstetric Anesthesia

William R. Camann, editor

Physiologic changes during pregnancy

Carlo Pancaro and William R. Camann

Pregnancy involves major anatomic and physiologic changes in all the maternal organ systems. The anesthesiologist caring for the pregnant patient must appreciate these physiologic changes, to provide safe analgesia and anesthesia to the mother and enable safe delivery of the fetus.

Cardiovascular system

Hemodynamic changes

Oxygen demand and consumption increase during pregnancy because of the growing fetoplacental unit. To meet these demands, maternal heart rate increases, and peripheral vascular resistance decreases (Table 120.1). The cardiac output increases progressively throughout pregnancy, beginning at 5 weeks and reaching a value 50% greater than that in nonpregnant women by the end of the second trimester. The next significant increase in cardiac output is during the active phase of labor. It reaches its peak increase immediately during the postpartum period, when the uterus contracts and uterine vascular resistance increases. Almost a liter of blood moves through the internal iliac veins and the common iliac vein to the inferior vena cava.

Systemic vascular resistance decreases by 20% primarily because of the development of the placental intervillous space, which is a low-resistance vascular bed. In addition, the vasodilation caused by prostacyclin, estrogen, and progesterone further lowers the systemic vascular resistance. Left ventricular ejection fraction and diastolic function are not significantly changed with pregnancy, nor are central venous or pulmonary arterial and venous pressures. In pregnant patients, the concentrations of markers for the diagnosis of congestive heart failure (e.g., brain natriuretic peptide) or myocardial ischemia (e.g., troponin I) are not different from those concentrations in nonpregnant women.

Aortocaval compression

At approximately the 20th week of gestation, the gravid uterus starts to compress the aorta and the inferior vena cava in the supine position.

Approximately 15% of pregnant patients near term develop the “supine-hypotension syndrome” characterized by a transient tachycardia followed by bradycardia, hypotension, changes in cerebation, nausea, vomiting, sweating, and pallor.

These symptoms are attributed to a lack of venous return to the heart because of the uterus compressing the inferior vena cava. Turning the gravid patient to the left (left uterine displacement) by 15° to 30° generally improves the symptoms (see Fig. 120.1). Left uterine displacement relieves the pressure not only on the inferior vena cava but also on the aorta, which is responsible for uterine perfusion pressure. When the uterus is tilted, uterine perfusion pressure increases and the fetal hemodynamics improve.

Compression of the vena cava diverts blood flow and increases the pressure into the venous azygous system, thereby increasing the pressure and volume of epidural veins. This can increase the likelihood of venous cannulation during epidural placement. Use of the lateral position, during which the epidural veins are less engorged, lessens this risk.

Blood volume

Red-blood-cell volume increases by 30% and plasma volume by 50%, resulting in an increase in the total blood volume of almost 50%. This increase causes a dilutional or physiologic anemia. A greater increase in blood volume occurs with twin pregnancies than with singleton pregnancies, which helps to prepare the parturient for the 500-ml average blood loss during a singleton vaginal delivery or the approximately 1000-ml blood loss during a vaginal delivery of twins or an uncomplicated cesarean delivery.

Auscultation, electrocardiogram, and echocardiogram

An accentuation of the first heart sound occurs with exaggerated splitting of the mitral and tricuspid components. The second heart sound is relatively unchanged. A third heart sound is easily heard during the latter half of pregnancy. Sinus tachycardia is common in pregnancy. Because there is some cardiac enlargement with pregnancy, the tricuspid annulus may enlarge, causing tricuspid regurgitation that can result in a grade I–II early- to midsystolic murmur. The aortic annulus is not dilated. Approximately 94% of term pregnant women exhibit tricuspid and pulmonic regurgitation, and 27% exhibit mitral regurgitation.

Blood pressure

Systolic blood pressure decreases by only 8% during pregnancy due to the increased aortic size and compliance. Diastolic blood pressure decreases by 20% due to the large decrease in systemic vascular resistance.

Hemodynamic changes during labor

Cardiac output increases from prelabor values by 15% in the first stage of labor, 30% in the second stage, and 45% in the third stage (between delivery of baby and placenta). During uterine contractions, cardiac output increases intermittently by an additional 20%, because the contracting uterus forces blood from the intervillous space through the ovarian venous system into the systemic circulation (autotransfusion). A progressive elevation of sympathetic nervous system activity and hence an increase in stroke volume, heart rate, and contractility, combined with the increased blood volume, is responsible for the increased cardiac output throughout labor.

The greatest increase in circulating blood volume occurs immediately after delivery when the uterus is steadily contracted and the obstruction to vena caval and aortic flow is relieved, increasing preload and increasing cardiac output. Patients with cardiac disease are thus most susceptible to worsening of their cardiac function in the postpartum period. In the hour following delivery, cardiac output decreases by 30%

because of a decline in both stroke volume and heart rate. Cardiac output declines to prelabor values after 2 days from the delivery and returns to prepregnant levels within 3 to 6 months.

Vasopressors

Ephedrine and phenylephrine are the vasopressors of choice for the treatment of hypotension in pregnant woman, following a regional anesthetic technique. Both drugs will increase maternal blood pressure without significant adverse effects on fetal perfusion or oxygenation. The mechanism of action differs, however, as ephedrine increases cardiac output and phenylephrine increases the peripheral arterial tone to a greater extent. Ephedrine has traditionally been recommended because it may preserve uteroplacental blood flow better in animal models. In clinical practice, however, neonatal condition is identical and umbilical cord blood gases are actually slightly better when phenylephrine is used.

Respiratory system

Upper airway changes

The nasal and oropharyngeal mucosa progressively become engorged early in the first trimester. Nasal endotracheal intubation and direct laryngoscopy should be performed with fine movements and extreme caution because oral, nasal, or pharyngeal bleeding may obscure the laryngoscopic view and make intubation difficult. For the same reason, oral temperature probes and orogastric tubes are preferred over the nasal route after the induction of anesthesia.

The Mallampati score increases during gestation and more so during labor. Because of edema, the pharyngeal volume becomes smaller as labor progresses; this may be responsible for the difficult visualization of the vocal cords under direct laryngoscopy. In addition, the false vocal cords increase in size due to capillary engorgement. Failed endotracheal intubation in obstetric patients is reported to be 1:200 to 1:750, about 10 times more common than the general population. In general, it is prudent to use smaller size endotracheal tubes for general anesthesia during pregnancy.

Changes in respiratory mechanics

The position of the diaphragm rises by as much as 4 cm, which would generally cause a decrease in the vital capacity in pregnancy at term. The chest circumference increases by 5 to 7 cm, which negates the decrease in vital capacity, keeping it unchanged (Table 120.2). Because chest excursions are limited because of the expanded thoracic cage in the resting position, the diaphragm becomes the main inspiratory muscle in term pregnant women. Due to the elevated resting position of the diaphragm and larger diaphragmatic excursions during inspiration, both tidal volume and minute ventilation increase. For these reasons, PaCO₂ decreases and PaO₂ increases. These changes and larger tidal volumes decrease physiologic dead space at term.

FEV₁/FVC
Closing capacity
Flow–volume loop
Anatomic dead space

The inspiratory reserve volume increases by only 5%, so the inspiratory capacity (inspiratory reserve volume + tidal volume) increases mainly because of the increase in tidal volume. In addition, the diaphragm in the resting position pushes up the bases of the lungs, which causes a reduction in expiratory reserve volume, residual volume, and functional residual capacity (FRC; expiratory reserve volume + residual volume). Because small airway function is unaltered by pregnancy, forced expiratory volume in 1 second (FEV₁), ratio of FEV₁ to forced vital capacity (FVC), closing volume, and flow–volume loops are all unchanged.

The anesthetic implications of these respiratory system changes are profound. FRC is reduced to 80% of the nonpregnant value by term gestation, bringing it closer to closing capacity. For this reason, and due to the increase in oxygen consumption, pregnant women become hypoxemic more rapidly than do nonpregnant women during episodes of apnea. During rapid-sequence induction of general anesthesia, the PaO₂ of parturients decreases at more than twice the rate when compared to nonpregnant women (139 mm Hg/min vs. 58 mm Hg/min). In addition, during induction of anesthesia, the alveolar inhaled anesthetic concentration increases more rapidly in pregnant women, owing to the decreased FRC and the increased minute ventilation. The decrease in PaCO₂ and plasma bicarbonate levels lower the plasma-buffering capacity and render the pregnant patient more vulnerable to metabolic acidosis in case of hemorrhage.

Nervous system

During pregnancy, minimum alveolar concentration (MAC) of volatile halogenated anesthetic agents decreases by 30%. In postpartum women, MAC returns to that of the nonpregnant state within 3 days of delivery. Three main factors account for this change during pregnancy:

- Elevated level of progesterone, which acts on γ -aminobutyric acid (GABA) receptors and has sedative effects;
- Increased central serotonergic activity; and
- Activation of the endorphin system.

For the same reasons, the induction dose of thiopental in parturients is reduced by 35% compared to that dose in nonpregnant women. Pregnancy also enhances sensitivity of peripheral nerves to local anesthetics. Despite enhanced neural susceptibility during pregnancy, epidural administration of large doses of local anesthetics (100–150 mg of bupivacaine) results in the same degree of spread in term pregnant and nonpregnant women. With spinal anesthesia, however, pregnant women exhibit a more rapid onset, longer duration of action, and higher spread (25% reduction in the segmental dose requirements) than do nonpregnant women, who receive the same dose of local anesthetic. In addition, women experience an elevation in their threshold to experimental heat pain at term pregnancy, a phenomenon called *pregnancy-induced analgesia*.

Dependence on the sympathetic nervous system for maintenance of blood pressure increases progressively throughout pregnancy. Spinal anesthesia in term pregnant women frequently results in a marked decrease in blood pressure, whereas nonpregnant women experience a lesser decrease.

Endocrine system

Pregnancy is associated with insulin resistance due to the hormone secreted by the placenta – “human placental lactogen.” Maternal hyperglycemia may be associated with fetal hyperglycemia, because maternal glucose (but not insulin) crosses the placenta. Near term, oxytocin is secreted by the posterior pituitary (which may initiate labor), and after the birth of the baby, prolactin is secreted by the anterior pituitary, which enhances the production of breast milk.

Approximately 0.1% of pregnancies are associated with a hyperactive thyroid gland. In addition, maternal estrogen and progesterone cause enhanced renin activity, which in turn stimulates the adrenal glands to secrete more aldosterone, resulting in water and sodium retention.

Gastrointestinal system

Pregnancy is associated with an anatomic shift in the position of the stomach caused by the gravid uterus. This shift changes the angle of the gastroesophageal junction, resulting in a decrease of the lower esophageal sphincter tone, which results in heartburn in most pregnant women by term. Many

anesthesiologists administer the antacid oral sodium citrate, 30 ml of a 0.3 M solution, prior to anesthesia or labor analgesia, which neutralizes gastric acid and raises its pH. This antacid may ameliorate the consequences of pulmonary aspiration of gastric contents should it occur. In addition, some anesthesiologists administer 10 mg of intravenous metoclopramide, which increases gastrointestinal motility and lower esophageal sphincter tone. It is important to remember that drugs that increase the risk of aspiration, primarily by lowering the esophageal sphincter tone, include glycopyrrolate, succinylcholine, and opioids.

Gastric emptying of liquid and solid materials is not altered at any time during pregnancy, but is slowed markedly during labor. Fentanyl (a 100- μ g bolus epidurally or 25 μ g intrathecally) and virtually all parenteral opioids also significantly delay gastric emptying during labor. On the other hand, epidural analgesia using local anesthetics and a low dose of fentanyl (e.g., 2 μ g/ml) does not delay gastric emptying during labor.

Liver size, morphology, and blood flow do not change during pregnancy, although the liver is displaced upward. Liver enzymes (alanine aminotransferase, aspartate aminotransferase, lactic dehydrogenase) and bilirubin increase to the upper limits of the normal range during pregnancy. The total alkaline phosphatase activity increases two- to fourfold, mostly from production by the placenta. The rate of gallbladder emptying slows, and the bile tends to concentrate, predisposing pregnant women to gallstone formation.

Renal system

The kidneys enlarge and the ureters and renal pelvis and ureters dilate as a result of increased progesterone levels. The dilation of ureters and the pressure on the bladder from the enlarging uterus predispose pregnant women to urinary tract infections. Glomerular filtration rate increases by 50%, resulting in a decrease of blood urea nitrogen (8–9 mg/dl) and serum creatinine (0.5–0.6 mg/dl) concentrations. The resorptive capacity of the proximal tubules for glucose decreases, which leads to mild glucosuria. In addition, increased secretion of erythropoietin by the kidneys leads to an increase in red cell mass.

Coagulation and immune system

Pregnancy is a hypercoagulable state compensated by enhanced fibrinolysis. D-dimer, a specific marker of fibrinolysis, which results from breakdown of cross-linked fibrin polymer by plasmin, increases as pregnancy progresses. The majority of coagulation factor levels are increased. The activated partial thromboplastin time (aPTT) is normal and the prothrombin time (PT) is shortened at term pregnancy. In addition, platelet turnover is increased during pregnancy, although the total count may remain normal or slightly decreased. Pregnancy-induced thrombocytopenia with levels around 100,000 occurs in approximately 8% of all pregnancies and is benign.

Plasma albumin concentration decreases from 4.5 to 3.9 g/dl. Levels of the α_1 -acid glycoprotein, the second most important plasma drug binding protein, are not changed during pregnancy. The plasma cholinesterase concentration decreases by 25% in term pregnancy and decreases further postpartum. In individuals with normal cholinesterase enzyme activity, there is no clinically significant change in the duration of action of succinylcholine. The blood leukocyte count increases progressively during pregnancy from 6000/mm³ to 9000 to 11,000/mm³ at term.

Syncytiotrophoblast lacks classic major histocompatibility complex (MHC) antigens, thus creating an immune-privileged surrounding to maintain the fetal allograft. Modulating thymic T-cell selection toward mature T-cell repertoire results in inhibited T-cell activation and tolerance toward paternal HLA as well as interleukin-10 (IL-10) production, which is required for maintenance of pregnancy. Progesterone alters the TH-1/TH-2 ratio toward the immunomodulatory TH-2 subset. These changes set the state for improvement in mainly proinflammatory sustained autoimmune disorders (i.e., multiple sclerosis) but also potential harm by a decrease in immunocompetence and predisposition to infections.

Musculoskeletal system

As the uterus enlarges during pregnancy, lumbar lordosis is enhanced. This change is the primary cause of low back pain that occurs in 50% of pregnant women. A widening of the pubic symphysis and the pelvis results in a head-down tilt when a parturient is in the lateral position. The head-down tilt might increase the rostral subarachnoid spread of hyperbaric local anesthetic solutions when the injection is made with the patient in this position. Pregnancy does not alter cerebrospinal fluid (CSF) pressure, so CSF flow from a spinal needle is unchanged (although uterine contractions during labor do increase CSF pressure).

Analgesia for labor

Arvind Palanisamy and B. Scott Segal

Labor pain causes extreme discomfort in most parturients, especially nulliparas. Labor pain has been assessed to be among the most severe types of pain. Therefore, to relieve the pain of labor is one of the most important services that an anesthesiologist can provide to parturients.

Pain pathways

Uterine pain, which occurs during the first stage of labor, is transmitted in the sensory fibers accompanying sympathetic nerves that end in the dorsal horns of T10–L1 (Table 121.1). Vaginal and perineal pain, which occurs during the second stage of labor, is transmitted by the afferent fibers of the pudendal nerve (S2–S4). The transmitted signals are relayed to the sensory cortex after processing in the spinal cord.

Anatomic changes in pregnancy

Several pregnancy-related anatomic changes are important for the anesthesiologist to consider. Hormone-induced ligamentous laxity, along with mechanical effects imposed by the enlarging fetus, induces a number of anatomic changes in the lumbar spine, which may lead to the following problems during attempted neuraxial analgesia:

- *Erroneous identification of the intervertebral space* is due to anterior rotation of the pelvis causing Tuffier's line (line connecting the interiliac crests) to cross the lumbar spine at a higher level than the usual L4–L5 interspace.
- *Unintentional head-down tilt* can occur in the lateral position, because the parturient's pelvis is often wider than her shoulders.
- *Increased technical difficulty* is due to a reduction in the physical dimensions of the lumbar intervertebral space as a result of exaggerated lumbar lordosis. Difficulty may be compounded in an actively laboring parturient who is unable to remain still.
- *Enhanced rostral spread of hyperbaric local anesthetics* is due to a cephalad shift of the apex of thoracic kyphosis from T8 to T6 in the supine position.
- *Increased likelihood of vascular cannulation during epidural placement* can occur as a result of the engorgement of the epidural venous plexus, due to inferior vena caval

compression by the gravid uterus and pregnancy-associated increase in plasma volume.

Classification of labor analgesic techniques

Labor analgesia is most commonly provided by regional anesthesia techniques, but there are a number of alternatives available (Table 121.2).

Inhalational analgesia

A mixture of 50% nitrous oxide (N₂O) and 50% O₂ (ENTONOX; The Linde Group, Worsley, Manchester, UK), which is widely used in the United Kingdom, has never become popular in the United States probably due to higher epidural rates along with concerns of bone marrow toxicity from prolonged exposure to N₂O. Halogenated agents, in sub-anesthetic concentrations, have also been shown to possess equianalgesic effects during the first stage of labor. This mode of analgesia requires an anesthetic delivery system in the labor room and the presence of an anesthesiologist. With accumulating laboratory evidence in rodent models implicating N-methyl-D-aspartate (NMDA) antagonists and γ -aminobutyric acid (GABA) agonists in fetal neurodegeneration, the use of such agents will continue to be widely debated.

Systemic opioids

Parenteral opioids are generally safe and reasonably effective analgesics. They are often used in the presence of contraindications to neuraxial techniques or, occasionally, as a means to defer the timing of epidural placement. The commonly used agents include morphine, hydromorphone, meperidine, fentanyl, and, recently, remifentanyl. The main disadvantages include sedation, maternal and neonatal dose-dependent respiratory depression, and delayed gastric emptying. The problem

Table 121.1. Stages of labor and dermatomes

Stage I	Uterine contractions to full cervical dilation	T10–L1 (early T11–T12)
Stage II	Full cervical dilation to birth	T10–S4 (addition of S2–S4 – pudendal nerve)
Stage III	Placenta removal	

Table 121.2. Labor analgesic techniques**Non-regional techniques**

 - CSE
 - Continuous spinal
- Non-neuraxial
 - Paracervical nerve block
 - Pudendal nerve block

of fluctuating plasma drug levels that are incongruent with analgesic requirements may be attenuated with the use of patient-controlled analgesia (PCA). The favorable properties of fentanyl (quick onset) or remifentanyl (unique non-saturable metabolic pathway and easy titratability) make them appealing choices for intravenous (IV) PCA. Unfortunately, most studies comparing neuraxial and IV analgesia find the latter to be far inferior in relieving labor pain. It should be remembered that all opioids (and most sedatives) suppress beat-to-beat variability (indicative of fetal well-being) in fetal heart rate (FHR).

Other methods

A variety of alternative and complementary methods exist for relief of labor pain. The efficacy is variable, risks are low, and, in most circumstances, other than perhaps water immersion, all are compatible with concomitant use of regional analgesic techniques. Because non-neuraxial nerve blocks are experimental (lumbar sympathetic block) or of largely historical interest (paracervical block – abandoned due to high fetal levels of local anesthetic), neuraxial techniques remain the widely used techniques.

Neuraxial analgesia

Indications

Maternal request is a sufficient medical indication for pain relief during labor and is a guideline repeatedly endorsed jointly by the American Society of Anesthesiologists (ASA) and the American College of Obstetrics and Gynecology (ACOG). Recently, the ACOG directly endorsed the provision of neuraxial analgesia without meeting arbitrary milestones of labor progress. More specific indications include:

- Maternal conditions that complicate or contraindicate general anesthesia (e.g., morbid obesity, difficult airway, malignant hyperthermia);

- Obstetric disease, which places the patient at high risk for emergency delivery (e.g., severe pregnancy-induced hypertension);
- Increased likelihood for operative delivery, such as malpresentation and multi-fetal gestation; and
- Maternal coexisting disease (e.g., severe cardiac or respiratory disease), where the sympatho-adrenal consequences of unmitigated labor pain may be detrimental.

Contraindications

Patient refusal, an uncooperative patient, uncorrected coagulopathy, uncontrolled hemorrhage with severe hypovolemia, and epidural site infection qualify as absolute contraindications. All other contraindications (e.g., elevated intracranial pressure, local anesthetic allergy, untreated systemic infection) are relative, and the risks versus benefits need to be carefully considered to make an individualized decision on whether to proceed with a neuraxial technique.

Preparation for neuraxial blockade

The usual preparation for any anesthetic should be undertaken prior to labor analgesia. Because of the unique clinical situation, there are some variations from the routine prior to surgical anesthesia.

- Pre-anesthetic evaluation is obtained, including the patient's medical and anesthetic history, obstetric course, and previous birthing experience, if applicable. A focused physical examination (including the spine) is required, and fetal well-being needs to be documented. The overall plan of care is finalized after discussion with the obstetric care provider.
- Consent is obtained after a detailed explanation of the procedure and a discussion of possible complications and alternatives should regional anesthesia fail. Ideally, consent should be completed prior to the onset of active labor so that the process is unhurried and unencumbered by severe pain.
- Availability of monitoring, resuscitation equipment, and IV access should be verified. It is customary for a majority of labor rooms to be fully equipped for maternal and fetal monitoring and have easy access to resuscitation equipment and drugs. Not all ASA standard monitors may be required for otherwise healthy patients. A large-bore IV catheter, if not already placed, should be secured.
- Aspiration prophylaxis and restriction of oral intake are commonly employed, but controversial. Administration of 30 ml of a nonparticulate antacid, such as sodium citrate, precedes epidural placement. One should generally follow prevailing institutional guidelines regarding restriction of oral intake, as there is no robust evidence to support or refute fasting. ASA guidelines recommend withholding

solid food but allowing moderate amounts of clear liquids in labor. Although it is routine to administer maintenance IV fluids prior to epidural blockade (1–2 liters), fluid preloading is not universally practiced.

- The Joint Commission “safety pause” should be performed prior to beginning the procedure. The name, date of birth of the parturient, and proposed technique should be verbally confirmed by all personnel in the labor room, including the patient.

Monitoring the fetus

FHR is generally monitored either intermittently or continuously during labor, and should be available when performing neuraxial analgesia. The most important features of the tracing are variability and periodic changes in relation to uterine contractions, although one should be aware of the risk of false-positive results. Normal FHR ranges between 120 and 160 bpm. Sympathetic stimulation, prematurity, and maternal fever increase the FHR, whereas parasympathetic (vagus) stimulation, hypoxia, uterine contractions, and fetal head compression decrease FHR. FHR varies constantly from the baseline, which reflects a healthy fetal nervous and cardiac system. FHR variability may be decreased by prematurity, hypoxia, depressant drugs (opioids, magnesium, barbiturates, benzodiazepines), and inadequate uteroplacental blood flow.

FHR decelerations can be classified as *early*, *late*, or *variable*, according to their characteristics (Fig. 121.1). Early decelerations are normal and are caused by fetal head compression during uterine contractions, resulting in vagal stimulation and slowing of FHR. The onset and offset of the deceleration coincides with the onset and offset of the uterine contraction, producing a mirror image. Late decelerations occur due to any cause compromising uteroplacental blood flow, such as maternal hypotension, acidosis, hypovolemia, and preeclampsia. The FHR usually falls at or after the peak of the uterine contraction and returns to baseline after the contraction has ended. The occurrence of late decelerations calls for urgent evaluation of fetal well-being. Variable FHR decelerations are variable in their duration, timing, and intensity and are often caused by compression of the umbilical cord. Variable decelerations are usually self-limiting and may be mild (<30 sec, FHR > 80 bpm), moderate (30–60 sec, FHR = 70–80 bpm), or severe (>60 sec, FHR < 70 bpm). Persistent or severe variable decelerations may lead to fetal acidosis and call for urgent evaluation and/or intervention.

Description of neuraxial techniques

Neuraxial analgesia for labor can be provided with epidural analgesia, combined spinal–epidural (CSE) analgesia, or continuous spinal anesthesia. Continuous spinal anesthesia is usually done to convert a “wet tap” or unintentional dural puncture into spinal anesthesia.

Figure 121.1. Early, late, and variable FHR decelerations.

Epidural analgesia

The anesthesiologist is called at the appropriate time (cervical dilation at 3–4 cm, engagement of fetal head, absence of fetal distress) to administer analgesia for labor. The technique of epidural analgesia is described in Table 121.3.

Table 121.3. Conduct of epidural analgesia for labor

Monitors	On
Position of patient	Supine (usually)/lateral
Back preparation	Povidone-iodine (Betadine; Purdue Pharma L.P., Stamford, CT) × 3 times and draped
Lumbar space	L3–L4/L2–L3
Local infiltration	1–2 ml of 1% lidocaine
Needle	17G or higher gauge Tuohy
Technique	Loss of resistance to air/saline
Wet tap	Remove needle and go one space above
Epidural catheter insertion	2–4 cm into epidural space
Aspiration of catheter	Negative for heme and CSF
Test dose	3 ml of 1.5% lidocaine with 1:200,000 epinephrine
Agent	0.25% bupivacaine 5- to 10-ml bolus
Desirable level of anesthesia	T10

Epidural test dose

Due to the risk of accidental dural puncture or intrathecal migration of catheter and a relatively high incidence of vascular cannulation, it is essential to exclude these in a setting where administration of large volumes of local anesthetics is anticipated, as during the course of labor. A traditional test dose addresses both of these concerns by using a combination of local anesthetic and epinephrine to identify intrathecal migration and intravascular location, respectively. Test dose regimens using air, opioids, or β -adrenergic agonists (e.g., isoproterenol) have also been described.

The commonly used test dose consists of 45 to 60 mg of lidocaine (occasionally bupivacaine, 6–10 mg) with 15 μ g of epinephrine. Development of motor block within 5 minutes of injection is considered evidence of intrathecal catheter location; an isolated increase in the baseline heart rate by 25 to 30 bpm 20 to 40 seconds after injection is highly suggestive of intravascular placement. Because of confounding influences associated with uterine contractions, an unpredictable incidence of heart rate elevation with epinephrine, and possible deleterious effects on uteroplacental circulation, employment of a test dose is not ubiquitous. Some authorities suggest that explicit test dosing is unnecessary when dilute concentrations of local anesthetics are used. Given potentially disastrous consequences, however, meticulous fractionation of every bolus dose, along with maintenance of verbal contact with the parturient to identify suspicious symptomatology (perioral tingling, tinnitus), seems prudent.

Local anesthetics

The ideal local anesthetic for labor analgesia should provide excellent sensory analgesia while minimizing motor blockade, have a rapid onset of effect and a long duration of action, and cause no disruption to maternal–fetal physiology. An excellent sensorimotor differential blockade at low concentrations, a reasonably long duration of effect, and an established safety profile in obstetric practice and minimal transplacental transfer make bupivacaine a popular choice. With the use of large-volume, low-concentration mixtures and the addition of opioids to facilitate segmental analgesia, the usual slow onset of action of bupivacaine is not a concern. Due to a reduction in the absolute mass of drug administered, bupivacaine cardiotoxicity is extremely uncommon in labor analgesia.

Ropivacaine, which has a lower potential for cardiotoxicity than does bupivacaine, is a reasonable alternative, albeit a more expensive one. Levobupivacaine (the selective S isomer of bupivacaine) is also less toxic but is currently unavailable in the United States. Lidocaine causes significant motor blockade at analgesic concentrations and has a higher rate of transplacental transfer and the potential to induce tachyphylaxis. For these reasons, lidocaine is not a good choice for maintenance of labor analgesia. Its use as a test for a questionable epidural catheter, or

to supplement analgesia (e.g., 5–10 ml of 1.5%–2% lidocaine), is reasonable.

Choice of adjuncts

The addition of neuraxial opioids, which display significant synergism with local anesthetics, enables an overall reduction of local anesthetic dose and minimizes toxicity. Lipophilic opioids (e.g., fentanyl), in particular, also produce segmental analgesia and are shown to reduce the required concentration of local anesthetic. Administration of α_2 -adrenergic agonists, such as clonidine, prolongs the duration of analgesia without causing excessive motor blockade. The main side effects are sedation and hemodynamic instability. Vasoconstriction associated with epinephrine use decreases the clearance of epidurally administered local anesthetics and opioids and prolongs the duration of analgesia. It also provides direct analgesic effects through α_2 agonism. Side effects include an increased density of motor block and possible β_2 -receptor–mediated tocolysis.

Maintenance of analgesia

Intermittent bolus administrations, either timed or on demand, can provide effective analgesia during labor. High incidence of maternal dissatisfaction, occurrence of dense motor blockade, and an increased anesthetic workload resulted in the use of continuous epidural infusion (CEI) of dilute local anesthetics with or without an opioid. Although CEI provides a more stable level of analgesia and hemodynamic stability, supplemental top-ups are usually required during the course of labor. Patient-controlled epidural analgesia (PCEA), with or without a background infusion, provides better maternal satisfaction as well as decreases the total dose of drug administered. Examples of sample mixtures and parameters are listed in [Table 121.4](#).

Ambulation and progress of labor

Effective analgesia with retention of the ability to ambulate (before placement of an epidural) remains the ideal goal in

Table 121.4. Examples of suggested PCEA regimens

Anesthetic mixture	Infusion rate, ml/h	Bolus dose, ml	Lockout interval, min	Hourly maximum, ml
Bupivacaine 0.125%	6	6	15	30
Bupivacaine 0.125% with 2 μ g/ml fentanyl	4–6	6	15	30
Bupivacaine 0.0625% with 2 μ g/ml fentanyl	10–15	5	10	45
Bupivacaine 0.08% with 2 μ g/ml fentanyl	10	5	15	30
Bupivacaine 0.125% with 1 μ g/ml sufentanil	5	5	15	25

most obstetric units. Apart from significantly enhancing maternal autonomy, ambulation is widely believed to reduce the duration of the first stage of labor, but randomized trials support neither this belief nor the common assertion that gravity-mediated increased fetal descent results in a decreased incidence of dystocia. The risk of postural hypotension, subtle motor blockade, and impaired proprioception associated with neuraxial blockade reinforces the need for constant monitoring and nursing supervision during ambulation. Several studies indicate that epidural analgesia does not increase the incidence of cesarean deliveries. Some studies do suggest, however, that it prolongs the first stage of labor, especially in nulliparous women.

Combined spinal–epidural analgesia for labor

Early in labor, especially nulliparous women, may benefit from a CSE analgesia technique (the “walking spinal”). The idea is to inject only opioid (10–25 µg of fentanyl/5–10 µg of sufentanil), or opioid and low-concentration local anesthetic (1 ml of isobaric 0.25% bupivacaine), through the spinal and activate the epidural when needed (when true labor starts). This technique provides a minimal motor block and adequate pain relief in the early stages of labor, allowing the parturient to move about. When active contractions set in, the epidural is activated after a test dose. Alternatively, especially when used in active labor, the CSE technique may be followed by immediate activation of the epidural catheter by beginning a continuous infusion without a bolus. Sufficient local anesthetic usually will be infused by the time the intrathecal analgesia subsides.

The epidural space is reached by using the Tuohy needle. A 4.5-inch to 6-inch, 25G or 27G spinal needle is then introduced through the epidural needle when a give-away sensation is felt (pop) and cerebrospinal fluid (CSF) flow is seen. The two needles are stabilized by one hand, and the spinal agent of choice is administered through the spinal needle. The spinal needle is then withdrawn and an epidural catheter is threaded (2–4 cm) into the epidural space. The patient is then quickly laid supine from the sitting or lateral decubitus position.

Side effects and complications

Serious complications are, fortunately, rare, and only minor side effects are more frequently encountered with labor analgesia. These are listed in [Table 121.5](#).

Table 121.5. Complications of epidural catheter placement for labor analgesia

Hypotension	Pruritus
Inadequate analgesia	Excessive motor block
Urinary retention	FHR abnormalities
Intrapartum fever	Back pain
PDPH	Subdural block
High or total spinal anesthesia	Epidural hematoma or abscess
Accidental IV injection of local anesthetics	

Hypotension

Transient hypotension is one of the commonest side effects occurring with approximately equal frequency during CSE or a standard epidural loading dose. Untreated hypotension causes maternal symptoms, decreases uteroplacental perfusion, and may result in fetal distress requiring prompt treatment. Intravascular volume expansion, left uterine displacement, bolus doses of IV ephedrine (5–10 mg) or phenylephrine (20–40 µg), and supplemental oxygen therapy are required in such cases.

Pruritus

Pruritus following intrathecal and, less commonly, epidural opioids is usually dose-related and transient and requires no pharmacologic intervention. Despite being distressful, reassurance is all that is required in a majority of cases. Although not supported by literature, it may be a good practice to avoid neuraxial opioids in patients with a previous history of severe opioid-induced pruritus and pruritus due to medical conditions in pregnancy, such as symptomatic cholestasis and pruritic urticarial papules and plaques of pregnancy (PUPPP). If treatment is required, administration of either 25 to 50 mg of diphenhydramine, 5 to 10 mg of nalbuphine, or 8 mg of ondansetron may be considered. Severe pruritus may have to be treated with a infusion of dilute naloxone.

Epidural failure

The causes of a failed epidural are numerous and can be arbitrarily classified into early- or late-onset failure. Early-onset failure is usually recognized immediately after epidural placement and can manifest as a unilateral or asymmetric block, a missed segment, or a complete absence of block. Common causes include a malpositioned catheter and altered epidural anatomy (e.g., previous back surgery, severe scoliosis) preventing uniform spread of local anesthetic. Recent evidence suggests that an epidural placed as part of a CSE technique is more likely to result in a successful block.

Late-onset failure manifests as breakthrough pain in a parturient with a previously effective epidural block. A visual inspection to exclude dislodgement of the epidural catheter or disconnection of the maintenance infusion is mandatory before attempting any corrective measures. In the absence of such causes, intravascular migration is the most likely reason, which necessitates replacement of the catheter. [Table 121.6](#) shows approaches to troubleshooting a poorly functioning epidural catheter.

Excessive motor block

With increasing emphasis on the use of dilute local anesthetic solutions for labor analgesia, the incidence of excessive motor block is considerably lower than it has been in the past. Although difficult to predict, it seems to occur more commonly

Table 121.6. Labor epidural troubleshooting

Problem	Presentation	Identification	Remedy
Total failure	No block immediately or at any time following placement	Ambiguous loss of resistance Dislodgement of the catheter Disconnection of the epidural infusion connectors Undetectable block after 10 ml of 0.25% bupivacaine or equivalent	Replace epidural catheter at or above previous site Replace epidural catheter and tape it securely Reconnect after ensuring adequate sterility Replace epidural catheter at or above previous site
Partial failure*	Unilateral block (Patient complains of motor and thermal asymmetry)	Dermatomal pattern with sensory testing	Top-up epidural with painful side in dependent position. If no response in 10 min, withdraw catheter by 1 cm and re-bolus (replace if unsuccessful)
	Missed segment	Usually a subtle unilateral block between T12 and L2 on sensory testing	Same as above, but add an opioid (50–100 µg of fentanyl) for segmental analgesia If in doubt, replace the catheter
	Back pain Perineal pain and rectal pressure	Possible occipito-posterior fetal head position Rapid progress to second stage of labor	Top-up with at least 5–10 ml of 0.25% bupivacaine + opioid in semi-sitting position Check sacral block and then same as above

* Always check PCEA usage, ensure an empty bladder, and verify progress of labor. Exclude possible uterine dehiscence in a parturient undergoing trial of labor after cesarean delivery complaining of disproportionate pain.

in patients who receive multiple boluses during the course of labor. A subjective complaint of excessive lower extremity heaviness is the usual harbinger. Reduction of the infusion rate or temporary discontinuation is the appropriate first step. If PCEA is employed, it may be prudent to discontinue the background infusion while permitting demand boluses so that the possibility of rapid regression of block is minimized.

Urinary retention

Urinary retention commonly accompanies lumbar epidural analgesia, and catheterization is routine in many labor units. Use of neuraxial opioids, in particular, significantly increases its incidence. Urinary retention in the postpartum period, following complete regression of the epidural block, is usually due to obstetric rather than anesthetic factors.

Fetal heart rate abnormalities

Changes in the fetal heart rate (FHR) tracing (decrease in baseline, decelerations) occur with both epidural and CSE techniques. Transient bradycardia, however, is more common with the CSE technique. Although distressing, these FHR changes are usually self-limited and subside with conservative therapy without modifying the obstetric outcome. Nevertheless, its occurrence reinforces the importance of vigilant fetal monitoring during and after the procedure. The mechanisms responsible for FHR changes are not clear, but uterine artery vasospasm due to acute perturbation in maternal catecholamine levels seems to be the most likely explanation. One recommendation is an IV administration of ephedrine.

Intrapartum fever

An observed association between epidurals and intrapartum fever has been confirmed by randomized studies. Maternal pyrexia causes an increase in maternal antibiotic exposure and

neonatal sepsis evaluations, and direct toxicity to the fetal brain has been suggested. Although the exact mechanism is still unclear, thermoregulatory imbalances, a suppressive effect of systemic opioids in women without epidurals, and inflammation have all been suggested as possible mechanisms. Recent evidence, however, consistently supports an inflammatory etiology.

Back pain

Forty percent of postpartum women experience lower back pain regardless of the choice of analgesia, neuraxial or otherwise. Multiple studies have consistently shown a poor correlation between epidural analgesia and postpartum backache.

Unintentional dural puncture

The incidence of unintentional dural puncture, the wet tap, is inversely related to the experience of the operator, varying from 1% to 8%. The consequences of a wet tap with the routinely used 17G epidural needle can be quite debilitating. Post-dural puncture headache (PDPH) complicates 50% to 80% of cases. The commonly used management strategies following a wet tap include:

- Placement of an intrathecal catheter: Threading an epidural catheter into the subarachnoid space provides reliable and excellent analgesia. It also obviates the need for replacement of the epidural catheter, which in itself carries a risk of an additional dural puncture. Intrathecal catheters left in situ for more than 24 hours have been suggested to reduce the incidence of PDPH compared to replacement of the catheter, although the data are not consistent. In addition, some anesthetists fear the risk of infection and the potential for iatrogenic disasters on postpartum units where the nursing staff are unfamiliar with such catheters.

Table 121.7. Conduct of an epidural blood patch

Monitors	On
Patient position	Lateral/sitting
Lumbar space	Same or near the first dural puncture site
Skin preparation	Betadine × 3 times, local 1–2 ml of 1% lidocaine
Needle	17G Tuohy
Loss of resistance	Air/saline
Autologous blood collection (15–20 ml)	By assistant with full aseptic precautions (Betadine skin preparation, sterile gloves, and syringe)
Blood injection	Via epidural needle
Patient position	Supine for approximately 1 h

- **Replacement of epidural at an alternate interspace:** This strategy requires no special precautions compared to an intrathecal catheter, but risks inducing another dural puncture and enhanced drug transfer across the preexisting dural hole during an epidural bolus. Doses, therefore, need to be fractionated and possibly reduced. Prophylactic blood patching has not been shown to give consistent results.

The headache usually occurs after 24 hours and is described as a severe fronto-occipital headache, sometimes with neck pain. Headache improves in the supine position and becomes severe on sitting or standing (traction on the brain). Nausea, vomiting, diplopia, or tinnitus may accompany the headache.

Treatment of PDPH includes conservative measures, such as bed rest, fluids, analgesics, and caffeine (500 mg in a liter of crystalloid) or an epidural blood patch, as described in Table 121.7. Use of saline for a patch (instead of blood) is a less effective means of treating the headache. Recently, fibrin glue has been shown to be an alternative to blood for an epidural patch. Although 85% to 90% of headaches are relieved after one patch, the rest of the patients may need a second blood patch (after 24 hours).

Rare complications

Location of the epidural catheter between the dura and arachnoid membrane results in a subdural block. Although rare, this

may also be the cause of patchy epidural blocks. High or total spinal block may occur due to unidentified subarachnoid placement, intrathecal migration of an epidural catheter, or deterioration of a subdural block with rupture of arachnoid induced by a bolus dose. Unappreciated intravascular injection may occur and lead to local anesthetic toxicity.

Anesthesia for cesarean delivery

Lawrence C. Tsen

The incidence of cesarean delivery (CD), which is defined as the birth of a fetus through incisions in the abdomen (laparotomy) and uterus (hysterotomy), has undergone progressive increases and currently accounts for 15% to 30% of all deliveries in developed countries worldwide.

Indications

The common indications for CD include previous CD, cephalopelvic disproportion, dystocia, fetal malpresentation, placenta previa or abruptio placentae, prematurity, non-reassuring fetal status, and patient request. A prior CD does not require subsequent pregnancies to be delivered in this manner, although a trial of labor after CD (TOLAC; which, if successful, is referred to as a vaginal birth after CD [VBAC]) is an alternative, albeit declining, option.

Conduct and complications of cesarean delivery

CD is usually performed via a low (suprapubic), transverse incision through the skin and uterus (Pfannenstiel incision), which offers improved cosmesis and wound strength as well as a reduction in bowel and omentum adherence, infection rates, and blood loss. Vertical uterine incisions can be used when the lower uterine segment is underdeveloped (prior to 34 weeks of gestation), in the presence of a large-for-gestational-age fetus or multiple fetuses, or in truly emergent cases. Uterine exteriorization following delivery of the fetus and placenta facilitates visualization and repair, particularly when the incision has been extended laterally.

Complications of CD include hemorrhage, infection, thromboembolism, hysterectomy, ureteral tract and vesical injury, abdominal pain, uterine rupture in future pregnancies, and death. Maternal morbidity and mortality still vary widely; however, in most developed nations, maternal death averages 10 to 30 per 100,000 CD, a rate minimally higher than for vaginal delivery. Infant and neonatal mortality follow similar patterns and rates, but are higher following CD, most likely reflecting the conditions prompting non-elective deliveries.

Preparation for anesthesia

A review of the maternal medical, anesthetic, and obstetric history, allergies and medications, an assessment of baseline hemodynamics, and an airway, heart, and lung examination should be performed before providing anesthesia care. Acknowledgment of the risks and benefits of each anesthetic option should be discussed as part of the informed consent. Major hemorrhage can occur at any time in the peripartum period and remains a leading cause of maternal mortality. Risk factors for peripartum hemorrhage should be identified and preparations made. Basic monitors should be applied; invasive hemodynamic monitoring should be considered in women with severe cardiac or renal disease, refractory hypertension, pulmonary edema, or unexplained oliguria. An evaluation of the fetal heart rate by a qualified individual may be useful before and after administration of anesthesia to reduce fetal and neonatal complications.

NPO status and gastric optimization

NPO status should be assessed, although gastric emptying of liquids during pregnancy occurs relatively quickly and similarly in lean or obese, non-laboring, pregnant women. The uncomplicated patient undergoing labor or elective CD can drink modest amounts of clear liquids up to 2 hours prior to induction of anesthesia. Patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes, difficult airway) or patients at increased risk for operative delivery (e.g., non-reassuring fetal heart rate pattern) may have further restrictions of oral intake, determined on a case-by-case basis. Solid foods should be avoided in laboring patients and in those undergoing elective surgery (e.g., scheduled CD or postpartum tubal ligation). A fasting period of 6 to 8 hours for solids has been recommended. A nonparticulate antacid (sodium citrate) is believed to decrease the damage to the respiratory epithelium if aspiration occurs, and is customarily administered. Additionally, metoclopramide may decrease nausea and vomiting and facilitate gastric emptying.

Selection of anesthetic technique

In addition to the urgency and anticipated duration of the case, the most appropriate anesthetic for a CD depends on maternal,

Table 122.1. Advantages/Disadvantages of neuraxial anesthesia*Advantages:*

Minimal fetal exposure to drugs
 Decreased incidence of maternal pulmonary aspiration
 An awake mother with greater bonding with the neonate

Disadvantages:

Greater incidence of hypotension
 Exposure to risks of neuraxial anesthesia

fetal, and anesthetic factors. In cases of dire fetal distress, a rapid evaluation of the patient and the situation should be performed as other preparations for the provision of anesthesia are being made. Regardless of the degree of urgency, the anesthesiologist should not compromise maternal safety by failing to obtain critical information, including previous medical and anesthetic histories and allergies, and to quickly assess the airway and basic hemodynamics.

Overall, neuraxial (epidural, spinal, and combined spinal-epidural [CSE]) techniques are the preferred methods for providing anesthesia for CD in both elective and emergent procedures, and specific benefits and risks of each technique dictate the eventual selection. Certain conditions or time constraints, however, may contraindicate their use. Such comorbidities include localized infection or generalized sepsis, severe uncorrected coagulation disorders, severe hypovolemia, or cardiac pathologies where acute onset of hypotension may be detrimental. Severe obstetric hemorrhage in the antepartum period, and severe preeclampsia or hypertension, may also complicate the choice of anesthetic technique. Advantages and disadvantages of neuraxial and general anesthetic techniques are summarized in Tables 122.1 and 122.2.

Spinal anesthesia

This technique is the most common for anesthesia in elective CD. For emergent CD, a general anesthetic is preferred. Spinal anesthesia in emergent situations is administered only if (1) time permits and (2) it is not contraindicated. A simple and reliable technique with rapid onset, spinal anesthesia provides an awake and comfortable patient with minimal risks for aspiration. Despite the lower abdominal cesarean incision, a T4 dermatome level is required to prevent referred pain from traction on the peritoneum and uterus.

Table 122.2. Advantages/Disadvantages of general anesthesia*Advantages:*

Rapid onset and reliability
 Airway control
 Less hypotension than neuraxial anesthesia

Disadvantages:

Increased risk of pulmonary aspiration
 Drug-induced fetal cardiorespiratory depression
 Difficult airway management

Table 122.3. Conduct of spinal anesthesia

Monitors	BP measurement every 2 min after spinal administration for 15–20 min, electrocardiogram, pulse oximetry
Patient position	Sitting or lateral recumbent
Back preparation	Betadine or chlorhexidine × 3 times
Lumbar space	L3–4/L4–5
Local infiltration	1–2 ml of 1% lidocaine
Needle	25G or higher (need an introducer)
CSF flow	Free flow; typically no heme or paresthesia
Agent	10–12 mg of hyperbaric (8.25% dextrose) bupivacaine (0.75%)
Additives	Fentanyl 10–25 mcg/morphine 0.2–0.3 mg, epinephrine 1:200,000
Desirable level of anesthesia	T4
Patient position	Supine with left uterine displacement; tilt table toward left and/or put a blanket roll under right hip)
Oxygen supplementation	Nasal cannula/face mask
Hypotension	Phenylephrine 40 µg, ephedrine 5–10 mg, epinephrine if life threatening, fluid supplementation, uterine tilt
Nausea	Check BP (usually due to impending hypotension), metoclopramide, ondansetron

BP, blood pressure; CSF, cerebrospinal fluid.

After a routine preoperative evaluation and obtaining informed consent, the patient is brought into the operating room. Typically, by this time the patient would have already received placement of a large-bore intravenous [IV] catheter, a nonparticulate oral antacid (30 ml of sodium citrate) and frequently a promotility agent (10 mg of metoclopramide IV). Anxiolytics are best avoided until after delivery. Patients are placed on the operating table with a left uterine tilt to prevent aortocaval compression. Supplemental oxygen via a nasal cannula or face mask is routinely provided to the mother, although currently there is some controversy regarding the necessity of this treatment. The conduct of spinal anesthesia is summarized in Table 122.3.

After the baby is born, sedation, if required, can be given to the mother (may interfere with recall). Times for skin and uterine incisions and for the birth of the baby should be recorded in the chart. Antibiotics are administered, per the request of the surgeon. As soon as the placenta is delivered, 20 U of oxytocin are added to each liter of fluid (40 U total) for increasing the uterine tone (may cause hypotension and nausea). Additionally, 0.2 mg of methylergometrine maleate (Methergine; Novartis, East Hanover, NJ) may be given, intramuscularly (IM), if requested by the surgeon. Parturients lose approximately 800 to 1000 ml of blood during the operation.

Epidural anesthesia

The use of epidural anesthesia for CD has increased during the past two decades, primarily due to the growing use of epidural labor analgesia converted to surgical anesthesia for CD (Table 122.4). Although the types of medications used in the spinal and epidural space are similar, epidural doses are 5 to 10 times greater and given in much larger volumes to encourage

Table 122.4. Conduct of epidural anesthesia with an epidural catheter in situ

Monitors	BP measurement every 2 min after spinal administration for 15–20 min, pulse oximetry; electrocardiogram when in the operating room
Patient position	Supine with left uterine displacement; tilt table toward left and/or put blanket roll under right hip)
Level check of existing analgesia	Typically T10
Aspiration of epidural catheter (gentle)	Negative for heme and CSF
Agent	2% lidocaine or 3% chloroprocaine; 5 ml × 4 times = 20 ml, as necessary
Additives	Sodium bicarbonate: 1 ml for each 10 ml of lidocaine or chloroprocaine
Desirable level of anesthesia	T4

adequate spread and subsequent blockade. Advantages of the epidural technique potentially include a lower incidence and range of maternal hypotension, due largely to a gradually developing sympathetic blockade. In addition, catheter-based techniques enable the anesthesiologist to titrate the level, density, and duration of anesthesia. Opioids may be administered via the epidural catheter, including morphine (2–3 mg) and fentanyl (50–100 mcg). Morphine (2–3 mg) or fentanyl (50 mcg) can be used. Sedation, oxytocin, and antibiotic administration are similar to when spinal anesthesia is used.

For CD, the most common epidural agents used are 2% lidocaine, with or without epinephrine (1:200,000), and 3% 2-chloroprocaine, which is the agent of choice for emergent CD due to its rapid onset and rapid maternal and fetal metabolism. Fetal accumulation, especially when acidosis is present, is therefore minimized. By contrast, chloroprocaine is avoided for routine, non-urgent deliveries, as the short duration requires multiple doses, and its use can adversely affect the efficacy of subsequent epidural opioid analgesia. In addition, when used in higher total volumes (>40 ml), chloroprocaine can increase the incidence of back pain. Alkalinization with sodium bicarbonate (1 ml of 8.4% sodium bicarbonate per every 10 ml of 2% lidocaine or 3% chloroprocaine) hastens the onset and increases the intensity of blockade significantly and may be used in urgent or emergent CD. Alkalinization should not be used with certain (particularly longer acting) local anesthetics (e.g., bupivacaine) due to the low threshold for precipitation.

Combined spinal–epidural anesthesia

The principle advantage of the CSE technique is the ability to deliver a quick and reliable spinal anesthetic with the opportunity to augment the density or duration of the anesthesia through the epidural catheter. This technique is particularly useful in obstetrics, where delays in the commencement or increases in the duration of surgery sometimes occur (e.g., possible placenta accreta, history of multiple abdominal surgeries, high index of suspicion for cesarean hysterectomy). The

CSE placement technique is discussed in [Chapter 121](#). Local anesthetic can be given through the epidural catheter if the duration of surgery exceeds that of the initial spinal.

General anesthesia

The mortality and morbidity associated with general anesthesia for CD disfavor its use. It is important to remember that pregnant patients have a 4 to 5 times higher risk of a failed intubation or pulmonary aspiration of gastric contents than does the general population. The speed of the surgeon is important, as skin incision to delivery times greater than 8 minutes or uterine incision to delivery times greater than 3 minutes are associated with greater fetal morbidity and mortality. In a case of failed intubation and in the absence of fetal distress, the patient could be awakened for a fiber-optic intubation or a regional anesthesia technique. If surgery is to be continued, however, the patient could be mask ventilated, a laryngeal mask airway (LMA) could be inserted, or an intubating LMA could be used for airway management. Conduct of general anesthesia is described in [Table 122.5](#).

After the surgical drapes have been applied and the operating personnel are ready at the bedside, the surgeon should be instructed to hold the initial incision until the anesthesia provider secures the correct placement of the endotracheal tube and gives a verbal confirmation to proceed with the operation. A rapid-sequence induction with full cricoid pressure after induction with thiopental at 3 to 5 mg/kg and succinylcholine at 1 to 2 mg/kg is performed. Ketamine at 1 to 1.5 mg/kg or etomidate at 0.2 to 0.3 mg/kg should be substituted for thiopental if hemodynamic instability is present prior to induction. It should be remembered that muscle relaxants do not cross the placenta and, therefore, do not affect the fetus. Oxygen (100% if fetal compromise) or in a 50% mixture with nitrous oxide and a volatile anesthetic as necessary should be provided until delivery. Upon delivery, nitrous oxide can be initiated or its concentration increased to 70%. The concentration of the volatile anesthetic, which causes uterine relaxation, should be reduced after delivery to limit its effect on uterine tone.

Table 122.5. Conduct of general anesthesia

Aspiration prophylaxis	Sodium citrate: 30 ml, within 30 min of induction, if possible Metoclopramide: 10 mg IV, preferably 30 min prior to induction; avoid rapid IV push
Position	Supine with left uterine displacement
Preoxygenation	3 min/4–8 deep breaths of 100% oxygen
Induction	Rapid-sequence with cricoid pressure, thiopental 3–5 mg/kg, succinylcholine at 1–2 mg/kg
Incision	If emergent CD as soon as patient is intubated
Intubation	Usually a smaller size endotracheal tube (6- to 6.5-mm diameter), orogastric tube
Maintenance	Oxygen, inhalational agent (low concentration), muscle relaxant
After baby is delivered	Antibiotics, oxytocin, opioids
Reversal of muscle paralysis	Neostigmine and glycopyrrolate
Extubation	Awake

Postoperative recovery

Postoperative recovery includes following the resolution of neuraxial block or recovery from general anesthesia and treating complications or patient concerns.

Pain management

Over the past three decades, the greater efficacy of epidural and spinal opioids for postsurgical analgesia has prompted a shift from a systemic (IV or IM) to a neuraxial route of administration. Morphine has emerged as the leading agent for post-CD analgesia, due to its long duration of action and low cost. Morphine administered intrathecally (0.2–0.3 mg) or epidurally (2–3 mg) appears to provide optimal post-CD pain relief with limited side effects. Due to a low lipid solubility, the peak analgesic effects of morphine are delayed (60–90 minutes), but provide reliable analgesia for up to 24 hours.

The local anesthetic selected for epidural anesthesia may influence the efficacy of epidural morphine. Parturients who received 2-chloroprocaine (a short-acting, rapid-onset local anesthetic used primarily for emergent CD) versus other local anesthetic agents appear to demonstrate significantly shortened duration of epidural morphine analgesia, in some cases to less than 3 hours. Because post-CD pain includes both somatic pain, which can be relieved by local anesthetics and opioids, and visceral pain, which can be more difficult to treat, a multimodal approach to pain relief, include nonsteroidal anti-inflammatory drugs (NSAIDs), such as ketorolac (15–30 mg IV), has been suggested.

Management of anesthetic complications

For a more detailed list of complications of obstetric regional anesthesia, please refer to [Chapter 121](#).

Inadequate neuraxial anesthesia

Approximately 4% to 13% of epidural anesthesia techniques and 0.5% to 4% of spinal anesthesia techniques fail to provide a sufficient anesthetic block for the initiation or completion of the surgical procedure. Epidural techniques are more likely to be associated with failure, given their often earlier placement during labor and the ability of the catheter to migrate out of the epidural space. Factors that may correlate with failed in-situ labor epidural catheter for CD include an increased number of bolus doses for the provision of labor analgesia, patient characteristics (body mass index [BMI], distance from skin to epidural space), initial type of technique used (CSE vs. epidural), and the time elapsed from the initial placement to the CD.

A failed block can be defined as insufficient in height, density, or duration after an appropriate dose of local anesthetic to provide anesthesia for a CD. Steps to reduce a failed block include being meticulous in the technical aspects of the original placement attempt, using solutions consisting of local anesthetics with opioids, and better understanding the characteristics

of an epidural versus spinal blockade. Moreover, the patient should be prepared to expect the sensation of deep pressure and movement, yet be reassured that reports of discomfort or pain will be addressed. Shoulder pain can originate from irritation of the diaphragm or prolonged extension of the arms and is mediated by the phrenic nerve (C3–C5). Additional discomfort can occur from visceral stimulation, such as uterine manipulation, which often involves the greater splanchnic nerve (T5–T10). Also, inadequate anesthesia can result from regression of the block from a cephalad or caudad direction.

If an inadequate, partial block exists in an elective situation prior to incision, either (1) the operative procedure can be postponed to allow resolution of the block, or (2) a repeat neuraxial technique may be performed. After a failed, but partial, epidural or spinal technique, the use (and amount of drug to be used) of a spinal technique is controversial. In this setting, a repeat spinal with more than 10 mg of bupivacaine has been observed to result in a high spinal block. Possible approaches to this problem include reducing the dose of anesthetic, using a semi-sitting (Fowler's) position to limit the cephalad spread of the local anesthetic, employing the CSE technique with a small intrathecal dose and titrating the level with drugs administered through the epidural catheter, or placing an epidural catheter intentionally into the dural sac for use as a continuous spinal catheter.

If the surgery has already commenced and the discomfort is reported, asking the surgeons to temporarily halt surgical manipulation while an assessment is made can be helpful. Low-dose IV opioid (e.g., fentanyl at 1–2 mcg/kg or alfentanil at 5–10 mcg/kg) or nitrous oxide inhalation (50% in oxygen) and anxiolysis (1–3 mg of midazolam) may be helpful. If a neuraxial catheter is in place, additional local anesthetics with opioids should be added. Severe pain may require IV ketamine in 5- to 10-mg increments, with the understanding that significant sedation, loss of consciousness, and psychomimetic and amnesic effects may occur. The obstetrician can use a local anesthetic to infiltrate the wound or instill it intraperitoneally; however, often at this point, the induction of general anesthesia with endotracheal intubation should be considered.

High spinal

It is not uncommon for the parturient to report mild dyspnea or reduced ability to cough, especially if the neuraxial blockade has achieved a T2 level. If impaired swallowing or phonation, unconsciousness, respiratory depression, or significant impairment of ventilation occurs, a conversion to a general anesthetic should be performed. High neuraxial blockade may also result in cardiovascular sequelae, including bradycardia and hypotension. High neuraxial block can be caused by several mechanisms, including an exaggerated spread of spinal drugs or an unintentional dural or subdural puncture with administration of epidural drugs. Although the use of lower doses of local anesthetics has been proposed for patients less than 5 feet tall,

patient variability may or may not allow a reduced dose to work with sufficient duration, or be entirely predictable in terms of the cephalad spread.

Hypotension

The incidence of hypotension, defined as a 20% to 30% decrease from the baseline systolic blood pressure or a systolic blood pressure \leq 100 mm Hg, ranges from 30% to 100% following spinal anesthesia in parturients undergoing CD. A lower incidence of hypotension (5%–63%) has been observed following the use of epidural anesthesia for CD, most likely due to the slower onset of sympathetic blockade and the ability to titrate intravenous fluids and vasopressors during this period.

When severe and sustained, maternal hypotension can lead to an impairment of uterine and intervillous blood flow, and can ultimately result in fetal hypoxia, acidosis, and/or neonatal depression. Moreover, hypovolemia can alter maternal well-being (i.e., mental status changes, nausea). The optimization of maternal perfusion should be a primary goal of fluid and vasopressor management throughout the perioperative period.

The frequency of hypotension can be reduced with the use of left uterine displacement and possibly by fluid administration. If hypotension ensues, however, the prompt selection and use of a vasopressor and supplemental oxygen is essential. In the absence of cardiac compromise or conditions that promote capillary leak (i.e., preeclampsia, sepsis), the administration of crystalloid at 10 to 20 ml/kg (approximately 500–1000 ml) within 15 minutes prior to anesthesia is customary. The ability of this maneuver to decrease the incidence of hypotension, however, remains doubtful. The higher cost and possibility of allergic reaction or other side effects of colloids make them less popular. The initiation of anesthesia, in any case, should not be delayed to administer a fixed or arbitrary volume of IV fluid, particularly in urgent or emergent cases. Hypovolemia may also be the result of uterine bleeding, which will continue until surgical correction.

Ephedrine, a mixed α - and β -adrenergic agent, is the most common vasopressor used to treat hypotension, causing less vasoconstriction and uteroplacental blood flow than other agents. Alternatively, phenylephrine (α -adrenergic agent) can also be used for the prevention and treatment of maternal hypotension. Definitive clinical data supporting the use of a single agent, either ephedrine or phenylephrine, are lacking. The restoration of maternal normotension is an important goal, and the best strategy is a proactive response based on the clinical situation. If hypotension is associated with low (<60 bpm) maternal heart rate, ephedrine is indicated; if associated with a relatively high (>80 bpm) heart rate, phenylephrine is indicated. Moreover, if one agent is ineffective, the other should be used. Epinephrine is the agent of choice to treat severe hypotension and bradycardia.

Nausea and vomiting

The incidence associated with CD is variable but as high as 80%, depending on the preexisting symptoms, the anesthetic and obstetric techniques, and the preventative and therapeutic measures taken. Correction of hypotension is an important early step. Nausea may be best prevented by controlling hypotension, optimizing the use of neuraxial and IV opioids, improving the quality of the block, minimizing the surgical stimuli, and judiciously administering the uterotonic agents. Further treatment of nausea and vomiting mirrors that in nonobstetric surgery.

Pruritus and shivering

Although pruritus following neuraxial blockade has a number of postulated mechanisms and treatments, a direct antagonist or partial antagonist, such as IV nalbuphine 5 mg, appears to have a greater effect than some other modalities. Alternately, a dilute infusion of naloxone may be given IV for severe cases. Intra- and postoperative shivering may also have several etiologies and treatments. IV meperidine (12.5–25 mg), clonidine (150 mcg), doxapram (100 mg), ketanserin (10 mg), and alfentanil (250 mcg) have all been demonstrated to be effective, although meperidine appears to be the most consistently effective and popular.

Obstetric hemorrhage

Cosmin Gauran and Lisa R. Leffert

Obstetric hemorrhage is an important cause of maternal and fetal morbidity and mortality. In Western Europe and the United States, it is the second leading cause of maternal mortality after pulmonary thromboembolism. During pregnancy, uterine blood flow increases from a baseline level of 50 to 100 ml/min to 500 to 800 ml/min at term. Whereas uterine blood flow represents less than 5% of cardiac output before pregnancy, it constitutes roughly 12% of cardiac output at term. As such, obstetric hemorrhage can lead to rapid maternal exsanguination. In addition, the resulting hypotension or disruption of the uteroplacental unit can lead to severe fetal hypoxia with high associated morbidity and mortality.

Antepartum hemorrhage

Placenta previa

Placenta previa is a relatively common condition occurring in 1/200 of pregnancies. It is defined as the implantation of the placenta in advance of the fetal presenting part, often involving partial or complete obstruction of the cervical os. Previa is classified by the degree to which the placenta covers the cervical os (Fig. 123.1): It is “complete” when the os is entirely covered, “partial” when a portion of the os is covered, and “marginal” when the placenta is adjunct to the os. Patients with placenta previa typically present with painless vaginal bleeding in the second or third trimester. Risk factors for placenta previa include multiparity and prior placenta previa and uterine surgery. The diagnosis is usually made by ultrasound examination.

Obstetric management

In general, placenta previa necessitates a cesarean delivery. If the placenta is low lying, with the border more than 2 cm from the cervical rim, then vaginal delivery is often an option. The decision of when to deliver the fetus represents a balance between maximizing fetal gestational age (thus minimizing the fetal morbidity associated with premature delivery) and minimizing maternal bleeding. Patients who are remote from term gestation are typically managed expectantly, with bed rest and occasionally tocolytics, blood transfusion as indicated, and monitoring of fetal well-being. In the event of persistent fetal distress and/or

significant maternal bleeding, prompt cesarean delivery is indicated, regardless of the fetal gestation.

Anesthetic management

As it is not uncommon for patients with placenta previa to present for urgent cesarean delivery, it is crucial that an anesthesia consult, including appropriate airway assessment, is undertaken in a timely fashion. Adequate intravenous (IV) access (usually peripheral, of at least 18G), and an active blood bank sample are indicated. In the case of elective cesarean delivery with a low risk of placenta accreta (see Placenta Accreta section), a regional technique (spinal) is usually preferred. Some practitioners advocate the use of an epidural (or combined spinal–epidural), so that the block can be extended if the surgery is prolonged. Emergent cesarean delivery due to severe fetal distress or maternal instability is best managed by general anesthesia. Etomidate may be indicated for induction if the patient is hypotensive.

Placental abruption

Placental abruption is defined as a premature separation of the placenta prior to delivery. The incidence in the general population is between 3.4 and 7.9 per 1000 pregnancies. This condition is associated with various maternal conditions, such as hypertension, current smoking, cocaine abuse, trauma, premature labor, and prior history of abruption.

The clinical presentation of placental abruption is more variable than that of placenta previa (Table 123.1). Notably, the hemorrhage may be concealed between the uterus and the placenta. In many instances, the accumulated blood serves

Table 123.1. Third-trimester bleeding

Placenta previa	Placental abruption
Painless third-trimester bleeding Bleeding usually obvious	Usually painful, third-trimester bleeding Bleeding can be concealed inside the uterus
Risk factors: multiparity, previous uterine surgery, advanced maternal age	Risk factors: smoking, cocaine use, hypertension

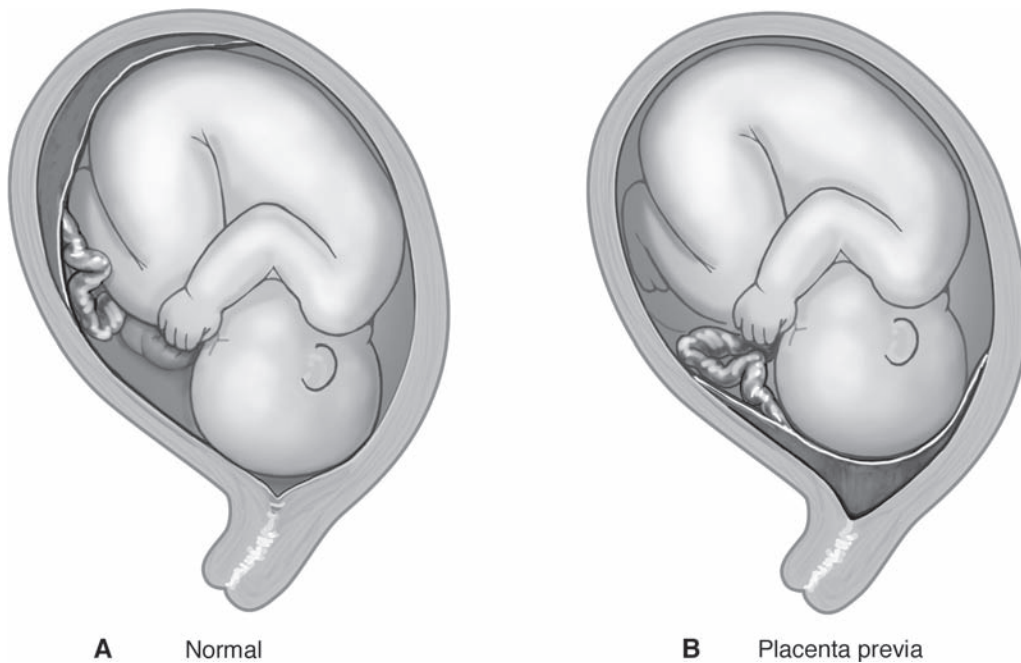

Figure 123.1. (A) Normal placenta; (B) placenta previa.

as a powerful uterine irritant, which in turn leads to uterine contractions and further placental separation. The premature separation of the placenta from the uterine wall can impair placental gas exchange. Depending on the size of the abruption and whether it is acute or chronic, the fetal effects can be minimal or severe, including intrauterine growth restriction (IUGR) or fetal demise.

Obstetric management

The obstetric management of placental abruption depends on the acuity of the presentation and the degree of fetal prematurity. A limited abruption in the premature fetus is usually managed by maternal and fetal monitoring, administration of steroids to the parturient to promote fetal lung maturity, and tocolysis, if needed. Abruption that results in maternal hemodynamic instability or severe fetal distress necessitates expeditious delivery, either cesarean or vaginal (if the patient has been laboring and delivery is imminent).

Anesthetic management

Regional anesthesia is the anesthetic technique of choice if mother and baby are stable. It is important, however, to consider that this patient population has the highest incidence of consumptive coagulopathy among pregnant patients and that routine coagulation tests (prothrombin time [PT], partial thromboplastin time [PTT], platelets) should ideally be checked before regional anesthesia. In the case of a large, acute abruption with fetal distress or maternal hemodynamic instability, general endotracheal anesthesia with a rapid-sequence

induction (RSI) provides for a more expeditious delivery. Invasive monitoring may be needed.

Uterine rupture

Uterine rupture is a relatively rare cause of obstetric hemorrhage, most often occurring during attempted vaginal birth after cesarean delivery (VBAC). Additional risk factors include abdominal trauma, multiparity and multiple gestation, and use of oxytocin for labor induction or augmentation. The typical presentation of catastrophic uterine rupture is sudden and unexplained fetal distress (fetal bradycardia, unexplained tachycardia, or late decelerations). Parturients either (1) may experience abdominal pain that persists between contractions, or (2) be asymptomatic (in some cases). Partial uterine scar dehiscence may occur without significant maternal or fetal consequences. The obstetric management of clinically significant uterine rupture is emergent cesarean delivery.

There is a theoretical concern that a labor epidural will mask the pain of a uterine rupture, thus eliminating an important early warning sign. In clinical practice, however, fetal signs are more reliable, and careful attention to maternal complaint of a sudden increase in character or timing of pain can actually facilitate identification of uterine rupture, even in the presence of labor analgesia. In addition, having an epidural in place that can be quickly dosed for an urgent cesarean delivery may decrease maternal and fetal morbidity associated with an urgent general anesthetic. If there is no epidural in place and/or there is significant fetal or maternal decompensation, then general anesthesia with an RSI is indicated.

Postpartum hemorrhage

Uterine atony

To effect hemostasis after the third stage of labor, the myometrium normally contracts. Uterine atony, the lack of adequate contraction, is the most common cause of postpartum hemorrhage, peripartum blood transfusion, and cesarean hysterectomy. The diagnosis of uterine atony is made clinically in the setting of a soft uterus to palpation and continued hemorrhage after delivery. The degree of blood loss may not be evident as the uterus can conceal a large volume of blood. Risk factors associated with uterine atony include multiparity, multiple gestation, polyhydramnios, prolonged labor requiring oxytocin, and use of tocolytic medications.

Obstetric management

Obstetric management proceeds in a stepwise fashion beginning with medical therapy and uterine massage. If these measures prove unsuccessful, additional options include internal iliac/uterine artery embolization, B-Lynch and other uterine sutures, and hysterectomy in case of hemodynamic instability or refractory bleeding.

The first line of uterotonic therapy is oxytocin, an anti-diuretic hormone (ADH)-related polypeptide. It is most commonly administered as a continuous infusion, titrated to effect. Oxytocin produces peripheral vasodilatation resulting in hypotension, especially if given in concentrated boluses. Hypotension can usually be avoided by careful titration of a dilute concentration (e.g., 20 units in 500–1000 cc of lactated Ringer's [LR]) and timely supportive measures (fluid and ephedrine as needed).

The ergot alkaloids ergonovine and methylergometrine maleate (Methergine; Novartis, East Hanover, NJ) are the second line of uterotonic agents. The mechanism of action for these medications is likely α_1 -receptor stimulation leading to smooth muscle contraction. Either drug is generally given as 0.2 mg, intramuscularly. Rarely, IV administration, in 0.02-mg increments (1/10 dilution) with careful monitoring of maternal blood pressure, is employed. Systemic and pulmonary hypertension can result, making the two drugs relatively contraindicated for patients with hypertensive disorders, such as preeclampsia, or valvular lesions, such as mitral stenosis. Other side effects include an increased incidence of nausea and vomiting and, rarely, coronary vasoconstriction.

The third line of uterotonic agents are prostaglandins E and F. The 15-methyl prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) derivative, carboprost tromethamine (Hemabate; Pfizer, New York, NY), is available for parenteral administration in the United States. It can be given intramuscularly, sometimes directly into the myometrium, in 250- μ g increments every 15 to 30 minutes. The side effects include bronchospasm and pulmonary hypertension, making its use relatively contraindicated in asthmatic patients. Misoprostol (Cytotec; Pfizer) is a prostaglandin E_1 (PGE_1) derivative with uterotonic activity that is typically

administered rectally (800–1000 μ g) or vaginally in this setting. It is a weak bronchodilator, so its use is relatively safe in asthmatic patients.

Anesthetic management

Administration of uterotonics in the operating room (OR) is typically the responsibility of the anesthesia team in concert with the obstetrician. Other care, such as resuscitation and correction of coagulopathy, is supportive. General anesthesia may be required in cases of severe hemodynamic instability; if volatile anesthetics are used, the concentration should be decreased to ≤ 0.5 minimum alveolar concentration (MAC) after the delivery of the fetus, to minimize interference with uterine contraction.

Retained products of conception

Retained products of conception (POC) can cause insidious or pronounced postpartum hemorrhage, with or without accompanying uterine atony. Diagnosis can be facilitated by careful inspection of the placenta to confirm that it is intact. Obstetric management of retained POC includes either manual or surgical (via dilation and evacuation [D&E]) extraction of retained POC followed by a continuous infusion of oxytocin to minimize uterine atony. These maneuvers can usually be accomplished by extending the block of a labor epidural and adding small IV doses of nitroglycerin (50–200 μ g IV or 800 μ g sublingually) for uterine relaxation. Alternatively, spinal anesthesia or small boluses of IV ketamine or opioid analgesia can be used in patients who do not have an epidural. In general, extraction of retained POC is best accomplished in the OR where emergency airway and resuscitation equipment are readily available.

Placenta accreta

Placenta accreta is defined by the absence of the decidua basalis layer between the placenta and the myometrium. Depending on the degree of invasion of the myometrium, it is classified as *placenta accreta* with the involvement of the superficial myometrium, *placenta increta* with deep myometrial penetration without violating the serosa, and *placenta percreta* invading the neighboring organs, notably the bladder. The absence of the decidua basalis makes the placenta adherent to the myometrium and impedes the proper separation during the third stage of the labor. Severe bleeding ensues.

The diagnosis can be difficult to make antepartum, as there may be no suggestive signs other than vaginal bleeding. Ultrasound and MRI examination can raise suspicion for the presence of placenta accreta, but usually cannot definitively confirm or exclude the diagnosis unless there is visible invasion of the bladder or associated structures (as in the case of percreta). There is a suggestion that placenta accreta may be associated with increased levels of maternal serum alpha protein (AFP).

Placenta previa and prior cesarean delivery represent the most common risk factors. Isolated placenta previa is associated

with a 5% risk of accreta, and the risk increases substantially if the patient has had prior cesarean deliveries; the recent increase in the cesarean delivery rate is likely to increase the incidence of placenta accreta.

Obstetric management

Obstetric management of placenta accreta often involves cesarean hysterectomy. To limit intraoperative blood loss, some centers employ uterine or internal iliac arterial balloon catheters with or without preoperative embolization. Whenever feasible, conservative therapy is preferred to preserve fertility. Conservative management, suitable for patients with limited or focal placenta accreta, can involve the use of uterine tonic agents, excision of the involved myometrium, uterine artery ligation or embolization, uterine sutures (e.g., B-Lynch), or medical treatment with methotrexate. Conservatively managed patients are at risk for rebleeding and may require urgent reoperation. Patients with placenta percreta involving other pelvic organs, often the bladder, are typically managed with a cesarean hysterectomy and/or selective arterial embolization.

Anesthetic management

General or regional anesthesia may be employed, even if hysterectomy is required. Irrespective of the anesthetic technique chosen, adequate IV access, typically two large-bore peripheral IVs, should be secured. Contact with the blood bank to ensure ready availability of blood products should be undertaken. Baseline hemoglobin/hematocrit (Hb/Hct) and platelet count should be determined and followed, along with coagulation status, during and after surgery. In more complex cases, an arterial line for blood pressure monitoring and laboratory samples should be considered, as should central venous access for central venous pressure (CVP) monitoring, volume replacement, and vasopressors.

Uterine inversion

Uterine inversion is a rare complication of vaginal delivery, usually in the context of excessive traction on the umbilical cord during the third stage of labor. It can lead to severe hemorrhage and vagally mediated bradycardia and hypotension, if the uterus is not reduced to its anatomic position in a timely fashion. Brief uterine relaxation and pain control are required and can be accomplished with a 50- to 200- μ g IV nitroglycerin bolus, IV fentanyl, or use of an existing epidural. Alternatively,

general anesthesia can be induced with rapid-sequence intubation. An oxytocin infusion is typically employed after the uterus is reduced, to prevent persistent uterine atony and to help maintain the uterus in the proper anatomic position.

Genital laceration

Laceration of the genital tract can be encountered after vaginal delivery and may require immediate attention. If an epidural was used for labor, then the block can be augmented for perineal repair. If no regional anesthetic is in place and the lesions are not amenable to repair under local anesthesia, the patient should be taken to the OR and preferentially regional or RSI general anesthesia should be undertaken.

Preeclampsia

Amy J. Ortman and Lisa R. Leffert

In the United States, hypertensive disorders are the second leading cause of maternal mortality, with an estimated rate of 1.5 per 100,000 live births; admissions for hypertensive disorders account for 15% of all antenatal hospitalizations. Hypertensive disorders in pregnancy are a spectrum of diseases that are classified in [Table 124.1](#).

Preeclampsia

Preeclampsia is diagnosed in 3% to 5% of all pregnancies in the United States and is most common in nulliparous women. A patient meets the criteria for a diagnosis of preeclampsia if she has (1) persistently elevated blood pressures after 20 weeks gestation in the setting of previously normal blood pressures, and (2) proteinuria of greater than 300 mg in 24 hours. Preeclampsia can be mild or severe, based on the presence or absence of specific signs, symptoms, and abnormal laboratory values ([Table 124.2](#)).

Preeclampsia may be associated with eclampsia and hemolysis, elevated liver enzymes and low platelets (HELLP) syndrome. Eclampsia is defined as the occurrence of seizures in a woman with preeclampsia that cannot be attributed to other causes. Eclamptic seizures may occur antepartum, intrapartum, or postpartum. Eclampsia is a cause of significant maternal and fetal morbidity and is present in approximately 50% of maternal deaths associated with preeclampsia.

HELLP syndrome involves a constellation of laboratory abnormalities and is generally regarded as a subset of severe preeclampsia ([Table 124.3](#)). Hypertension, however, may not be present in a substantial portion of patients. The diagnosis of HELLP syndrome is also associated with an increased risk of adverse outcomes including abruption, renal failure, hepatic subcapsular hematoma formation, liver rupture, recurrent preeclampsia, maternal and/or fetal death.

For the fetus, preeclampsia may be associated with growth restriction, preterm delivery, hypoxia, oligohydramnios, neurologic injury, and death.

Etiology and risk factors

Although the precise etiology of preeclampsia remains unknown, it is a disease that occurs only in the presence of placental tissue. The maternal manifestations are consistent with

a process of vasospasm, ischemia, and changes in the normal balance of humoral and autocrine mediators.

An imbalance in placental angiogenic and antiangiogenic growth factors is believed to play a central role in the development of preeclampsia. Recent investigations have revealed that increased levels of soluble fms-like tyrosine kinase-1 (sFlt-1) and reduced levels of both phosphatidylinositol glycan anchor biosynthesis, placental growth factor (PGF), and vascular endothelial growth factor (VEGF) shift the balance toward antiangiogenesis and predate the development of the disease. The increased presence of another antiangiogenic protein-soluble endoglin (sEng) has been shown to correlate with the onset of preeclampsia and in vivo causes increased vascular permeability and hypertension. Preeclampsia is also associated with significant alterations in the immune system, and increased levels of circulating inflammatory cytokines in the maternal circulation and placenta have been found.

The earliest clinical manifestation of preeclampsia occurs with placental implantation when there is attenuated trophoblastic invasion into the uteroplacental spiral arteries. The final common feature in preeclampsia is vascular endothelial damage in the maternal circulation. Endothelial dysfunction is manifested in several ways. There is an imbalance between thromboxane, prostaglandins, endothelin, and nitric oxide, resulting in increased vascular reactivity and vasospasm that leads to hypertension and end-organ dysfunction. Endothelial dysfunction also results in increased vascular permeability and subsequent edema, increased sensitivity to endogenous

Table 124.1. Hypertensive disorders of pregnancy

Gestational hypertension
<i>Transient hypertension of pregnancy without proteinuria, which resolves after delivery</i>
Preeclampsia: mild or severe
<i>A pregnancy-specific syndrome characterized by elevated blood pressure and proteinuria after 20 weeks gestation</i>
Chronic hypertension
<i>Hypertension present before pregnancy, diagnosed before 20 weeks gestation, or diagnosed after 20 weeks gestation that does not resolve by 12 weeks postpartum</i>
Chronic hypertension with superimposed preeclampsia

Table 124.2. Criteria for diagnosis of preeclampsia

Physical findings	Mild preeclampsia	Severe preeclampsia
Blood pressure	>140/90 but <160/110 mm Hg	>160/110 mm Hg
Proteinuria	0.3–5 g in 24-h urine collection, or 1–2+ on urine dip	>5 g in 24-h urine collection, or 3–4+ on urine dip
Additional signs or symptoms	None	Persistent headache Cerebral or visual disturbances Impaired liver function Epigastric or RUQ pain Thrombocytopenia Pulmonary edema or cyanosis Fetal growth restriction (IUGR) Oliguria < 500 ml in 24 h

RUQ, right upper quadrant.

pressors, and the predisposition to hemolysis and thrombocytopenia. Multiple risk factors have been identified and are listed in Table 124.4.

Physiologic changes in preeclampsia

Cardiovascular system

Physiologic changes in preeclampsia are listed in Table 124.5. Preeclamptic patients have a decreased intravascular volume as a result of decreased oncotic pressure, increased vascular permeability, and elevated peripheral vascular resistance; they also exhibit increased sympathetic nervous system activity and increased sensitivity to endogenous and exogenous pressors.

Preeclamptic patients are usually managed empirically, using measures such as urine output and fetal well-being as signs of adequate organ perfusion. In preeclamptic patients with comorbidities such as anuria, pulmonary edema, massive hemorrhage, or underlying cardiac or pulmonary disease, invasive monitoring with particular focus on trends, rather than absolute values, may be useful.

Pulmonary system

Women with preeclampsia may have a predisposition to upper airway obstruction and difficult intubation from diffuse pharyngolaryngeal edema. Also, they are at risk for development of pulmonary edema, likely due to the combination of increased vascular permeability, decreased oncotic pressure, and a redistribution of intravascular volume into the central compartment.

Table 124.3. Criteria for diagnosis of HELLP syndrome

- Hemolysis: abnormal peripheral blood smear – schistocytes and helmet cells from microangiopathic hemolysis; increased total bilirubin > 1.2 mg/dl
- Elevated liver enzymes: AST > 2 times normal; increased lactic dehydrogenase > 600 U/L
- Low Platelets: Platelet count < 100,000 mm³

Table 124.4. Risk factors for the development of preeclampsia

Pregnancy-related	Presence of underlying disorders
Multiple gestation	Chronic hypertension and renal disease
Nulliparity	Obesity
Gestational diabetes	Preexisting diabetes
Hydatidiform mole	Inherited and acquired hypercoagulable states
Structural congenital anomalies	Sickle cell disease
Partner-related	Other
Partner who previously fathered a pregnancy complicated by preeclampsia	Age and the interval between pregnancies
Donor insemination and limited sperm exposure	Family history
	History of preeclampsia in a prior pregnancy

Renal system

Relative to normotensive non-preeclamptic patients, glomerular filtration rate and renal blood flow decrease by approximately 25% in preeclamptic patients. One proposed mechanism for this finding is glomerular enlargement related to endothelial dysfunction. Fractional urate clearance decreases, and, as a result, serum uric acid levels increase – a frequently measured serum marker for preeclampsia. Nonetheless, because of the significant increase in renal function that occurs with pregnancy, serum creatinine levels may not increase above normal pregnancy levels, and renal insufficiency is uncommon.

Central nervous system

A variety of symptoms may be present in preeclamptic patients, including headache, blurred vision, scotomata, and (rarely) cortical blindness. Focal, lateralizing, neurologic signs are uncommon and warrant prompt evaluation. The precise pathophysiology of eclamptic seizures remains unknown although hemorrhage, edema, and hypoxia are possible mechanisms. If eclamptic seizures occur, they should be promptly treated with magnesium sulfate.

Coagulation

Thrombocytopenia associated with severe preeclampsia is the most common coagulation abnormality. Platelet levels <100,000 mm³ signal serious disease; if the pregnancy is maintained, platelet levels may continue to fall and increase maternal morbidity. Antithrombin III levels may be decreased,

Table 124.5. Physiologic changes in preeclampsia

Physiologic change	Normal pregnancy	Preeclampsia
Blood pressure	Decreased or normal	Increased
Cardiac output	Increased	Decreased to increased
PVR	Decreased	Increased
Intravascular volume	Increased	Decreased
CVP and PCWP	Normal	Normal

PVR, pulmonary vascular resistance; CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure.

particularly in the setting of significant proteinuria, signaling more severe disease and putting the patient at risk for thrombotic events. Circulating levels of fibrin degradation products may be elevated, but fibrinogen levels are usually normal unless the situation is complicated by placental abruption.

Placental and fetal compartment

In preeclamptic patients the placenta has increased vascular resistance relative to the low-resistance vascular bed typically found in non-preeclamptic pregnancies. This increased vascular resistance is thought to be a result of the attenuated angiogenesis during placental formation and a predisposition to placental infarction. Thus any decrease in uteroplacental blood flow further compromises a fetus that is already predisposed to development of growth restriction, oligohydramnios, abruption, and decreased fetal reserve.

Obstetric management

All patients in whom the diagnosis of preeclampsia is suspected should be evaluated with serial blood pressures, fetal monitoring, and urine and laboratory studies to establish the diagnosis and ensure maternal and fetal well-being.

Delivery

The definitive treatment for preeclampsia is delivery of the fetus and placenta. The decision of when to deliver is made based on the gestational age and the severity of the disease. In preeclamptic patients at or near term, delivery should be initiated after the diagnosis is made. In the setting of prematurity, however, it may be prudent to prolong the pregnancy in an attempt to minimize neonatal morbidity.

In an effort to minimize maternal complications, vaginal delivery is preferred. Cesarean delivery should be reserved for obstetric indications. Because of compromised uteroplacental blood flow, however, the fetus of a preeclamptic patient may tolerate labor poorly, making this patient at increased risk of operative delivery. Additionally, in an unstable patient with an unfavorable cervix, a prompt elective cesarean delivery may be in the patient's best interest. In summary, each patient and clinical situation should be individualized, with a management strategy that seeks to balance and minimize both maternal and fetal morbidity.

Medical management

Eclamptic seizures are a serious complication of preeclampsia and are associated with significant maternal and fetal morbidity and mortality. Although the mechanism of action is unknown, magnesium sulfate is the medication of choice for prophylactic prevention and treatment of eclamptic seizures. Magnesium is administered during labor, delivery, and for up to 24 to 48 hours postdelivery. The treatment is initiated with a 4- to 6-gm intravenous bolus over a 15- to 30-minute period, followed by an infusion of 2 gm/h.

Due to its relaxant effect on vascular and visceral smooth muscle, magnesium therapy may decrease maternal blood pressure and predispose the patient to postpartum atony and hemorrhage. Magnesium also potentiates the effects of nondepolarizing neuromuscular blockers, and caution should be used when administering nondepolarizing neuromuscular blockers in this patient population. Historically, the data have been mixed regarding the interaction between succinylcholine and magnesium; however, more recent studies have shown no potentiation of the depolarizing neuromuscular blockade.

Antihypertensive medications, such as labetalol, hydralazine, and calcium-channel blockers are frequently administered to preeclamptic patients for control of blood pressure. The goal is not to normalize blood pressure, but to keep patients from progressing to a hypertensive crisis, encephalopathy, or stroke. When administering antihypertensive medications, it is important to remember that the placenta lacks the ability to autoregulate flow, and a sudden decrease in maternal blood pressure may decrease placental perfusion and result in significant compromise to the fetus. Dietary supplements of vitamin D, calcium, selenium, and bed rest (with controlled exercise) may be beneficial in the prevention of preeclamptic complications.

Anesthetic management

Labor analgesia

Neuraxial anesthetic techniques have potential benefits in preeclamptic patients, including the reduction of circulating catecholamines and stress hormones and facilitation of blood pressure control. Diminished maternal respiratory response to pain may also improve oxygen delivery to the fetus. In addition, placement of an epidural catheter in labor helps to facilitate expeditious conversion to an operative delivery. The American Society of Anesthesiologists (ASA) Practice Guidelines for Obstetric Anesthesia recommend that practitioners consider early placement of neuraxial anesthesia in high-risk populations (i.e., severe preeclamptic patients), in an effort to reduce the need for general anesthesia. In this situation, the placement of an epidural may precede labor or the patient's request for analgesia.

For placement of neuraxial anesthesia, the same techniques, procedures, and precautions that are practiced in non-preeclamptic patients should be used. More specifically, preeclamptic patients should be routinely monitored with a noninvasive blood pressure (NIBP) monitor and pulse oximetry. Some institutions also advocate the use of maternal electrocardiography (ECG) in this patient population. Because of concern for hypotension and compromised uteroplacental perfusion, continuous fetal monitoring should be performed during placement of neuraxial anesthesia whenever possible. Finally, preeclamptic patients may not be able to tolerate a sitting position for placement because of side effects of magnesium infusion or hemodynamic lability. In this setting the lateral decubitus position may be used.

After initiation of neuraxial analgesia and the onset of sympathetic blockade, preeclamptic patients are at risk for hypotension and impaired uteroplacental perfusion. Epidural labor analgesia in the preeclamptic patient can be initiated with the same medications used for normal labor analgesia, although some experts advocate elimination of epinephrine in the test dose. Although the risk of hypotension may not be significantly affected by pretreatment with intravenous (IV) fluids in normal pregnancy, fluid loading may be prudent in the setting of preeclampsia, as intravascular volume is decreased.

If hypotension occurs after local anesthetic administration, judicious use of IV fluids and pressors is warranted to restore maternal blood pressures. Initial use of reduced doses of pressors (e.g., 2.5 mg of ephedrine or 20 µg of phenylephrine) is recommended by some authorities due to the clinical impression of enhanced sensitivity to vasopressors.

Cesarean delivery

In a small, randomized trial of general, epidural, or spinal anesthesia for cesarean delivery in women with severe preeclampsia, there were no statistically significant differences between the three groups with regard to hypertension, hypotension, and maternal or fetal outcomes attributable to any of the anesthetic techniques.

General anesthesia offers rapid initiation and is an option in patients with a contraindication to a regional technique, but carries the risk of presence of difficult airway and hypertension that may occur with airway management. In contrast, spinal anesthesia affords an almost equally fast onset and blunts the hemodynamic and neuroendocrine responses to pain and stress, but may be associated with significant hypotension. Epidural anesthesia allows the practitioner to titrate the level of neuraxial blockade while carefully monitoring the hemodynamics. Regional anesthesia is contraindicated in the setting of severe thrombocytopenia and is relatively contraindicated in patients with an altered sensorium.

Management of HELLP syndrome

Patients with HELLP syndrome experience progressive thrombocytopenia, and prompt delivery is indicated, perhaps following a course of glucocorticoids to minimize morbidity to the preterm fetus. Administration of glucocorticoids has also been shown to reduce the severity of laboratory abnormalities, resulting in a dose-dependent improvement in platelet count, possibly increasing the use of regional anesthesia.

Although several studies have reported safe neuraxial anesthetic techniques in patients with thrombocytopenia, there is no evidence to support choosing a single value as the appropriate minimum acceptable platelet count. Because no clear correlation exists between the severity of thrombocytopenia and the likelihood of bleeding complications from neuraxial anesthesia, the decision of whether to proceed is typically made on an individual basis. Most anesthesiologists are comfortable at a platelet count of 100,000, and some with counts as low as 70,000

to 80,000. Factors such as the trend in platelet count in addition to other concerns – such as an anticipated difficult airway – should factor into the decision process.

Placement of a prophylactic epidural before the development of worsening thrombocytopenia is an approach that may be of benefit in this patient population. Lastly, some practitioners report that they feel more comfortable in placing a spinal with a 24G to 26G needle in the setting of thrombocytopenia than in placing an epidural that entails a large-bore needle and an indwelling catheter. Although this seems appropriate, there is no good evidence to support this approach.

Obstetric and anesthetic management of eclampsia

Eclamptic seizures are typically self-limited, last 1 to 10 minutes, and are frequently associated with transient fetal distress. The goals of therapy are supportive care and patient safety. The patient should be given supplemental oxygen, protected from injury, and placed in the lateral decubitus position if possible. Magnesium sulfate therapy should be initiated or increased, and blood pressure controlled. Rarely, thiopental or benzodiazepines will be required to control seizures. Although the diagnosis of eclampsia necessitates prompt delivery, immediate cesarean delivery is usually not indicated as fetal well-being will improve with maternal resuscitation and cessation of seizures. Magnesium sulfate should be continued 24 hours postpartum as prophylaxis against additional eclamptic seizures.

Pregnant patients with comorbid diseases

Anasuya Vasudevan and Stephen D. Pratt

Anesthetic management of the parturient with comorbid diseases requires a multidisciplinary approach involving the obstetrician, obstetric anesthesiologist, neonatologists, and appropriate medical specialists. Obstetricians should be encouraged to send pregnant patients with major comorbidities to be seen by an obstetric anesthesiologist during pregnancy. The obstetric anesthesia provider must understand the normal pregnancy-related physiologic changes in the affected organ system, how these changes might affect the underlying medical condition, how the conduct of anesthesia for delivery or obstetric procedures might be influenced by the condition, and what medical or surgical interventions might be performed to ensure that the underlying medical condition is well-managed during gestation and parturition.

Cardiovascular disease

Depending on the type and severity of the condition, parturients with cardiovascular disease may tolerate the physiologic changes with little problem (e.g., patients with aortic insufficiency) or may face a 60% risk of maternal death (e.g., patients with pulmonary hypertension). Hypertension and valvular lesions are the most common cardiovascular disease processes seen in pregnancy. Much less commonly, pregnant women may present with complex congenital cardiac lesions, cardiomyopathies, acute or chronic ischemic heart disease, or pulmonary hypertension. Up to 13% of women with heart disease will experience a significant complication during pregnancy. Decreased left ventricular systolic function, significant left-sided valvular obstruction, previous cardiac events (congestive heart failure [CHF], dysrhythmia), and New York Heart Association (NYHA) functional status of II or worse are predictors of adverse cardiac outcomes in parturients with valvular disease.

Unless contraindicated, regional anesthesia is frequently a good choice for the laboring patient with cardiac disease, as it blunts the hormonal response to labor pain and can minimize the cardiac stress. The use of invasive hemodynamic monitoring may be appropriate for some patients, especially during cesarean delivery, when shifts in blood volume may be rapid and significant and the effects of anesthesia (general or regional) are more profound. The use of antibiotics to prevent bacterial endo-

carditis should be considered. Recent guidelines recommend that only patients with significant congenital cardiac lesions, a history of endocarditis, or prosthetic cardiac valves should receive prophylaxis during labor and delivery.

Chronic hypertension

Parturients with chronic hypertension generally tolerate pregnancy well, as blood pressure tends to decrease in early gestation. These patients, however, are at increased risk for developing pregnancy-induced hypertension (PIH). They may present with a relative decrease in their intravascular volume, leading to hemodynamic instability during induction of neuraxial or general anesthesia. Long-standing hypertension can be associated with end-organ damage, including renal or cardiac failure. Finally, many medications used to treat hypertension, including the angiotensin-converting enzyme inhibitors, are contraindicated in pregnancy. No specific changes are necessary in the anesthetic management of the parturient with hypertension without other organ system involvement.

Valvular lesions

In general, left heart stenotic valve lesions are poorly tolerated during pregnancy because the fixed valve lesion prevents the pregnancy-associated increase in cardiac output (CO) and increases the likelihood of pulmonary edema. Invasive monitors are sometimes employed for patients with severe mitral stenosis. Conversely, regurgitant lesions are generally well tolerated through gestation and labor, although acute decompensation can occur after delivery. Many patients with stenotic and some regurgitant lesions may be taking anticoagulants, complicating or contraindicating the use of regional anesthesia. The hemodynamic goals for each valve lesion are outlined in [Table 125.1](#) (also see [Chapter 5](#)).

- *Mitral stenosis* is the most common isolated valvular lesion seen in pregnancy, and is the most difficult to manage. The physiologic changes of pregnancy all tend to increase the gradient across the stenotic valve and place the pregnant patient at risk for pulmonary edema. Auto-transfusion following delivery can cause acute decompensation and cardiac failure. Maternal mortality is approximately 1% in

Table 125.1. Optimal cardiovascular physiologic parameters in valvular lesions

	HR	Preload	SVR	Contractility
Mitral stenosis	Avoid tachycardia to allow LV filling; treat atrial fibrillation aggressively (cardioversion)	At risk for pulmonary edema. Keep PCWP ~ 15; avoid hypoxia, hypercarbia, pain (↑ PVR)	Keep normal to high	Normal
Aortic stenosis	Avoid extremes of HR; atrial “kick” necessary for LV filling	High pressures are needed to fill noncompliant LV; risk for pulmonary edema	Keep high to maintain LV perfusion pressure (decrease causes hypotension and possibly cardiac ischemia)	Keep normal to high to maintain CO; low if dynamic subvalvular lesion
Mitral regurgitation	↑ HR (decreases regurgitant flow)	Keep normal to low; LV at risk for volume overload	Low SVR augments forward flow	Normal
Aortic insufficiency	↑ HR (decreases regurgitant fraction)	Keep normal to low; LV at risk for volume overload	Low SVR augments forward flow	Normal

LV, left ventricle; PCWP, pulmonary capillary wedge pressure.

the presence of mitral stenosis (although it is much higher if atrial fibrillation occurs).

- *Aortic stenosis* is less common in pregnancy because lesions that predispose to aortic stenosis generally do not become clinically apparent until after childbearing age. The fixed and reduced aortic valve area prevents these patients from increasing their stroke volume or CO.
- Patients with *regurgitant valvular lesions* generally tolerate well the physiologic changes of pregnancy and the effects of regional anesthesia, because increased preload and heart rate (HR), and decreased afterload, help to augment forward flow in these lesions.
- *Pulmonary hypertension*, either primary or secondary, is uncommon during pregnancy, but, if present, maternal mortality may exceed 60%. The anesthetic goals include: (1) prevention of increases in pulmonary vascular resistance (PVR) related to hypercarbia, hypoxia, acidosis, stress, or pain; and (2) prevention of major hemodynamic perturbations, especially decreases in systemic vascular resistance (SVR) or preload.

Rarely, but with increasing frequency, pregnancy may be complicated by congenital cardiac lesions, cardiomyopathy, primary cardiac rhythm disturbances, ischemic heart disease, or cardiac transplantation. Patients with these processes require an individualized, team approach to ensure that the effects of gestation and parturition can be safely navigated.

Pulmonary disease

Chronic respiratory disease, most commonly asthma, and pregnancy-related respiratory distress are often best managed with regional anesthesia, as it limits the increases in ventilation associated with maternal pain avoids the negative consequences of general anesthesia on the lungs. Some caution must be used in patients with severe obstructive lung disease as a dense spinal or epidural anesthesia impairs intercostal muscle function and decreases expiratory volumes. Patients who depend on these accessory muscles of respiration may not tolerate a high regional block.

Asthma

Effect of pregnancy on asthma

Asthma is the most common pulmonary disease in women of child-bearing age and complicates approximately 1% of pregnancies. The course of asthma during pregnancy is highly variable. It has been reported that asthma symptoms are worse during pregnancy in approximately one third of patients, improve in one third, and remain unchanged in one third. A large percentage of those with severe pre-pregnancy asthma, however, will experience an exacerbation during pregnancy. Multiple pregnancy-related factors may influence the course of asthma, including an increase in the production of prostaglandin $F_{2\alpha}$ (a bronchoconstrictor), decreased cellular immunity leading to increased risk of infection, and the bronchodilating effects of progesterone.

Effect of asthma on pregnancy

With appropriate treatment, asthma does not increase risks to the mother or fetus during pregnancy. Severe or poorly controlled asthma, however, has been associated with many adverse obstetric outcomes, including preterm delivery, small-for-gestational-age birth weights, preeclampsia, cesarean delivery, postpartum hemorrhage, and increased neonatal morbidity. It is safer to treat asthma appropriately during pregnancy than to expose the mother and fetus to the negative effects of hypoxia and hypercarbia that may occur with poorly treated disease. Management of asthma during pregnancy should follow the same principles as for the nonpregnant patient, including identification and treatment of triggers (respiratory infections, allergens, etc.) that may precipitate acute exacerbations, appropriate use of inhaled β_2 -agonists and steroids, and judicious use of oral steroids or theophylline as indicated. Use of oral corticosteroids in the first trimester may increase the risk for preterm delivery or preeclampsia.

Anesthetic implications

Anesthesia management goals regarding the parturient with asthma in labor should focus on reducing maternal hyperventilation and minimizing physiologic stress. Control of the

hyperventilation in response to labor pain is especially important in patients whose asthma is triggered by exercise or stress. Pain relief with neuraxial analgesia is most effective, but systemic opioids or other pain relief techniques, such as pudendal nerve blocks, may also be effective. All asthma medications should be continued throughout labor. Additional concerns during cesarean delivery include the inability to lie flat due to severe disease, respiratory failure due to motor block of accessory muscles of respiration from high regional anesthesia, and life-threatening bronchospasm associated with endotracheal intubation. If general anesthesia is required for cesarean delivery, care must be taken to balance the risk of aspiration against risks associated with bronchospasm from endotracheal intubation. General anesthesia with a laryngeal mask airway (LMA) has been used safely for cesarean delivery in a large series of parturients at low risk for aspiration and might be useful in the parturient with severe reactive airways. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be used with caution for postpartum pain relief in parturients with asthma. Finally, should postpartum hemorrhage occur, 15-methyl prostaglandin F_{2α} and to a lesser extent methyl-ergonovine maleate should be used with caution, as they can precipitate bronchospasm.

Little information exists on other chronic pulmonary diseases and pregnancy. The obstetric anesthesiologist may be asked to help manage parturients with chronic obstructive pulmonary disease, interstitial lung disease, cystic fibrosis, sarcoidosis, and others. A multidisciplinary approach involving obstetricians, anesthesiologists, primary care physicians, and appropriate pulmonary specialists is necessary to adequately care for these patients.

Pregnancy-related pulmonary disease

The parturient is also at risk for acute respiratory failure due to one of many pregnancy-specific disease processes, including pulmonary embolus, amniotic fluid embolus, and pulmonary edema associated with preeclampsia, fluid overload, peripartum cardiomyopathy, sepsis, or massive transfusion after maternal hemorrhage. For each of these disorders, the primary concern is treatment of the underlying disease process. The obstetric anesthesiologist may be required to assist in the management of the pulmonary status until the primary process is stabilized. Management may include aggressive diuresis, bronchodilator therapy, or endotracheal intubation.

Diabetes mellitus

Diabetes mellitus (DM) is a common endocrine disease in pregnancy, complicating approximately 4% of all pregnancies. With optimal glycemic control and multidisciplinary management of the diabetic parturient, the perinatal outcomes are similar to those observed in normal pregnancy.

Effect of pregnancy on DM

Progesterone, human placental lactogen, and cortisol increase during pregnancy and exert an anti-insulin effect. The combination of increased lipolysis, insulin resistance, and ketogenesis renders the diabetic parturient susceptible to metabolic disturbances. Insulin requirements increase during pregnancy and decrease significantly soon after delivery. Diabetic ketoacidosis is more common in pregnancy, particularly in parturients with hyperemesis, infection, steroid therapy (i.e., for fetal lung maturation), or poor medication adherence. Hypoglycemia occurs with increased frequency in the patient with type 1 DM, particularly in the first trimester, probably due to a combination of emesis and reduced calorie intake. The risk of hypoglycemia is higher when tight glycemic control regimes are followed.

Effect of DM on pregnancy

Patients with pregestational DM are at increased risk for gestational hypertensive disorders. Pregestational diabetic nephropathy especially increases the incidence of pregnancy-induced hypertension and intrauterine growth restriction. DM also increases the risk of preterm labor, polyhydramnios, macrosomia, shoulder dystocia, and fetal anomalies. Cesarean delivery is more common in both pregestational and gestational diabetic parturients. Glycosylated hemoglobin has a higher affinity for oxygen, decreasing oxygen transfer to the fetus and increasing the likelihood of fetal asphyxia. Rigorous glycemic control should be instituted from an early gestational age.

Anesthetic implications

Preanesthetic evaluation should include a thorough history, physical examination and laboratory tests focused on identifying end-organ complications related to DM (e.g., neuropathy, nephropathy, retinopathy, gastroparesis, and coronary artery disease). The airway should be carefully assessed, with particular attention paid to the possibility of the stiff joint syndrome involving the cervical spine or temporomandibular joint (TMJ).

The options for pain relief during labor in the diabetic patient are no different from those in the nondiabetic population. Preexisting neuropathy is not a contraindication to neuraxial techniques. In the presence of gastroparesis, it may be prudent to administer a nonparticulate antacid and a prokinetic agent, such as metoclopramide, prior to any anesthetic technique. Severe retinopathy may be a contraindication to maternal pushing during the second stage of labor, and the anesthesiologist may be asked to provide dense epidural anesthesia to prevent maternal expulsive efforts and to facilitate an operative vaginal delivery. Finally, the anesthesiologist must be prepared for an emergent delivery should shoulder dystocia occur.

Regional anesthetic techniques are preferred for cesarean delivery. Preexisting autonomic neuropathy may predispose the diabetic parturient to greater hemodynamic instability after spinal or epidural anesthesia. If general anesthesia is needed,

the possibility of a difficult airway should be anticipated. Equipment for advanced airway intubation techniques, including a fiber-optic bronchoscope, various sized laryngoscopes and LMAs, and transtracheal ventilation equipment, should be readily available.

Rheumatoid arthritis

Rheumatoid arthritis (RA) affects 1% of the population and is more common in women.

Effect of pregnancy on RA and of RA on pregnancy

As with most immune disorders, the symptoms from RA improve over the course of pregnancy.

Corticosteroids and NSAIDs are usually continued during pregnancy. Methotrexate, chlorambucil, and cyclophosphamide are teratogenic and are stopped preconception. Women with vasculitis may have intrauterine growth restriction. The combination of pleural effusion and kyphoscoliosis can cause restrictive lung disease, which can further reduce the respiratory reserve in a gravid RA parturient.

Anesthetic implications

The preanesthetic evaluation should focus on the following physical and laboratory findings:

1. Stability of cervical spine: may be asymptomatic; radiograph of cervical spine may be needed.
2. Mobility of the TMJ: more than 45% of RA patients have TMJ ankylosis, causing limited mouth opening.
3. Assessment for cricoarytenoideus: symptoms include dysphonia, dysphagia, wheezing and sore throat; if suspected, obtain an otolaryngologic consult.
4. Evaluation for micrognathia: juvenile RA may be accompanied by mandibular micrognathia.
5. Lumbar or thoracic kyphoscoliosis.
6. Complete blood count to evaluate for thrombocytopenia and anemia.

Patients with mild disease can be managed the same way as a normal parturient. Management of patients with significant disease and joint involvement will need careful planning. The mode of delivery will depend on the severity of skeletal deformity. In a parturient with severe pelvic deformity, a cesarean delivery may be planned.

If a decision is made to proceed with labor in a parturient with a known difficult airway, placement of an epidural catheter early in labor to provide analgesia is ideal. Regional anesthesia, however, may not be possible in patients with severe skeletal deformities. The obstetric team should be made aware of the challenges of the difficult airway, and a plan should be developed to minimize the likelihood of an emergent delivery.

If a cesarean delivery is planned, any regional technique is appropriate but, again, may be difficult. If general anesthesia is

required in the parturient with cervical spine involvement or with a difficult airway, an awake intubation may be necessary. The neck should be carefully positioned when the patient is still awake, and excessive flexion and/or extension of the cervical spine should be avoided as it can precipitate spinal cord injury. Extremities should be padded and positioned carefully. Extubation should be carried out only when the parturient is awake, alert, and hemodynamically stable.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a chronic inflammatory autoimmune disease characterized by the presence of multiple autoantibodies. SLE is more common in women (especially in women of childbearing age).

Effect of pregnancy on SLE

The incidence of SLE flare during pregnancy is low in women who are in remission. Flares in the postpartum period may occur due to an increase of proinflammatory hormones (e.g., prolactin) and reduction of anti-inflammatory steroids. It remains unclear if the flares are more frequent in pregnancy, as flares and remission characterize the natural course of the disease. The drugs used in the treatment of SLE comprise steroids, azathioprine, mycophenolate, cyclophosphamide, and cyclosporines. Steroids can be administered during pregnancy and breastfeeding, but the rest of the cytotoxic drugs should be avoided, even in the preconceptional stage, as they are teratogenic.

Effect of SLE on pregnancy

SLE increases the incidence of gestational hypertension, infection, DM, preterm labor, low platelet count, and thrombotic episodes. Lupus nephritis is likely to worsen during pregnancy in women who experienced nephritis prior to conception. Patients with SLE may have anti-phospholipid antibodies that can cause thromboembolic events (e.g., cerebrovascular accidents, pulmonary embolism). Thrombocytopenia may be a manifestation of SLE and may be difficult to differentiate from the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome. Neonatal lupus presents as congenital heart block or lupus rash. It is a rare occurrence in SLE pregnancies. Fetal four-chamber echocardiography is recommended at 16 to 28 weeks gestation to evaluate for neonatal lupus. If heart block is found, treating the mother with steroids may be beneficial.

Anesthetic implications

Management of the parturient with SLE includes a careful history and physical examination focused on identifying evidence of end-organ damage (e.g., cardiac tamponade, pericarditis, endocarditis, nephritis). Activated partial thromboplastin time (aPTT) may be increased in patients with antiphospholipid

or lupus anticoagulants. Although the aPTT is prolonged, the antibody has no anticoagulant effect in vivo, and these individuals are at increased risk for thromboembolic events.

The mode of delivery will be determined by the fetal well-being and extent of maternal disease. The incidence of cesarean delivery is higher in the SLE group when compared with normal pregnant women. Regional analgesia can be safely provided for both labor deliveries and cesarean deliveries if the platelet count and the results of coagulation studies are normal. In patients with nephritis, NSAIDs should be avoided as they can precipitate renal failure.

Multiple sclerosis

Multiple sclerosis (MS) generally has a relapsing and remitting course. The common clinical presentations are optic neuritis, diplopia, ataxia, and weakness of the limbs. Physiologic stress, exhaustion, and elevated temperature can all exacerbate the disease.

Effect of pregnancy on MS

Women with MS tend to experience fewer exacerbations during pregnancy (especially in the third trimester), but they are also at an increased risk for exacerbation within the first several months after delivery.

Effect of MS on pregnancy

MS does not have a direct effect on pregnancy or pregnancy-related disease. Patients with bladder involvement may be prone to more urinary tract infections.

Anesthetic implications

Local anesthetics, especially when administered neuraxially, can unmask the symptoms of MS. Even subtherapeutic concentrations of local anesthetics produce a profound conduction block on nerves containing demyelinated plaques, and thus may unmask symptoms. Thus, practitioners may be concerned about performing a regional anesthesia technique for labor or cesarean delivery. Based on the evidence available to date, however, MS by itself is not a contraindication to subarachnoid or epidural anesthesia (and these techniques prevent exposure to the risks of failed intubation associated with general anesthesia). Preexisting neurologic signs and symptoms should be clearly documented.

Hematologic diseases

Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) is characterized by thrombocytopenia due to increased destruction of the platelets caused by anti-platelet antibodies. ITP can be treated by administering corticosteroids, but splenectomy usually is the more definitive treatment. Some patients require plasmapheresis to

remove the autoantibodies. Platelet transfusion may not be effective in maintaining a normal platelet count as the transfused platelets may be destroyed.

Effect of ITP on pregnancy and of pregnancy on ITP

Maternal ITP can cause neonatal ITP, since the antibodies cross the placenta. The fetal thrombocytopenia can lead to severe fetal or neonatal hemorrhage.

Pregnancy does not appear to influence the course of ITP. This time, however, is common to diagnose subclinical disease. Other causes of thrombocytopenia (HELLP syndrome, thrombocytopenia of pregnancy, etc.) must be excluded.

Anesthetic implications

The platelet count above which it is safe to perform a neuraxial anesthetic has not been established. Current literature frequently cites a cutoff of 100,000/mm³. It is clear, however, that many practitioners safely administer regional anesthesia when the platelet count is well below this number. In the parturient with thrombocytopenia and no clinical evidence of abnormal bleeding, the obstetric anesthesiologist must balance the risk of epidural hematoma against the risks of general anesthesia. Thromboelastography may prove to be a useful test to determine the adequacy of maternal clotting.

Von Willebrand disease

Von Willebrand disease (vWD) is the most common autosomal inherited coagulation disorder. Von Willebrand factor (vWF) facilitates coagulation by providing multiple bridging sites between platelets and endothelium. There are multiple types of vWD; type 1 accounts for approximately 85% of cases and is simply a low vWF level.

Effect of vWD on pregnancy

There are no specific effects of vWD on pregnancy. As the disease is inherited in an autosomal dominant pattern, however, there is a 50% chance that the fetus will be affected.

Effect of pregnancy on vWD

vWD may be difficult to diagnose during pregnancy as vWF levels tend to normalize. Patients with severe disease, however, may still present in labor with bleeding abnormalities.

Anesthesia implications

Laboratory diagnosis includes vWF level assay, vWF activity (ristocetin-induced platelet aggregation test), factor VIII level, and a prolonged aPTT. Clinical bleeding is often mild with type 1 disease (but may be significant with types 2 and 3). Treatment includes desmopressin acetate (DDAVP; Sanofi-Aventis U.S., Bridgewater, NJ), cryoprecipitate, and pasteurized, fractionated fresh-frozen plasma (Humate-P; CSL Behring, King of Prussia, PA). Patients with untreated vWD may be at an elevated risk for epidural hematoma. Regional anesthesia can be performed in patients with normal aPTT or in desmopressin-sensitive

patients 30 minutes after administration of the drug. Even if general anesthesia is used, severe perturbations in clotting should be corrected as laryngoscopy can lead to life-threatening bleeding in the airway.

Anesthesia for fetal intervention

Roland Brusseau and Linda A. Bulich

Introduction

The development of successful fetal intervention has introduced the possibility of in utero correction or modification of severe developmental defects that, left untreated, would lead to either preterm demise or severe postpartum morbidity or mortality. Powered by advances in fetal imaging and an improved understanding of fetal intervention, the range of diseases, treatments, and intervention types has grown significantly (Table 126.1).

As experience with fetal intervention has grown, so too has knowledge about fetal anesthesia and analgesia. Anesthesia provision for fetal intervention differs from most other anesthetic situations insofar as the anesthesiologist (or anesthesiologists) must care for two, or possibly more, patients – each with potentially conflicting requirements. The first is the mother who can readily indicate discomfort and can be monitored directly, and to whom drugs may be administered directly and easily. For the fetus (or fetuses), nociception must be assumed or inferred indirectly, monitoring is limited at best, and drug administration is complicated and often indirect. Both fetal and maternal hemodynamic stability must be assured, and a plan to resuscitate the fetus, should problems occur during the procedure, must be developed.

Types of fetal intervention

Fetal interventions may be roughly divided into three categories. Open midgestational (or hysterotomy-based) procedures are generally performed between 18 and 26 weeks and typically involve exteriorization of the fetus (or affected body part) with subsequent replacement in the uterus, allowing further maturation. Such procedures are generally performed on fetuses with well-defined lesions and for whom there is the expectation of preterm demise or significant postpartum morbidity or mortality without intervention.

Ex utero intrapartum therapy (EXIT) procedures, also known as operations on placental support (OOPS), are generally performed on term or near-term fetuses with significant airway obstruction or pulmonary insufficiency. In such cases, surgical intervention is performed with intact uteroplacental function prior to cord clamping. EXIT-to-ECMO (extracorporeal membrane oxygenation) cases similarly depend on intact placental function prior to ECMO cannulation and

initiation. Congenital diaphragmatic hernia (CDH) patients with poor predicted lung volumes are often managed by an EXIT-to-ECMO strategy to avoid unnecessary hypoxemia and pulmonary barotrauma.

Finally, there is an ever-increasing variety of techniques for minimally invasive fetal procedures. Fetoscopic, ultrasound guided, and fetal transesophageal echocardiographically assisted procedures may be undertaken at nearly any gestational age for the ligation or ablation of aberrant fetoplacental vessels, the placement of shunts or plugs, or modification of cardiac anatomy. Such techniques are typically employed in situations in which severe morbidity will result and other therapeutic options (typically medical) have failed.

Maternal anesthetic considerations

For procedures requiring hysterotomy and the maintenance (even if only briefly) of uteroplacental function, general anesthesia is the technique of choice. High concentrations of inhaled anesthetics, typically in the range of 2 times minimum alveolar concentration (MAC), are required to maintain appropriate uterine relaxation for maintenance of fetal perfusion, to optimize fetal exposure, and to provide continuous tocolysis. Such anesthetic depth also assures appropriate fetal anesthesia prior to hysterotomy and intervention. This anesthetic depth, however, may compromise maternal blood pressure, requiring pressor support to maintain maternal blood pressure within 10% of baseline and thus provide appropriate myometrial and placental perfusion for fetal oxygenation. In addition, consideration must be given to the multiple maternal physiologic changes associated with pregnancy that are discussed elsewhere in this volume.

Uteroplacental anesthetic considerations

Uterine and umbilical blood flow, as well as placental barriers to diffusion, govern fetal oxygen delivery. As noted, volatile anesthetics beneficially decrease myometrial tone but also decrease maternal blood pressure, leading to decreased maternal placental blood flow. This diminution of flow has been shown to result in decreased fetal oxygenation and underlies the recommendation to maintain maternal blood pressure within 10% of baseline.

Table 126.1. Diseases eligible for fetal intervention

Disease	Intervention type(s)
CCAM (cystic adenomatoid malformation)	EXIT, EXIT-to-ECMO (if significant airway obstruction)
CDH	EXIT, EXIT-to-ECMO, or minimally invasive (ultrasound or fetoscopically guided tracheal plug placement and removal)
Cervical teratoma	EXIT, EXIT-to-ECMO (if significant airway obstruction)
CHAOS (congenital high airway obstruction syndrome)	EXIT, EXIT-to-ECMO (if significant airway obstruction)
Congenital goiter	EXIT, EXIT-to-ECMO (if significant airway obstruction)
Cystic hygroma	EXIT, EXIT-to-ECMO (if significant airway obstruction or high-output cardiac failure)
HLHS (hypoplastic left heart syndrome)	Minimally invasive (ultrasound-guided percutaneous aortic valve dilatation)
Hydronephrosis and bladder outlet obstruction	Minimally invasive (ultrasound or fetoscopically guided shunt placement)
MMC (myelomeningocele)	EXIT, minimally invasive (fetoscopic patch application)
Pulmonary sequestration, bronchogenic cysts, and mixed or hybrid pulmonary lesions	EXIT
SCT (sacroccygeal teratoma)	EXIT, EXIT-to-ECMO (for high-output cardiac failure)
TRAP (twin reversed arterial perfusion sequence)	Minimally invasive (fetoscopic laser/photoablation of aberrant vasculature)
TTTS (twin–twin transfusion syndrome)	Minimally invasive (fetoscopic laser/photoablation of aberrant vasculature)

Studies in both animals and humans have demonstrated that maternal hypocapnia may also influence fetal oxygenation via umbilical venous flow. Maternal hypocapnia significantly reduces umbilical venous blood flow and has been shown to produce fetal hypoxia and metabolic acidosis. Conversely, maternal hypercapnia and acidosis have been demonstrated to increase umbilical venous flow and increase fetal arterial PO_2 .

Although umbilical venous flow is clearly dependent on intrinsic factors, as above, it is also influenced by extrinsic factors, such as umbilical cord compression or kinking. During open procedures, the loss of amniotic fluid and its impact on fetal and umbilical buoyancy may lead to inadvertent cord compression or kinking and profound fetal hypoxemia. To avoid this complication, amniotic fluid or warmed saline should be continuously infused into the uterine cavity and appropriate volumes should be assured at myometrial closure.

Fetal anesthetic considerations

Fetal dependence on the placenta for oxygenation, gas, drugs, and waste exchange makes maintenance of uteroplacental circulation the highest priority for fetal anesthetic management. As the fetal pulmonary system is essentially offline in utero, enhanced umbilical blood flow is the chief determinant of increased fetal oxygenation. Fetal cardiac output is almost entirely rate-related, making the maintenance of fetal heart rate a similar priority to ensure adequate umbilical blood flow. The disproportionately vagal tone of the fetal nervous system, as well as the immaturity of baroreflex mechanisms, adds a further challenge, as fetal distress, including hypoxemia, will often present as a decreased fetal heart rate. Volatile anesthetics, which function as myocardial depressants and vasodilators, further complicate fetal hemodynamics and oxygen delivery. Indeed, fetal pH is routinely depressed by volatile anesthetics, furthering myocardial depression.

Surgical conditions also threaten the fetus during open repairs. Fetal blood volume is approximately 100 to 110 ml/kg, but given the small size of most intervention patients, even a

small amount of blood loss can lead to severe hemodynamic compromise. Immature fetal hepatic and hematologic function may lead to impaired hemostasis and enhanced surgical losses. Such coagulopathy may be worsened by fetal cooling during open interventions. Great care must be taken to limit fetal heat loss.

Rationale for fetal anesthesia and analgesia

The proliferation of minimally invasive fetal interventions and the apparent lack of a requirement for maternal general anesthetics in such cases has called into question the need for fetal anesthesia and analgesia. In such cases, anesthetized mothers could be considered an anesthetic conduit for the fetus, placing them at unacceptable levels of risk for a questionable fetal benefit. A significant body of evidence, however, has grown to suggest the importance of mitigating the fetal stress response to enhance fetal outcome and possibly limit preterm labor.

It is clear that the fetus is capable of mounting a physiochemical stress response to noxious stimuli as early as 18 weeks gestation. Given the state of current knowledge, it is impossible to know exactly when the fetus first becomes capable of experiencing pain, although most agree that the gestational age range in which this occurs is between 20 and 30 weeks. It so happens that this range coincides with the gestational ages during which most fetal interventions occur. Indeed, the fetal experience of pain may be even greater than that of the term neonate or young child, due to the immaturity of systems of descending inhibition. Descending inhibition is the process whereby ascending nociceptive signals in the ascending spinal neurons are dampened via inhibitory descending neurons of the dorsal horn of the spinal cord. These inhibitory tracts develop late in gestation and are still immature at birth.

For this reason, most practitioners provide fetal anesthesia or analgesia of some sort during both open and minimally invasive procedures. Because access to the fetus is limited in the latter cases, alternative routes of administration are frequently required (Table 126.2).

Table 126.2. Routes for fetal drug delivery

Route	Disadvantages	Notes
Transplacental	Delayed delivery; significantly higher maternal levels required to achieve therapeutic fetal concentrations	Fetal isoflurane levels reach 70% of maternal isoflurane levels in 60 min; most commonly used induction agents rapidly cross the placenta
IM	Variable absorption, bleeding, tissue damage	Fentanyl (20–50 µg/kg) and pancuronium (200 µg/kg) may be given for open procedures and with ultrasound guidance during minimally invasive procedures
IV	Difficult to obtain access, bleeding, vessel thrombosis	Standard neonatal doses may be delivered; blood may be given via this route
Intracardiac	Difficult to establish, may produce arrhythmias, may lead to pericardial effusion and tamponade	Best reserved for emergent resuscitation; dose volumes should be as small as possible, generally between 0.2 and 0.5 ml
Intraamniotic	Experimental; correct dosing currently unknown	Allows for minimally invasive drug delivery; may be useful for sustained delivery of medications

Challenges of fetal monitoring

Fetal monitoring provides another significant challenge for the anesthesiologist. Access to the patient and the presence of amniotic fluid greatly limit available monitoring modalities. In open cases, during which a fetal limb may be exposed, fetal pulse oximetry can serve as a marker of general oxygenation and cardiovascular state (via heart rate). Fetal arterial oxygen saturation (SaO₂), even with a maternal fraction of inspired oxygen content (FiO₂) of 1.0, rarely exceeds 70%, and an intraoperative SaO₂ greater than 40% is generally considered acceptable. Whereas fetal electrocardiography has proven notoriously difficult to reliably obtain and assess, fetal transesophageal echocardiography in both open and minimally invasive procedures may provide information about heart rate, stroke volume, and cardiac function. Surface or transmyometrial echocardiography may also be of use. In situations in which fetal blood may be aspirated, fetal blood gas sampling and analysis may help in the assessment of fetal well-being.

Doppler ultrasonographic measurement of fetal cerebral blood flow, as well as experimental use of near infrared spectroscopy (NIRS), may help to reveal the adequacy of cerebral blood flow and cerebral oxygenation during fetal interventions. Fetuses will preferentially redistribute circulation to the brain and other vital tissues during hypoxemic and generalized fetal distress. These technologies may reveal signs of fetal distress and provide early indications of fetal compensatory failure.

Intrauterine fetal resuscitation

Given the immaturity of fetal organ function, the fetal disposition to cardiovascular instability and collapse, and the multiple stresses of surgery and its associated anesthetics on fetal compensatory mechanisms, a plan for fetal resuscitation must always be prepared in advance (Table 126.3).

Both maternal and fetal factors may contribute to fetal decompensation, and both maternal and fetal interventions may contribute to effective fetal resuscitation. Whether or not uteroplacental insufficiency is implicated, measures should be undertaken to maximize oxygen delivery to the fetus. These maternal measures include left lateral positioning to relieve aortocaval compression, FiO₂ of 1.0 if intubated, or high-flow oxygen administration with a face mask to increase fetal oxygen saturation. A rapid intravenous (IV) fluid infusion, possibly including vasopressor administration, may be employed to improve uterine blood flow. If there is evidence of uterine contraction, efforts must be undertaken to enhance uterine relaxation, including tocolysis if necessary.

Limited access to the fetus with hemodynamic decompensation may complicate resuscitation measures. Hemodynamic compromise may result from hypoxemia, acute fetal hemorrhage or routine surgical bleeding, preexisting fetal cardiac disease and/or anemia, electrolyte abnormalities, hypothermia, and/or other forms of generalized fetal distress. Open procedures lend direct access to the fetus and allow direct cardiac compressions (100–150 compressions per minute),

Table 126.3. Fetal resuscitation interventions

Intervention	Dose	Notes
Atropine	20 µg/kg (minimum dose 0.1 mg)	Useful to counteract significant fetal vagal responses to stress and hypoxemia; useful as prophylaxis prior to intervention
Epinephrine	10–20 µg/kg	May be repeated every 3 min; increasing doses may be of limited benefit
Calcium gluconate	100 mg/kg	Calcium chloride (20 mg/kg) may be substituted
Sodium bicarbonate	1–2 mEq/kg	Of unclear benefit; given acidemia inherent to anesthesia with volatile anesthetics, may be reasonable to enhance efficacy of epinephrine
PRBCs	10–15 ml/kg to achieve an Hb increment of 2–3 g/dl	Generally reserved for acute loss of > 25% estimated blood volume

Hb, hemoglobin.

intravascular (IV) or intramuscular (IM) delivery of routine resuscitation medications (epinephrine, atropine, sodium bicarbonate), and packed red blood cells (PRBCs). When giving PRBCs, consideration should be given to their pH correction to limit excess potassium delivery. Calcium gluconate may be needed to limit citrate-induced hypocalcemia. To assure normothermia and prevent umbilical kinking, the fetus should be continuously bathed in warm fluids.

During minimally invasive procedures, similar medications may be given, but delivery is generally limited to IM or intracardiac administration under ultrasound guidance. Even PRBCs may be delivered via an intracardiac route, but special care must be taken to adjust blood pH and temperature as well as to deliver volume slowly so as not to distend the fetal heart or produce excessively hypoxemic cardiac output. Large pericardial effusions should be drained. If resuscitation fails, maternal transabdominal or transmyometrial compressions may also be considered, although utility may be limited. Consideration should also be given to emergent delivery in viable fetuses, although preparation for such should be a part of preprocedure planning.

Postoperative considerations

Preterm labor poses the greatest risk to the postoperative fetus. Maternal and fetal stress, and hysterotomy in particular, greatly increase the risk of preterm delivery, compromising fetal well-being directly via preterm delivery and limiting the maturational efficacy of the intervention. Maternal prophylaxis with tocolytic agents and aggressive pain control are standard therapy following open interventions. There is some suggestion in an animal model that IV opioid analgesia provided to the mother may inhibit postoperative myometrial contractions. Epidural anesthesia using a low concentration of local anesthetics and a high concentration of opioids may provide effective maternal and fetal analgesia, but the effect on preterm labor is not yet known.

Fetal assessment is more difficult. Fetal heart rate analysis in the immediate postoperative period may be useful for determining fetal distress; echocardiography may also reveal the fetus's general cardiovascular state, and cerebral artery pulsatility indices may further help to assess fetal well-being. The fetal ductus arteriosus should also be monitored for patency and diameter change following indomethacin exposure.

A look to the future

Clearly, with advances in surgical and anesthetic techniques and technologies, significant progress may be made in midgestation fetal intervention. Already there is movement toward expanding treatment to include not only life-threatening fetal pathologies but also preemptive management of fetal disorders that are not necessarily life-threatening but have significant, disabling postpartum morbidities.

The particular challenges for anesthesiologists are to develop methods to provide selective fetal anesthesia and analgesia as well as techniques of targeted uterine relaxation so that safer, specifically tailored anesthetics may be provided to all patients involved in the fetal intervention. Enhanced fetal monitoring will help the anesthesiologist provide better care for the fetus during both the procedure and the postoperative period. With such advances, the provision of fetal anesthesia may become a more routine part of pediatric surgical and anesthetic practice, bringing with it new opportunities for practice and research and new problems to be solved.

Pediatric Anesthesia

Lucinda L. Everett, editor

Basic considerations for pediatric anesthesia

Alina Lazar and Patricia R. Bachiller

Anesthetic care of infants and children requires an understanding of the differences that exist between the adult and pediatric population with respect to anatomy, physiology, and pharmacology. It also requires attention to the unique psychology of the child and family, which has an effect on the conduct of anesthesia.

Anatomy and physiology relevant to pediatric anesthesia

Respiratory

By approximately 24 weeks gestation, the lung has developed primitive gas exchange. Over 26 to 35 weeks of gestation, respiratory epithelial cells begin to form terminal sacs (which will later become mature alveoli), and the cells begin to differentiate and to produce surfactant. Mature alveoli develop beginning at 35 weeks gestation. At birth, children have approximately one sixth of their adult number of alveoli; this helps to explain the sensitivity of premature and newborn lungs to mechanical ventilation and other insults. The majority of alveoli are formed by the age of 2 years, and the adult number is reached by ~8 years. Relative to body size, infant tidal volumes approximate adult values (7–10 ml/kg). Respiratory rate is higher to match the infant's greater oxygen consumption (6 ml/kg/min vs. 3 ml/kg/min in adults) and metabolic rate. (See Table 127.1 for normal pediatric vital signs by age.) The infant chest wall lacks rigidity, and the lung has poorly developed elastic fibers, which leads to less negative intrapleural pressure and predisposes to early airway closure and decreased functional residual capacity (FRC). Compensatory mechanisms are abolished by anesthesia, causing FRC to fall markedly. High compliance of the infant chest wall means that less positive airway pressure is required during mechanical ventilation. The infant's increased alveolar ventilation to FRC ratio and greater oxygen consumption results in faster oxygen desaturation during ventilatory depression. Lung mechanics approach the adult state by 1 year of age.

Rhythmic breathing begins at approximately 30 weeks gestation, and control of breathing matures over the first month of life. *Periodic breathing* (5- to 10-second episodes of apnea without hemoglobin [Hb] desaturation) is common in full-term and especially in premature neonates, up to 12 months of age.

Apnea of prematurity is defined as apnea \geq 20 seconds or a shorter apnea episode (\geq 10 seconds) associated with bradycardia (heart rate $<$ 100) or oxygen desaturation to $<$ 80% to 85%. Apnea is more common in premature infants and in infants with upper respiratory tract infection (URI). See further discussion in Chapter 128.

Cardiovascular

At birth, the fetal circulation changes to the neonatal as pulmonary vascular resistance (PVR) decreases and systemic vascular resistance (SVR) increases. As a series circulation is established through the lungs and body, there is normally functional closure of the foramen ovale and the ductus arteriosus, which will close anatomically over the next few months. The foramen ovale closes anatomically over months to years but remains patent in up to 25% of adults. Hypoxemia, acidosis, or elevated pulmonary pressures can return a neonate's circulation to a fetal-like circulation with shunting. Changes in myocardial function, conduction, and autonomic innervation also occur during the first days and months of life. The cardiac output of neonates is especially dependent on heart rate because the less compliant myocardium limits increases in stroke volume. Neonates have less cardiac reserve than older infants and children because of higher baseline preload, afterload, and decreased contractility. Hypoxemia, acidosis, and large anesthetic doses can profoundly depress the neonatal myocardium. The development of the cardiac conduction

Table 127.1. Normal vital signs in children, by age

Age	Respiratory rate	Heart rate	Systolic blood pressure	Diastolic blood pressure
Preterm	60	140 (90–180)	50	35
Neonate	45–50	140 (90–180)	60	45
6 mo	35–40	120 (80–150)	70	55
1 y	25–30	110 (80–150)	80	65
6 y	20–25	100 (60–110)	90	60
10 y	20	90 (50–90)	100	65
16 y	12–16	80 (50–90)	120	70

Table 127.2. Estimated circulating blood volume

Patient age	Estimated blood volume, ml/kg
Premature neonate	90–100
Full-term neonate	80–90
3–12 mo	75–80
1–6 y	70–75
>6 y	65–70

Modified from Chapter 11, p. 367, of Motoyama EK, Davis PJ (eds.). *Smith's Anesthesia for Infants and Children*. 7th ed. Philadelphia: Mosby Elsevier; 2006.

system is less well studied, but it is worth noting that the premature infant and neonate have shorter refractory periods. Arterial baroreceptors and chemoreceptors are mature at birth, and autonomic–cardiovascular interactions are well developed although they continue to mature over the first 6 months of life.

Hematologic

At birth, the Hb concentration averages 17 g/dl with approximately 80% HbF, which has a higher oxygen affinity than does adult HbA. At birth, levels of 2,3-diphosphoglycerate (2,3-DPG) increase, compensating for this high oxygen affinity to allow oxygen unloading in the tissues. The high PaO₂ after birth reduces erythropoiesis, and Hb decreases to a nadir of approximately 10 to 11 g/dl at 2 to 3 months (7–10 g/dl at age 6 weeks in premature infants). Over the first 6 months of life, the switch to HbA occurs. Coupled with the higher 2,3-DPG levels in infants, the switch to HbA leads to Hb oxygen affinity lower than that of adults (arterial PO₂ at which hemoglobin is 50% saturated with oxygen [P₅₀] of ~30 mm Hg vs. 27 mm Hg in an adult). These factors slowly approach adult levels over the first decade of life, and, because they allow more tissue unloading of oxygen, they may be the reason that children normally have lower Hb levels than adults (11.5–12 g/dl from age 3 months to 2 years, increasing to adult levels by puberty). Estimated blood volumes by age are shown in Table 127.2. The coagulation system matures slowly over the first decade of life. Platelet function improves over the first few days of life. Vitamin K–dependent coagulation factors at birth are ~50% of adult values; a single prophylactic dose of vitamin K is generally given to newborns. Preterm neonates are especially at risk for bleeding.

Neurologic

Neuronal growth and development continue throughout childhood. The sympathetic nervous system matures more slowly than the parasympathetic, leading to exaggerated vagal responses to stimuli, such as airway manipulation or hypoxia, in infants. In animal studies, it has been found that young neurons are more sensitive to therapeutic and toxic effects of local anesthetics. Studies in rodents also show apoptosis of neonatal brain cells after exposure to several types of anesthetics, including ketamine, isoflurane, and midazolam. Other studies in humans show, however, that pain and surgical stress in neonates lead to long-term effects on pain sensitivity,

behavior, and cognition. Current recommendations are to provide appropriate anesthesia in neonates for necessary procedures with care to avoid excessively high doses.

The neonatal brain is less tolerant of extremes. In neonates, the blood–brain barrier is more easily injured by hypoxemia. Premature infants are at risk for intracerebral and intraventricular hemorrhage, which can be triggered by high blood pressure, hypoxia, hypercarbia, anemia, overtransfusion, and rapid administration of hypertonic fluids (e.g., bicarbonate, glucose). Similarly, the premature and neonatal retina is sensitive to high oxygen, and retinopathy can result from oxygen supplementation in infants up to 44 weeks post-conceptual age (PCA).

Renal and hepatic

Nephrogenesis is complete in the term neonate. Renal blood flow and glomerular filtration rate are low at birth and increase to adult levels by 2 years of age. Concentrating and diluting capacity are also low at birth and mature during early childhood. Neonates, especially preterm, are sensitive to fluctuations in fluid and solute loads and are prone to dehydration, hyponatremia (which can lead to cerebral edema), hyperkalemia, hypocalcemia, and hypo- and hyperglycemia.

The fetal and neonatal liver stores glycogen, makes and metabolizes proteins, metabolizes drugs and toxins, and is the site of hematopoiesis (up to 6 weeks of age). Protein synthesis and protein and drug metabolism are decreased in neonates, reaching adult levels by approximately 1 year of age.

Temperature regulation

Infants and young children are more easily cooled or warmed because of increased surface area-to-volume ratio, a thinner subcutaneous fat layer, less keratinized skin, and high minute ventilation. They are thus more susceptible to hypothermia under anesthesia. Nonshivering thermogenesis is the major mechanism of heat production in neonates and is gradually replaced by the more effective shivering thermogenesis by approximately 2 years of age.

Pharmacology

Pharmacokinetic and pharmacodynamic differences between children and adults are most pronounced and clinically significant in infants up to the age of 3 to 6 months. In this population, the volume of distribution is larger, protein binding is reduced, and hepatic metabolism and renal excretion are diminished, whereas the sensitivity to various drugs may be enhanced.

Inhaled anesthetics

The minimum alveolar concentration (MAC) of most volatile anesthetics is greater in infants than in older children and adults, but is lower in term neonates and especially preterm neonates (see Table 127.3). The MACs of sevoflurane for neonate and infant are similar. The MAC of sevoflurane for endotracheal intubation (the inhaled anesthetic concentration

Table 127.3. MAC value (%) and age

	Sevoflurane	Isoflurane	Desflurane	Halothane
Neonate	3.3	1.3–1.7	9.2	0.87
Infant	3.3	1.7	9.4	1.1
Child	2.5	1.6	8.0	0.9
Adult	2.0	1.2	6.0	0.75

Modified from Chapter 11, p. 368, Motoyama EK, Davis PJ (eds.). *Smith's Anesthesia for Infants and Children*. 7th ed. Philadelphia: Mosby Elsevier; 2006.

that would allow intubation with no coughing or movement in 50% of pediatric patients) is 2.8%, and the MAC for extubation is 2.3%. Similarly, the MAC of sevoflurane for laryngeal mask airway (LMA) placement and removal are 2.0% and 1.5%, respectively. In children, nitrous oxide has a blunted effect on the MAC of sevoflurane and desflurane (60% inspired nitrous oxide reduces the MAC by only 25%).

Inhaled anesthetic drugs increase in concentration in the alveoli more rapidly in children than in adults due to a higher minute ventilation-to-FRC ratio and higher blood flow to vessel-rich organs. High concentrations of potent inhalational agents can cause bradycardia, hypotension, or cardiac arrest in infants and young children, particularly when ventilation is controlled. Halothane causes more pronounced bradycardia and is more of a myocardial depressant than is sevoflurane; halothane also sensitizes the myocardium to catecholamines. In addition, the halothane vaporizer allows more MAC-equivalents than does the sevoflurane vaporizer, which may have contributed to the reported cases of halothane overdose.

The lack of pungency of sevoflurane and halothane makes these agents useful for inhalational induction. Induction of anesthesia is slightly shorter with sevoflurane than with halothane due to sevoflurane's lower solubility in blood. The incidence of coughing, breath holding, laryngospasm, and bronchospasm may be slightly lower with sevoflurane. Isoflurane and desflurane are not used for induction due to airway irritation. Emergence agitation, primarily in preschool-age children, may be more common after administration of insoluble anesthetic gases such as sevoflurane and desflurane, although the literature is not conclusive.

Muscle relaxants

The use of succinylcholine in pediatric anesthesia has declined primarily because of life-threatening complications, such as malignant hyperthermia, and hyperkalemic cardiac arrest in children with undiagnosed muscular dystrophy. The administration of succinylcholine is accompanied by varying degrees of masseter muscle rigidity and/or spasm in 1% of children. Mild rigidity may represent a normal response to succinylcholine, especially if underdosed. Fifty percent of patients with severe masseter rigidity test positive for malignant hyperthermia. If definitive masseter spasm occurs, triggering agents should be discontinued and the surgical procedure postponed, unless urgent.

Bradycardia, junctional rhythm, and sinus arrest may be seen after succinylcholine in pediatric patients, but pretreat-

Table 127.4. Intubating doses of neuromuscular blockers in children^a

Drug	Dose, mg/kg	Minutes to intubation	Minutes to recovery, T ₂₅ ^b
Succinylcholine	IV: 2.0 IM: 4.0	<1.0 3.0	3–5 20
Vecuronium	IV: 0.1	2.0	73 (infants) 35 (children) 53 (adults)
Rocuronium	IV: 0.6 IV: 1.2	1.0 0.5	10–30 40–75
Cisatracurium	IV: 0.2	1.5	43 (infants) 36 (children)
Pancuronium	IV: 0.1	2.5	45–60

^a Maintenance doses (one-fourth of the intubating dose) may be given when one twitch is present.

^b T₂₅ is the time from injection to recovery of 25% of baseline neuromuscular transmission or three to four twitches to a train-of-four stimulus.

ment with atropine (0.02 mg/kg) reduces this complication. Fasciculations are often not seen because of the small muscle mass. Succinylcholine may increase intraocular pressure. Despite its drawbacks, succinylcholine remains valuable when immediate securing of the airway is necessary or for treatment of laryngospasm. It may be used for rapid-sequence induction (RSI) in patients with a full stomach; RSI with rocuronium (1.2 mg/kg intravenously [IV]) is also acceptable if succinylcholine is contraindicated. Infants and young children require a larger dose of succinylcholine because of a larger volume of distribution (see Table 127.4), and the duration of action is shorter partly because the drug is more rapidly distributed away from the effector site by a greater cardiac output.

Neonates are more sensitive to nondepolarizing muscle relaxants: Vecuronium, rocuronium, and pancuronium have a lower 95% effective dose (ED₉₅) and a longer time to recovery in infants; cisatracurium has a longer recovery time in infants, but the ED₉₅ is the same as in children or adults. The vagolytic effect of pancuronium prevents bradycardia associated with fentanyl administration for cardiac and other high-risk procedures in infants when a longer duration is appropriate. Nondepolarizing blockade may be reversed with neostigmine (0.07 mg/kg) administered with atropine (0.02 mg/kg) or glycopyrrolate (0.01 mg/kg).

Opioids

Fentanyl is the most commonly used opioid in pediatric anesthesia. Because of its lipid solubility, its brain concentration is not affected by the immaturity of the blood–brain barrier, but neonates metabolize fentanyl more slowly than infants do. The initial dose is typically 1 to 5 µg/kg IV, depending on the duration and magnitude of surgery. High-dose fentanyl (10–50 µg/kg) is sometimes used as the major component of anesthesia for cardiac surgery or in sick neonates to provide cardiovascular stability and to blunt the stress response. Intranasal fentanyl (1–2 µg/kg) may be given for analgesia when an IV is not used, such as in myringotomy. Oral transmucosal fentanyl is formulated for premedication, but its utility is limited by respiratory

depression, nausea and/or vomiting, dysphoria, and oversedation. The initial IV dose of morphine is 0.05 to 0.1 mg/kg. Due to decreased clearance and immaturity of the blood–brain barrier, morphine should be administered with caution in infants less than 1 month of age (0.025–0.05 mg/kg IV). Significant histamine release may follow an IV bolus of morphine. Infants and young children require higher bolus and infusion doses of remifentanyl than do adults, reflecting the larger volume of distribution and increased elimination clearance, respectively. Bolus doses of 1 to 2 $\mu\text{g}/\text{kg}$ administered over several minutes are followed by an infusion dose of 0.1 to 0.5 $\mu\text{g}/\text{kg}/\text{min}$ titrated to effect. If remifentanyl is chosen as the major intraoperative opioid, adequate longer-acting opioid must be administered for postoperative analgesia.

Sedatives and hypnotics

Thiopental may be used for IV induction in pediatric anesthesia as its injection into small veins is painless. Due to a higher volume of distribution, the induction dose is higher in infants and young children than in adults (5–7 mg/kg). Neonates require a lower dose (3–4 mg/kg), reflecting a higher free fraction of the drug. The elimination half-time (6 ± 3 hours) is significantly shorter than in adults (12 ± 6 hours). Propofol is used for induction in doses of 3 to 5 mg/kg for infants and 1.5 to 2.5 mg/kg for older children. Maintenance doses are also larger in children because of greater elimination clearance. Infusion doses of 150 to 250 $\mu\text{g}/\text{kg}/\text{min}$ preserve spontaneous ventilation and can be used for nonpainful procedures that require immobility (CT, MRI). When used for general anesthesia in conjunction with opioids or other agents, ventilatory assistance may be required. Long-term infusions (>12 hours) in the intensive care unit (ICU) setting have been associated with metabolic acidosis, myocardial failure, and death. Propofol produces more suppression of pharyngeal and laryngeal reflexes than an equipotent dose of thiopental. Etomidate (0.2–0.4 mg/kg) may be used for induction in cases of severe hypovolemia or decreased cardiovascular function. The potential for adrenal suppression should be noted.

Ketamine is used in pediatric anesthesia as intramuscular (IM) premedication for extremely uncooperative patients, as oral premedication, for brief sedation for painful procedures, or as an adjunctive intraoperative analgesic. It may also be used for induction in patients with a difficult airway, severe bronchospasm, or marginal cardiovascular status as respiration and blood pressure are usually preserved. Anesthesia after a single IV dose lasts 5 to 10 minutes and can be maintained with repeated doses of 0.5 to 1.0 mg/kg; 0.25 to 0.5 mg/kg IV may be adequate to provide analgesia. Infants <6 months old may require up to fourfold higher doses than older children. For premedication, ketamine is administered in doses of 2 to 3 mg/kg IM, or 4 to 10 mg/kg orally (PO). A small dose of midazolam may prevent distressing nightmares and hallucinations associated with ketamine use. Ketamine increases intracranial pressure for approximately 15 minutes and intraocular pressure

for approximately 30 minutes. Ketamine stimulates salivation and may predispose to laryngospasm; an antisialogogue is often given.

Midazolam is administered for preoperative sedation in doses of 0.5 to 0.7 mg/kg PO, not exceeding a 20-mg total dose, with minimal incidence of respiratory depression. The clinical effect begins at ~ 10 minutes, peaks at 15 to 30 minutes, and dissipates by ~ 45 minutes. It can also be administered intranasally (0.2 mg/kg) with faster onset, or IV (0.05–0.1 mg/kg).

Initial studies suggest that the α_2 -receptor agonists clonidine and dexmedetomidine may have utility in pediatric anesthesia. As premedication, oral clonidine (4 $\mu\text{g}/\text{kg}$) requires approximately 40 minutes until peak effect. IV clonidine (1 to 2 $\mu\text{g}/\text{kg}$) or IV dexmedetomidine (0.1–0.3 $\mu\text{g}/\text{kg}$, slowly over 10 minutes) may augment analgesia and reduce the incidence of emergence agitation. Dexmedetomidine is given by infusion in some centers as a sole agent for pediatric procedural sedation. Clonidine and dexmedetomidine are alternatives to meperidine for treatment of postoperative shivering at doses of 1 and 0.5 $\mu\text{g}/\text{kg}$, respectively, given as a single bolus slowly IV.

Anticholinergic agents are used infrequently with modern anesthetics but may be used to reduce oral secretions or to prevent vagally mediated bradycardia during induction. The doses are (1) atropine IV or IM at 0.02 mg/kg, or (2) glycopyrrrolate IV or IM at 0.01 mg/kg. Potential side effects include temperature elevation, central nervous system (CNS) irritation, and flushing.

Nonopioid analgesics and other adjuvant medications

Acetaminophen is a useful nonopioid analgesic. The oral loading dose is 20–30 mg/kg followed by 10–15 mg/kg every 4 to 8 hours; an initial oral dose may be given in combination with sedative premedication. The rectal loading dose is 30 to 40 mg/kg (20 mg/kg in neonates) followed by 20 mg/kg every 6 to 8 hours. Absorption following rectal administration is variable, with peak concentration reached 1 to 3 hours after administration. Maximum daily doses, which should be followed scrupulously due to the risk of hepatotoxicity, are 100 mg/kg for children > 1 year old, 75 mg/kg for infants (age 1 month to 1 year), 60 mg/kg for neonates > 32 weeks PCA, and 40 mg/kg for preterm neonates ≤ 32 weeks PCA; the dosage interval is longer in neonates due to decreased metabolism. An IV form of acetaminophen was recently approved by the Food and Drug Administration and is given in a dose of 15 mg/kg.

Ketorolac doses of 0.5 mg/kg IV every 6 hours for less than 5 days have been used successfully for postoperative pain control in neonates, infants, and children. Bleeding potential and renal dysfunction are relative contraindications to nonsteroidal anti-inflammatory agents.

Ondansetron (0.05–0.15 mg/kg) and dexamethasone (0.15–0.5 mg/kg, up to a maximum of 10 mg) are often used for prophylaxis during procedures with a high risk of postoperative nausea and vomiting (PONV; ophthalmic surgery, inner ear

surgery, tonsillectomy, or adenoidectomy) or in patients with a history of PONV or motion sickness.

Patient preparation

Preoperative preparation of pediatric patients must take into account their psychological development as well as the family dynamics. The goals of preoperative preparation are to reduce anxiety and stress before induction and minimize behavioral problems that may occur days and weeks after surgery, such as temper tantrums, separation anxiety, enuresis, and sleep and appetite disturbances. Parental anxiety reduction and satisfaction with the perioperative experience are also important.

Many preoperative preparation techniques have been evaluated in the literature. Individualized preoperative interventions, such as seeing a child-life specialist at age-appropriate times before surgery (approximately 1 week for children >6 years old, a shorter time for ages 3–6, and probably no preparation for those <3 years old), are most likely to successfully diminish patient anxiety in the holding area. Listening to music may reduce anxiety in the holding area and possibly during anesthesia induction, especially if live-interaction music is provided by a music therapist. Limiting sensory stimulation (using dim lighting and soft music and interacting with only one person, usually the anesthesiologist) may also alleviate anxiety during induction. Sedative premedication reduces preoperative anxiety and improves cooperation with mask induction in the majority of children.

Reducing parental anxiety can be helpful in calming pediatric patients as anxious parents are less able to respond to their children and may increase the child's anxiety. Informational videotapes and acupuncture for parents have been shown to allay anxiety about anesthesia preoperatively. Being invited to be present for their child's anesthesia induction also increases parental satisfaction with the perioperative experience but has not been shown to reduce parental or patient anxiety (preoperatively or postoperatively) or to change the incidence of postoperative behavioral disturbances in pediatric patients, although it may be beneficial in a subset of child–parent pairs.

Induction

Inhalation induction of anesthesia is the most common choice for pediatric patients in the United States because most children dread needles, and it is practical due to the rapid onset in children. Maintaining spontaneous ventilation during induction allows the patient to self-regulate anesthetic depth and may protect against overdose. When an inhalational induction is inappropriate (full stomach or intestinal obstruction, risk of malignant hyperthermia, acutely elevated intracranial pressure) IV induction is performed. The pain of venipuncture can be reduced by EMLA cream (eutectic mixture of local anesthetics) applied 45 minutes ahead of time or lidocaine delivered via a needleless injection system immediately before IV placement. Sedative premedication or nitrous oxide (70% in oxygen) may also help to facilitate IV placement.

The anesthesiologist should adapt the induction to fit the child's age, temperament, and personality; the family dynamic; and any relevant medical issues. Common methods to calm a child include allowing parental presence during induction, applying a scent to the inside of the mask, and distracting the patient with songs, storytelling, games, jokes, and so forth. Options for inhalation induction range from starting with a pre-filled breathing circuit of 70% nitrous oxide and 8% sevoflurane in oxygen (pungent smelling but rapid-acting) to starting with just 70% nitrous oxide in oxygen for a few minutes, slowly introducing sevoflurane, and increasing the concentration every few breaths (often better tolerated initially but slower).

A larger tongue, smaller oral cavity, and smaller nasal passages predispose children to obstruction after anesthesia is induced. Airway obstruction is managed by applying gentle chin lift and jaw thrust, opening the mouth (ensuring that the tongue is not against the roof of the mouth), obtaining a tight mask fit, and slightly closing the pop-off valve to generate 5 to 10 cm of continuous positive airway pressure (CPAP). One hand should remain on the breathing bag as much of the time as possible to confirm adequate, easy gas exchange. When the patient is sufficiently anesthetized, an oral airway can be inserted if necessary. IM doses of succinylcholine (4 mg/kg) and atropine (0.02 mg/kg) should be readily available in case laryngospasm or bradycardia develops prior to securing IV access. After the patient has passed through the excitatory stage and is more deeply anesthetized, an IV cannula is inserted, the concentration of the agent is decreased, and nitrous oxide is discontinued in preparation for securing the airway.

Securing the airway

Intubation can be facilitated with muscle relaxant, deep inhalational anesthesia, a bolus of propofol, or a short-acting opioid. For all but the shortest cases, endotracheal intubation is usually chosen for infants less than 6 months of age because of potential difficulty in maintaining upper airway patency, decreased FRC with faster oxygen desaturation, and higher likelihood of inflating the stomach during mask ventilation. For some procedures, in children 6 to 12 months or older, maintenance of anesthesia with a mask or LMA is acceptable. Due to the relative cephalad location of the pediatric larynx, adequate positioning of the LMA is more difficult in pediatric patients, and delayed airway obstruction may occur in up to 25% of the patients. Indications for endotracheal intubation are otherwise similar to those in adults.

There are major anatomic differences in the airway anatomy of infants and children that should be taken into consideration for pediatric intubation. Infants have a larger occiput, obviating the need for neck flexion to attain the “sniffing position”; a shoulder roll may allow better ability to extend the head and open the mouth.

The more cephalad larynx (C3–4 in infants vs. C4–5 in adults) and the proximity of the tongue lead to a more acute angle between the plane of the tongue and the plane of the larynx (see Fig. 127.1). The epiglottis is short and omega-shaped

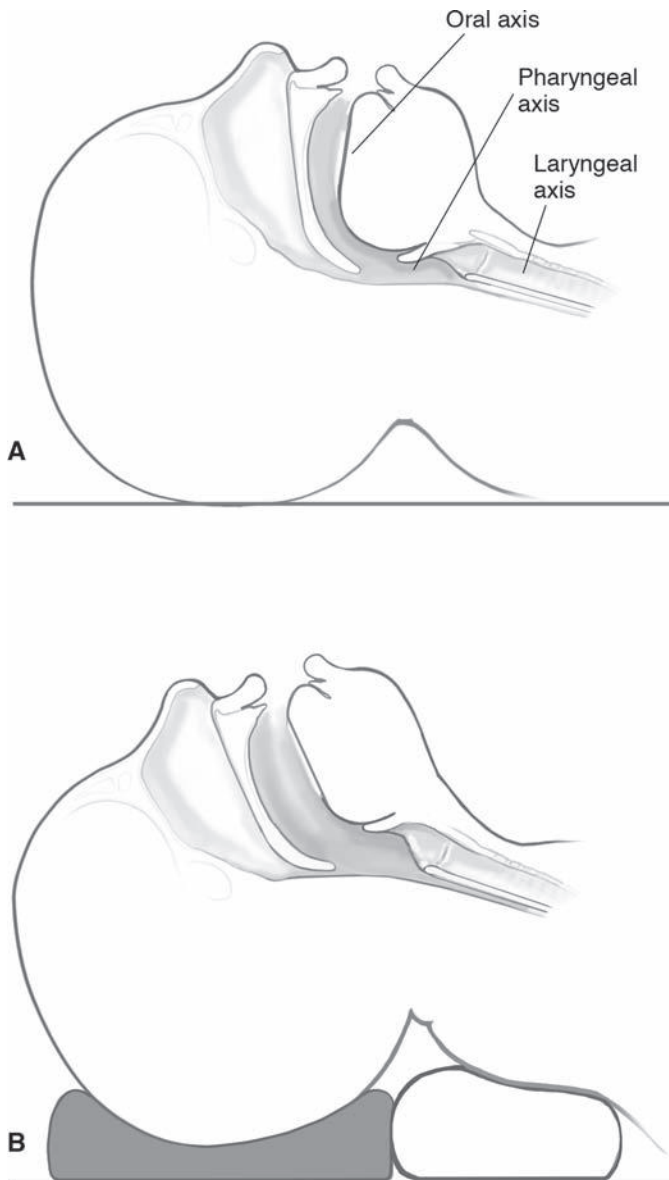

Figure 127.1. (A) The three axes requiring alignment in order to intubate the trachea via direct laryngoscopy. (B) Alignment of the axes with proper positioning.

in the infant and small child, and longer and U-shaped in the older child. It is stiffer, and angled into the lumen of the airway, making it more difficult to displace during laryngoscopy. A straight laryngoscope blade displaces the tongue anteriorly, lifts the epiglottis out of the way, and improves the angle between the tongue and larynx. It may be difficult to lift the epiglottis without its slipping off the laryngoscope blade. If this happens, the blade should be advanced further into the hypopharynx and slowly withdrawn until only the glottis slips off the blade. The infant glottis is shown in Fig. 127.2. The vocal cords have a lower insertion anteriorly than posteriorly, and occasionally the endotracheal tube (ETT) is held up at the anterior commissure. Pushing the tube posteriorly or flexing the head will facilitate

Figure 127.2. Appearance of the infant glottis. Courtesy A. Inglis, MD.

advancement. Excessive laryngoscopic lifting can angle the trachea forward and impede advancement of the tube.

The narrowest part of the infant larynx is the cricoid ring. As the child grows (at approximately 10–12 years of age), the triangle-shaped glottis becomes the narrowest part of the larynx. A small degree of mucosal edema can significantly increase the airway resistance in smaller children. The appropriate ETT size (see Table 127.5) is approximately the diameter of the child's fifth finger or nostril. The modified Cole's formula may also be used for patients > 2 years old:

$$\text{Internal tube diameter (mm)} = \left[\frac{\text{age(years)} + 16}{4} \right].$$

Because there is great variability in tracheal size, ETTs 0.5 mm larger and smaller than predicted should be readily available. A tight ETT may cause trauma, whereas a loose tube may not protect against aspiration or permit adequate ventilation. The pressure at which a leak is audible (auscultating over the neck or mouth) approximates the pressure against the tracheal wall. Because tracheal damage occurs with pressures exceeding capillary pressure (20–25 mm Hg), it is recommended to avoid leak pressures exceeding 30 cm H₂O. The use

Table 127.5. ETT size guidelines for patients less than 2 years old

Age	Weight, kg	ETT ID, mm
Premature	<2	2.5–3.0
Term	3–4	3.0–3.5
0–6 mo	3–5	3.5
6–12 mo	5–10	4.0
1–2 y	10–14	4.5

Table 127.6. Simplified pediatric transfusion guidelines

Component	Indication	Volume to transfuse	Change in parameter expected from transfusion
Packed RBCs	Hb <7–8 g/dl with symptoms Acute blood loss \geq 15% of total blood volume Hb <12 g/dl with severe cardiopulmonary disease (<15 g/dl for neonates and premature infants)	10–15 ml/kg	Hb increase of 2–3 g/dl
Platelets	<10,000 per μ l <50,000 per μ l if active bleeding or major surgery planned <100,000 per μ l with CNS bleeding or planned CNS surgery or in sick, premature infant with active bleeding	5–10 ml/kg	Platelet increase of 50,000–100,000 per μ l
FFP	Emergency reversal of warfarin PT > 1.5 \times midrange of normal value or PTT > 1.5 \times top range of normal value; Replacement for specific factors when their concentrates are unavailable	10–15 ml/kg	Factor activity increase of 15%–20%
Cryoprecipitate	Hypofibrinogenemia or dysfibrinogenemia with active bleeding or invasive procedure; If DDAVP or factor VIII is unavailable; in a patient with von Willebrand disease with active bleeding or invasive procedure	1–2 U per 10 kg of patient weight	Fibrinogen increase of 60–100 mg/dl

PT, prothrombin time; PTT, partial thromboplastin time; FFP, fresh frozen plasma.

Modified from Roseff SD (ed). *Pediatric Transfusion: A Physician's Handbook*. 1st ed. Bethesda, MD: American Association of Blood Banks; 2003.

of oversized tubes is associated with postintubation croup, especially in young children with a URI or a prior history of croup. If, however, the passage of the ETT was without resistance and the procedure is expected to be short, a tight tube may be kept in place, considering the additional tracheal trauma associated with reintubation. Mucosal swelling may be reduced by dexamethasone (0.5 mg/kg).

Traditionally, uncuffed tubes have been used in patients less than 8 years of age, based on the fact that, in this age group, the cricoid ring provides a natural seal around the ETT. The slightly larger lumen obtained by creating a seal with an uncuffed tube was also considered an advantage. The use of cuffed ETTs (internal diameter [ID] 0.5–1.0 mm smaller than that of uncuffed tubes) has been shown to be safe in all ages, and their use has become more popular in recent years to avoid multiple intubation attempts, allow lower fresh gas flows, and decrease operating room pollution. The ability to adjust cuff pressure may decrease the incidence of mucosal trauma compared to sealing with an uncuffed tube, particularly with prolonged intubation. Care must be taken not to inflate the cuff with pressures higher than 20 to 25 mm Hg and to position the cuff in the midtrachea, not straddling the larynx. The pressure of the cuff should be checked periodically, especially when using nitrous oxide.

The ETT insertion distance (measured at the teeth or gums) is roughly equal to the size of the ETT multiplied by 3, but the insertion distance should be confirmed by visually noting, during direct laryngoscopy, the point at which the ETT is 2 to 3 cm past the vocal cords. Some ETTs have black line markings designed to rest at the level of the vocal cords. An easy estimate of the appropriate length of the tube at the gums is 10 cm for a newborn, 11 cm for a 1-year-old, and 12 cm for a 2-year-old. The ETT may be positioned by advancing it until no breath sounds are heard in the left axilla (right mainstem intubation) and then

withdrawing the ETT to 2 cm above the point where bilateral breath sounds are again noted (the carina). In neonates, the distance from carina to vocal cords is only 4 to 5 cm, increasing the risk of accidental extubation and mainstem intubation with neck extension and flexion, respectively.

Fluid management and transfusion

Healthy term neonates and infants can often be managed for routine anesthetics using an hourly maintenance fluid guideline of 4 ml/kg for the first 10 kg, 2 ml/kg for the next 10 kg, and 1 ml/kg for the remainder of the body weight. Glucose supplementation is important in premature or debilitated infants and in term neonates within the first few days of life, and should be considered separately from fluid boluses. Although healthy term neonates and infants have higher glucose requirements than do older children, the stress response to surgery usually increases the serum glucose under anesthesia, and hypoglycemia (glucose < 45 mg/dl) is rare in older children.

Guidelines for intraoperative transfusion are listed in Table 127.6. In general, signs of hemodynamic instability (hypotension, tachycardia), coupled with significant observed blood loss, strongly suggest the need for red-blood-cell transfusion. In procedures during which it is more difficult to measure blood loss accurately, the anesthesiologist must have increased suspicion, especially in neurosurgical, craniofacial, and major orthopedic (e.g., scoliosis) operations.

Maintenance and emergence

Anesthesia is maintained with the same agents used in adult patients. (See Pharmacology section earlier in this chapter). Meticulous care should be taken to maintain fluid and temperature homeostasis and to monitor for accidental extubation or mainstem intubation, ETT kinking or occlusion by secretions,

infiltration of the IV line, and excessive pressure by equipment or the surgical team.

At the end of the procedure, all anesthetics are discontinued, muscle relaxants are reversed, and the stomach is emptied if indicated. Tracheal extubation may take place after the patient is fully awake or during deep anesthesia, depending on the patient and care setting. Before awake tracheal extubation, the child should be able to maintain regular nonparadoxical breathing, demonstrate adequate muscular tone (sustained hip flexion, forceful cough, grimace using the eyebrows) and spontaneously open the eyes or perform purposeful movements. During emergence through the second stage of anesthesia, infants and young children may exhibit breath holding, bronchospasm, and chest wall rigidity or desaturation. Bucking on the tube may lead to postintubation croup if extubation is unnecessarily delayed; however, full return of reflexes and a regular respiratory rate must be sustained prior to extubation. After careful oropharyngeal suctioning, the ETT is removed, the face-mask is applied, and oxygen is administered. If the patient is not moving air, laryngospasm should be suspected and treated with positive pressure and a small dose of succinylcholine if needed (see section below on laryngospasm).

Some anesthesiologists favor deep extubation for patients with severe reactive airways disease and for those in whom severe coughing could jeopardize surgical outcome (e.g., ophthalmic surgery). Adequate depth must be confirmed prior to extubation (e.g., no reaction to movement of the ETT). After removal of the breathing tube, an oral airway is placed to prevent upper airway obstruction and the mask is held for a few minutes to verify ventilation. The patient is placed in the lateral decubitus position to keep the airway clear; it is important to understand that these patients remain at risk for laryngospasm and aspiration until full consciousness is regained.

Compared with adults, children develop more coughing, laryngospasm, and breath-holding during emergence. Therefore, in children, LMAs are often removed during deep anesthesia, followed by insertion of an oral airway as described earlier in this chapter. A small bolus of propofol (1 mg/kg) may also facilitate smooth removal of the LMA while preserving spontaneous respirations.

Pediatric anesthesia risk and complications

Respiratory complications, such as laryngospasm, bronchospasm, or oxygen desaturation, represent the most common intraoperative adverse events (Fig. 127.3). Factors identified as being predictors of respiratory complications are asthma, URIs, passive smoking, younger age, anesthetic care by a nonpediatric anesthesiologist, ENT surgery, and tracheal intubation not facilitated by the use of a muscle relaxant.

Cardiovascular causes, followed by respiratory causes, account for the highest proportion of anesthesia-related cardiac arrests. The most frequent cardiovascular cause seen in cases submitted to the POCA (Pediatric Perioperative Cardiac Arrest) registry between 1998 and 2004 was hypo-

Figure 127.3. Rate of adverse events during anesthesia and in postanesthesia care unit (PACU) in different age groups. Adapted from Murat I, Constant I, Maud'huy H. Perioperative anaesthetic morbidity in children: a database of 24,165 anaesthetics over a 30-month period. *Pediatr Anesth* 2004; 14:158–166 (Fig. 1, p. 161).

volemia related to blood loss (e.g., scoliosis surgery, craniofacial surgery), usually as a result of underestimation of bleeding, insufficient peripheral venous access, and/or inadequate monitoring of hemodynamic parameters. The two second-most-common causes of cardiac arrest were (1) laryngospasm and (2) hyperkalemia resulting from rapid transfusion of old or irradiated blood. Use of fresh red blood cells (RBCs) as well as washing old blood (stored > 2 weeks) and RBCs irradiated more than 48 hours prior to administration reduces the incidence of transfusion-related hyperkalemia. The decline of halothane use in favor of sevoflurane over the past decade has led to a significant reduction in the proportion of medication-related arrests although medications remain the most common cause of anesthesia-related cardiac arrests in ASA 1–2 children.

Laryngospasm

Children are at higher risk than adults are for laryngospasm, and this risk is increased by an ongoing or recent respiratory infection. Laryngospasm represents reflex closure of the glottis triggered during light anesthesia by stimuli such as blood, secretions, or a foreign body in the airway or by other stimuli, such as manipulation of the neck, venipuncture, removal of adhesive tape, and surgical incision. The obstruction can be partial (manifested by inspiratory stridor) or complete (manifested by loss of ventilation and paradoxical movement of the chest). Partial laryngospasm is treated by applying chin lift and jaw thrust, which stretch and widen the partially obstructed airway, ventilating with 100% oxygen, and maintaining moderate CPAP while squeezing the bag synchronously with inspiratory efforts of the patient. Small amounts of propofol (1–2 mg/kg), succinylcholine (0.25–0.3 mg/kg), or a nondepolarizing muscle relaxant may be administered if these maneuvers fail to break laryngospasm. Complete laryngospasm may also resolve with a short trial of CPAP but otherwise requires rapid administration of propofol (IV only) or succinylcholine (IV or IM, if no intravascular access has been obtained). Negative-pressure pulmonary edema may develop after upper airway obstruction.

Pulmonary aspiration

The risk of aspiration in children is low (1–10:10,000) but slightly higher than that in adults, according to several studies. Factors that may make infants and young children more susceptible to regurgitation are a shorter esophagus, lower gastroesophageal sphincter tone, excessive swallowing of air during crying, and a tendency for upper airway obstruction complicated by insufflation of air into the stomach during positive pressure ventilation. There is a higher incidence of aspiration in patients with intestinal obstruction or ileus, higher American Society of Anesthesiologists (ASA) status (3 and 4), emergency surgery, and severe obesity. Pulmonary aspiration may cause bronchospasm, laryngospasm, atelectasis, and chemical pneumonitis; however, clinical effects in healthy patients may be minimal or short-lived. If the patient remains asymptomatic with normal oxygen saturation for at least 4 hours after emerging from anesthesia, it is unlikely that symptoms will appear later. Chest radiography is indicated in the presence of respiratory distress or persistent hypoxemia.

Emergence agitation/delirium

Children ages 2 to 5 years are at the highest risk for emergence agitation/delirium, a state of hyperexcitation that includes disorientation, inconsolable crying and/or screaming, and violent movements (flailing, kicking, rolling). Patients may demonstrate increased sensitivity and reactivity to their environment. The causes are unknown but appear to be related to untreated pain, preoperative anxiety, volatile anesthetics, and patient temperament. This agitation usually appears immediately after emergence but can occur up to 30 minutes afterward. It is self-limited, lasting 5 to 20 minutes (rarely longer).

Certain medications given preoperatively or intraoperatively may help to reduce the incidence of emergence delirium. Ensuring that patients awaken pain-free by using regional anesthesia, opioids, α_2 -receptor agonists, or ketorolac has been associated with less emergence agitation. In several studies, premedication with oral midazolam also reduced emergence delirium without increasing length of stay. Other approaches include premedication with ketamine or melatonin.

The primary goal of treating emergence agitation/delirium is to keep the patient safe from self-injury. Often treatment is best limited to holding the child in a comforting and gentle manner while avoiding stimuli such as noise or bright light. If pain is suspected as a potential cause, a small dose of IV fentanyl (1 $\mu\text{g}/\text{kg}$) can be effective. Bringing a parent to the bedside may help to resolve the agitation. If the agitation/delirium is especially severe or prolonged, it may be treated with sedatives such as midazolam (0.02–0.1 mg/kg), propofol (0.5–1 mg/kg), or dexmedetomidine (0.5 $\mu\text{g}/\text{kg}$), along with careful monitoring.

Pediatric facility requirements and credentialing of providers

Patient care facilities that wish to provide anesthesia for pediatric patients must have a full selection of pediatric equipment

Table 127.7. Pediatric anesthesia equipment and drugs

- Airway equipment for all ages of pediatric patients: ventilation masks, tracheal tubes, oral and nasopharyngeal airways, laryngoscopes with pediatric blades, fiber-optic airway equipment
- A separate, fully stocked “difficult airway cart” containing specialized equipment for management of the difficult pediatric airway
- Positive-pressure ventilation systems appropriate for infants and children
- Devices for the maintenance of normothermia (e.g., warming lamps, circulating warm-air devices, airway humidifiers, and fluid-warming devices)
- IV fluid administration equipment including pediatric volumetric fluid administration devices, intravascular catheters in all pediatric sizes, and devices for intraosseous fluid administration
- Noninvasive monitoring equipment for electrocardiography, measurement of blood pressure, pulse oximetry, and capnography
- Equipment for the measurement of arterial and central venous pressures in infants and small children
- Pediatric resuscitation cart, including pediatric defibrillator paddles
- Resuscitation cardiac drugs in appropriate pediatric concentrations

and drugs (see Table 127.7), laboratory and radiology capabilities, as well as nursing and physician staff with documented competence in the care of these patients. The only exception is an operative procedure required in a life-or-death emergency. Pediatric patients designated as being at increased anesthesia risk (e.g., neonates, patients requiring postoperative intensive care, patients with other coexisting medical conditions) should be under the care of an anesthesiologist with special training in pediatric anesthesia or a provider with documented, demonstrated competence in the care of this population. The general anesthesiologist should be able to provide safe anesthesia for routine pediatric surgery; recognize when the clinical condition of the patient requires skills, facilities, or support beyond the capabilities of the anesthesiologist or institution; and be able to resuscitate neonates, infants, and children. All other health care providers involved in the perioperative care of an infant or child, such as nurses and respiratory therapists, should be trained and experienced in routine and emergent pediatric care.

Preoperative evaluation of the pediatric patient and coexisting diseases

Scott A. LeGrand and Thomas M. Romanelli

The practice of pediatric anesthesia may be particularly challenging because the formulation of an appropriate perioperative technique requires not only a physiologic assessment of the patient and the disease processes that have prompted surgical intervention, but a reasonable understanding of the child's and family's emotional state as well. The increasing frequency of pediatric outpatient procedures may limit the time that an anesthesiologist has to conduct a thorough review of all the issues pertinent to the pediatric patient. This chapter will focus on the psychological and physiologic assessment of the pediatric patient with an emphasis on commonly encountered issues affecting their management. Evaluation of the child with congenital heart disease is detailed in a separate chapter.

Psychological assessment

Many factors will influence how a patient and his or her family respond to the prospect of having anesthesia. These factors include the child's age and medical history, cultural issues, experience with previous anesthetics, and the reasons for which surgery is needed. Anticipating and recognizing these factors may aid in forming a trusting bond with the patient and family and relieving anxiety. It is helpful if information regarding the anesthetic is available in advance through books, pamphlets, videos, and so forth that can provide education without disrupting perioperative flow. It is important to reassure patients and their families, and time should be spent to explain the process from induction to postprocedure care. Children tend to interpret words literally, and it is best to use simple language to explain procedures. Prior to administering any preoperative sedation, discuss with parents its risks and benefits and what they can expect after the medication is given. Encourage the child to hold a comfort object such as a toy, doll, or blanket. Consider allowing the parents to be present for induction of anesthesia (in accordance with hospital policy); calm, well-prepared parents can provide emotional support for the child. The inclusion of child-life specialists, if available, may also smooth the induction period.

Physiologic assessment

Physiologic assessment of a child about to undergo anesthesia begins with a thorough history of present illness, a review of the

indication for surgery and presenting symptoms, and pertinent organ system involvement. Current medications and hyperalimentation (if any) must be recorded, and the patient's NPO status confirmed.

Features of the past medical history that are of particular importance to pediatric patients include gestational age and birth weight, any complications of labor and delivery, the presence of congenital disorders, prior hospitalizations, a history of apneic or bradycardic spells, and previous anesthesia and any side effects. Drug, food, or latex allergies should be documented. Additionally, inquire about sick contacts and an up-to-date immunization schedule. Seek out symptoms of upper respiratory tract infection (URI) and environmental smoke exposure, because both may result in increased airway sensitivity. Ask the parents if the child's physical activity is normal or decreased. Difficulties with feeding in young infants may indicate cardiorespiratory embarrassment. Previously diagnosed cardiopulmonary dysfunction (e.g., known patent foramen ovale, pulmonary hypertension, congenital heart disease, sleep apnea, tracheal stenosis) should be assessed for current severity. Family history is of particular importance in pediatric patients and should include history of malignant hyperthermia (MH), sickle cell, von Willebrand disease, hemophilia, plasma cholinesterase deficiency, muscular dystrophies, and cystic fibrosis.

General assessment of the patient's mental status, level of alertness, and ease of interaction can be made during the preoperative interview. Physical examination in most healthy children may be limited to a cardiopulmonary focus. Airway assessment includes the presence of micrognathia, loose teeth, or obvious caries. Dysmorphic facial features may indicate a congenital syndrome associated with a difficult airway. Signs of respiratory compromise include nasal flaring, nasal discharge, wheezing, stridor, and retractions. Heart murmurs or cyanosis should be noted as these may indicate congenital heart disease. Abdominal distention or emesis may influence management of the airway in addition to indicating possible gastrointestinal disease. Bruising, oozing, or pallor from anemia may be signs of hematologic disease.

Laboratory studies should be ordered based on the presenting illness, anticipated surgery, and postoperative course. Baseline hemoglobin values are useful for surgery with

potential for large blood loss. Coagulation studies are indicated for hemophiliacs or for long surgeries with significant blood volume replacement. Glucose levels should be monitored in newborns due to their higher metabolic rates and limited stores. Pulmonary function tests are useful to quantify the severity of chronic lung disease (e.g., cystic fibrosis). Echocardiogram results should be reviewed in patients with congenital heart disease. Other imaging studies and relevant anatomy should be reviewed based on the presenting complaint.

Coexisting disease in the pediatric patient

Respiratory

Apnea of prematurity

Apnea of prematurity is common among newborns born at less than 34 weeks gestation with its incidence being inversely related to both gestational and postconceptual age. Central apnea is related to central nervous system (CNS) immaturity as well as abnormal responses to hypercapnia and hypoxia. Obstructive apnea may also occur in which uncoordinated upper airway musculature causes cessation of airflow. Apnea of prematurity is often mixed apnea (i.e., a combination of both central and obstructive apnea).

Therapy for apnea of prematurity includes patient positioning to prevent airway obstruction, gentle tactile stimulation to elicit arousal responses in the setting of brief apnea, and respiratory stimulants such as aminophylline, theophylline, or caffeine for chronic therapy or in the perioperative period.

Volatile agents, opioids, and hypnotic drugs used in anesthesia have the potential to worsen apnea as many decrease the ventilatory response to hypercarbia and hypoxia. Central apnea may be exacerbated by hypothermia, hypoglycemia, and anemia. Although they are thought to be associated with a lower risk of apnea than is general anesthesia, regional techniques have also been associated with postoperative apneic spells. Therefore, for newborns less than 60 weeks post-conceptual age who are at risk for apnea of prematurity, outpatient surgery is generally not recommended, and appropriate cardiorespiratory monitoring should be available, regardless of anesthetic technique.

Bronchopulmonary dysplasia

Bronchopulmonary dysplasia (BPD), sometimes referred to as chronic lung disease of the newborn, has changed in its presentation since it was first described in 1967. The diagnosis of BPD is based on the need for oxygen therapy and/or ventilatory support in relation to the infant's developmental age and birth weight. This consensus definition has not yet been universally accepted, however, and the strength of its correlation to long-term pulmonary and neurodevelopmental outcomes remains unclear.

The older form of BPD resulted from aggressive mechanical ventilation and the delivery of high concentrations of oxygen in the premature newborn. The constellation of edema and

Table 128.1. Causes of chronic lung disease and definition of BPD

Causes of chronic lung disease:	
Premature newborns	BPD (old or new)
	Prematurity
	Status after respiratory distress syndrome
Term and near-term newborns	BPD (old)
	Pneumonia or sepsis
	Aspiration syndromes
	Persistent pulmonary hypertension of the newborn
	Pulmonary hypoplasia
	Diaphragmatic hernia
	Congenital heart disease
Current definitions of BPD:	
Diagnosis	Oxygen dependence for at least 28 postnatal days
Grading	at 36 postmenstrual wk for infants born at <32 wk or at 56 d of life for infants born at ≥32 wk
	Mild: $FiO_2 < 0.21$
	Moderate: $FiO_2 0.22-0.29$
	Severe: $FiO_2 \geq 0.30$ or continuous positive airway pressure or mechanical ventilation required

FiO_2 , fraction of inspired oxygen. The definition of BPD was adapted from Jobe and Bancalari; also adapted from Bimkrant DJ, Panitch HB, Benditt JO, et al.

inflammatory processes in the conducting airways resulted in pulmonary fibrosis and emphysematous changes in many of the survivors. These patients developed smooth muscle hypertrophy and pulmonary hypertension with associated right-sided cardiac dysfunction.

The introduction of corticosteroid therapy as well as exogenous surfactant replacement and gentler modes of ventilatory support have advanced the survival of premature, low-birth-weight infants. Surprisingly, the overall incidence of BPD has not changed, but rather a new pattern of lung injury has emerged. This change in pathophysiology has led to the present form of BPD. (See Table 128.1.)

Premature infants younger than 30 weeks gestational age may display evidence of pulmonary developmental arrest. The disruption of parenchymal organization leads to fewer alveoli and a reduced surface area for effective gas exchange. There is also evidence that microvascular angiogenesis is adversely affected. Some recent studies suggest that BPD may be influenced by genetic and environmental factors. The preterm survivors who grow into adulthood may develop chronic respiratory symptoms and pulmonary volumetric abnormalities, but, unlike the prior cohort, tend not to suffer from pulmonary hypertension or fibrosis.

It is important to consider the persistence of pulmonary dysfunction when conducting anesthesia for these patients, especially because BPD represents a spectrum of disease and physiologic embarrassment. A focused history and physical, documenting baseline symptoms and limitations of physical activity, is critical for planning. It is also important to note that airway hyperreactivity is common, and patients are prone to respiratory infections. Preoperative consultation with

pulmonary and intensive care specialists may be useful for those patients with severe BPD.

Supportive care in these patients has focused on limiting barotrauma (e.g., modes that closely regulate mean airway pressures and I:E ratios), techniques and medications that enhance secretion clearance, inhaled corticosteroids, β_2 -agonists, and diuretics. Invasive monitoring for serial blood-gas measurements should be considered, especially for those patients with severe disease. Appropriate postprocedure care, including admission to an intensive care setting, should be considered on an individual basis. Regional anesthesia, whether used as the primary anesthetic or for supplemental postoperative pain control, may be appropriate for selected patients.

Asthma

Asthma results in reversible airway obstruction, inflammation, and increased reactivity to a variety of stimuli. Common symptoms include wheezing, coughing, breathlessness, and chest tightness. With severe cases, however, air movement may be so minimal that wheezing is no longer audible. Airway obstruction causes air trapping and hyperinflation of the lung, and impairs ventilation–perfusion matching. Initially, hyperventilation causes a decreased PaCO₂. With worsening obstruction and fatigue of respiratory muscles, however, PaCO₂ begins to increase. Therefore, a normal PaCO₂ level in a child with a severe asthma attack is an ominous sign. Management of asthma includes supplemental oxygen, inhaled agents (including albuterol and ipratropium bromide), epinephrine, and intravenous steroids.

The history of a child with asthma should include the documentation of asthma triggers; frequency of inhaler use; history of hospitalization, intubation, or pneumothorax; and need for systemic steroids. Asthma medications should be continued until the time of surgery. As endotracheal intubation may cause bronchospasm, adequate depth of anesthesia should be ensured, and bronchodilators should be available for administration intraoperatively. Additionally, if full stomach precautions are not necessary, deep extubation may help to limit bronchospasm.

Upper respiratory tract infection

URIs are extremely common in pediatric patients, with most children having at least six to eight infections per year. The majority of URIs are viral, with rhinovirus being the most common cause. Other infections, such as croup, influenza, and streptococcal pharyngitis, may mimic URI. Additionally, non-infectious etiologies, such as allergic rhinitis, may cause URI-like symptoms. Although URI is typically self-limited, airway hyperreactivity may persist for weeks following infection. Thus, controversy exists as to the timing of surgery for children with current or recent URI. Tait and colleagues examined 1078 children (1 month to 18 years old) who presented for elective surgery, and found that children with a URI within 4 weeks prior to surgery had significantly more episodes of breath holding, oxygen desaturation, and overall adverse respiratory events

than did children without URI, although incidence of laryngospasm and bronchospasm were no different between groups. Risk factors for adverse respiratory events in children with URI included use of an endotracheal tube, history of prematurity, history of reactive airway disease, paternal smoking, surgery involving the airway, presence of copious secretions, and nasal congestion. There were no long-term adverse sequelae for the children with adverse respiratory events. A suggested algorithm for the management of children with URI is presented in Fig. 128.1.

Anesthetic management for children with current or recent URI is aimed at reducing the risk of airway complications. To that end, avoidance of endotracheal intubation in favor of a mask airway or even a laryngeal mask airway (LMA) may be beneficial. If the nature of the surgical procedure necessitates use of an endotracheal tube, sufficient depth of anesthesia should be ensured prior to intubation. If a volatile anesthetic is used for maintenance, it is preferable to use a non-irritating agent, such as sevoflurane or halothane. Deep versus awake extubation may be appropriate depending on the specific patient situation and the experience or preference of the anesthesiologist.

Secondhand smoke exposure

Exposure to secondhand smoke is known to have negative health consequences. Recent studies have shown anesthetic complications to be among these deleterious effects. Jones and colleagues performed a prospective study of a cohort of 405 children who had outpatient procedures performed under mask anesthesia. The children with secondhand smoke exposure were at increased risk for nearly all airway complications examined, including laryngospasm, bronchospasm, hypersecretion, and airway obstruction, both during anesthesia and in the recovery room. For this reason, it is prudent to screen for secondhand smoke exposure in the preoperative evaluation for all children scheduled to undergo general anesthesia.

Sleep apnea

Sleep apnea is discussed in detail in the section on pediatric otolaryngologic procedures. Although this is an obvious component of the preoperative evaluation of the child presenting for tonsillectomy, it is important to remember that children with enlarged tonsils or sleep apnea of other etiologies may present for other types of procedures. History of snoring, disordered sleep, and daytime somnolence are important historic features. Children with sleep apnea may require overnight admission for monitoring and may also exhibit an exaggerated response to opioids.

Cystic fibrosis

Cystic fibrosis is an autosomal recessive disorder seen in the Caucasian population. Typical manifestations of the disease include meconium ileus, inadequate weight gain, protein malabsorption, recurrent pulmonary infections, nasal polyps, and pancreatic insufficiency. Early in the course of cystic fibrosis,

Figure 128.1. Suggested algorithm for the assessment and anesthetic management of the child with a URI. Hx, history; ETT, endotracheal tube. Reproduced with permission from Tait, AR, et al, *Anesth Analg* 2005; 100: 59–65.

Staphylococcus aureus is typically isolated from the respiratory tract; with disease progression, however, *Pseudomonas aeruginosa* becomes more common. Treatment of the disease includes pancreatic enzyme replacement, chest physiotherapy, and treatment of respiratory infections.

Anesthetic management of patients with cystic fibrosis begins preoperatively with an evaluation of the manifestations of disease for the particular patient. Preoperative pulmonary function studies may help to quantify the degree of pulmonary disease and difference from baseline; these results often show an obstructive pattern. Additionally, any pulmonary fibrosis or intraluminal secretions can cause increased alveolar–arterial oxygen tension differences on arterial blood gas analysis. Increased arterial carbon dioxide concentrations may be seen in advanced disease. Liver involvement may lead to impaired synthesis of clotting factors. Other preoperative tests that are useful include a complete blood count, electrolyte analysis, liver function tests, chest radiograph, and sputum culture results.

Intraoperative management is dependent on the severity of the patient's cystic fibrosis and the nature of the surgical procedure. Local anesthetic techniques offer the advantage of maintaining spontaneous respiration but may not be appropriate, depending on the operation and the child's ability to cooperate. If general anesthesia is required, induction may be by inhalational or intravenous routes. Sevoflurane, due to its bronchodilating properties, is probably the best choice for maintenance of anesthesia. Given the risk of pneumothorax in patients with cystic fibrosis, nitrous oxide may be avoided. Intraoperative monitoring should be guided by the severity of disease and the extent of the surgical procedure, but may include an arterial catheter and a central venous line. In the case of pulmonary hypertension and right heart failure, use of a pulmonary artery catheter or transesophageal echocardiography may be considered.

Postoperatively, patients with cystic fibrosis need close monitoring for respiratory compromise. Clearance of secretions is essential, and the use of humidified oxygen or nebulized hypertonic saline is often of benefit.

Neurologic

Seizure disorder

Seizures may result from a variety of pathologies in the pediatric population, including fever, trauma, infection, toxic ingestion, electrolyte disturbance, and hypoglycemia, in addition to idiopathic seizure disorder. They may be partial (limited to a focal region of one cerebral hemisphere) or generalized (involving both hemispheres). Partial seizures are further classified as simple or complex based on impairment of consciousness. Generalized seizures may be convulsive or non-convulsive.

Anesthetic care of patients with seizure disorder should focus on the patient's presenting symptoms and pattern, the pharmacologic treatment regimen, and information regarding

the degree of control that drug therapy provides. Blood levels, if available, should be reviewed as well as any side effects or end-organ effects from the seizure medications. Anti-seizure medications should typically be continued during the perioperative period. Several anesthetic drugs or metabolites may lower the seizure threshold, including the meperidine metabolite normeperidine, and laudanosine, a metabolite of atracurium and cisatracurium. Ketamine and methohexital may also precipitate seizures. Increased doses and shortened dosing intervals of nondepolarizing neuromuscular blockers may be necessary due to enzyme induction from antiseizure medications. In addition, children with refractory seizures may be on a ketogenic diet, in which case dextrose administration is relatively contraindicated.

Muscular dystrophy

Muscular dystrophy refers to a group of progressive muscle disorders that result in differing patterns of muscle weakness. Of the muscular dystrophies, Duchenne muscular dystrophy is the most common, with an incidence of approximately 1 in 3500 male births. This X-linked disorder results in a lack of dystrophin, a muscle cell membrane protein, and causes weakness starting in the proximal muscle groups of the pelvic and shoulder girdles. Symptoms generally occur before the age of five and may include frequent falls, difficulty standing, and gait abnormalities. Progression of the disease leads to these patients becoming wheelchair bound prior to their teenage years. Cardiac involvement is common and may include arrhythmias and dilated, hypertrophic cardiomyopathy. Additionally, musculature of the pulmonary system, including the diaphragm and accessory muscles, may be involved, leading to decreased lung capacity, weakened cough, and hypoventilation.

A recent consensus statement has been published to help guide care for patients with Duchenne muscular dystrophy who are undergoing anesthesia or sedation. Suggestions for preoperative care include evaluations by anesthesiologists, pulmonologists, cardiologists, and nutritionists for the optimization of patient status prior to the procedure. Preoperative pulmonary function testing is also recommended. Discussion with the patient and family should include risks and benefits of anesthesia as well as advance directive planning. Intraoperative suggestions include avoidance of both volatile anesthetics and succinylcholine given the possibility of acute rhabdomyolysis with exposure to these agents. Use of an endotracheal tube, LMA, or noninvasive positive pressure ventilation are all acceptable and should be guided based on the clinical status of the patient and the surgical procedure. Postoperatively, patients with compromised respiratory function, defined as a forced vital capacity (FVC) less than 50%, may be extubated directly to noninvasive positive pressure ventilation. Adequate pain control should be ensured. If analgesics lead to hypoventilation or sedation, extubation may be delayed. Assisted cough, as well as an aggressive bowel regimen, may be necessary postoperatively.

Table 128.2. Representative mitochondrial disorders

Mitochondrial syndromes caused by known mutations
MELAS: mitochondrial encephalopathy with lactic acidosis and stroke-like episodes
MERRF: myoclonic epilepsy with ragged red fibers
LHON: Leber hereditary optic neuropathy
NAPR: Neuropathy, ataxia, and retinitis pigmentosa
Chronic progressive ophthalmoplegia
MNGIE: Mitochondrial neurogastrointestinal encephalomyopathy
Syndromes based on clinical features
Lethal infantile mitochondrial disease
Leigh syndrome
Cardiomyopathy and myopathy
Sengers syndrome (congenital cataracts, hypertrophic cardiomyopathy, mitochondrial myopathy, and lactic acidosis)
Barth syndrome (left ventricular noncompaction, skeletal myopathy, 3-methylglutaconic aciduria, and diminished statural growth)
Nonspecific encephalomyopathy

Summarized from Scaglia F, Towbin J, Craigen W, et al. Clinical spectrum, morbidity, and mortality in 113 pediatric patients with mitochondrial disease. *Pediatrics* 2004; 114:925–931.

Metabolic and genetic disorders

Malignant hyperthermia

MH is a genetic, hypermetabolic disorder of calcium reuptake triggered by volatile anesthetic agents and succinylcholine. The pathogenesis, clinical features, and treatment are described elsewhere in this text.

Mitochondrial disease

Mitochondrial disease encompasses a genetically diverse group of enzyme-complex defects that result in altered energy metabolism. The energy-intensive organ systems (brain, heart, and muscle) are most commonly affected. There is an estimated incidence of 1 in 5000 patients with a variable age of onset and presentation. Specific clinical syndromes are listed in [Table 128.2](#).

Symptoms reflect the organ systems that are affected by the impairment of adenosine triphosphate (ATP) production. Neurologic sequelae include seizures, spasticity, ataxia, and developmental delay. Muscle weakness and hypotonia are common. Cardiomyopathies, conduction defects, failure to thrive, and gastrointestinal dysmotility may present in various combinations.

Many anesthetic techniques have been successfully applied in children with mitochondrial diseases with no adverse effects. Previous concerns about an association between MH and mitochondrial disease have not been firmly established, and the current literature does not support the avoidance of volatile agents. It is possible that children with mitochondrial disorders may have an increased sensitivity to volatile agents, presenting with cardiovascular depression in the usual clinical dose ranges. There is also some concern that the use of propofol may be associated with metabolic acidosis in some of these patients because of further impairment of mitochondrial function in the setting of impaired fatty acid oxidation.

Patients with mitochondrial disorders do not metabolize lactate well; administration of normal saline may be preferable to lactated ringers. In addition, these patients require availability of sugar or carbohydrate substrates and so do not tolerate prolonged fasting; dextrose supplementation is recommended.

Trisomy 21

Trisomy 21, also known as Down syndrome, is a common chromosomal disorder with an estimated incidence of 1 in 600 to 800 live births. Manifestations of the disease vary from patient to patient but typically include some degree of developmental delay and a characteristic facial appearance. Children with Down syndrome frequently have a large tongue and small pharynx, predisposing them to both sleep apnea and difficult mask ventilation. The trachea may also be somewhat smaller than expected based on age. Cardiac defects, particularly those of the atrioventricular canal, are present in approximately 40% of children with Down syndrome. Therefore, an echocardiogram, particularly in a newborn with a heart murmur, may be indicated prior to surgery. Intestinal obstruction (e.g., duodenal atresia) may also be present.

Atlantoaxial instability, wherein laxity of the transverse ligament allows C1 to sublux anteriorly on C2 causing spinal cord compression, is another relatively common finding in children with Down syndrome (estimated incidence 10% to 20%). A pre-anesthetic examination focusing on signs and symptoms of cord compression is important. Positive findings warrant postponing elective surgery for further cervical spine evaluation. If the child has never had radiographic imaging of the cervical spine, particularly if there is an anticipated or known difficult airway or if the surgery requires patient positioning in a nonneutral position, flexion and extension views of the cervical spine may be useful. Even in the presence of normal radiographs, however, cervical spine movement should be minimized during the course of the anesthetic.

Diabetes

Type 1 (juvenile) diabetes is marked by a failure of appropriate insulin secretion resulting in hyperglycemia. The mechanism is believed to be an autoimmune reaction that destroys the islet cells of the pancreas. Diabetes in this setting may accelerate macrovascular disease, leading to early-onset coronary atherosclerosis as well as microvascular disease and end-organ damage (retinopathy, neuropathies, etc.).

The ability to achieve normoglycemic control in young children is confounded by sensitivity to insulin, variability in physical activity, and unpredictable eating patterns. The recognized increase in childhood obesity is yet another complicating factor, with significant implications in long-term outcomes.

The preanesthetic interview should focus on the current insulin regimen(s) and a review of the patient's daily glucose measurements. The time of last meal and most recent dose of hypoglycemic agent should be documented. The threshold for additional glucose measurement (bedside glucometer testing) should remain low.

Some pediatric patients with diabetes may have an implanted subcutaneous pump as part of their therapy. Most anesthesia providers will not discontinue its use in the intraoperative period, but will perform frequent (every hour) glucose measurements to avoid potential complications.

Hematologic

Sickle cell disease

Sickle cell disease is an autosomal recessive disorder common among African Americans, which results from abnormal hemoglobin production. A valine for glutamate substitution at position 6 on the β -globin chain of hemoglobin produces a molecule, hemoglobin S, that is prone to polymerization (i.e., sickling) during periods of deoxygenation, acidosis, hypothermia, or dehydration. The aggregation of hemoglobin molecules leads to capillary occlusion and hemolysis. The disease frequently becomes apparent at approximately 6 months of age, when hemoglobin F levels decline and production of hemoglobin S begins. At this point, a hemolytic anemia may be noted. Vaso-occlusive crises may be frequent during childhood and are caused by ischemia from capillary occlusion. This ischemia precipitates further polymerization and can result in pain and tissue infarction. Strokes may be caused by vaso-occlusion of the cerebral vasculature. Sickled red blood cells may be sequestered in the spleen, resulting in splenomegaly. Repeated splenic infarction may cause splenic dysfunction and susceptibility to infection from encapsulated organisms. Thus, vaccination against organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae* is of particular importance in these patients. Acute chest syndrome, a medical emergency, is the leading cause of death in patients with sickle cell disease. Precipitating causes are not fully understood but may include fat embolism and community-acquired pneumonia. Patients may present with chest pain, fever, hypoxia, wheezing, or pain in the arms and legs. Neurologic complications or respiratory failure may develop. Treatment is supportive and includes blood transfusion (and possibly exchange transfusion), bronchodilator therapy, analgesics, broad-spectrum antibiotics, and supplemental oxygen therapy.

Anesthetic considerations for patients with sickle cell disease include ensuring adequate oxygenation, maintaining sufficient intravascular fluid volume, and avoiding acidosis. For procedures with large anticipated blood losses, preoperative transfusion to a hematocrit of 30% has been advocated. Intraoperatively, hypotension should be promptly treated to prevent prolonged periods of inadequate tissue perfusion. Normothermia is also important to prevent hemoglobin aggregation. Adequate analgesia is important to prevent splinting, but careful monitoring and supplemental oxygen are required in the postoperative period.

Sickle cell disease is distinguished from sickle cell trait in which a child is heterozygous for the sickle cell gene. Patients with sickle cell trait are typically phenotypically normal, although some of them may have painless hematuria and

be unable to concentrate their urine. They do not, however, experience anemia, vaso-occlusive crises, acute chest syndrome, or any of the other features of sickle cell disease.

Hemophilia

Hemophilia refers to a group of X-linked disorders resulting in insufficient production of a coagulation factor. Hemophilia A is the more common type and causes low to absent levels of factor VIII, whereas hemophilia B results in deficient or absent levels of factor IX. These clotting factors are necessary for the conversion of fibrinogen to fibrin; therefore, these patients are unable to stabilize platelet plugs. Signs and symptoms of the disease are variable and depend on the degree of factor insufficiency. Patients may present with joint or muscle hemorrhages which, in children, frequently start after they begin to ambulate. Laboratory tests will show a prolonged partial thromboplastin time and low to absent concentrations of the deficient factor. Treatment involves replacement of the appropriate factor. For patients with mild hemophilia A, desmopressin (which causes release of factor VIII from endothelial cells) may also be used. Anesthetic considerations include avoidance of intramuscular injection of medications and of regional anesthesia. For patients undergoing major operations, perioperative factor replacement is required.

Von Willebrand disease

Von Willebrand disease is the most common inherited bleeding disorder and results in qualitative and/or quantitative abnormalities of von Willebrand factor, a glycoprotein necessary for platelets to adhere to damaged endothelium. Type 1 von Willebrand disease, the most common form, is caused by insufficient production of normal von Willebrand factor. Its severity depends on the degree of factor insufficiency, and patients range from being asymptomatic to having frequent mucosal bleeding. Frequently, these patients may be undiagnosed until they have excessive bleeding following mucosal surgery. Patients with type 1 disease typically respond to desmopressin, which causes release of factor VIII and von Willebrand factor from endothelial cells. Type 2 von Willebrand disease is further divided into five subtypes but is generally caused by both qualitative and quantitative defects in von Willebrand factor. Desmopressin is generally not effective for patients with type 2 disease, and treatment with cryoprecipitate is often necessary. Type 3 is the most severe form of the disease and results in little, if any, functional von Willebrand factor. As with type 2 disease, type 3 von Willebrand disease does not respond to desmopressin, necessitating use of cryoprecipitate.

Anesthetic concerns for patients with von Willebrand disease vary depending on which type of disease is present and the nature of the surgical procedure. For patients with asymptomatic disease undergoing minor surgical procedures, no intervention may be necessary. For more complex procedures, however, pretreatment with desmopressin or cryoprecipitate, depending on disease type, may be necessary during the perioperative period.

Aspiration risk

Full stomach

Pediatric patients, like adults, may present for emergent surgery without a sufficient period of preoperative fasting, or they may have pathologies that predispose them to aspiration. In these patients, as in adults, full stomach precautions must be used, with placement of an intravenous catheter prior to induction of anesthesia. Induction may be performed with propofol or thiopental, without mask ventilation, followed by either succinylcholine or rocuronium. Given the potential for bradycardia with succinylcholine, atropine may also be administered. Cricoid pressure is traditionally performed, although its efficacy has been questioned; it is maintained until confirmation that the airway is secure. Extubation should not be performed until the full return of airway reflexes. Depending on the nature of the surgical procedure and the age and cooperation of the child, regional techniques with minimal sedation may also be used when full stomach precautions are necessary.

NPO guidelines

In 1999, the American Society of Anesthesiologists published guidelines for preoperative fasting for healthy patients undergoing elective procedures. For pediatric patients, the recommendations are as follows: 2 hours for clear liquids, 4 hours for breast milk, 6 hours for infant formula or nonhuman milk, 6 hours for a light meal (e.g., toast and clear liquids), and 8 hours for solid foods. These recommendations, however, may be modified, depending on each patient's individual pathology.

Anesthetic considerations for common procedures in children

Tonya L. K. Miller, Noah E. Gordon, and Mary Ellen McCann

A number of procedures occur frequently in pediatric anesthesia. Building on the basics discussed in prior chapters, anesthetic considerations for some common surgical procedures are presented in this chapter. Anesthesia for other diagnostic and therapeutic procedures is also discussed. This chapter concludes with a summary of considerations in pediatric recovery, including postoperative nausea and vomiting (PONV).

General pediatric surgery

Anesthesia for hernia and hydrocele in young infants

Inguinal hernias in infants are indirect hernias in which abdominal contents protrude through the internal inguinal canal. Hydrocele includes the presence of fluid in the potential space of the processus vaginalis. Hernias are 20 times more common in infants weighing less than 1500 grams than in the general population, and are often repaired in infants to prevent incarceration of the hernia contents. Clinically, most hernias or hydroceles present as a unilateral, nonpainful bulge in the inguinal area, which may be intermittent in nature. Surgery is indicated if there is a bulge noted during consultation or if there is a history of a bulge and the surgeon notes a thickening of the cord structures. An incarcerated hernia, occurring when abdominal contents become trapped in the hernia sac, can lead to a cycle of swelling and pain, impaired venous return, and impaired arterial inflow. Eventually, strangulation can occur, which can lead to bowel perforation, sepsis, and death. Thus, an incarcerated hernia that can not be manually reduced is a surgical emergency.

The most common surgical repair of inguinal hernias is a through a small inguinal incision and involves reducing abdominal contents and ligating the processus vaginalis at or above the internal ring. Many surgeons explore or laparoscopically examine the contralateral inguinal area because inguinal hernias are found bilaterally in 10% of infants. Recently, a technique of completely repairing inguinal hernias laparoscopically (the hernia sac is closed at the neck with a suture) has been pioneered in Europe.

Inguinal herniorrhaphy can be performed under regional (spinal block, spinal with single shot caudal block, continuous caudal block) or general anesthesia with an ilioinguinal or

single shot caudal block for postoperative analgesia. Regional anesthesia as an adjunct may allow for a lighter plane of general anesthesia and eliminate the need for opioids. Spinal anesthesia may be the preferred anesthetic for infants with a history of apnea or bradycardia. The success rate of spinal anesthesia depends on the anesthesiologist placing the spinal and on the surgeon doing the surgery. Spinal anesthesia has a low risk of postoperative apnea and bradycardia; however, addition of any sedative or hypnotic agents confers the same risk as general anesthesia. Spinal anesthesia is generally performed with hyperbaric bupivacaine (0.75%) or tetracaine (1.0%) dosed at 0.8 to 1.0 mg/kg, mixed with an equal volume of 10% dextrose in patients who weigh up to 5 kg.

General anesthesia may be preferred for emergency cases (strangulated or nonreducible incarcerated hernias), when the patient is uncomfortable and unable to easily be positioned for a spinal, and also for cases done completely laparoscopically. Preterm or former preterm infants less than 60 weeks post conception have an increased risk of apnea and bradycardia, and a small percentage of them may need postoperative ventilatory support. Caffeine given prophylactically in a dose of 10 mg/kg intravenously (IV) has been shown to decrease the incidence of apnea and bradycardia, although some neonatologists have concerns about the long-term safety of caffeine on the neurodevelopment of preterm infants. Overnight apnea monitoring is advised after anesthesia in all former preterm infants under the age of 60 weeks postconceptual age; the need for monitoring in term infants is controversial. The advantages and disadvantages of regional and general anesthesia are summarized in [Table 129.1](#).

Pediatric neurosurgical procedures

Hydrocephalus

Hydrocephalus is dilatation of the cerebral ventricles with an excessive amount of cerebrospinal fluid (CSF). It usually occurs when there is a blockage to the absorption of CSF. This blockage can lead to increased CSF pressure, which can cause neurologic symptoms. Communicating hydrocephalus refers to hydrocephalus in which the blockage to flow occurs outside the ventricular system, and noncommunicating hydrocephalus occurs when the blockage occurs within the ventricular system.

Congenital causes of hydrocephalus include intrauterine infections, such as syphilis, toxoplasmosis, cytomegalovirus, and rubella; isolated aqueductal stenosis; Dandy–Walker malformation; and Chiari type 2 malformation. Acquired causes of hydrocephalus in childhood include infections of the nervous system, such as bacterial meningitis, tumors that obstruct CSF flow, and intracranial hemorrhage, including intraventricular hemorrhage of premature and newborn infants.

Chronic obstruction of CSF flow in infants with open cranial sutures will lead to head enlargement, bulging fontanelles, frontal bossing, ventricular dilatation, and a gradual loss of cerebral white matter. Rapid obstruction to CSF flow results in nonspecific findings, such as headaches, often accompanied by nausea and vomiting. Patients may be irritable at first, and eventually they will become lethargic and drowsy. Papilledema and diplopia from compression of the third and sixth cranial nerves may occur. Cushing's triad (bradycardia, hypertension, and disordered breathing) indicates impending herniation.

Surgical therapy consists of mechanically shunting CSF to bypass the normal pathways. Usually, a catheter is placed in a lateral ventricle and connected to a one-way valve that opens when the pressure reaches a preset value. The distal end of the shunt is usually placed within the peritoneal space but occasionally is placed within the atrium. Third ventriculostomy, which may be performed endoscopically, can be used to treat some forms of hydrocephalus. Shunts can become disconnected, obstructed, infected, or outgrown by the patient; revision may need to be done emergently if there is rapid obstruction to CSF flow.

Shunt placement is done under general anesthesia. Intravenous induction with full stomach precautions should be performed in patients who are exhibiting signs and symptoms of increased intracranial pressure. These cases are true emergencies, and the patients need to be thoroughly evaluated by the neurosurgical and anesthesia teams. Emergence after any neurosurgical case should be as smooth as possible with careful assessment that the patient has a regular and adequate respiratory pattern.

Pediatric brain tumors

Fifteen percent of all pediatric solid tumors consist of brain tumors. The most common tumor is astrocytoma, accounting for almost 50% of the brain tumors in children. Other com-

mon types include ependymoma, medulloblastoma, and craniopharyngioma. Many children with brain tumors will eventually be treated with a shunting procedure as well as resection. Brain edema may be treated acutely with dexamethasone, but patients should be considered to be at risk for increased intracranial pressure. Large tumors may require urgent resection if the clinical condition deteriorates.

Craniopharyngioma is a benign tumor arising from the anterior portion of the sella turcica which causes neurologic complications, such as headache, hydrocephalus, visual loss, and pituitary and hypothalamic failure. A full endocrine workup is required prior to surgery, and patients who are found to be hypothyroid or hypoadrenal need to have replacement therapy prior to surgery because these conditions have been linked to increased intraoperative mortality. In infants and young children, a frontal craniotomy approach between the frontal lobes provides the best access to the pituitary gland. Transsphenoidal surgery is generally performed only in adolescents and older children with pituitary adenomas. In many patients, a subtotal resection followed by radiation is done to avoid damaging crucial neurologic structures. Nonetheless, postoperatively, it is common for patients to exhibit transient or permanent pituitary failure and for some patients to exhibit diabetes insipidus. Up to a third of children will demonstrate recurrence of this tumor and will need to have another resection.

Any pediatric craniotomy requires general endotracheal anesthesia with adequate venous access as well as arterial monitoring. If the patient is not exhibiting signs of hydrocephalus and increased intracranial pressure, then a mask induction with a parent present is permitted. Central access and precordial Doppler monitoring may be considered, depending on the risk of air embolus in the individual patient. Normal saline for replacement of intraoperative fluid loss is generally preferable to Ringer's lactate solution. Depending on the location of the tumor, and particularly with pituitary tumors, diabetes insipidus or secretion of antidiuretic hormone (SIADH) may develop intraoperatively.

Anesthesia for pediatric otorhinolaryngology surgery

Otorhinolaryngology (ORL) procedures are some of the most common procedures in pediatrics. These are typically short in duration, requiring a deep level of anesthesia and immobility, followed by prompt awakening with modest postoperative pain requirements. Pediatric patients presenting for routine ORL procedures are often American Society of Anesthesiologists (ASA) physical status 1 or 2 and appropriate for an ambulatory setting. Any hospital can also see pediatric airway emergencies, including foreign body (FB), croup, or acute epiglottitis. (See [Table 129.2](#).) Airway bleeding after tonsillectomy can present emergently and require capable airway management skills provided by an experienced anesthesiologist. When planning the anesthetic management of any airway procedure, whether emergent or elective, one should consider the perioperative

Table 129.2. Common conditions causing airway obstruction in children

Diagnosis	Onset	Breathing on examination	Miscellaneous	Typical presenting age
Croup (laryngotracheobronchitis)	Insidious with prodrome of URI; also seen postoperatively after traumatic intubation	Inspiratory stridor, barking cough, slow inspiratory phase	Stridor and respiratory compromise worsened with increased respiratory rate	Infants, children younger than 3 years
Epiglottitis, acute supraglottitis	Rapid, fulminant onset with sore throat and dysphagia	Sitting up, drooling, dysphonia or aphonia, dysphagia with inspiratory obstruction	Limited air flow from the obstruction can muffle or obviate the inspiratory stridor	Children 2–7 years
Subglottic stenosis	Congenital, posttrauma, or prolonged intubation	Respiratory distress, notable retractions, biphasic stridor	Most common cause is prolonged intubation	Neonates, infants, or children of any age after prolonged intubation
Foreign body	Insidious or rapid	Decreased air exchange and/or wheezing	Organic foreign bodies cause more inflammation; small, inert foreign bodies may cause chronic wheeze or cough	Toddler

expertise and resources that are needed. In some cases, transport of a stabilized patient to a more specialized facility may be required.

Although pediatric patients presenting for ORL procedures are usually healthy, they frequently have recurrent upper respiratory infections (URIs) or other respiratory issues. Elective ORL cases may be performed despite the patient having a current or recent URI because the enlarged tonsils and adenoids predispose these children to upper airway congestion which is only relieved by the surgery. Special focus on the history of breathing symptoms, including sleep apnea, and careful attention to the respiratory examination are important to planning the intraoperative and postoperative care of these patients.

Tonsillectomy and adenoidectomy

The vast majority of tonsillectomy and adenoidectomy (T&A) procedures are performed for treatment of obstructive sleep apnea (OSA), with a significant minority performed for the treatment of recurrent streptococcal throat infections. OSA is defined as “a disorder of breathing during sleep characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep and normal sleep patterns.” The incidence of OSA is approximately 2% to 3% of the pediatric population, with the peak incidence occurring between the ages of 2 and 6 years. There is a continuum between snoring and OSA, but there also exist variations on thresholds for arousal, as well as degrees of obstruction that lead to hypopnea or apnea. The incidence of habitual snoring is up to 10% of the pediatric population, but the majority of these patients do not show symptoms of OSA, such as sleep disturbance, excessive daytime somnolence, attention disturbances, emotional instability, and headaches. Children with disordered breathing by clinical symptoms and history or by diagnostic polysomnog-

raphy (sleep study) may present for T&A to improve airway patency by removal of the enlarged lymphoid tissue. It is important to recognize that these patients may also have some degree of altered ventilatory response to hypercarbia and hypoxia and increased sensitivity to opioids and sedatives. Because of edema, the airway obstruction may not be completely resolved in the initial postoperative period. Children with significant sleep apnea, especially those younger than 3 years or those with concurrent diseases, should be observed overnight after tonsillectomy.

With anesthesia induction, these patients are at risk for partial or complete obstruction as the pharyngeal muscle tone decreases. During inhalation induction, holding continuous positive airway pressure (CPAP) by mask until the patient reaches a deeper plane of anesthesia may minimize the obstruction, or an oral airway may be required. Airway management is with either a midline endotracheal tube (ETT) or a flexible laryngeal mask airway [LMA]). Attention must be paid to not kinking or dislodging the ETT on placement and removal of the surgical instrument such as a Boyle–Davis mouth gag (Fig. 129.1). Maintenance of anesthesia can be achieved with inhaled or IV agents along with narcotic or by use of muscle relaxant to lessen the amount of anesthetic agent needed. In patients with a history of significant OSA, it is prudent to avoid sedative premedication and use morphine at 0.05 mg/kg or fentanyl at 1 µg/kg as intraoperative analgesia, and then titrate in more narcotic if needed after the patient is awake. Acetaminophen is routinely administered; there is also some interest in other analgesic adjuncts, such as small doses of ketamine or dexmedetomidine. Upon completion of the procedure, the surgeon may pass an orogastric tube to eliminate any blood that may have accumulated in the stomach; the oropharynx should be suctioned carefully to avoid initiating bleeding. Many anesthesiologists prefer awake extubation of tonsillectomy patients with OSA.

Figure 129.1. Patient positioning for tonsillectomy, with mouth gag in place.

Bronchoscopy

Bronchoscopy is performed to evaluate structural or functional airway abnormalities (subglottic stenosis, laryngomalacia) or for emergency situations, such as to remove a FB or to secure the airway in epiglottitis. Paramount to a safe anesthetic and successful operation involving a shared airway is close communication between the anesthesiologist and surgeon to discuss surgical objectives and patient comorbidities and to decide on an airway management plan prior to the procedure. Preparation includes having any equipment that could potentially be needed present and ready to use. Spontaneous ventilation may be preferable in some situations, relaxation and controlled ventilation in others. If cautery or laser is to be used, oxygen concentration should be decreased to minimize the potential for airway fire. If postoperative airway swelling is likely, dexamethasone at 0.25 to 0.5 mg/kg (maximum of 12 mg) should be considered.

Sevoflurane is frequently used for mask induction because it is the least pungent to the airways and is less arrhythmogenic in the presence of frequently used hemostatic sympathomimetics. It may be used by insufflation for airway procedures with spontaneous ventilation; however, patients will not remain in a deep plane of anesthesia for long if the agent is turned off, and operating room (OR) pollution may be an issue. Propofol's ability to blunt laryngeal reflexes and its antiemetic qualities make it useful in airway surgery, often in conjunction with remifentanyl infusion or a small dose of fentanyl.

Understanding of the specific bronchoscopic system to be used is crucial, and the anesthesiologist must know how to use it to deliver oxygen and agents or to ventilate. Jet ventilation can be used with a suspension laryngoscope from a supraglottic position, where the risk of barotrauma is minimized. In this position, the adequacy of the ventilation is assessed by watching the chest rise and recoil; an inspiratory:expiratory (I:E) ratio of 1:3 (at a minimum) is suggested. Topical anesthesia by the

anesthesiologist or surgeon prior to starting the procedure may be accomplished by application of 1% to 4% lidocaine to the larynx, cords, and trachea (maximum of lidocaine at 4 mg/kg without epinephrine). Whether or not neuromuscular blocking agents are used, immobility of the patient is critical during both suspension of the larynx and, especially, when the trachea is instrumented to avoid tracheal injury and rupture. A laser may be used for treatment of laryngeal clefts, papillomas, or other airway lesions. Goggles should be worn by OR personnel to avoid retinal injury from direct or indirect laser beams, and the patient's eyes should be covered with a flame-retardant, light-impenetrable barrier. The airway device should be non-flammable, such as metal tubes or reinforced and/or wrapped tubes, and the cuff should be filled with water.

Some specific concerns exist for location and removal of a FB in the airway. FBs may not be radio-opaque and so may not be seen on chest radiograph; air trapping may also be indicative of a FB. A FB lodged in an airway can cause complete or partial fixed obstruction of all airways distal to its location or a dynamic obstruction creating a ball-valve obstruction leading to distal air trapping. The anesthesiologist must be prepared for bronchospasm, difficult ventilation, and possible hypoxemia during the time it takes for FB retrieval. The anesthetic technique of paralysis and controlled ventilation, or keeping the patient breathing spontaneously, is best chosen by preference consensus between the anesthesiologist and surgeon to optimize patient safety and surgical outcome. After the surgeon has grasped the FB with the surgical instrument, it is important to minimize patient movement or cough, which could cause the FB to be dislodged during removal. Nuts, like any organic FB, can cause a severe inflammatory reaction, and can also be very friable and difficult to extract. Postoperative care for these children can involve prolonged respiratory support in an intensive care unit (ICU) setting and treatment of acute respiratory distress syndrome (ARDS). A sharp FB can cause airway injury and bronchopleural fistulas. If the FB cannot be retrieved, open thoracotomy may be required.

Ear procedures

The most common procedure on the ear is bilateral myringotomy (BMT) with placement of ventilation tubes (tympanostomy tubes or grommets). Ear tubes are generally placed while the patient is under a brief mask anesthetic; the anesthesiologist must ensure a patent airway with the head turned and be able to maintain a still working field at critical points. Analgesia is usually provided with oral (PO) or rectal (PR) acetaminophen, or nasal fentanyl, because intravenous (IV) catheters are not usually inserted unless the patient has underlying medical issues such as cardiac disease.

Cochlear implant or cosmetic ear reconstruction may involve having the patient's head a significant distance away from the anesthesiologist and turned to the side; for this reason, and because of procedure duration, the patient is usually intubated. Patients having cosmetic ear reconstruction may

have hemifacial microsomia or other syndromal abnormalities and should be evaluated carefully for possible difficult airway. Middle ear surgery requires a still and bloodless field for microscopic dissection, ability to monitor facial nerve function (avoidance of muscle relaxants), and avoidance of nitrous oxide during closure. Smooth emergence is desirable to minimize bleeding and disruption of the tympanic membrane.

Nasal surgery

Patients presenting for nasal surgery typically have some degree of nasal obstruction and often come for revision of a congenital anomaly (e.g., cleft lip or palate) or correction of a traumatic injury. Nasal surgery or manipulation of nasal bones may cause bleeding, so protecting the airway from nasal secretions with an LMA or oral ETT (OETT) is recommended. If significant bleeding is expected, a throat pack may be placed after the patient is intubated. The operative team must have a group approach to ensure that the pack is removed at the end of surgery. Careful vigilance to eye care is important as the eyes are often in the surgical field. Likewise, care should be taken to avoid placing too much pressure on a repaired nose with a face mask during airway management.

Choanal atresia (present in 1:7000 births) can occur incidentally or associated with other syndromes, such as CHARGE syndrome or association (coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies, and often including facial palsy, cleft palate, and dysphagia). Bilateral choanal atresia produces respiratory distress immediately after birth and requires respiratory support because infants are obligate nose breathers. Partial or unilateral atresia can sometimes be picked up from a history of cyanosis or respiratory distress when feeding.

Patients with nasal polyps or with chronic sinusitis will present for functional endoscopic sinus surgeries (FESS) to debride and clear soft tissue and bone and to open up the sinus cavities. Patients with cystic fibrosis are a large percentage of FESS patients, and, hence, associated perioperative concerns with this disease entity must be considered. To ensure adequate visualization for the surgeon, careful management of blood pressure with the use of controlled hypotension may be beneficial.

Topical vasoconstrictors (oxymetazoline, epinephrine, phenylephrine, and cocaine) are frequently used during nasal procedures, and the anesthesiologist must be aware of the potential for systemic absorption with cardiovascular side effects. The total dose should be appropriate for weight; phenylephrine should not exceed 20 µg/kg for 25 kg or less or 0.5 mg total for 25 kg and over. The use of pure β-blockade to treat elevated blood pressure from phenylephrine has caused cardiovascular collapse.

Neck surgery

Excision of thyroglossal duct or brachial cleft cysts, neck mass biopsy or excision, or removal of hemangiomas or other

vascular malformations typically require general anesthesia with an OETT. Preoperative imaging is often available to view to ascertain if there is any airway compromise from the lesion. An array of ETT sizes is useful to have at hand in the event that the airway anatomy is not as anticipated. Also, if external hemangiomas exist, one should have a high suspicion that they may also exist within the airway. Airway hemangiomas or other vascular malformations can create blood in the airway on instrumentation. Induction and maintenance of anesthesia can be with IV or inhalational agents. Intra- and postoperative analgesia requirements are usually mild to minimal but may depend on the extent of the lesion excised. In the absence of patient comorbidities, these procedures can typically be day surgery in the absence of unusual findings or intraoperative airway events.

Pediatric anesthesia in remote locations

There is an increasing demand for anesthesiologists to provide anesthesia and sedation to children for therapeutic and diagnostic procedures that adults might tolerate with minimal or no sedation. Typically these locations are far removed from the OR in both physical location as well as type of environment. Provision of anesthesia or sedation in remote locations requires careful planning and coordination, as well as appropriately trained staff. The ASA has standards that should be met for non-OR anesthesia locations.

Institutions vary on specifics of who may provide pediatric sedation, but all should comply with guidelines from the American Academy of Pediatrics and the ASA as well as with individual institutional guidelines. In general, these guidelines speak to the need for an individual not involved in the procedure to monitor the patient, appropriate training and credentialing, appropriately sized equipment, and appropriate patient evaluation, monitoring, and discharge criteria. Clear consensual definitions of different levels of sedation within the institution are imperative for the safe care of patients. Understanding of the pharmacology and ability to “rescue” from a deeper-than-intended level of sedation are also hallmarks of the safety guidelines. Goals of sedation include minimizing physical discomfort and pain; controlling anxiety, minimizing psychological trauma, and providing amnesia; controlling behavior and/or movement to allow safe completion of the procedure; guarding the patient’s safety and welfare throughout the procedure; and returning the patient to a state allowing safe discharge as determined by recognized criteria. Potential “red flags” for sedation by non-anesthesia providers include apnea, unstable cardiac disease, respiratory compromise (including recent URI), active gastroesophageal reflux or vomiting, hypotonia, tremor, allergy to barbiturates, and prior failed sedation. Medications used in pediatric sedation are listed in [Table 129.3](#).

The choice of anesthetic technique for maintenance of general anesthesia during procedures in remote locations depends on patient, equipment, and procedural factors. Frequently, anesthesia can safely consist of spontaneous ventilation using a propofol infusion with nasal cannula oxygen and carbon

Table 129.3. Commonly used sedative medications

Drug	Usual dosing
Chloral hydrate	PO/PR: 25–50 mg/kg
Fentanyl	IV: 0.5 µg/kg
Midazolam	PO: 0.25–0.5 mg/kg IV: 0.025–0.05 mg/kg
Pentobarbital	IM/PO: 2–6 mg/kg IV: 2 mg/kg
Ketamine	IM: 3–7 mg/kg IV: 0.5–2 mg/kg

IM, intramuscular.

dioxide (CO₂) detection. For procedures that are long, involve pain, or affect the airway, or for patients with airway concerns, increased risk of aspiration, or cardiopulmonary or neuromuscular comorbidities, alternative strategies must be employed. Other considerations during the procedures include airway access, patient positioning, ability of the anesthesiologist to be in the room during the procedure, drugs or contrast agents used during the procedure, risks for life-threatening blood loss, and possible postoperative implications from the procedure. Adequate IV access, appropriately secured airways, availability of resuscitation medications and blood products, and possibly invasive pressure monitoring, urinary catheters, and temperature maintenance equipment should be used when appropriate. Anaphylactic reactions are rare for PO or IV agents but should be watched for and appropriately treated when contrast or other exogenous agents are used.

Postoperative management requires recovery staff experienced in the care of children and also familiar with issues that may arise after particular procedures. Small recovery locations within the radiology suite may be useful, but using the OR postanesthesia care unit (PACU) may be appropriate after hours or for complicated patients.

Anesthesia related to specific off-site locations

Computerized tomography

For these short, painless procedures it is not uncommon for PO as well as IV contrast to be given. The oral contrast is typically a clear iodine-containing solution that is diluted to an iso-osmolar liquid and given in a relatively large volume. Most anesthesiologists prefer waiting 2 hours before sedating or anesthetizing patients who have received oral contrast; in general, the quality of the scans is not adversely affected by this wait. CT scans that require only the briefest of immobility and no contrast may be done with mask sevoflurane and spontaneous ventilation.

Magnetic resonance imaging

MRI scans typically last 30 to 90 minutes and frequently involve IV contrast, such as gadolinium. Side effects of MRI contrast are relatively rare and mild but include nausea, vomiting, hives, or irritation at the injection site. Recent literature

suggests that renal complications may occur with preexisting renal insufficiency, so patients should be screened clinically (and by laboratory evaluation if indicated) prior to gadolinium administration. Airway access is more limited than in other procedures especially in patients getting brain or spine imaging. Care should be taken to ensure that the airway device of choice is not kinked or dislodged after the coils are positioned.

Also of note are routine magnet safety issues and contraindications. Equipment incompatibilities can lead to patient burns or injury, magnet interference, and malfunction of implantable devices, such as pacemakers. Induction of general anesthesia and resuscitation of patients in the MRI suite can pose unique equipment-limiting problems. All equipment must be checked for compatibility. If at any time a patient needs to be resuscitated, he or she should be removed from the MRI room and the resuscitation should ensue in an area without magnet safety concerns.

Interventional radiology

Typical cases in the interventional radiology (IR) suite include angiography, image-guided biopsies and drain placements, placement of peripherally inserted central catheter (PICC) lines or indwelling central lines, and sclerotherapy or embolization of vascular or lymphatic malformations. Anesthetic management is tailored for variable lengths of procedures that often require controlled ventilation to facilitate breath holding for cineangiography or manipulation of CO₂ levels to control the amount of cerebral vasodilation. Maintaining temperature for a pediatric patient in the IR suite can be challenging because the IR suite must be maintained at a low ambient temperature to ensure proper function of the imaging equipment. Forced air warmers, fluid warmers, and warm blankets should be available.

Gastrointestinal endoscopy

Gastroenterology suites are designed to do esophagogastroduodenoscopies (EGDs) and colonoscopies in an efficient manner. As with any remote location, careful patient selection is paramount. Routine EGDs can be done with the patient in a lateral position, O₂ via nasal cannula, and routine monitoring including CO₂ detection. In straightforward patients, maintenance anesthesia may be by an IV technique using propofol with or without an opioid (fentanyl or remifentanyl). Airway vigilance is crucial as complications of apnea, respiratory distress, and airway obstruction can occur during or after the EGD. Patients at high risk for aspiration, small patients, or those needing a larger endoscope may need intubation for upper endoscopy.

Radiation therapy

Daily treatments for several days at a time can create much patient anxiety and family stress. Planning should be done with the family to ensure that the NPO times are not excessive to ensure that patients maintain their nutrition during treatments. These treatments, although usually short, require

complete immobility of the patient. To avoid staff exposure to radiation, the patient is monitored from a separate room via video cameras and remote monitors. The airway is typically not instrumented to minimize tracheal damage, and frequently a body mold or head mask, even for prone patients, is used to ensure consistent patient positioning for treatments. Oxygen delivery and CO₂ detection are accomplished by nasal cannula or by taping the mask and sampling line to the outside of the head mask.

Postanesthetic considerations for the pediatric patient

Skilled PACU nurses appropriately treating pain and nausea, and orienting patients with a parent, can ensure an uncomplicated recovery. PONV is frequent in middle ear surgeries or in cases in which blood collects in the stomach. Emergence delirium can complicate the recovery phase in young children. The etiology of this phenomenon is not clearly understood, but it occurs most frequently in patients from 2 to 5 years old and, more frequently, with volatile anesthetics. Comfort measures and adequate analgesia may be adequate in some patients, but in others resedation may at times be required. An anesthesiologist available to the PACU is important for appropriate respiratory vigilance and potential airway management. For more involved procedures or for patients with comorbidities, facilities should have the appropriate resources to care for the postoperative needs of these children (e.g., intensive care unit capability for patients with difficult airways or OSA).

Pediatric postoperative nausea and vomiting

PONV is seen commonly in pediatric patients. Despite the fact that PONV may be associated with significant complications, including wound dehiscence, pulmonary aspiration of gastric contents, bleeding, dehydration, and electrolyte disturbances, many reports and reviews in the literature suggest that PONV may be undertreated. Even mild PONV may lead to delayed hospital discharge, decreased parental satisfaction, and increased use of resources (physician and nursing care, administration of IV fluids and medications). PONV remains a major cause of unanticipated admission to the hospital after day surgery; consequently, prevention and management are seen as increasingly important (see Table 129.4).

Pediatric patients have a higher incidence of PONV than adults do, with a peak incidence of 30% to 50% in school-age children. The lowest incidence occurs in infants (5%), whereas preschool-age children have an intermediate incidence (20%). For prepubertal children, female sex is not consistently associated with an increased risk for PONV, although, in teenage patients, studies show that girls vomit significantly more often than boys do after general anesthesia. Children undergoing adenotonsillectomy, strabismus repair, orchidopexy, herniorrhaphy, middle ear surgery, dental procedures, or laparotomy are at

Table 129.4. Strategies to reduce baseline PONV risk

Perioperative period	Strategy	Evidence
Preoperative	Premedication (clonidine or midazolam)	Weak
	Intraoperative	Avoidance of general anesthesia through use of regional anesthesia
Postoperative	Use of propofol for induction and maintenance of anesthesia	Strong
	Avoidance of nitrous oxide	Strong
	Avoidance of volatile anesthetics	Strong
	Minimization of opioids	Weak
	Minimization of neostigmine	Weak
	Adequate hydration	Strong
	Minimization of opioids	Strong
	Minimization of movement	Weak
	Timing of oral intake	Weak
	Adequate hydration	Strong

increased risk of PONV. The risk of PONV increases with duration of surgery and anesthesia. Pain has been shown to increase PONV, but opioid therapy is also a risk factor. Practitioners have long maintained that gastric distention, early movement, early drinking, and dehydration all contribute to a higher incidence of PONV.

Recently, Eberhart and colleagues published a study of a large series of pediatric patients in which a multivariable analysis was applied to identify PONV risk factors in children. This study identified four independent predictors of PONV: duration of surgery of at least 30 minutes, age of at least 3 years, strabismus surgery, and a positive history for PONV in the patient, sibling, or parent. Depending on the presence or absence of these factors, Eberhart and colleagues demonstrated that the risk for PONV was 9%, 10%, 30%, 55%, and 70% for 0, 1, 2, 3, or 4 or the independent predictors, respectively. Kranke and colleagues later validated this score, demonstrating comparable predictive value to the results in adult patients.

Benzodiazepines, particularly midazolam, have been shown to reduce PONV in children after strabismus repair and adenotonsillectomy. Clonidine has also been noted to have an antiemetic effect when given as a premedication during strabismus surgery. Not surprisingly, opioid analgesics used for preoperative and preprocedural sedation lead to increased PONV. Etomidate and ketamine are both associated with increased PONV, and several barbiturates, including methohexital and thiopental, have been shown to be more emetogenic than propofol. A large systematic review of propofol, involving several thousand pediatric patients, suggested that the best results may be achieved by using propofol for both induction and maintenance of anesthesia. Omission of nitrous oxide seems to lower the incidence of vomiting for some types of surgery, with less effect for other types of surgery. This practice has little effect, however, on the incidence of late PONV. Possible explanations for the greater emetogenic effect of nitrous oxide include diffusion of the gas into the middle ear or bowel, which through distention of these confined structures (vestibular apparatus

Table 129.5. Properties of antiemetic drugs

Class	Drug	Receptor antagonism	Dose, mg/kg	Antiemetic efficacy	Relative cost	Timing of administration

and loops of bowel) might lead to activation of the medullary dopaminergic system and increased endogenous cerebrospinal opioid receptor agonists. Potent volatile anesthetic agents are all associated with a higher risk of nausea with few differences among the modern agents.

The cost effectiveness of therapy is one of the primary considerations governing whether or not to use PONV prophylaxis (see Table 129.5). In general, pharmacologic prophylaxis against PONV with older, less expensive antiemetics is cost-effective when the risk of emesis is as low as 10%, whereas prophylaxis with the more expensive agents may not be cost-effective until the risk of emesis is as high as 30% to 60%. A suggested hierarchical approach to managing PONV based on a child's calculated risk is to give no prophylaxis for low-risk patients, a selective serotonin 5-hydroxytryptamine type 3 (5-HT₃) antagonist for medium risk, and combination therapy (a serotonin antagonist and dexamethasone or a serotonin antagonist and a butyrophenone) or multimodal therapy (antiemetics from additional classes, use of strategies to minimize baseline risk for PONV, and nonpharmacologic prophylaxis) for high-risk patients.

The 5-HT₃ receptor antagonists (ondansetron, dolasetron, granisetron, and tropisetron) are most effective in the prophylaxis of PONV when given at the end of surgery. The 5-HT₃ antagonists for the most part have a favorable side-effect profile, although this class of drugs can prolong the QT interval. By a mechanism yet to be elucidated, the glucocorticoid dexamethasone effectively prevents nausea and vomiting. Droperidol, a neuroleptic antagonist of central dopamine receptors and a butyrophenone, is an effective drug for the prevention of PONV. One meta-analysis evaluating prophylaxis for children undergoing strabismus repair revealed that droperidol had the greatest antiemetic benefit with a number needed to treat (NNT)

of 4. Although sedation, lethargy, agitation, and extrapyramidal effects have been reported with the commonly used pediatric doses, the most serious adverse effects are estimated to occur in less than 1% of all children. The 2001 US Food and Drug Administration (FDA) black box warning regarding possible QT prolongation leading to torsades de pointes has limited the use of droperidol. Some initial adult studies have shown the efficacy of haloperidol, another butyrophenone, but without large enough numbers to suggest that it is safer from a cardiovascular standpoint. Antihistamines, such as dimenhydrinate, have shown moderate efficacy in some studies but not in others; they can also have profound sedative effects, but are inexpensive and therefore have a relatively favorable cost/efficacy ratio. Central nervous system antimuscarinics effectively prevent emesis related to vestibular stimulation, one of the proposed mechanisms for morphine-induced PONV. Transdermal scopolamine has been found useful for the control of nausea in the setting of morphine PCA in older children but is not recommended in children < 40 kilograms in weight. Drugs with a lack of evidence of effect include metoclopramide in standard clinical doses, ginger root, and cannabinoids. Examples of agents with possible efficacy but too little evidence include the phenothiazines (promethazine and prochlorperazine) and ephedrine. A new class of antiemetic drugs, the neurokinin-1 (NK₁) receptor antagonists, has been shown to provide protection against multiple different emetogenic stimuli (motion, chemotherapy, radiation therapy, narcotics, other emetogenic drugs and treatments), whereas other conventional antiemetic drugs are typically effective against only a few of these stimuli. In addition, preliminary evidence shows promising results with opioid antagonists (naloxone, nalmefene) for reduction of nausea, vomiting, and a need for rescue antiemetic medication in children and adolescents.

In adults, a meta-analysis of nonpharmacologic PONV prophylaxis demonstrated antiemetic efficacy with acupuncture, transcutaneous electrical nerve stimulation, acupoint stimulation, and acupressure. Pressure, puncture, or stimulation of the P6 or Neiguan point located on the anterior surface of the wrist approximately three finger breadths above the distal skin crease of the wrist and between the tendons of the flexor carpi radialis and palmaris longus muscles reduced the incidence of nausea and vomiting and need for rescue medication in adults. In children, acupuncture after induction of anesthesia was ineffective in reducing PONV after strabismus repair, although the antiemetic efficacy of this technique may in fact depend on the timing and duration of therapy. Further studies in children are needed to confirm the beneficial antiemetic effect that these nonpharmacologic techniques are reported to have in randomized controlled trials for adults.

Neonatal surgical emergencies

Noah E. Gordon and Mary Ellen McCann

Introduction

The impact of congenital malformations in pediatrics is significant. Three percent of newborns are born with congenital malformations, and 20% of neonatal mortality is secondary to congenital malformations. The care of a neonate with a major congenital malformation is resource-intensive. In one study, newborns with congenital malformations accounted for one-fourth of all neonatal intensive care unit (NICU) referrals, one-third of total NICU days, and nearly half of NICU costs. Surgical interventions and their accompanying sequelae are major contributors to the costs, morbidity, and mortality of these neonates. The disease processes, anesthesia, and surgery all can interfere with developmental changes and threaten survival.

General approach to the neonate

Preanesthetic considerations

Neonates requiring urgent or emergent surgical intervention are approached in the standard fashion, with steps taken to gain an understanding of the patient's physiology, the disease process, and implications of the surgical plan. A detailed history and physical examination are essential. Of particular interest in the history are the mother's pregnancy, the course of labor and delivery, and events over the first hours to days of life. Depending on the results of the history and physical, it may be important to do laboratory and radiologic assessments as well. (See Table 130.1.)

Transitional circulation

Many newborns requiring urgent or emergent surgical procedures arrive in the operating room (OR) with a transitional circulation – so-called because it has aspects of both the adult series circulation and fetal parallel circulation owing to the presence of a patent ductus arteriosus (PDA), as well as possible interatrial and/or interventricular communications. There is the potential for these nonrestrictive shunts to lead to large right-to-left or left-to-right shunts, depending on the balance between the pulmonary and systemic vascular resistances (PVR and SVR, respectively). With left-to-right shunting, overcirculation of the pulmonary vascular bed can lead to pulmonary edema, a low-cardiac-output state (with impaired flow to the

cerebral, coronary, renal, and splanchnic beds), and, eventually, pulmonary vascular occlusive disease. With right-to-left shunting, bypassing the pulmonary bed leads to impaired oxygenation and ventilation with ensuing cyanosis.

Apnea

Unlike older infants, premature and term neonates paradoxically decrease their respiratory rates in response to hypoxia (a response that is further exacerbated by hypothermia) and exhibit little, if any, increased minute ventilation in response to increasing arterial carbon dioxide levels. Risk factors for true apnea in the postoperative period include a postconceptual age of 60 weeks or less and anemia in ex-premature neonates. Caffeine is a centrally acting respiratory stimulant that, in doses of 10 mg/kg (20 mg/kg caffeine citrate), can prevent or reduce apnea in this population.

Hypoglycemia

Glycogen stores are small in premature infants and neonates; therefore, newborns are at a high risk for hypoglycemia when

Table 130.1. Perinatal conditions and their associated potential perioperative problems

Condition	Perioperative problems
Asphyxia	Hypoglycemia, hypocalcemia, hyperkalemia, impaired cerebral autoregulation, depressed myocardial function, decreased gut perfusion, shock, coagulopathy
Infants of diabetic mothers Maternal IV drug use	Hypoglycemia, hypocalcemia Opioid withdrawal, infectious agents (hepatitis B/C, human immunodeficiency virus), seizures
Prematurity	Hypoglycemia, respiratory distress syndrome, postoperative apnea, ROP, temperature instability
Small for gestational age	Hypoglycemia, hypocalcemia, polycythemia/hyperbilirubinemia, temperature instability, congenital anomalies, increased incidence of pulmonary aspiration/pneumonia
Large for gestational age	Birth injury (brachial/phrenic nerve, fractured clavicle), hypoglycemia, hypocalcemia, polycythemia/hyperbilirubinemia, meconium aspiration

Table 130.2. Glucose and electrolyte requirements in the premature and term newborn

Nutrient/ Electrolyte	Requirement	Comment
Glucose	2–4 mg/kg/min 8–10 mg/kg/min >15 mg/kg/min	Most newborns SGA/LGA infants Infants of diabetic mothers
Sodium	None 2–4 mEq/d >4 mEq/d Variable	For first 24h for most newborns Day 2 and beyond GI, renal, skin losses Drug and metabolic effects
Potassium	None 1–3 mEq/d <1 mEq/d >3 mEq/d	First 24–48 h for most newborns Day 2–3 and beyond, ensure normal urine output Requirements lower in VLBW and ELBW infants GI, renal, iatrogenic losses – replace cautiously
Calcium	200–400 mg/kg/d Variable	Calcium gluconate dosing (calcium chloride contains three times as much elemental calcium) Premature, SGA/LGA infants

LGA, large for gestational age; SGA, small for gestational age; VLBW, very low birth weight; ELBW, extremely low birth weight.

exogenous glucose is not administered. The threshold for defining hypoglycemia in the neonate is controversial but the American Academy of Pediatrics suggests an operational definition of <36 mg/dl in an asymptomatic neonate with the goal of maintaining the plasma glucose level of 45 mg/dl or greater. There are no recent data to support a lower threshold for premature infants.

In the newborn, hypoglycemia has profound consequences, including apnea, hypotension, bradycardia, seizures, and neurologic injury. If a bolus of glucose is needed, dextrose 10% in water (D₁₀W) at 1 to 2 ml/kg should be administered, followed by careful monitoring of serum glucose. Whereas term neonates need glucose at 5 to 8 mg/kg/min to prevent hypoglycemia, premature and small-for-gestational-age newborns generally require an infusion rate of 8 to 10 mg/kg/min. Intraoperative infusion of D₁₀ at maintenance rates will deliver glucose at approximately 7 mg/kg/min and should be adequate to avoid hypoglycemia. Fluids for replacement of insensible deficit, and blood losses should not contain glucose, to avoid hyperglycemia. (See Table 130.2.)

Retinopathy of prematurity

Retinopathy of prematurity (ROP) is a progressive vascular overgrowth of the retinal vessels eventually leading to intraocular hemorrhage, retinal detachment, and blindness. Seen primarily in premature newborns exposed to a high fraction of inspired oxygen content (FiO₂), ROP has also been described in term babies on room air or in infants with cyanotic congenital heart disease. Despite the fact that prematurity and oxygen exposure are just two of many (mostly unknown) risk factors for ROP, it is recommended that the inspired oxygen concentration

be minimized for babies less than 44 weeks postconceptual age to achieve a target oxygen saturation in the low to mid-90s.

Temperature management

Neonates lose heat rapidly because of a reduced amount of subcutaneous fat and a large surface area. With limited ability to maintain their body temperatures through shivering or even nonshivering thermogenesis, the newborn is at risk for significant temperature fluctuations in the perioperative period – with transport, exposure during placement of intravascular lines and invasive monitoring, and heat losses during surgery. Measures must be taken to protect against heat loss. During transport to the OR, the neonate should remain covered with care taken to continue adequate monitoring and access in a heated isolette. The OR should be warmed to greater than 27°C. A radiant heat warmer is useful during line placement and preparation. Forced-air warming blankets are now available that go under the entire infant and include plastic drapes to cover noninvolved areas. Other intraoperative strategies include heating and humidifying inspired gases, warming intravenous (IV) fluids and blood products, and warming the surgical prep and irrigation solutions.

Monitoring

Two pulse oximeter probes should be available – one preductal (right hand) and one postductal (either foot) – to measure and compare the magnitude and direction of possible shunting across a PDA. Capnography may be unreliable owing to a large dead space in the breathing system, which can be reduced with specialized endotracheal tubes and low-volume connections. A precordial or esophageal stethoscope will permit detection of changes in heart rate or intensity of heart sounds, which may serve as useful indicators of cardiac function, intravascular volume status, and depth of anesthesia. A urinary catheter is of assistance for fluid balance in long cases. Neuromuscular monitoring is often challenging in small, premature newborns.

Invasive monitoring, principally an intra-arterial catheter, should be placed for cases with anticipated sudden or dramatic changes in hemodynamics, acid-base status, or oxygenation and ventilation to allow beat-to-beat monitoring of blood pressure and repeated sampling of hemoglobin and platelet counts, coagulation status, electrolytes, and arterial blood gases. Central venous catheters are infrequently used, and pulmonary artery catheters are rarely used in neonates for hemodynamic monitoring; however, the anesthesiologist can gain valuable information from the arterial line tracing. In hypovolemia, the arterial waveform is narrow, suggesting low stroke volume from inadequate preload, and there is marked respiratory variation in the tracing, suggesting collapse of great veins and changes in preload during the respiratory cycle. The dicrotic notch is present in the middle third of the downstroke in euvoolemia, but in the outer third (or absent) in hypovolemia. A sluggish increase and decreased slope of ascent of the arterial waveform suggests diminished left ventricular function or the presence of

aortic valve disease. Low amplitude and a rapid rate of increase of ascent suggests low SVR.

Fluid requirements

Intraoperative fluid therapy has four main components: maintenance fluid, replacement of fluid deficit, replacement of blood loss, and replacement of insensible and other losses. Maintenance fluid covers the normal insensible water loss from the respiratory epithelium and evaporative losses from the skin. Based on estimations of the interaction between metabolic rate and fluid requirements, this maintenance fluid can be calculated as: 4 ml/kg for the first 10 kg, 2 ml/kg for the next 10 kg, and 1 ml/kg for each additional kg over 20 kg. Fluid deficits are simply calculated by multiplying the hourly maintenance deficit by the number of hours since the last fluid intake, and can be replaced in most cases over 3 hours: 50% of the fluid deficit is given in the first hour, 25% in the second hour, and the final 25% in the third hour in the OR. Greater insensible losses above maintenance can take place from surgical trauma resulting in translocation of extracellular fluid from the intravascular space into the interstitial space, producing edema in the bowel wall and mesentery or in the subcutaneous tissues and muscle. Initial guidelines for replacement of these “third-space” losses are as follows: 2 to 5 ml/kg/h for peripheral or superficial surgeries, 5 to 10 ml/kg/h for open abdominal or thoracic surgery, and greater than 10 ml/kg/h for extensive abdominal surgery, titrated to heart rate and perfusion. As in older children and adults, hemorrhage can be acutely replaced with 3 ml of crystalloid per 1 ml of estimated blood loss to re-expand the intravascular blood volume. If colloids, such as albumin, are preferred, this can be accomplished using a 1:1 volume ratio.

Management of surgical urgencies and emergencies

Gastroschisis and omphalocele

Gastroschisis and omphalocele are defects of the abdominal wall at or near the umbilicus. Gastroschisis is a defect of the abdominal wall that occurs to the right of the umbilicus and lacks a peritoneal covering (see Fig. 130.1). It is hypothesized that this defect results from a weakening of the abdominal wall as the right umbilical vein regresses during development. Gastroschisis is typically not associated with major congenital anomalies or syndromes, although as many as 10% of affected infants will suffer intestinal atresia secondary to vascular compromise of the affected segment arising from a constricting fascial defect. In contrast, omphalocele (Fig. 130.2) is considered to be a more serious abdominal wall defect, given that associated anomalies are common (trisomies 18 and 21, other midline defects including bladder exstrophy, and congenital heart disease). Pathophysiologically, omphalocele is a herniation of abdominal viscera through the base of the umbilical cord and possesses a covering of peritoneum. Like gastroschi-

Figure 130.1. Gastroschisis Courtesy of Roberta E. Sonnino, M.D.

sis, the intestines fail to rotate normally prior to returning to the abdominal cavity during development.

Newborns presenting for repair of abdominal wall defects require urgent surgery, as the large exposed surface area allows for substantial evaporative fluid and heat losses and presents a significant infection risk. For patients with omphalocele, there is a 20% incidence of cardiac anomalies, and there should be a low threshold for an echocardiogram, particularly if a murmur is noted. In addition, omphalocele may be seen in Beckwith–Wiedemann syndrome, with associated hypoglycemia, which requires frequent glucose monitoring during the perioperative period and macroglossia, which can make intubation challenging.

If not already intubated, these babies should be treated as having full stomachs, and gastric decompression should be undertaken prior to induction and intubation. Given the possible depleted intravascular volume status, care should be exercised by using an induction agent that would further reduce preload (propofol, thiopental) or contractility in patients with

Figure 130.2. Omphalocele Courtesy of Roberta E. Sonnino, M.D.

congenital heart disease (where etomidate would be the better choice). If blood cultures are negative, an epidural catheter can be inserted and used intraoperatively in conjunction with a light general anesthetic or for postoperative analgesia, threaded via either the lumbar or caudal route. If an epidural is not placed, an opioid-based technique with some vapor may be most hemodynamically stable (these patients will remain intubated). Good IV access should be established for the large anticipated third-space fluid losses (use crystalloid and/or colloids such as 5% albumin) and possible bleeding.

In general, surgical planning will involve either reducing the defect through staged procedures or undertaking primary closure if possible. If there is insufficient space in the abdomen, reduction may cause bowel ischemia and deleterious respiratory mechanics from increased intra-abdominal pressure leading to difficulties with oxygenation and ventilation. The anesthesia team will need to effectively communicate any observed decreases in pulmonary compliance (increased peak inspiratory pressures [PIPs], decreased tidal volumes, decreased minute ventilation) or increases in central venous pressure (if a central line is present) with surgical manipulation, placement of packing and retractors, or attempted abdominal closure. A primary repair is typically aborted if bladder pressures are transduced at greater than 20 mm Hg or if PIPs are noted at 35 mm Hg. Clinical changes suggestive of decreased peripheral perfusion or impaired venous return may also indicate inability to successfully reduce these defects during the initial procedure. In the case of staged closure, a prosthetic material is applied to the edges of the defect, creating a tubular silo. After gradually being reduced in the NICU over a period of several days, the abdomen is finally closed primarily. Intestinal function typically returns within a week for omphalocele and within a couple of weeks to a month for gastroschisis. Given the obvious nutritional concerns with this delayed bowel function in a catabolic newborn, a central line is often placed during the initial operation for parenteral nutrition.

Congenital diaphragmatic hernia

Congenital diaphragmatic hernia (CDH) is a posterolateral defect of the diaphragm that occurs in 1:4000 live births. A Bochdalek hernia results from a failure of the normal closure of the pleuroperitoneal canal during the eighth week of gestation, leading to a communication between the abdominal and thoracic cavities. Consequently, the intestine migrates into the chest as it returns from the umbilical cord. (See Fig. 130.3.) Resultant compression of the developing lung leads to a small and abnormally developed lung or lungs. Because the bowel is in an abnormal location, malrotation may occur (as mentioned earlier in the case of abdominal wall defects). Whereas more than 90% of hernias are on the left side, only 5% are on the right, which typically contain only a portion of the liver and a small amount of intestine. The earlier in gestation the hernia occurs, the greater the degree of ensuing pulmonary hypoplasia

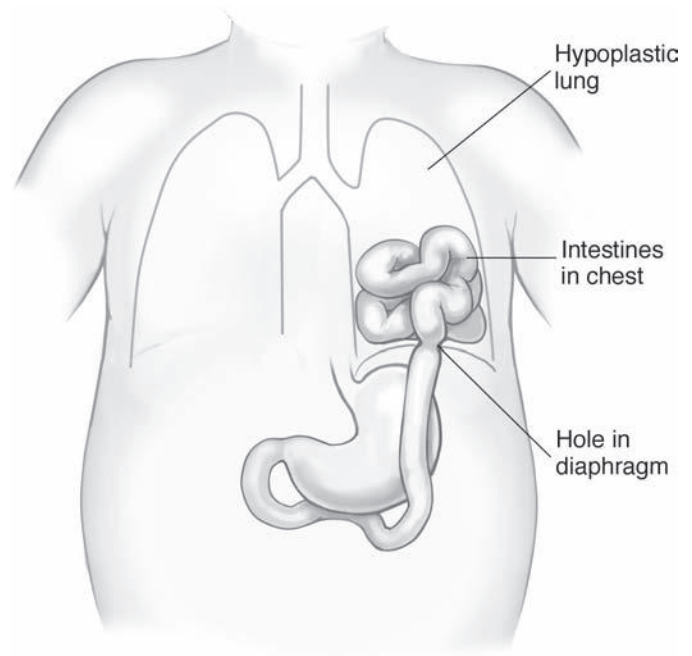

Figure 130.3. Congenital diaphragmatic hernia.

on both sides – with mediastinal shift, the development of the contralateral lung is restricted as well. As the hypoplastic lung contains fewer alveolar and capillary units; the pulmonary vasculature is also abnormal. Both undeveloped and composed of abnormally increased smooth muscle, the pulmonary circulation may be highly reactive to factors affecting PVR (see Table 130.3). One-quarter of afflicted babies have associated congenital diseases.

Now that immediate surgical repair is no longer routine, these patients are stabilized in the NICU (sometimes requiring extracorporeal membrane oxygenation [ECMO] if oxygenation and ventilation are significantly impaired), where additional cardiac and pulmonary evaluation and optimization can be performed preoperatively. For initial intubation, the stomach

Table 130.3. Factors affecting PVR and SVR in the premature and term newborn

PVR		SVR	
Increase	Decrease	Increase	Decrease
↑ Hematocrit	↓ Hematocrit	↑ Hematocrit	↓ Hematocrit
↑ PaCO ₂	↓ PaCO ₂	Vasopressin	Nitrates

should be decompressed and mask ventilation avoided. The approach to ventilatory management of the infant with CDH has changed over the last decade, with the recognition that barotrauma probably caused the most significant morbidity and mortality. Thus management has evolved from maintaining adequate oxygenation and normocarbina at all costs to permissive hypercapnia and early use of therapies to minimize mean airway pressure. Whereas small defects may be closed primarily, larger defects may require use of a thin patch of synthetic material. During transport and in the OR, inotropes and pressors (dopamine and epinephrine) should be available for boluses and infusions, while avoiding overaggressive volume administration. Good IV access and an arterial line should be available for surgery and are frequently in place from ICU care. Assuming normal coagulation (check coagulation if the liver is up in a right-sided CDH), an epidural catheter can be threaded via the caudal or lumbar region and used for both intraoperative and postoperative analgesia. If no epidural is planned, an opioid-based technique can be used for sympathetic suppression to control potentially deleterious surges in PVR.

In the OR, it should be remembered that overaggressive ventilation can lead to pneumothorax (usually of the overdistended “good lung” opposite the herniation), manifesting as sudden respiratory embarrassment or cardiovascular collapse. This diagnosis should always be at the top of the differential.

Ventilation should be managed by mimicking the ventilator settings that were successful preoperatively (if applicable), and it should be realized that pressures and tidal volumes will change as the compliance changes when the intestines are returned to the abdominal cavity. Muscle relaxation should be continued to optimize chest wall compliance and pulmonary mechanics. After the abdominal contents are reduced, the lungs should be expanded with manual ventilation (limiting PIPs to 35 mm Hg to avoid the potential for barotrauma, volutrauma, and/or possible pneumothorax). As always, good communication in the OR is essential: Alert the surgeons if abdominal closure leads to worsening PIPs, oxygenation, or ventilation. All but the most minimal of these defects will require postoperative ventilation and ongoing management of PVR.

Tracheoesophageal fistula and esophageal atresia

Esophageal atresia (EA) encompasses a spectrum of anomalies that occur early in gestation (22–36 days), as the trachea buds from the primitive foregut. Failure of the normal development of the esophagus and separation of the trachea from the esophagus result in one of five possible outcomes: EA with distal tracheoesophageal fistula (TEF; 85%), isolated EA (8%), TEF without EA (5%, also referred to as “H-type”), EA with proximal TEF (1%), or EA with proximal and distal TEF (1%). (See Fig. 130.4.) Because other developing organs are vulnerable to the

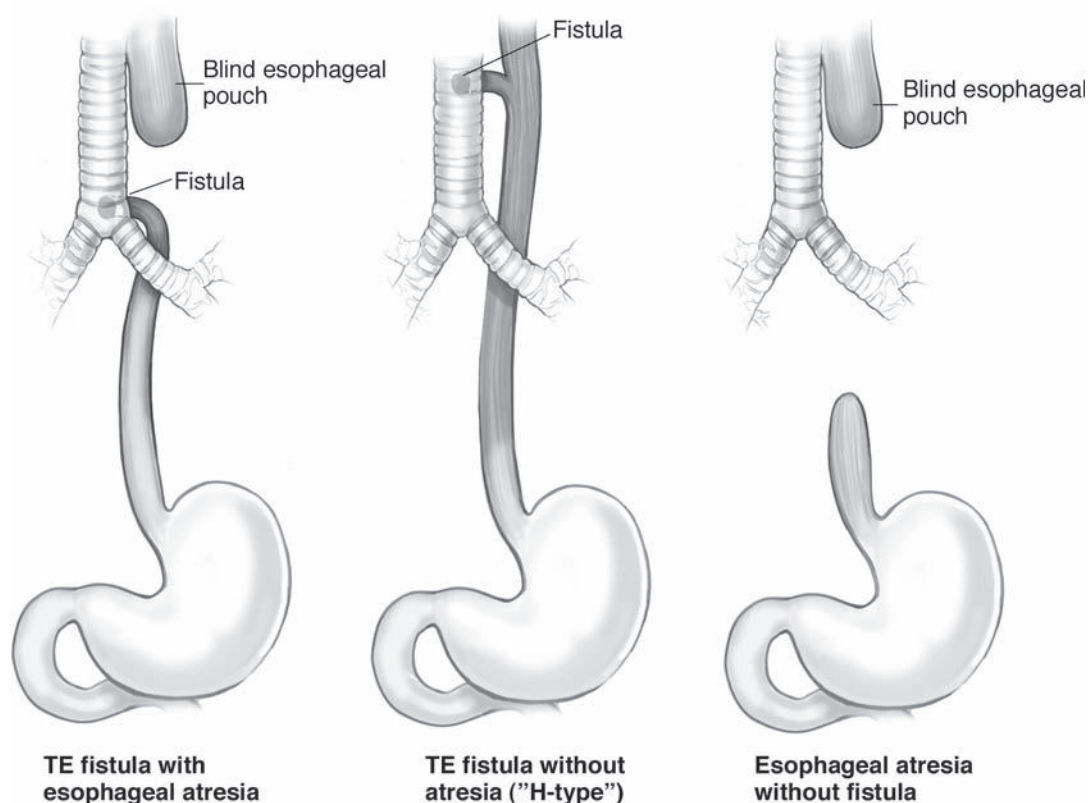

Figure 130.4. Tracheoesophageal fistula types.

same insult, associated anomalies are common (50% or more), particularly vertebral, anal atresia and other GI abnormalities, cardiac (ventricular septal defect [VSD], PDA, tetralogy of Fal-lot, atrial septal defect [ASD], coarctation of the aorta), renal abnormalities, and limb malformations otherwise known as the VACTERL associations. There is also a high incidence of TEF among children born with trisomy 21. The diagnosis is made presumptively when a nasogastric tube cannot be advanced past 10 cm and gas is present in the stomach on radiograph. These babies get into trouble because they aspirate from pooling oropharyngeal secretions and because increasing amounts of stomach gas can worsen pulmonary compliance and lead to atelectasis, hypoxemia, and impaired ventilation. The risk of aspiration can be minimized if repair is undertaken within a few days of birth. Repairs are performed all at once or in a staged manner (for babies weighing less than 1000 g, with pure EA, or critical anomalies, often a gastrostomy tube is placed first, followed by patient stabilization, and deferred repair). The operation is typically performed in the left lateral decubitus position for a right thoracotomy (90% of cases), via a retropleural or transpleural approach. Some isolated TEF (H-type) can be approached through a neck incision.

General anesthesia is used, but can be augmented with a caudal or lumbar epidural catheter after the airway is secured. To minimize gastric distention, spontaneous ventilation is maintained or minimal pressures are used if mask ventilation is required prior to intubation. It is important to position the endotracheal tube to avoid ventilating into the fistula. Classically, the endotracheal tube is advanced to the right mainstem bronchus and slowly withdrawn until breath sounds are heard bilaterally, at which point the tip will be just above the carina (hopefully distal to the fistula), and the tube is rotated so that the bevel opens anteriorly – away from the posteriorly positioned fistula. If a large fistula exists, bronchoscopy with placement of a Fogarty catheter prior to intubation may improve ventilation. A gastrostomy tube, if placed, may help by serving as a pop-off valve for the gastric air, but can also encourage ventilation into the stomach as gases follow the path of least resistance (in which case the gastrostomy tube may have to be clamped or placed to water seal).

Blood loss is typically minimal, and an arterial line is typically placed for monitoring blood gases as well as perfusion with potential compression of great vessels. If no epidural is placed, muscle relaxation and moderate-to-high dose opioid is used (unless spontaneous ventilation is still being used until ligation of the fistula). At the point where the surgeon is approaching the fistula, it may be necessary to pass an orogastric tube to identify the proximal pouch. At the end of the repair, a nasogastric tube is passed under direct visual inspection by the surgeon and carefully taped in place. At the end of the case, extubation may be considered with competing pros and cons: immediate extubation in the OR would limit the time the endotracheal tube spends lying against the suture line, but the need for urgent reintubation might compromise a new esophageal anastomosis. If not extubated in the OR, the baby is typically

sedated and ventilated for a few days in the NICU to allow healing.

Necrotizing enterocolitis

Necrotizing enterocolitis (NEC) results from ischemia and/or inflammation of the GI tract. It most commonly affects the terminal ileum and occurs in stressed, premature infants, with a severity of symptoms, complications, and a mortality rate that is inversely proportional to gestational age. Although its specific etiology is not completely understood, NEC is linked to mucosal injury from decreased mesenteric blood flow, which may be caused by reduced cardiac output from fetal asphyxia, a PDA, postnatal apnea, heart failure, arrhythmia, or severe bradycardia and hypoxemia. Other factors include enteral feeding of small preterm infants, use of hyperosmolar formula, bacterial infection, intestinal dysfunction, gram-negative endotoxemia, polycythemia, congenital heart disease, and a history of umbilical artery catheterization or exchange transfusion. The combination of bacteria and ischemia seems to be critical, with a wide range of organisms associated with NEC, including *Escherichia coli*, *Enterobacter*, *Klebsiella*, and *Pseudomonas*.

Although NEC may resolve with conservative management (antibiotics, gastric decompression, no enteral feeds), it may progress to necrosis and perforation requiring either laparotomy with bowel resection and stoma formation or a drainage procedure, according to surgeon preference (evidence supports drains for weight < 1500 g). Absolute indications for operation include pneumoperitoneum and intestinal gangrene (positive paracentesis). Relative indications for surgical intervention include signs of clinical deterioration (e.g., worsening metabolic acidosis, respiratory failure, oliguria or hypovolemia, thrombocytopenia, leucopenia or leukocytosis), portal vein gas or dilated loops of bowel on abdominal imaging, erythema of the abdominal wall, or discoloration of the abdominal wall (suggestive of intraperitoneal meconium).

Most infants will be intubated for stabilization in the NICU, but, if not, full-stomach precautions should be employed after effective preoxygenation. Atropine may be considered prior to laryngoscopy. With concern for ROP, avoid excessive inspired oxygen concentration with an oxygen–air mixture during the maintenance. Consider use of a NICU ventilator if high ventilator support settings are needed. Because extubation will not usually be planned, a hemodynamically stable opioid-based anesthetic is appropriate. An arterial line, preferably preductal, is needed for hemodynamic monitoring, to follow oxygenation and ventilation, and for sampling laboratory tests. Good IV access is needed for volume resuscitation (a central line may be necessary if access is difficult). Five percent albumin boluses, at 10 to 20 ml/kg at a time, are typically needed to maintain intravascular volume, although dopamine and even epinephrine may be needed for additional hemodynamic support. Fluid therapy is geared to attempt to maintain intravascular volume but minimize bowel wall edema, which may make ventilation difficult with closure. Transfusion of packed cells

Table 130.4. Anesthetic considerations for various surgical urgencies and emergencies

Surgical diagnosis	Preoperative considerations	Intraoperative considerations	Postoperative considerations
Gastroschisis and omphalocele	RDS if premature Cardiac anomalies (omphalocele) Sepsis Intestinal atresia Hypovolemia Hypoglycemia	Hypovolemia Hypothermia Hypercarbia Hypoxemia Respiratory acidosis Metabolic acidosis Atelectasis Volume overload/pulmonary edema	Oxygenation/ventilation problems Bowel ischemia Renal failure Peritonitis Sepsis Metabolic acidosis Hypothermia Analgesia (epidural or opioid)
CDH	Overexpanded contralateral lung Hypoplastic ipsilateral lung Pneumothorax and barotrauma Pulmonary HTN May be on ECMO Respiratory acidosis Metabolic acidosis IVH Hypoglycemia Hypokalemia if on diuretics	Epidural or opioid-based technique Pneumothorax Hypovolemia Pulmonary HTN Suprasystemic RVBPs Hypoventilation Hypothermia Metabolic acidosis Right-to-left shunting Volume overload	Analgesia (epidural or opioid) Pneumothorax and barotrauma Hypovolemia Pulmonary HTN Suprasystemic RVBPs Hypoventilation Hypothermia Metabolic acidosis Right-to-left shunting Volume overload May require HFOV or ECMO after “honeymoon period” within 24–48 h of repair
TEF	Aspiration Gastric distention RDS if premature Cardiac anomalies GI anomalies Renal anomalies	Epidural or opioid-based technique Aspiration Hypothermia Metabolic acidosis Respiratory acidosis Pneumothorax Atelectasis/hypoxemia Mucus plugging Gastric distention Extubate in OR if possible	Analgesia (epidural or opioid) Pneumothorax Apnea Hypoventilation Tracheal leak Weakness RLN injury Pneumonia
NEC	Respiratory compromise from abdominal distention Respiratory and metabolic acidosis Sepsis Volume depletion Hypoglycemia Hypocalcemia DIC	No epidural if septic Minimize FiO ₂ (retinopathy) Vasopressors/ionotropes Hypovolemia Metabolic acidosis Hypoglycemia Hypocalcemia Bowel wall edema Respiratory compromise with abdominal closure	ROP Hypovolemia Metabolic acidosis Sepsis Pulmonary edema with fluid remobilization Opioids for postoperative analgesia

RDS, respiratory distress syndrome; HTN, hypertension; ECMO, extracorporeal membrane oxygenation; IVH, intraventricular hemorrhage; RVBP, right ventricular blood pressure; HFOV, high frequency oscillatory ventilation; RLN, recurrent laryngeal nerve; DIC, disseminated intravascular coagulation.

and possibly fresh frozen plasma (FFP) and platelets may be required. Epidurals are generally not used because of the concern for sepsis and are not needed if the patient is intubated for several days. Potential complications in the OR include hypothermia, metabolic acidosis, hypovolemia, hypocalcemia, hypoglycemia; postoperatively, pulmonary edema may be seen as fluid mobilizes. (See Table 130.4.)

Pyloric stenosis

Pyloric stenosis is caused by idiopathic hypertrophy of the muscular layers of the antrum and pylorus, and usually manifests in the 2nd to 8th week of life. Occurring more frequently in boys (and perhaps first-born boys), this lesion has an incidence of approximately 1:500 live births. Neonates present with nonbilious projectile vomiting, and the hypertrophied muscular layers can often be palpated as an olive-sized mass

located between the midline and right upper quadrant. Radiologic diagnosis was historically accomplished with barium swallow, and is now increasingly performed with the widespread availability of ultrasound. Clinical awareness has also led to earlier diagnosis, leading to less severe physiologic derangements of these babies when they present for preoperative evaluation before the definitive surgical treatment, pyloromyotomy – division of the hypertrophied fibers.

Pyloric stenosis is not a surgical emergency, but fluid resuscitation may be urgent depending on the severity of dehydration. Chloride and hydrogen ions are lost from the GI tract through severe vomiting, and this loss is accompanied by a renal response that begins with excretion of bicarbonate, sodium, and potassium. With ongoing depletion of sodium and potassium, conservation of these electrolytes in the distal tubules leads to excretion of hydrogen ions and a resultant worsening of the

metabolic alkalosis. With protracted vomiting, these infants can have a mixed metabolic alkalosis (from GI and renal proton losses) and metabolic acidosis (lactic acidosis from pronounced intravascular depletion from the dehydration accompanying ongoing vomiting and decreased effective enteral intake), with hypokalemia and hypochloremia. Prior to a patient's arrival in the OR, his or her electrolytes should be checked to ensure that they have been normalized, and volume status should be assessed to ensure adequate preoperative fluid resuscitation (sometime requiring as much as 50–100 ml/kg in fluid boluses if severely dehydrated).

Pyloromyotomy is performed through either an open approach or laparoscopically. If open, the operation involves either a right upper quadrant or periumbilical incision. If laparoscopic, three trocar incisions are typically made for cameras, tools, and intraperitoneal carbon dioxide insufflation. After being identified, the serosa and hypertrophic muscle of the pylorus are divided with a scalpel or electrocautery, with care not to advance the division so deep as to cause a tear of the fragile gastric mucosa. Adequate myotomy is usually indicated by visible herniation or bulging of the submucosa into the myotomy site.

Anesthetic preparation is as for most neonatal cases, including warming the room. To minimize the risk of aspiration, the stomach is emptied by passing a large-bore orogastric tube prior to induction and suctioning with the baby in the right lateral, left lateral, and supine positions. Atropine at 20 $\mu\text{g}/\text{kg}$, with a minimum dose of 100 μg may be given before induction to minimize bradycardia if succinylcholine is used and as an antisialogogue. The two usual approaches to intubation include (1) an awake technique or (2) a rapid sequence or modified rapid-sequence induction after careful preoxygenation. Maintenance is achieved with a balanced technique of volatile agent delivered in either an air–oxygen mixture or a nitrous oxide–oxygen mixture (the latter probably best avoided in laparoscopic procedures). Even term infants with pyloric stenosis may be more sensitive to postoperative apnea with opioids, probably related to residual central nervous system (CNS) acid–base changes; adequate postoperative analgesia can be achieved by local anesthetic infiltration of the incision site in conjunction with acetaminophen and possibly ketorolac. Emergence is accompanied by adequate reversal of muscle relaxation (hip flexion is a good indicator for return of strength in an infant) and extubation when fully awake. Postoperatively, the neonate should be monitored for apnea for 12 to 24 hours given the risk of apnea after general anesthesia (and perhaps greater risk if opioids are also administered).

Meningomyelocele

Neural tube defects occur with an incidence of 0.5/1000 to 1/1000 live births and are more common in female infants than males; they are generally diagnosed prenatally by ultrasound and are associated with elevated maternal serum alpha-fetoprotein levels. Low levels of maternal folate and maternal ingestion of valproic acid have been associated with these

defects. Spina bifida occurs when the posterior neural tube fails to close properly starting in the 4th week of fetal life. The least severe form of spina bifida is spina bifida occulta, which is a failure of the vertebral arches to form, usually with a normal spinal column; this defect may be detected by skin dimpling or a lipoma in the area. Another form of spina bifida is a meningocele, in which a fluid-filled sac composed of skin and meninges protrudes from the back. The spinal cord function may remain normal in a patient with a meningocele. A third type is a meningomyelocele, in which the fluid-filled sac also contains neural elements. Spinal cord function is never normal in patients with meningomyelocele, although patients with low lumbar or sacral meningomyeloceles can learn to walk with braces. Finally, in raschism, much of the spinal cord is abnormal and covered with skin and meninges. This birth defect is usually incompatible with life.

These defects may be associated with lower extremity weakness, bowel and bladder dysfunction, orthopedic abnormalities such as hip dysplasia and club feet, and congenital heart disease. Some lumbar meningomyeloceles are associated with an Arnold–Chiari type 2 malformation, which consists of displacement and elongation of the brainstem and protrusion of the cerebral tonsils through the foramen magnum. The fourth ventricle is also displaced below the level of the foramen magnum, which may be small. This malformation is almost always accompanied by hydrocephalus and usually requires surgical shunting. Cranial nerve difficulties are also common and include vocal cord paresis, stridor, apnea, facial weakness, and strabismus.

Although clinical trials of intrauterine repair of meningomyelocele are being done, the majority are repaired within 48 hours of birth. A cesarean delivery is advised because it is associated with less perinatal infection. At delivery, the sac should be covered with a moist, occlusive, antibiotic dressing, and great care should be taken to maintain the sac's integrity. Surgical repair is done with the patient in the prone position, and the goal of surgical treatment is create a repair with secure dural coverage, free of cerebrospinal leaks and tension. Primary closure is often done, but, for large defects, musculocutaneous or cutaneous flaps or grafts may be required and involve the services of plastic surgeons in addition to neurosurgeons. Patients with symptomatic hydrocephalus may have a ventriculoperitoneal shunt placed during their initial meningomyelocele repair.

Meningomyelocele repair is usually done with a general anesthetic, although there are case reports of spinal anesthesia being used for repair. It is critical to preserve the integrity of the sac prior to repair, and thus the patient should not be positioned in the supine position if possible. For induction and intubation, the patient can be either positioned lateral or placed on a foam “donut” (or on rolls under the shoulders and hips) to allow the sac to hang free from all pressure. Most infants will have an IV catheter in place for fluid replacement and antibiotics, but there is no contraindication to inhalation induction. Because of both multiple surgical procedures and some atopic

predisposition, this patient population is at increased risk for development of latex allergy, so latex precautions are generally taken from birth.

Because infants have the potential for cranial nerve dysfunction, it is critical to extubate these patients at the conclusion of the surgery only if they demonstrate alertness, a normal breathing pattern, and the ability to protect their airway. These patients are initially cared for in an intensive care setting. Opioids are used with caution in this patient population. Positioning for extubation is as for induction; the patient is generally positioned prone again after extubation after it is clear that there are no airway issues.

Congenital heart disease

Denise M. Chan and Annette Y. Schure

Introduction

Congenital heart disease (CHD) is the most common congenital defect. It affects 4 to 9 per 1000 live-born, full-term infants and is two to three times more common in premature babies. There are currently more than 1.2 million patients with CHD living in the United States, and 300,000 of them are younger than 21 years. Over the last few decades, mortality rates have declined dramatically, and more and more of these patients will require both cardiac and noncardiac surgical procedures. Thus it is imperative for all anesthesiologists, not only cardiac specialists, to understand the basic principles of managing patients with CHD.

Classification

Congenital heart defects can be broadly categorized as cyanotic (“blue babies”) or acyanotic (“pink babies”) and then can be further classified according to the underlying pathophysiology into shunts, obstructions, and complex lesions with mixing of pulmonary and systemic blood flow (Table 131.1).

The most common congenital cardiac lesions are ventricular septal defect (VSD), transposition of the great arteries (TGA), tetralogy of Fallot (TOF), and coarctation of the aorta. Together these comprise approximately half of all CHDs.

Pathophysiology

Left-to-right shunts

Children with significant left-to-right shunts will demonstrate increased pulmonary blood flow as soon as the initially high pulmonary vascular resistance (PVR) of the perinatal period starts to decline, usually around 6 to 8 weeks of age. The pulmonary overcirculation leads to increased pulmonary artery (PA) pressures and progressive left ventricle (LV) volume overload, which will eventually result in congestive heart failure (CHF), low cardiac output, and pulmonary congestion or edema. Clinically this will manifest as poor peripheral circulation with cold extremities and mottled skin, as well as tachypnea, rales, increased work of breathing, and hepatomegaly. Persistent increases in pulmonary blood flow and pressure provoke changes in the pulmonary microvasculature that cause vasoconstriction and, ultimately, the development of

pulmonary vascular obstructive disease (PVOD). Initially, these changes are reversible, but they can be fixed as early as 6 months, depending on the type and size of the defect. If left untreated, increasing PA pressures will eventually compromise right ventricle (RV) function. With further increases in PVR, either sudden or gradual, PA pressure may exceed LV pressure and can lead to reversal of the shunt, resulting in right-to-left flow and cyanosis (Eisenmenger syndrome).

Right-to-left shunts

In cardiac defects with a right-sided flow obstruction and a connection between the right and left sides of the heart, venous blood will be shunted away from the pulmonary circulation and directly mixed with arterial blood, leading to hypoxemia and cyanosis. To maintain adequate tissue oxygenation, these patients develop polycythemia. Unfortunately, this compensatory mechanism causes significant hyperviscosity and increases the risk for spontaneous thrombus formation and ischemic strokes. These negative effects on blood rheology can be further exacerbated by dehydration and prolonged fasting periods. Depending on the location and extent of the right-sided flow obstruction, the pressure load on the RV can result in marked hypertrophy and progressive RV dysfunction and arrhythmias.

Table 131.1. Classification of CHD (incidence of lesion as percentage of all CHD)

Cyanotic	Acyanotic
Right-to-left shunts Tetralogy of Fallot (10%) Pulmonary atresia (1%) Tricuspid atresia (<1%)	Left-to-right shunts VSD (20%–25%) ASD (5%–10%) Endocardial cushion defect (AV canal) (4%–5%) PDA (5%–10%)
Complex “mixing” lesions Transposition of the great vessels (5%) Total anomalous pulmonary venous return (1%) Truncus arteriosus (1%) HLHS (1%) Double-outlet RV (<1%)	Obstructive lesions (left-sided) Coarctation of the aorta (8%–10%) Aortic stenosis (5%)
Obstructive lesions (right-sided) Pulmonary stenosis (5%–8%)	

Table 131.2. Manipulation of PVR**Factors increasing PVR**

- PEEP
- High airway pressure
- Atelectasis
- Low FiO₂
- Acidosis and hypercapnia
- Increased hematocrit
- Sympathetic stimulation
- Pain and agitation
- Epinephrine, dopamine
- Direct surgical manipulation

Factors decreasing PVR

- No PEEP
- Low airway pressure
- Normal FRC
- High FiO₂
- Alkalosis and hypocapnia
- Low hematocrit
- Blunted stress response
- Nitric oxide
- Vasodilators (milrinone)

PEEP, positive end-expiratory pressure.

Obstructive lesions

Left- or right-sided outflow obstructions impose primarily pressure loads on the respective ventricles, resulting in significant hypertrophy and increased oxygen consumption. With critical stenosis or obstruction, cardiac output and tissue perfusion are markedly decreased, leading to hypoxemia and metabolic acidosis. Decreased coronary perfusion can manifest as ventricular failure and arrhythmias. During the neonatal period, adequate systemic or pulmonary blood flow is often maintained through a patent ductus arteriosus (PDA). Closure of the PDA can lead to sudden decompensation.

Complex “mixing” lesions

Defects in which venous and arterial blood are mixed at various levels before reaching the systemic circulation are known as complex mixing lesions. Often additional intra- or extracardiac flow obstructions are present. Arterial oxygen saturation and adequate tissue perfusion are highly dependent on a well-balanced ratio of pulmonary and systemic blood flow. Pulmonary overcirculation will initially lead to high saturations (>90%), but it will also result in inadequate systemic cardiac output and metabolic acidosis. Predominance of the systemic circulation and poor pulmonary perfusion will result in hypoxemia and cyanosis. This form of circulation is described as “parallel circulation” in contrast to the “series circulation” of a normal heart. PVR and systemic vascular resistance (SVR) are important determinants for a heart with parallel circulation (Tables 131.2 and 131.3).

Table 131.3. Manipulation of SVR**Factors increasing SVR**

- Sympathetic stimulation
 - Pain and agitation
 - Epinephrine, dopamine
 - Norepinephrine
 - Ketamine
- Negative intrathoracic pressure
- Hypothermia

Factors decreasing SVR

- Adequate sedation and analgesia
- Vasodilators
 - Milrinone, dobutamine
 - Nitroprusside
 - ACE inhibitors
- Positive pressure ventilation
- Fever, sepsis

Preoperative evaluation of patients with congenital heart disease

A thorough understanding of the anatomy and pathophysiology of the cardiac defect is important for the safe perioperative management of patients with CHD. For complex lesions it can be useful to contact the pediatric cardiologist. Table 131.4 highlights the important aspects of the preoperative assessment. However, all evaluations must be adjusted for the specific lesion and planned procedure; not all patients need cardiac catheterization or MRI.

For patients with repaired congenital heart defects who present for cardiac or noncardiac procedures, specific information about the type and outcome of previous surgeries is important. Palliative repairs (e.g., PA banding, Blalock–Taussig shunts) with significant residual pathophysiology must be differentiated from definitive repairs. The anesthesiologist should be aware of any residual defects, such as patch leaks or outflow obstructions, surgical complications, or altered anatomy and physiology. A history of frequent interventional procedures can be a strong indicator of residual problems. All patients should be specifically asked about signs and symptoms of exercise-induced ventricular dysfunction or arrhythmias. In addition, sites of previous vascular shunts and cut-downs for access need to be documented.

The indication for perioperative endocarditis prophylaxis has to be assessed on an individual basis, according to the latest guidelines published by the American Heart Association (<http://www.americanheart.org>). The current version recommends prophylaxis only for CHD with the highest risk of adverse outcome from endocarditis and for specific surgical procedures.

General considerations for anesthetic management

Premedication in children with complex CHD is desirable, as it improves oxygen saturation, decreases myocardial oxygen consumption, and facilitates a smooth induction. Opioids and benzodiazepines, alone or in combination with ketamine, may be used, but care must be taken to avoid oversedation, because hypoventilation and bradycardia are often poorly tolerated.

Induction of anesthesia may be accomplished using a variety of techniques, depending on the type of cardiac defect and extent of ventricular dysfunction. For patients with well-preserved ventricular function, a careful inhalation induction is an option. Of note, a significant right-to-left shunt can slow down an induction with inhaled anesthetics. When a substantial portion of the cardiac output is shunted away from the lungs, the uptake of inhaled anesthetics is decreased, and the time to reach adequate partial pressures in the brain is prolonged. This effect is more pronounced for insoluble gases.

Patients with significant ventricular dysfunction and poor cardiac reserve may be unable to tolerate the cardiodepression

Table 131.4. Important aspects for the preoperative evaluation

History	<ul style="list-style-type: none"> ● Signs and symptoms of CHF: <ul style="list-style-type: none"> – Failure to thrive (FTT), poor feeding, tachypnea, sweating – Recurrent pulmonary infections (secondary to congestion) – Decreased activity level and fatigue in older patients ● Palpitations or syncope ● Additional congenital anomalies (e.g., airway, genitourinary) ● Recent and current medications (e.g., diuretics, digoxin, ACE inhibitors) ● Review of previous surgeries and interventional procedures ● Last follow-up with the patient's pediatric cardiologist
Physical examination	<ul style="list-style-type: none"> ● Characteristic heart murmur, precordial thrill, arrhythmias ● Tachypnea, increased work of breathing, rales ● Poor peripheral perfusion, delayed capillary refill ● Bounding or diminished pulses ● Cool extremities, mottled skin, sweating ● Hepatomegaly ● Peripheral edema

CBC, complete blood count; EKG, electrocardiography; CXR, chest radiograph.

and hypotension that are often associated with inhalation induction. For intravenous (IV) induction, a combination of benzodiazepine, opioid, and a small dose of an induction agent is frequently used. Maintaining a good airway for effective oxygenation and ventilation as well as an optimal ratio of PVR to SVR are also extremely important.

The plan for maintenance of anesthesia will depend on many factors, including the type of CHD; the age, condition, and comorbidities of the patient; the surgical procedure; the expected duration; the use of cardiopulmonary bypass (CPB); and the need for postoperative ventilatory support. In general, more complex or fragile patients should be maintained with an opioid-based anesthetic, whereas patients with simple or straightforward defects and preserved cardiac function can be anesthetized with a balanced technique with inhalation agent and opioid.

The risk and benefits of invasive monitoring are determined by the complexity of the cardiac defect, the patient's condition, and the surgical procedure. For patients with complex lesions having extensive procedures with possible hemodynamic instability, major fluid shifts, or poor vascular access, central venous cannulation and invasive blood pressure (BP) monitoring should be established prior to the procedure. Additional monitoring modalities include intraoperative transesophageal echocardiography and cerebral oximetry.

Depending on the patient's history and condition, the need for inotropic support, nitric oxide, or antiarrhythmic therapy (e.g., defibrillation, adenosine, or amiodarone) must be anticipated.

Common congenital heart defects

Ventricular septal defect

Incidence and pathophysiology

VSDs are the most common form of CHD, affecting 20% to 25% of CHD patients; 30% to 40% of VSDs will close spontaneously within the first year of life.

VSDs are differentiated according to location: perimembranous (80%), outlet (just beneath the pulmonary valve; 5%–7%), inlet (posterior and inferior; 5%–8%), or muscular (within the trabecular area; 5%–20%). Muscular VSDs are often multiple and have a “Swiss-cheese” appearance (Fig. 131.1).

The resulting left-to-right shunt is dependent on the size of the defect and the pressure gradient across the septum, which is determined by LV and RV pressures, PVR, and SVR. Large left-to-right shunts lead to pulmonary overcirculation, CHF, and poor cardiac output.

Signs and symptoms

Small VSDs can be completely asymptomatic and found incidentally on physical examination. Infants with a large VSD will usually develop CHF at 6 to 8 weeks of age when PVR declines. Cardiac examination may reveal a holosystolic murmur and possibly a systolic thrill at the left sternal border. Poor cardiac output results in tachypnea, mottled skin, and cool extremities. Additional signs and symptoms include failure to thrive (FTT), poor feeding, and delayed growth and development, as well as recurrent pulmonary infections due to pulmonary overcirculation and congestion.

Figure 131.1. Location of various types of ventricular septal defects.

Associated anomalies

Fewer than 5% of VSDs are associated with chromosomal abnormalities, such as trisomy 13, 18, and 21.

Treatment

Medical treatment of CHF may include digitalis, angiotensin-converting enzyme (ACE) inhibitors, and/or diuretics. VSD closure may be performed either with a device placed by an interventional cardiologist or surgically. Surgical management is considered in infants with CHF and FTT who are unresponsive to medical treatment or in patients with large left-to-right shunts with a ratio of pulmonary to systemic flow $> 2:1$. Asymptomatic children may undergo elective repair at approximately 2 years of age to prevent long-term complications. Direct patch closure is performed via an atrial approach or a ventriculotomy. Infants who are unable to tolerate CPB may alternatively undergo PA banding to reduce pulmonary blood flow.

Anesthetic considerations

Patients with a small VSD and no obvious CHF will usually tolerate a careful inhalation induction; however, one must still be aware of reduced cardiac reserve. Conversely, patients with a large VSD and significant CHF should have a careful IV induction aiming for a stable PVR/SVR ratio and normoventilation. Hyperventilation and high fraction of inspired oxygen content

(FiO_2) will increase left-to-right shunting and therefore should be avoided. Severe hypotension or an increase in PVR places the patient at risk for shunt reversal (i.e., right-to-left).

Considerations for patients with repaired VSDs

Endocarditis prophylaxis should be given for the first 6 months after patch repair. Dysrhythmias and conduction defects, such as right bundle branch block (RBBB), ventricular arrhythmias, and heart block, may persist, as well as ventricular dysfunction after ventriculotomy.

Patent ductus arteriosus

Incidence and pathophysiology

The ductus arteriosus is a normal fetal structure that connects the main pulmonary artery and the upper descending aorta. In utero, approximately 60% of RV output bypasses the lungs via the ductus arteriosus. In full-term infants, functional closure (i.e., smooth muscle contraction) usually occurs 10 to 15 hours after birth as a result of lung expansion, decreases in PVR, exposure to increased PaO_2 , decreased prostaglandin levels, and the release of vasoactive substances. Permanent closure is completed by the first 2 to 3 weeks of life, leaving a fibrosed band (the ligamentum arteriosum), which is the only remnant of this intrauterine connection. In approximately 1:2500 live births, however, the ductus fails to close.

The degree of left-to-right shunting via the PDA depends on the size of the PDA and the ratio of PVR to SVR. Small PDAs are often hemodynamically insignificant and asymptomatic. Left-to-right shunting through medium PDAs increases as PVR decreases over the first few months of life. With large PDAs, a significant left-to-right shunt leads to LV overload and progressive CHF, usually within the first few weeks of life, and, eventually, pulmonary hypertension. Additionally, sudden increases in PVR can lead to shunt reversal with right-to-left shunting and cyanosis.

Signs and symptoms

The classic finding on physical examination is a continuous machine-like murmur best heard at the left sternal border. Signs of CHF include tachypnea, hepatomegaly, poor peripheral perfusion, and FTT. A widened pulse pressure with low diastolic pressures may be seen, due to a “steal effect” from left-to-right shunting. Patients also commonly have pulmonary congestion or edema and recurrent respiratory infections.

Associated anomalies

A PDA is often essential for pulmonary or systemic blood flow in patients with complex cardiac lesions (see sections on TGA and hypoplastic left heart syndrome [HLHS]).

In preterm infants, the cardiovascular changes associated with a PDA can exacerbate conditions such as necrotizing enterocolitis, intracranial hemorrhage, or respiratory distress syndrome.

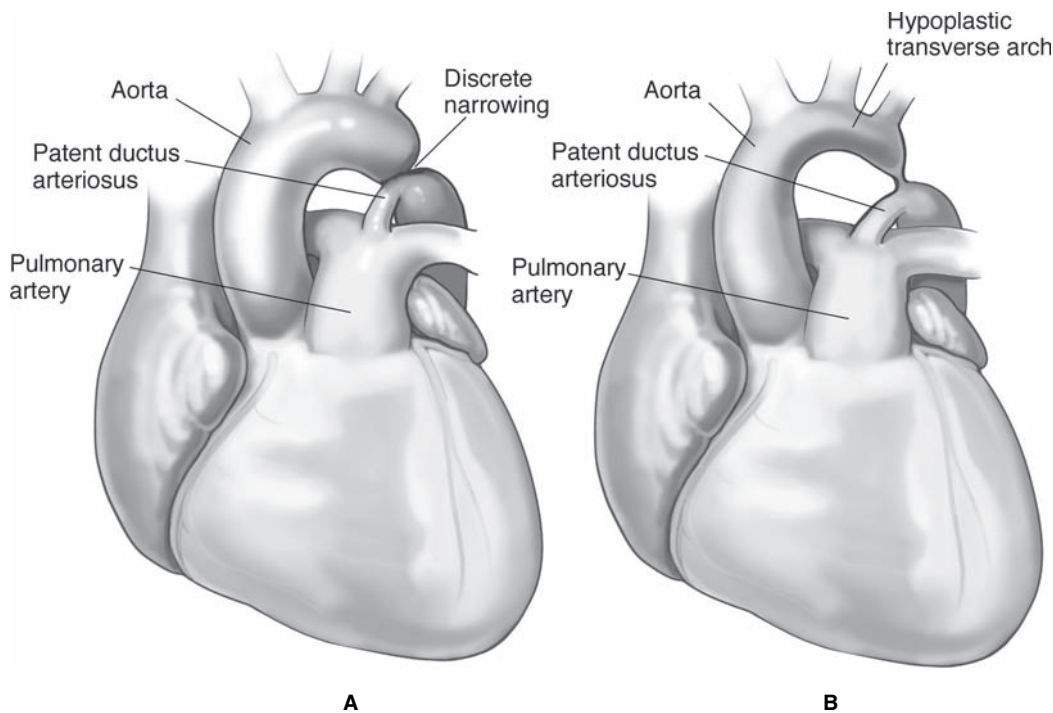

Figure 131.2. Coarctation of the aorta. Anatomic spectrum of coarctation of the aorta, ranging from a discrete narrowing (A) to a diffuse hypoplasia of the transverse arch (B).

Treatment

Medical treatment in preterm infants includes a trial of indomethacin, as well as treatment of CHF and pulmonary edema. Device closure may be performed by the interventional cardiologist but has a high incidence of residual shunts (~5%–10%). Surgery is indicated for neonates who fail medical therapy and for older asymptomatic children, usually at 2 to 4 years of age. Current surgical options include PDA ligation or division via posterolateral thoracotomy or hemoclip occlusion via video-assisted thoracoscopic surgery (VATS).

Anesthetic considerations

Pre- and postductal pulse oximetry are important tools to detect ligation of wrong vessels, and upper and lower extremity BP monitoring are used to determine pressure gradients. Upon PDA closure, the diastolic pressure should increase and the murmur should disappear. In older children, lung isolation with an endobronchial blocker or a double lumen tube may be requested.

In preterm infants, PDA ligation is often performed at the bedside to avoid transport and the risks associated with it (e.g., hypothermia, respiratory changes, or accidental extubation). Surgical exposure and retraction cause “functional” single-lung ventilation. Short periods of desaturation may have to be accepted to complete the procedure.

Considerations for patients with repaired PDAs

Recurrent laryngeal nerve injury is a potential complication of surgical repair. In cases of late repair, pulmonary hypertension and ventricular failure may develop.

Endocarditis prophylaxis should continue for the first 6 months after device closure or for residual shunts.

Coarctation of the aorta

Incidence and pathophysiology

Coarctation of the aorta is present in 5% to 10% of patients with CHD. Most patients have a discrete stenosis of the upper thoracic aorta, but the anatomic spectrum can range from a long tubular hypoplasia of the transverse arch to bandlike strictures in the descending aorta (Fig. 131.2). The hemodynamic picture is highly dependent on the severity of the stenosis and the presence of associated cardiac defects and collateral circulation. For instance, a newborn with critical stenosis may decompensate acutely when the ductus arteriosus closes. In contrast, older patients with mild and slowly progressive pressure gradients will develop systemic hypertension and compensatory LV hypertrophy. Later in childhood, some form of collateral arterial circulation often supports the perfusion in the distal descending aorta.

Signs and symptoms

There are two major clinical presentations of patients with coarctation of the aorta. An infant with severe coarctation has CHF and low cardiac output. A child or adolescent with mild to moderate coarctation presents with hypertension and a murmur; these patients, although often asymptomatic, may occasionally have exercise-induced claudication or headaches. A systolic pressure gradient exists between upper and lower extremities.

Associated anomalies

Coarctation of the aorta is often associated with other congenital anomalies: Fifty percent of patients have an additional intracardiac lesion; 85% have a bicommissural aortic valve. In addition, variations of the brachiocephalic vessels with an abnormal origin of the subclavian arteries may occur, and 3% to 5% of patients have berry aneurysms of the circle of Willis. Patients with Turner syndrome have a high incidence of coarctation; other congenital malformations are present in 25% of patients.

Treatment

Prostaglandin E is used to establish or maintain ductal patency in infants. Older children are placed on β -blockers for treatment of hypertension prior to repair. Symptomatic neonates will undergo surgery as soon as possible, usually after a 12- to 24-hour period of stabilization. Otherwise, asymptomatic patients should have their defect corrected after 3 months of age to reduce the risk of long-term sequelae (e.g., persistent hypertension, increased cardiovascular morbidity). Balloon angioplasty and stenting, although the procedure of choice for recoarctation, is controversial for primary treatment of coarctation because of the higher incidence of restenosis and complications.

Anesthetic considerations

Newborns and infants with CHF usually need a careful IV induction and an opioid-based maintenance technique. Older infants and children will generally tolerate an IV or inhalation induction and maintenance. Invasive BP monitoring should be placed in the right radial artery (the left subclavian artery may be clamped during repair), unless there is an anomalous right subclavian artery. Additional BP monitoring and pulse oximetry are placed in lower extremities. During cross-clamping, isoflurane and short-acting vasoactive agents (e.g., esmolol, nitroprusside, or nitroglycerin) decrease wall tension and oxygen consumption. Upon unclamping, goals include correction of metabolic acidosis and volume replacement. In the postoperative phase, it is important to watch for hypertension and postcoarctectomy syndrome (e.g., abdominal pain, vomiting).

Considerations for patients with repaired coarctation

Endocarditis prophylaxis should continue for the first 6 months following patch repair. Patients are at risk of recoarctation and exercise-induced pressure gradient, as well as persistent hypertension and myocardial hypertrophy with diastolic dysfunction. Patients with coarctation repaired late in life are at higher risk of premature coronary artery disease.

Atrial septal defect

Incidence and pathophysiology

In its isolated form, atrial septal defects (ASDs) comprise 5% to 10% of congenital heart defects, but they are part of more

Figure 131.3. Location of the different types of atrial septal defects.

complex cardiac defects in 30% to 50% of CHD patients. There are three basic categories of ASDs: an ostium secundum defect (50%–70%) is located in the fossa ovalis; an ostium primum ASD (15%–30%) is an endocardial cushion defect and is commonly associated with a cleft mitral valve and mitral regurgitation; and a sinus venosus ASD (10%–30%) is most commonly located at the junction of the superior vena cava (SVC) and right atrium (RA), and is often found in combination with partial anomalous pulmonary venous return (Fig. 131.3). Occasionally, an unroofed coronary sinus may be considered as a form of ASD.

The underlying pathophysiology is a left-to-right shunt with slowly progressive RA and RV dilation and eventually development of pulmonary hypertension. More than 80% of ASDs, especially those < 8 mm in size, will close spontaneously within the first 2 years of life.

Signs and symptoms

Most patients are asymptomatic; large, untreated ASDs may cause CHF and significant pulmonary hypertension in the third or fourth decade of life. ASDs are often incidental findings on physical examinations or later in life during the evaluation of supraventricular tachyarrhythmias or paradoxical embolization. Cardiac examination classically reveals a widely split and fixed S2 and a II-III/VI systolic murmur along the left sternal border. Patients may have a slender body build and exhibit decreased exercise tolerance and dyspnea on exertion. Later in life, they may have palpitations, atrial flutter, or atrial fibrillation.

Associated anomalies

ASDs may be associated with virtually any congenital anomaly. The most commonly associated cardiovascular defects include pulmonary stenosis, partial anomalous venous return, and VSD. There is a higher incidence of secundum ASDs in patients with Holt–Oram, Noonan, Marfan, and Turner syndromes.

Treatment

Device closure may be performed by the interventional cardiologist for patients with suitable anatomy. Surgery is usually indicated for infants with CHF and FTT who are too small for device closure. Surgery may also be performed electively in asymptomatic children around 2 to 5 years of age to prevent long-term complications (e.g., arrhythmias, Eisenmenger syndrome). Via a mini or full median sternotomy and an atrial approach, the defect is directly closed with a suture or a pericardial patch.

Anesthetic considerations

Careful removal of all air bubbles from lines is essential to prevent paradoxical air embolus. Inhalation induction is usually well tolerated, except in sick infants with CHF. Most patients can be extubated at the end of the surgical repair.

Consideration for patients with repaired ASDs

Endocarditis prophylaxis should be given during the first 6 months after device or patch closure. These patients frequently have perioperative dysrhythmias, and they may have persistent RV dilation or pulmonary hypertension if the repair has been delayed.

Tetralogy of Fallot

Incidence and pathophysiology

Approximately 5% to 10% of all CHDs are classified as TOF. It is by far the most common cyanotic lesion.

Embryologically, TOF is caused by an underdevelopment of the RV infundibulum and malalignment of the infundibular septum, leading to the classic tetrad: RV outflow tract (RVOT) obstruction; a large, nonrestrictive VSD; an overriding aorta; and RV hypertrophy (Fig. 131.4). The most important pathophysiologic aspect of TOF is the obstruction to pulmonary blood flow, which leads to a right-to-left shunt via the VSD and subsequent hypoxemia and cyanosis.

The obstruction to pulmonary blood flow can be located at any level of the pulmonary outflow tract: in the area of the RV infundibulum, the pulmonary valve or annulus, the main PA, or even the branch PAs. The vast majority of cases will have a combination of infundibular and valvular stenosis, where the degree of obstruction can be highly dependent on RV contractility and preload. Dehydration, tachycardia, and positive inotropes are usually not well tolerated.

Signs and symptoms

Depending on the morphology, the clinical presentation can vary significantly, from a severely cyanotic newborn to a “pink

Figure 131.4. Typical features of tetralogy of Fallot: RV hypertrophy, RV outflow tract obstruction, large VSD and overriding aorta.

Tet” with CHF. Physical examination reveals a pansystolic murmur at the left upper sternal border, representing flow through the VSD. Patients often have cyanosis and hypoxemia, with oxygen saturations between 70% and 90%, as well as decreased exercise tolerance, dyspnea on exertion, and easy fatigability. Squatting increases SVR and arterial oxygenation. Chronic hypoxemia leads to polycythemia and an increased risk of spontaneous thrombosis and ischemic strokes. Hypercyanotic spells or “tet spells” (episodes of severe cyanosis, abnormal respirations, and altered level of consciousness) occur in 20% to 30% of patients, with a peak incidence at 2 to 3 months of age.

Associated anomalies

Only 68% of TOFs are isolated cardiac lesions. Associated chromosomal abnormalities include trisomy 13, 18, and 21; genetic syndromes such as DiGeorge, CHARGE (Coloboma of the eye, Heart defects, Atresia of the choanae, Growth retardation and/or developmental delay, Genital and/or urinary abnormalities, Ear abnormalities and deafness), and VACTERL association (Vertebral, Anal, Cardiac, Tracheal, Esophageal, Renal, Limb anomalies) are also associated with TOF. TOF is often seen with other cardiac anomalies, such as a right-sided aortic arch and coronary anomalies, which may affect the surgical approach to repair.

Treatment

Asymptomatic infants with minimal cyanosis are initially managed conservatively. Some patients may be given prophylactic propranolol to prevent hypercyanotic spells while waiting

for surgery. Treatment of hypercyanotic spells includes “knee-chest position” or abdominal compression to increase venous return; supplemental oxygen; volume expansion with crystalloid or colloids; vasoconstrictors (e.g., phenylephrine); β -blockade with esmolol or propranolol; and sedation with morphine or ketamine.

Surgical management

Historically, surgical treatment involved a multistage approach: palliation in infancy via an arterio-pulmonary shunt to provide adequate flow to the lungs and definitive repair later in life. More recently, with improved bypass and surgical techniques, the one-stage repair has been the procedure of choice. For stable patients with a favorable anatomy, most centers will plan surgery for 3 to 4 months of age.

Depending on the specific morphology, definitive surgical repair consists of the following components: patch closure of the VSD; excision of RVOT muscle bundles; ventriculotomy versus an atrial and transpulmonary approach; transannular or infundibular patch; or complex repair with an extracardiac RV to PA conduit for TOF with pulmonary atresia.

Anesthetic considerations

Polycythemia predisposes these patients to strokes, especially during periods of dehydration and prolonged fasting. Optimal timing of procedures and adequate rehydration are important. Care should be taken to remove all air bubbles from lines to avoid systemic air embolism. The potential for “hypercyanotic spells” must also be considered. Generally, a gentle IV induction is used to maintain SVR and preload; in patients with mild forms of TOF, a careful inhalation induction is possible.

Considerations for patients with repaired tetralogy of Fallot

These patients may need continued endocarditis prophylaxis, depending on the presence of residual VSDs, RVOT obstructions, or pulmonary valve regurgitation and RV dilation (after transannular patch repair). There is also a potential for arrhythmias and significant RV dysfunction after ventriculotomy due to scarring and fibrosis. LV dysfunction can result from ischemic injury in patients with anomalous coronaries. In addition, aortopulmonary collaterals may persist, especially in patients with TOF and pulmonary atresia.

Transposition of the great arteries

Incidence and pathophysiology

TGA is a complex mixing lesion that comprises 5% to 7% of all CHDs. It is the most common cyanotic CHD diagnosed in the newborn period. Abnormal rotation and septation of the arterial truncus results in transposition of the aorta and pulmonary artery. The aorta arises anteriorly from the RV and transports deoxygenated blood to the body, whereas the PA originates posteriorly from the LV and carries oxygenated blood back to the lungs. Thus, pulmonary and systemic circulations are in parallel

Figure 131.5. Transposition of the great arteries. Aorta arises from the RV and the PA originates from the LV: Deoxygenated blood from the SVC and IVC is transported back to the body via the aorta; and oxygenated blood from the pulmonary veins goes back to the lungs via the PA. Complete separate and parallel circulations, compatible with life only if some mixing of blood occurs via an ASD, VSD, or PDA.

(Fig. 131.5). This situation can be fatal if it is not coupled with another defect to provide a connection between the two circulations; an associated ASD, VSD, or PDA will allow for some mixing of oxygenated and deoxygenated blood. The RV has to support the relatively high-pressure systemic circulation, whereas the LV is exposed only to the slowly declining PVR. Over time this situation will lead to RV failure and LV underdevelopment.

Signs and symptoms

Clinical manifestations are determined by the extent of mixing and the presence of associated cardiac defects. Cyanosis is present within hours of birth, and arterial hypoxemia and acidosis may be unresponsive to oxygen inhalation. Signs of CHF develop over the first few weeks, especially in TGA patients with a large VSD.

Associated anomalies

Associated cardiac defects that provide mixing between the two circulations are necessary for survival; in more than 50% of patients, it is a PDA or patent foramen ovale (PFO), whereas in 40% a VSD is present. Coronary anatomy variances and ventricular outflow tract obstructions can complicate the picture

(e.g., subpulmonary stenosis is seen in 30% of patients). TGA is rarely associated with extracardiac anomalies or syndromes.

Treatment

Prostaglandin E₁ infusion is used to maintain ductal patency if necessary. CHF and metabolic acidosis are treated accordingly. Balloon atrial septostomy can be performed to increase mixing at the atrial level as the patient awaits surgical correction.

TGA can be repaired with the so-called “switch” procedures, which redirect blood flow to the appropriate circulation. Switch procedures can be done at all levels within the heart but with different physiologic consequences. With a Senning or Mustard procedure, an intra-atrial baffle redirects flow from the SVC and inferior vena cava (IVC) to the left atrium (LA) and from the pulmonary veins to the RA. The RV remains the systemic ventricle, however, and complications can include baffle obstructions, arrhythmias and RV failure later in life.

In a Rastelli or Damus–Kaye–Stansel procedure, an intra-ventricular baffle and an RV-to-PA conduit are used to redirect the blood flow. These patients are at risk for conduit stenosis, ventricular scars, and arrhythmias.

Last, an arterial switch or Jatene procedure involves the switching of the great vessels just above the ventricles – transection of the aorta and PA, transfer of coronary arteries, and reanastomosis over the appropriate ventricle. Kinking or obstruction of the coronary arteries may occur.

Historically, TGA was repaired using the Senning or Mustard technique, which was often associated with poor long-term results. Currently the procedure of choice is the arterial switch operation. When performed within the first week of life, before the LV is “deconditioned,” it has by far the best long-term results.

Anesthetic considerations

Goals for induction and maintenance include careful preservation of cardiac output and intercirculatory mixing. Decreases in contractility, heart rate, or preload can lead to further impairment of tissue oxygenation, increased oxygen extraction, and venous desaturation, and thereby cyanosis. Additionally, increases in PVR relative to SVR should be avoided. Elevated PVR will reduce pulmonary blood flow, whereas decreases in SVR will promote systemic recirculation. Both can result in inadequate mixing and lower arterial oxygen saturation.

Considerations for patients with repaired TGA

Patients who have undergone an atrial switch are susceptible to progressive RV dysfunction, tricuspid regurgitation, and right heart failure. They are at increased risk of arrhythmias, sick sinus syndrome, and sudden death, as well as baffle obstruction, which leads to pulmonary edema and/or SVC syndrome. Conversely, long-term problems are rare in arterial switch patients. Supravulvar pulmonary stenosis or regurgitation into the neo-aorta is possible. Occasionally patients may have asymptomatic occlusion of coronary arteries.

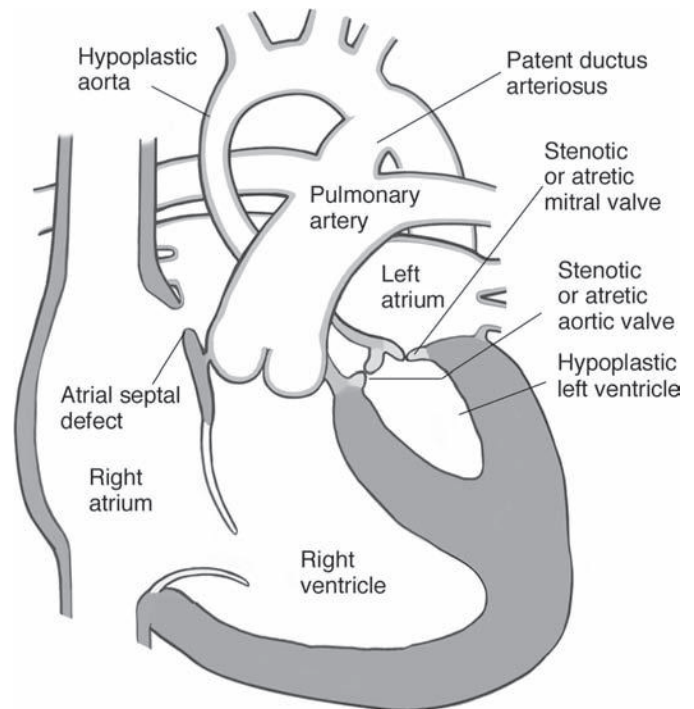

Figure 131.6. Hypoplastic left heart syndrome. Severe underdevelopment of all left-sided structures: mitral valve stenosis or atresia, aortic valve stenosis or atresia, hypoplastic left ventricle, ascending aorta and aortic arch. Systemic perfusion via PDA including retrograde perfusion of coronary arteries.

Hypoplastic left heart syndrome

Incidence and pathophysiology

HLHS accounts for ~1% of all CHDs. It is the most common cause of death from CHD within the first month of life. This syndrome involves a wide spectrum of cardiac anomalies characterized by a combination of severe mitral and aortic valve stenosis/atresia and marked hypoplasia of the LV, ascending aorta, and aortic arch (Fig. 131.6). In utero, impaired blood flow through the stenotic left-sided valves prevents adequate growth of the LV and aortic arch. Typically, left-to-right shunting via a PFO or ASD decompresses the left atrium, and a large PDA provides flow to the descending aorta as well as retrograde flow to the ascending aorta and coronary arteries. This anatomy results in a classic univentricular physiology with parallel systemic and pulmonary circulations. Oxygenated and deoxygenated blood mixes in the single ventricle and may enter, depending on the PVR/SVR ratio, either the pulmonary or systemic circulation. Pulmonary overcirculation will lead to decreased systemic output and acidosis, whereas systemic overcirculation will result in significant cyanosis and hypoxemia. Therefore, a careful balance between PVR and SVR must be maintained.

Signs and symptoms

Signs and symptoms of cardiogenic shock manifest within the first few hours of life as the PDA closes.

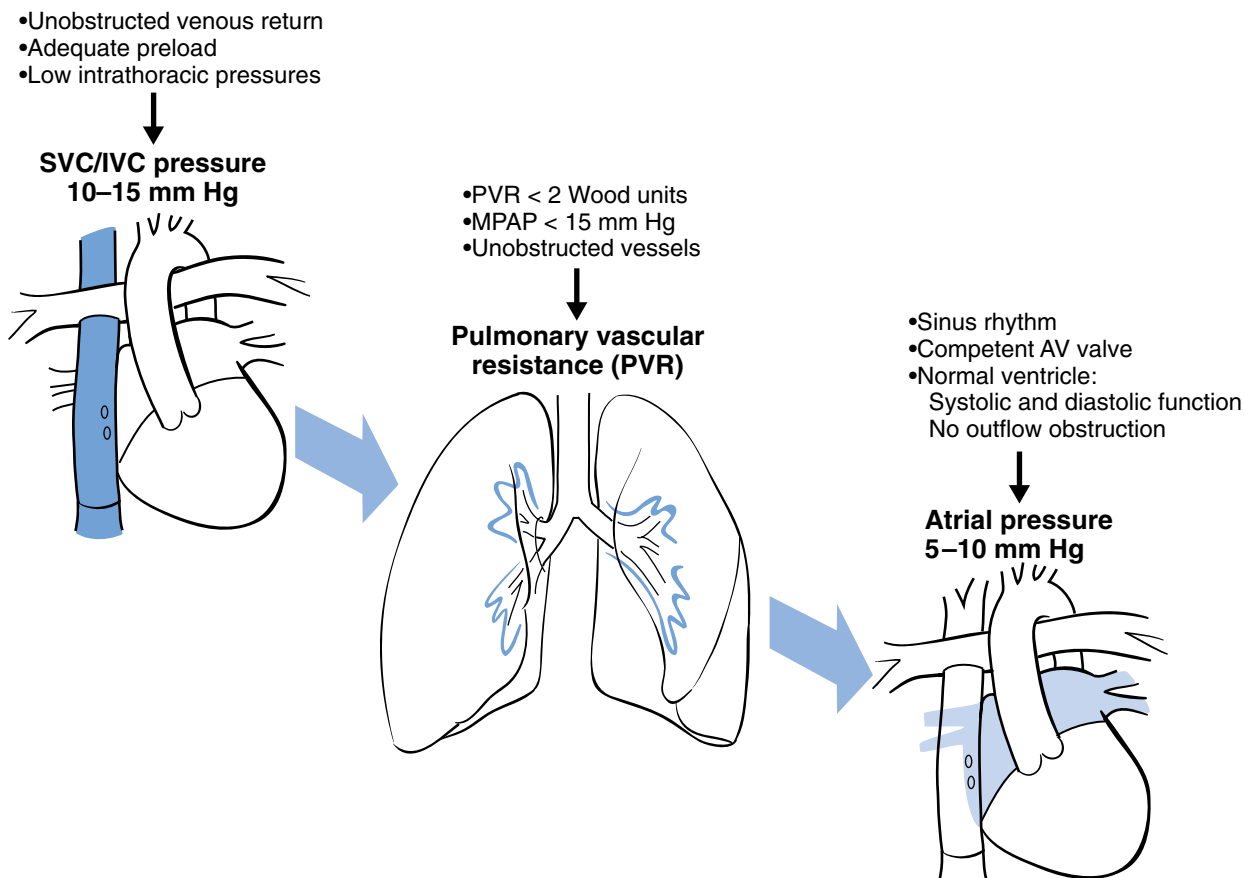

Figure 131.7. Transpulmonary gradient after a modified Fontan procedure. Factors influencing the transpulmonary gradient: Unobstructed venous return, adequate preload, and low intrathoracic pressure on the “venous side,” unobstructed PAs with low pressures and PVR in the pulmonary circulation and low atrial pressure on the “ventricular side,” requiring normal sinus rhythm, a competent atrio-ventricular valve and normal ventricular function without residual outflow obstruction.

Associated anomalies

In addition to the associated cardiac defects (PDA, ASD, and coarctation), 12% of patients with HLHS have extracardiac anomalies (e.g., trisomy 12 or 18, Noonan or Turner syndrome, and agenesis of the corpus callosum).

Treatment

Ductal patency is maintained with prostaglandin E₁. Stabilization of the patient may require intubation, inotropic support, and correction of metabolic acidosis. It is important to balance pulmonary and systemic blood flow distribution, maintaining arterial oxygen saturation at approximately 80% to 85%. Atrial balloon septostomy is occasionally needed to enlarge a PFO and decompress the LA.

Early surgical intervention within the first few days of life is necessary for survival. Surgical options are basically cardiac transplantation or palliative surgery (the “Fontan pathway”). Neonatal cardiac transplantation is usually limited by the lack of adequate donors, so most patients are initially treated with several staged surgeries. Palliative procedures in the neonatal period aim for balanced systemic and pulmonary blood flows, allowing the baby to grow for several months despite cyanosis and volume load on the ventricle.

The first stage (Norwood procedure), is performed within the first week of life. This procedure includes the creation of a neo-aorta originating from the RV using the main PA and patch augmentation of the hypoplastic aorta, an atrial septectomy, ligation of the PDA, and a modified Blalock–Taussig (mBTS, subclavian artery-to-PA) or Sano (RV-to-PA) shunt to provide pulmonary blood flow. The goal is to secure systemic perfusion independent of the PDA and allow for adequate maturation of the pulmonary vascular bed while preserving the function of the single ventricle.

The second stage (bidirectional Glenn procedure), is performed at 3 to 6 months. The mBT or Sano shunt is replaced by a direct anastomosis between the SVC and right pulmonary artery, providing passive pulmonary blood flow. The IVC remains connected to the heart. As a result, the volume load on the ventricle is significantly reduced, but oxygenated and deoxygenated blood still mix, and oxygen saturation remains in the low 80s.

The third and final stage (modified Fontan procedure), is performed at 18 to 24 months. With adequate growth and maturation of the pulmonary vascular bed, the resistance should be low enough to allow for complete separation of systemic and pulmonary flow. The IVC is now also connected to the

pulmonary artery, via either a lateral tunnel in the atrium or an extracardiac conduit, with or without a small fenestration. Pulmonary blood flow is completely passive, driven only by the pressure gradient across the pulmonary vascular bed. A fenestration can act as a pop-off valve and provide a residual right-to-left shunt in case of sudden increases in PVR.

Anesthetic considerations

Induction and maintenance are aimed at preserving a careful balance of pulmonary and systemic circulations. The goal is a normotensive, well-perfused, nonacidotic patient with an arterial oxygen saturation ~80% to 85%. Pulmonary overcirculation with poor cardiac output should be treated by increasing the PVR with controlled hypoventilation and low FiO₂ and providing inotropic support. Systemic overcirculation with profound cyanosis can be addressed by decreasing PVR and optimizing afterload. Systemic hypotension can lead to poor coronary perfusion, cardiac ischemia, and sudden ventricular fibrillation. Patients are mechanically ventilated for at least 3 to 5 days postoperatively. During CPB for the first stage of repair, significant total body edema develops; the chest is usually left open for a few days until the edema resolves.

Considerations for patients after the modified Fontan procedure

Pulmonary blood flow and cardiac output are dependent on the transpulmonary pressure gradient, which is determined by several factors: adequate preload and venous return, low PVR, and good ventricular function (Fig. 131.7). All factors that increase PVR (e.g., acidosis, atelectasis, hypoxia, hypercapnia, hypothermia) need to be corrected immediately.

In addition, prolonged dehydration and fasting periods should be avoided. These patients have a high incidence of arrhythmias, thrombosis, strokes, and clot formation. They are also susceptible to sudden right-to-left shunting if a fenestration is present.

Management of postoperative pain in children

Rahul Koka and Navil F. Sethna

Introduction

Acute postoperative pain in adults and children is a well-recognized inherent consequence of tissue damage no matter how minor the procedure or trauma might be. Considerable efforts have been made in recent years to standardize and improve acute pain management through the establishment of guidelines. Historically, management of acute pain has been undervalued for a variety of reasons, including a lack of adequate training. A recent nationwide survey from Sweden demonstrated that a large proportion of children had poor pain relief after surgical procedures (23%) and from nonsurgical conditions (31%) due mainly to organizational deficiencies rather than knowledge deficiency or lack of time or other burdens on health care providers.

The Joint Commission and other organizations have mandated systematic pain assessment, informing patients of their right to pain relief, prompt and effective treatment of unrelieved pain, access to specialists in pain management, and hospital-wide efforts at continuous quality improvement in pain treatment. These initiatives develop a set of pain protocols specifically for pediatric care, foster combined use of nonpharmacologic and pharmacologic approaches, and promote collaboration of multiple disciplines to manage a child's anxiety and fear as well as pain. These goals are best achieved through implementation of an acute pain management consult service to provide 24-hour consultation and supervise and administer analgesics requiring specialized interventions, such as epidural analgesia, continuous peripheral nerve blocks (PNBs), or complex pharmacologic management. Such a service is usually staffed by anesthesiologists, anesthesia trainees, and trained nurses.

Practitioners should strive to alleviate pain whenever possible to minimize the complex sequence of events that sets up an intense nociceptive afferent input, sensitizes peripheral and central nociceptive neurons, releases inflammatory mediators, and activates adrenocortical responses. Pain has psychological as well as physiologic effects and causes anxiety, fear, and insomnia in children. It is not always possible to eliminate all forms of pain, fear, anxiety, or distress, and no ideal analgesic strategies exist for controlling acute postoperative pain. Optimal pain management requires striking a balance between analgesia and adverse effects and risks. Considering these challenges, a multi-

modal analgesia approach is embraced to improve recovery and resume normal activities of daily living.

Assessment of pain

As with adults, considering the subjective nature of pain experience, direct measurement of pain is not feasible, and so children should be permitted to self-report pain by using developmentally appropriate pain assessment scales. Family members should report their observations regarding the child's pain, and special approaches of surrogate measures should be used for the assessment of pain in children with special needs (those who are neurologically impaired and/or noncommunicating). For newborns and infants, validated composite measures that combine physiologic (heart rate, respiratory rate) and behavioral (facial expression, position) parameters are available for use at the bedside to assess pain during procedures and in the postoperative period. Pain assessment remains a challenge in premature and critically ill infants. Consideration should always be given to provide analgesia as these infants have adequately mature nociceptive pathways and the neural substrates to process pain stimuli at the level of spinal cord and supraspinal nociceptive centers.

Analgesic strategies

A combination of cognitive-behavioral and various pharmacologic strategies is useful for successful control of postoperative pain. It is well-recognized that the extent of tissue damage does not necessarily correlate with the patient's report of pain intensity after surgery as many other factors contribute to the pain experience, including interindividual variability in analgesic pharmacokinetics, pharmacogenetics, pharmacodynamics, mood state, and trait reaction.

Nonpharmacologic strategies

Cognitive behavioral therapy (CBT) is an effective strategy for supporting children with developmental maturity (usually 7 years or older) to deal with an acute painful event such as procedural pain by addressing factors, such as cognition, affect, and behavior, that may affect the individual child's pain experience. The more a person is aware of his or her illness and what to expect during a painful procedure, the more control

Table 132.1. Recommended doses of IV opioids for moderate to severe pain^a

Opioid	Age	IV bolus and PRN frequency dose/kg	Continuous infusion, microgram/kg/h
Morphine	Preterm neonates	4 µg q2h or 8 µg q4h	2–10
	Term neonate	15 µg q2h or 30 µg q4h	5–20
	>6 mo	50 µg q2h or 100 µg q4h	15–30
Hydromorphone	>6 mo ^b	0.015 mg q4–6h	No data available
Fentanyl	Preterm neonates	0.25–0.5 µg q1–2h	0.5–1
	Term neonate	0.5–1 q1–2h	0.5–2
	>6 mo	1 µg q1–2h	1–2
Meperidine	<6 mo	See text	Not recommended ^c
	>6 mo	0.5 mg q2h or 1 mg q4h	No data available
	Adults	0.5–1 mg q2–3h	2.5 mg/h
Methadone	Children >1 y	0.5–1.0 mg q4h for 24 h, followed by 0.5 mg q4–6h prn ^c	

^a All IV doses should be administered slowly over 10 to 15 minutes, at lower starting doses in infants from 0 to 3 months old. There should be close monitoring for respiratory depression in infants younger than 6 months.

^b Morphine clearance approaches that of adult values between the ages of 6 and 12 months.

^c Prolonged elimination half-life; suggests the need for longer observation periods.

PRN, as needed.

that person has; with appropriate knowledge and techniques, episodes of emotional distress occur less often and are usually less severe in intensity and duration. Other strategies, such as acupuncture, acupressure, transcutaneous electrical nerve stimulation (TENS), distraction, play therapy, and so forth, are also useful but of limited value in early postoperative pain control.

Pharmacologic strategies

There is a wide variability in drug response among infants and children based on age and genetic, environmental, and disease processes that may influence absorption, distribution, metabolism, and excretion. The larger extracellular and total body water and a higher water to adipose ratio lead to a larger volume of distribution and therefore lower initial plasma concentration of drugs. The lower concentration of total plasma proteins (including albumin and α -1 glycoprotein) increases the biologically free active fraction of protein-bound drugs. In neonates, the circulating fetal albumin, which has an affinity to strong acids, binds to bilirubin and free fatty acids and can displace drugs from albumin-binding sites, leading to a higher free fraction of biologically active drug (e.g., diazepam).

The bioavailability of extensively metabolized drugs (e.g., acetaminophen) administered by the rectal route may be increased in neonates and infants due to the immaturity of their hepatic metabolism.

Delayed maturation of phase II drug-metabolizing enzyme (e.g., glucuronidation of morphine) decreases clearance. The total body clearance reaches 80% that of adults by 6 months and 96% of that predicted in adults by 1 year. Similarly, delayed maturation of phase I drug-metabolizing enzymes, hepatic cytochrome P-450 isoforms, decreases the clearance of drugs metabolized by these systems. Both glomerular filtration and tubular secretion are immature at birth and reach adult capacity at 8 to 12 months.

Opioids

Opioids are commonly used postoperative analgesics in patients of all ages. If dosed correctly, opioids produce excellent analgesia with a reasonable margin of safety. Morphine is the most commonly used opioid in children and has been extensively studied in all ages, including premature infants. Infants younger than 6 months clear total body morphine at rates up to 80% of the adult value. Morphine-3-glucuronide is the predominant metabolite. Suggested dosing guidelines are presented in Tables 132.1 and 132.2. Opioids are administered by a variety of routes: orally, intravenously (IV), rectally, transdermally, or transmucosally. Several opioids are available in elixir form for children who are not able or willing to swallow pills. Recently, the fentanyl patch and oral transmucosal fentanyl citrate (the fentanyl “lollipop”) have garnered support among physicians for their usefulness in the treatment of cancer pain; these formulations may also be used for preoperative sedation and postoperative analgesia.

Table 132.2. Recommended oral opioids for acute pain management

Opioid	Age	Dose, mg/kg	Daily frequency	Maximum daily dose, mg/kg
Tramadol	≥7 y	1–2	q4–6h	8 (maximum 400 mg/d)
Oxycodone	>6 mo	0.05–0.15	q4–6h	NA*
Codeine	>1 y	0.5–1	q4–6h	NA
Morphine	<6 mo	0.1	q4h	NA
	>6 mo	0.2–0.5	q4–6h	NA
Morphine ER	>6 mo	0.3–0.6	q12h	For chronic use
Hydromorphone	>6 mo	0.03–0.08	q4–6h	NA

* Data on dosing schedule is lacking for infants younger than 6 months, and half-life of elimination varies widely (2.4–14 hours). The dose must be titrated to a lowest effective dose individually.

NA, not available; ER, extended release.

Table 132.3. Close clinical and cardiorespiratory monitoring is mandatory for children at risk for opioid-induced respiratory depression in conditions including (but not limited to) the following:

- Term infants <6 months old or infants <1 years old with history of apnea and/or bradycardia
- Compromised airways
- Muscle weakness (e.g., neuromuscular disorders)
- Somnolence
- Opioid naïve and concurrent use of sedative agents
- Significant lung disease (e.g., obstructive, restrictive)
- Neurologic impairment
- All children receiving epidural morphine and hydromorphone

Patient-controlled analgesia in children

Maintaining steady-state serum concentrations of opioids has been at the core of postoperative pain relief. In years past, pain relief consisted mainly of opioids given via ineffective routes such as by intramuscular injections, with needle sticks causing anxiety and pain. This mode of opioid administration caused periods of inadequate pain control between the peaks of plasma concentrations, leading to the distressing cycle of sedation, analgesia, and discomfort. Many young patients were reluctant to report pain because of fear of receiving injections. Continuous infusions of low-dose opioids have been used and offer some advantages, particularly in neonates, as these opioids maintain a nearly constant plasma drug concentration. This method, unfortunately, does not consider dynamic changes in analgesic need or variation in drug clearance or effective plasma concentration. In addition, routine use of opioid infusions in ventilated premature newborns has become controversial. Opioid-induced respiratory depression is the most concerning side effect and should be monitored, particularly in those children who have conditions that may predispose to airway and ventilatory compromise (Table 132.3).

Patient-controlled analgesia (PCA) has been used effectively in the pediatric population. The theory of PCA is that only patients know when they are in pain, so they can titrate their own analgesic requirements (within a window of safety) based on their fluctuating needs. It has been demonstrated that children older than 7 years (as well as some mature children ages 5 and 6) can understand the concept, purpose, and instructions of PCA use and use it appropriately to derive adequate pain relief. Patients appear to learn quickly to administer medication before painful procedures or activities and tend to accept some degree of incomplete analgesia with minimal adverse effects rather than achieving no pain.

Controversy exists in the adult and pediatric literature regarding the use of PCA with a continuous background infusion as it does increase the incidence of brief episodes of hypoventilation and hypoxia, particularly during night sleep. Although PCA therapy is used safely in children, respiratory depression remains a major concern with any IV administration of opioid. Therefore, all children receiving PCA therapy should be assessed periodically as outlined in our institutional monitoring policy (Table 132.4). The prescription of the vari-

Table 132.4. Minimum assessments for patients who receive patient- or nurse-controlled IV opioids^a

Assessment items	Assessment frequency
Pain assessment	4 h

Heart rate, blood pressure, temperature	4 h
Side effects of analgesia	4 h

^a Continuous electronic monitors (electrocardiogram [EKG]–apnea monitor system and pulse oximetry) are used in children at risk for respiratory compromise, infants younger than 6 months, and children receiving epidural hydrophilic drugs, such as morphine and hydromorphone.

ous doses of opioids and parameter settings depends on institutional policies and type of PCA equipment used. Our regimen for routine initial postoperative and acute pain management is outlined in Fig. 132.1.

Nurse-/parent-controlled analgesia

Some pediatric institutions allow nurse-controlled analgesia (NCA), which can provide a reasonable, effective alternative to PCA in children younger than 6 years and in those with developmental or physical disability. This form of drug delivery does sidestep one of the inherent safety features, that sedated patients will not trigger the device. Fear of overmedicating patients by the analgesic provider remains stronger and the repercussions remain greater than the fear of undermedicating patients in pain, however. Fear of respiratory depression, addiction, and lack of confidence in titration to relieve a patient's pain may result in persistent reports of inadequate pain management.

Parent-assisted PCA is a useful mode of effective pain control in children who are incapable of self-administration of PCA because of age or severity of illness (e.g., cancer patients). For safety reasons, parents are allowed to administer opioids via a parent-activated delivery system after demonstrating that the child is not opioid-naïve and that the parents are well-informed in assessing the child's pain and monitoring adverse effects.

Nonopioid adjuvant agents

Adjuvants such as *N*-methyl-*D*-aspartate (NMDA) receptor antagonists (low-dose IV or subcutaneous ketamine), α -2 agonists (clonidine via oral, IV, transdermal, epidural, intrathecal, or PNB), anticonvulsants (oral gabapentin, pregabalin), tricyclic antidepressants (e.g., oral amitriptyline), and sodium channel blockers (e.g., IV lidocaine) are proposed as a component of multimodal postoperative pain management to minimize sensitization and reduce hyperalgesia and allodynia in postoperative pain. Adjuvant use is also proposed to diminish the development of acute neuropathic pain after surgery and trauma as well as for its opioid-sparing effect. Limited data are available on improved outcomes with the use of these agents in children. Several studies in children reported that the addition of clonidine (1–5 μ g/kg) to caudal local anesthetic increased the duration of analgesia by 2 to 3 hours, whereas others showed

no significant benefit. A recent controlled trial suggests that caudally administered clonidine is likely absorbed systemically and acts centrally rather than at the dorsal horn level. Potential benefits are an opioid-sparing effect and reduction of postoperative agitation, shivering, and vomiting. Doses $\geq 2 \mu\text{g}/\text{kg}$ may produce dose-dependent sedation, hypotension, bradycardia, and respiratory depression, particularly in infants younger than 1 year. Administration of epidural ketamine and midazolam cannot be recommended because of lack of safety data on neurotoxicity.

There is conflicting evidence on the analgesic effect of IV ketamine in children. The use of low dose ketamine (most commonly 0.25 or 0.5 mg/kg) in pediatric trials of tonsillectomy is shown to be effective in some and equivocal in others. The risk of psychomimetic adverse effects of hallucinations

remains a major deterrent to its use. Addition of benzodiazepines may minimize this risk but also prolong recovery time.

Nonsteroidal anti-inflammatory drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective analgesics and appealing substitutes for opioids in the management of moderate to severe pain because they lack the common opioid-related side effects of nausea, emesis, pruritus, sedation, and respiratory depression. Their use is limited, however, by adverse effects, including inhibition of platelet function in patients who are at risk for postoperative bleeding, renal impairment, gastric irritation, and inhibition of osteoblast function that may impede growth of new bone and healing. The lowest effective dose should be chosen, then used for the shortest

Table 132.5. Recommended doses of acetaminophen for oral and rectal routes^a

Age	Oral maintenance dose, mg/kg	Rectal loading dose, mg/kg	Rectal maintenance dose, mg/kg	Maximum daily dose, mg/kg	Duration, days ^b
28–32 wk postconceptual age	15 mg q12h	20	15 mg q12h	35	2
33–37 wk postconceptual age	20 mg q8h	30	20 mg q12h	60	2
Term to 3 mo	20 mg q8h	30	20 mg q12h	60	2
>3 mo	15 mg q4h	40	20 mg q6h	90	3

^a The relative bioavailability of the rectal route is formulation-dependent and decreases with age.

^b The proposed doses may cause hepatotoxicity in some infants if used for longer than 2 to 3 days or in the event of drug interactions.

possible duration while monitoring effects on gastrointestinal, renal, and hepatic functions. Reports of severe bronchospasm have been observed in adults and in adolescents with severe asthma. Although bleeding after tonsillectomy has been reported, a Cochrane review showed that NSAIDs were not associated with an increase in bleeding requiring return to the operating room for hemostasis.

Ketorolac is an NSAID available in IV form; it reversibly inhibits cyclooxygenase (COX)1 and 2, limiting prostaglandin synthesis and thereby decreasing inflammation and the pain response centrally and peripherally. It can provide excellent analgesia, is used routinely to manage acute pain, and is available in IV form. A pharmacokinetic study in children ages 1 to 16 years found that ketorolac disposition is similar to that reported in adults, and a recent study of pharmacokinetics of ketorolac in infants and toddlers ages 6 to 18 months showed no accumulation, rapid elimination of ketorolac isomers, and no clinical or laboratory adverse effects. The recommended dose in children is 0.5 mg/kg IV every 6 hours with a possible need for a shorter dosing interval in infants.

The NSAID of first choice is ibuprofen because of its safety profile. It is available over the counter in a variety of forms (pills, suspension) as an antipyretic and analgesic.

Acetaminophen

Acetaminophen (paracetamol) is an effective antipyretic and analgesic that has been used for many decades. It is often used alone for mild to moderate pain or in combination with opioids for patients with moderate to severe pain, and is the most commonly used analgesic and antipyretic in the pediatric population, including premature infants. Its popularity burgeoned after the withdrawal of pediatric aspirin formulations because of their association with Reye syndrome in the 1980s. It is thought to have an analgesic effect on NMDA receptors in the spinal cord. The therapeutic plasma concentration for analgesia with acetaminophen is unknown, but it is assumed to be similar to that of the concentration range required for antipyresis (10–20 µg/ml). Recent research has shown the existence of an isoenzyme of COX3 found only in the brain and spinal cord, which is selectively inhibited by acetaminophen.

Acetaminophen is administered via oral and rectal routes (Table 132.5); an IV preparation was recently approved in the

United States. Acetaminophen has few contraindications or side effects in therapeutic doses, but should be used with caution in children with hepatic disease or in critically ill children, particularly in the larger loading doses in current use. Neonates are capable of producing the reactive intermediary by conjugating acetaminophen to the sulfate metabolite rather than the glucuronide metabolite, which causes hepatic damage in overdose.

Regional anesthesia

The majority of regional anesthesia techniques used in adults are applied in children and infants. With a refinement in technique and use of suitably sized equipment, these techniques can be adapted to the pediatric population. Regional anesthesia techniques are used as an analgesic adjunct to general anesthesia or primarily to manage postoperative pain (Table 132.6). Unlike in adults, in the pediatric population regional techniques are often performed after the induction of general anesthesia for safety reasons. Lack of cooperation of most children during needle insertion and use of nerve stimulation requires that they be anesthetized or heavily sedated. There are no reports or studies

Table 132.6. Indications and types of central blocks and PNBs in children

Type of block	Type of surgical indication
Caudal epidural single injection block	Inguinal herniorrhaphy, penile surgery, perineal and anorectal surgery, muscle biopsy, lower extremity orthopedic surgery
Lumbar-to-thoracic epidural catheter block	Lower and mid-abdominal surgery, urologic surgery, renal and bladder surgery, pelvic and lower extremity surgery
Thoracic epidural catheter block	Upper abdominal surgery, thoracotomy, pectus repair, sternotomy, renal surgery
Femoral nerve block (with/without catheter)	Femur fractures and surgery, quadriceps muscle biopsy, anterior knee surgery (arthroscopic surgery)
Sciatic nerve block (subgluteal, distal, popliteal nerves) supplemented with sensory femoral nerve block	Foot surgery

Table 132.7. Caudal epidural anesthesia/analgesia in infants

Prerequisites	Skills and experience in performing adult epidural techniques
Indications	Surgical procedures below T10
Benefits when combined with general anesthesia	Reduces neuroendocrine responses, amount of inhaled anesthetics requirement, perioperative opioids, and postoperative vomiting
Position	Lateral decubitus and hips and knees flexed
Entry site	Sacral hiatus is identified as a slit cephalad to coccyx tip and flanked by sacral cornua. In newborn, the dural sac ends at S4 and spinal cord at L3, and both recede to S2 and L1, respectively, by age 1 y
Needle	22- or 20-gauge blunt stylet needle inserted at 60° and directed cephalad to sacral surface
End point	“Give” as the needle pierces the sacrococcygeal ligament and enters the epidural space; further advancement of the needle at 60° results in contact with anterior table of sacral bone; cephalad advancement of the needle is unnecessary once the sacral epidural space is entered; to avoid complications such as dural puncture and intravascular and marrow entry can be avoided
Test dose: lidocaine 1% or 1.5% with epinephrine 1:200,000	0.1 ml/kg maximum 3 ml; positive test dose in anesthetized child = HR increase of 10 bpm or change of 25% in T-wave amplitude
Local anesthetics: bupivacaine 0.25% or ropivacaine 0.2%	Administer fractionated dose with repeated aspiration for blood and CSF detection; duration of analgesia 4–6 h; significant postoperative motor block if administered at the end of surgery
Bupivacaine 0.125%	Minimal motor block particularly when administered at end of the surgery; may be inadequate for longer procedures
Dose	0.7 ml/kg (0.06 ml/spinal segment/kg) for children younger than 8 y and < 20 kg
Complications (many of these may occur with use of sharp or overly long needles, or cephalad advancement after the epidural space is entered)	Subcutaneous injection; bloody tap; inadvertent intravascular injection; intraosseous injection; hematoma (the sacral canal is wide and neurologic consequence from hematoma is less of an issue than other epidural sites); dural puncture; total spinal; local and epidural infection (with lack of adequate sterile precautions); some believe that use of hollow needles can result in implanting devascularized skin with microorganisms into the epidural space; rectal perforation and pelvic entry with forceful advancement through the soft anterior table of the sacrum which could be mistaken for sacral ligament “give”

HR, heart rate; CSF, cerebrospinal fluid.

to suggest that heavy sedation or general anesthesia increases the risk of neurologic complications or local anesthetic toxicity in children. Therefore, practice of regional anesthesia in anesthetized patients is universally accepted in this population with appropriate attention to technique.

Both peripheral and neuraxial (central) regional anesthetic (RA) techniques have an important and evolving place in the practice of pain management in infants and children. RA may afford many of the same advantages for pediatric patients as it does for adult patients, but there are few controlled clinical trials evaluating the its advantages and adverse effects in children

compared to conventional analgesic strategies. The safe and successful performance of central and peripheral neural blockade techniques in infants and toddlers demands specific knowledge of anatomic, pharmacologic, and psychological domains of development (Tables 132.7 and 132.8). A thorough knowledge of the developmental differences and sufficient prior skills in practice of regional neural blockade in adults greatly enhance the safe and successful application of these techniques in the pediatric population. Hepatic degradation of amide-type local anesthetics involves aromatic hydroxylation, *N*-dealkylation, and amide hydrolysis. Hepatic clearance is slower in newborn

Table 132.8. Pediatric lumbar and thoracic epidural anesthesia technique

Epidural access most easily achieved	Midline via intervertebral space to avoid injury to venous plexus and nerve roots
Needles: Tuohy (lumbar) and Crawford (thoracic)	18- or 20-gauge
Needle angle	15°–20° to median plan to avoid dural puncture and to freely thread the catheter cephalad through the widest part of the epidural space
LOR to saline	LOR to air can produce air embolism and potential for serious hemodynamic and neurologic changes if inadvertently injected into a vein
Catheter (20- or 22-gauge) advancement	2–3 cm if epidural space is accessed at the target spinal segments; threading the catheter at a greater length is unpredictable; it may coil, exit intervertebral foramina, and enter a blood vessel, subarachnoid, paravertebral, or pleural space
Aspiration test	May not be reliable in infants and young children due to low IV pressure; expect slow reflux of blood or CSF by gravity and aspiration may collapse the vein
Test dose: lidocaine 1% or 1.5% with epinephrine 1:200,000	0.1 ml/kg, maximum 3 ml; positive test dose in anesthetized child = HR increase of 10 bpm or change of 25% in T-wave amplitude
Epidural infusion rates; volume per spinal segment of anesthesia/analgesia for children ≤ 8 y ^a	Lumbar and lower thoracic (T10–S1): 0.06 ml/kg; mid-thoracic (T6–T9): 0.03 ml/kg; upper thoracic (T1–T5): 0.02 ml/kg

LOR, loss of resistance; CSF, cerebrospinal fluid; HR, heart rate.

^a The proposed dosing should be calculated for ideal body weight. The infusion rates are average starting doses that may require adjustment based on an individual child's response and proper placement of the epidural catheter within the spinal segments innervating the surgical zone.

Table 132.9. Representative epidural amide and ester local anesthetic doses in children

Local anesthetics	Age in reference studies	Maximum single injection, mg/kg	Maximum continuous infusion rate, mg/kg/h
Bupivacaine	Premature–term neonate ^a	1.5	0.15–0.2
Levobupivacaine	1–3 mo	2	0.25
Ropivacaine	3–6 mo	2.5	0.3
	Children	2.5	0.4
2-Chloroprocaine 1.5%	Preterm and term neonates (via lumbar route)	15	7.5–12
	Preterm and term neonates (via thoracic route)	7.5	3–6

^a Limited data are available on use of local anesthetics for premature infants, thus smaller dose regimen is advised in preterm infants and in those with impaired hepatic metabolism.

infants and approaches adult functional capacity by 3 to 6 months of life. Bupivacaine and lidocaine, the most commonly used amide local anesthetics, have prolonged elimination half-lives in infants younger than 6 months; repeated doses or continuous infusions of local anesthetics should be administered at lower dose ranges (Table 132.9).

RA (skin infiltration, epidural, PNBs) is commonly used in daily clinical practice as an adjunct to general anesthesia and for management of postoperative pain. Potential benefits include a reduction in the requirements for both volatile anesthetics and opioids both intra- and postoperatively, thereby minimizing adverse effects such as nausea, vomiting, pruritus, ileus, and urinary retention.

Peripheral nerve block

In the past decade, the application of PNB has increased in pediatric anesthesia practice. The advent of ultrasound-guided PNB has improved the success rate, quality of block, and ease of placement of continuous perineural catheters. In addition, it has facilitated the performance of PNB, which was until recently performed only in adults and only as infraclavicular, brachial plexus, popliteal, and rectus sheath nerve blocks. PNB may be associated with a lower incidence of neurologic and systemic toxicity compared to neuraxial blocks when performed under general anesthesia. Preliminary safety studies of continuous PNB via an indwelling catheter in both the inpatient and outpatient settings show encouraging results.

Local infiltration

Local anesthetic infiltration of the skin and subcutaneous tissue, or field blocks, are technically easy, minimally time-consuming, highly effective, and safe. Local infiltration or field blocks can be used to prevent incisional pain and for suturing lacerations. These techniques produce a low plasma blood concentration of local anesthetics and minimal motor block, demand no special equipment, require minimal postoperative care, and yet are quite underused in daily practice. Both ester and amide local anesthetics are used for local infiltration with longer duration of action with bupivacaine and ropivacaine. Addition of

epinephrine improves hemostasis and prolongs duration of analgesia but should be avoided at end artery sites, such as the nose, fingers, and penile shaft.

Neuraxial analgesia

Caudal blocks may be used in pediatric anesthesia as an adjunct to general anesthesia and to provide postoperative analgesia for common pediatric surgical cases below the umbilicus. Anatomy and landmarks are shown in Figs. 132.2 and 132.3, and the technique is summarized in Table 132.7.

Continuous lumbar or thoracic epidural infusion may be used as an adjunct to general anesthesia (balanced anesthesia) to effectively control severe pain with medical diseases and extensive surgery and trauma, avoid the need for systemic opioids, allow early tracheal extubation, and for continuation of the infusion for management of postoperative pain. Such a combination technique is appealing where postoperative intensive care support is scarce. Epidural analgesia is particularly useful in children undergoing upper abdominal and thoracic procedures and in those children with chronic restrictive and obstructive chest wall and lung disease, such as neuromuscular disorders, cerebral palsy, and encephalomyopathies. It can prevent a serious decline in pulmonary function after upper

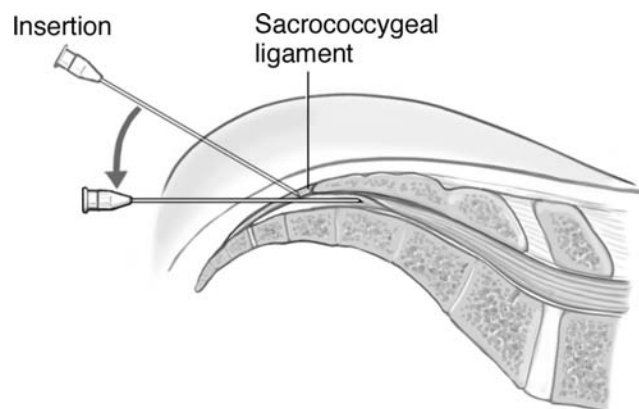

Figure 132.2. Anatomy of the caudal space.

Figure 132.3. Caudal block.

abdominal and thoracic surgery by rapid restoration of functional residual capacity (FRC) to normal values, and it decreases the duration of ileus after upper abdominal surgery. The incidence of common side effects of opioids, such as nausea, vomiting, and pruritus, can be significantly diminished by using local anesthetic with an adjuvant such as clonidine, reducing or eliminating the dose of opioid. Common postoperative epidural infusions use dilute bupivacaine (0.1%–0.0625%) with opioid (fentanyl or hydromorphone) or clonidine. Target hourly opioid doses by the epidural route are fentanyl at 0.5 µg/kg/h or hydromorphone at 1 to 2 µg/kg/h. Hemodynamic side effects (hypotension and bradycardia) are rare in younger children.

Considering the higher failure rate with both the advancement of caudal-to-thoracic and lumbar-to-thoracic catheters (7%–83%), several approaches are proposed to improve the reliability and safety of epidural catheter placement in infants and children. Radiographic guidance (fluoroscopy and/or epidurography), electrical motor nerve stimulation guidance, or ultrasound techniques have been recommended. In infants undergoing thoracotomy, an epidural catheter may be placed directly into the thoracic epidural space or the extrapleural paravertebral space prior to closure.

Complications

As with adults, complications associated with RA in children and infants are rare. A large prospective trial involving 24,409 infants, children, and adolescents reported an overall complication rate of 9 per 10,000. These complications were generally minor and temporary, with no residual morbidity and no mortality, but did include a few cases of inadvertent intravascular injection and of total spinal blockade. More than half of these complications were avoidable by the use of proper equipment and techniques (e.g., oversized needle, avoidance of excessive threading of epidural catheters) and appropriate doses of local anesthetics and epidural opioids.

Conclusion

In summary, proactive prevention and control of pain before it is established by surgical and medical procedures can offer both short- and long-term benefits. Pain that is established and severe is difficult to control. Although it may not be realistic to entirely abolish procedural and disease-related nociception and pain, various safe and effective analgesic strategies are available to reduce pain to a magnitude that is tolerable and least disruptive to the resumption of normal functioning.

Neonatal resuscitation: clinical and practical considerations

Denise M. Chan, Thomas J. Mancuso, and McCallum R. Hoyt

Introduction

There are more than 4 million babies born in the United States each year. Approximately 10% of them will need some assistance with ventilation at birth, and approximately 1% will need extensive resuscitation. Birth asphyxia accounts for nearly 1 million deaths each year worldwide. As a vital member of the labor and delivery team, the anesthesiologist should be skilled in the techniques of neonatal resuscitation. Although our primary focus is the care of the mother, we may be called on to care for the newborn as well.

Initial assessment

Evaluation of the newborn should begin as soon as the baby is handed over, and what to do next is determined by the condition of the child as well as knowledge of predisposing conditions. The fundamental ABCs (Airway, Breathing, and Circulation) underlie the initial steps and are the core of determining ongoing efforts.

Assessment begins with answering the following questions:

- Is the oropharynx clear of meconium?
- Is the baby breathing or crying?
- Is there good muscle tone?
- Does the baby have good color?
- Is the baby full term?

If the answer is yes to all of these questions, routine care can proceed with warming and drying the baby and clearing the airway as needed. If the answer is no, give additional stimulation while warming and drying, and position and clear the airway while providing supplemental oxygen. See [Table 133.1](#) for a list of recommended supplies and equipment for neonatal resuscitation. Prevention of heat loss is important, as cold stress can increase oxygen consumption. Hyperthermia, however, is associated with perinatal respiratory depression.

Although evaluation begins prior to assigning the 1-minute Apgar score ([Table 133.2](#)), this score can be helpful in determining whether interventional steps need to be initiated or maintained. The Apgar score is conventionally performed at 1 and 5 minutes after birth. If the 5-minute score is less than 7, ongoing evaluation and the assignment of scores continue every 5 minutes, up to 20 minutes. There are no consistent data on the significance of the Apgar score in preterm infants.

The need for resuscitation can often be predicted prior to delivery, as certain risk factors increase the likelihood of difficulties at birth ([Table 133.3](#)).

Airway, breathing, circulation

Although the current recommendation is to use 100% oxygen in the resuscitation of the newborn, recent studies have suggested that this may be of no benefit, and perhaps even harmful, when compared to resuscitation with room air. In a Cochrane Database meta-analysis of five studies comparing resuscitation with room air versus 100% oxygen, four of the studies showed a significant reduction in the rate of death in the room air group, whereas one study showed no significant differences in rates of adverse neurodevelopmental outcomes at 18- to 24-month follow-up. If resuscitation is performed with room air, supplemental oxygen should be readily available, especially if central cyanosis is present. Additionally, the fraction of inspired oxygen content (FiO_2) that is delivered should be determined by the neonatal saturation of peripheral oxygen (SpO_2), which should read in the low 90s. The FiO_2 should be increased only as necessary to reach this goal, noting that 100% saturation is *not* the goal.

If meconium is present (as is seen in approximately 12% of deliveries), but the infant is vigorous (i.e., strong respiratory effort and good muscle tone), suctioning may not be necessary beyond the usual need to clear the oropharynx and nose. If meconium is present at delivery and the baby is not vigorous, the trachea should be intubated and suctioned via the endotracheal tube (ETT) as the ETT is withdrawn. Ideally this process is performed only once, as trauma to the trachea from repeated suctioning and hypoxemia may occur. In addition, care must be taken not to suction too vigorously as pharyngeal stimulation may cause a vagal reflex resulting in severe bradycardia and/or apnea.

Evaluate the newborn for respiration, heart rate, and color within 30 seconds of birth. If the baby is apneic or has a heart rate of < 100 bpm, give positive-pressure ventilation (PPV) at 40 to 60 breaths per minute for 30 seconds. Peak inspiratory pressures of 30 to 40 cm H_2O are often needed for initial expansion because of fluid-filled lungs, but subsequent breaths for healthy lungs require only 15 to 20 cm H_2O . Endotracheal intubation may be considered at any point; for example,

Table 133.1. Neonatal resuscitation supplies and equipment**Suction equipment**

Bulb syringe
Wall suction and tubing
Suction catheters, 5F or 6F, 8F, and 10F or 12F
8F feeding tube and 20-ml syringe
Meconium aspiration device

Bag-and-mask equipment

Neonatal resuscitation bag with a pressure-release valve or pressure manometer (the bag must be capable of delivering 90%–100% oxygen)
Face masks, newborn and premature sizes (masks with cushioned rim preferred)
Oxygen with flowmeter (flow rate up to 10 L/min) and tubing (including portable oxygen cylinders)

Intubation equipment

Laryngoscope with straight blades, No. 0 (preterm) and No. 1 (term)
Extra bulbs and batteries for laryngoscope
Tracheal tubes 2.5, 3.0, 3.5, and 4.0 mm ID
Stylet
Scissors
Tape or securing device for tracheal tube
Alcohol sponges
CO₂ detector
Laryngeal mask airway (optional)

Medications

Epinephrine 1:10,000 (0.1 mg/ml) – 3-ml or 10-ml ampules
Isotonic crystalloid (normal saline or Ringer's lactate) for volume expansion – 100 or 250 ml
Sodium bicarbonate 4.2% (5 mEq/10 ml) – 10-ml ampules
Naloxone hydrochloride 0.4 mg/ml – 1-ml ampules; or 1.0 mg/ml – 2-ml ampules
Normal saline, 30 ml
Dextrose 10%, 250 ml
Normal saline “fish” or “bullet” (optional)
Feeding tube, 5F (optional)
Umbilical vessel catheterization kit or supplies
Sterile gloves
Scalpel or scissors
Povidone–iodine solution
Umbilical tape
Umbilical catheters, 3.5F, 5F
Three-way stopcock
Syringes, 1, 3, 5, 10, 20, and 50 ml
Needles, 25-, 21-, and 18-gauge or puncture device for needleless system

Miscellaneous

Gloves and appropriate personal protection
Radiant warmer or other heat source
Firm, padded resuscitation surface
Clock (timer optional)
Warmed linens
Stethoscope
Tape, 1/2 or 3/4 inch
Cardiac monitor and electrodes and/or pulse oximeter with probe (optional for delivery room)
Oropharyngeal airways

ID, internal diameter.

low-birth-weight infants may be difficult to mask ventilate and may need to be intubated early. A colorimetric carbon dioxide (CO₂) detector should be used to ensure proper ETT placement: Remember that there may be no color change in the detector if the baby's cardiac output is low.

Although still controversial, a laryngeal mask airway may be considered if bag-mask ventilation or endotracheal intubation is unsuccessful. In addition, ventilation may be inadequate for

Table 133.2. Apgar score

Physical examination	0	1	2
Heart rate	None	<100/minute	100/minute
Respiratory effort	Apnea	Irregular, slow	Crying, good effort
Muscle tone	Limp	Flexed extremities	Actively moving
Irritability	No response	Facial grimace	Cough, cry
Color	Blue or pale	Peripheral cyanosis	All pink

other reasons despite endotracheal intubation, such as mechanical blockage of the airway (e.g., choanal atresia, meconium, or mucus plug) or impaired lung function (pneumothorax, pleural effusion, pneumonia, congenital diaphragmatic hernia, pulmonary hypoplasia, or extreme prematurity).

If the heart rate is < 60 bpm, chest compressions should be started at 90 compressions per minute. Ventilation and chest compressions (see Fig. 133.1) should be synchronized at a 3:1 ratio (i.e., 30 breaths and 90 compressions per minute, performed simultaneously).

Medications and fluids

If, after 30 seconds of chest compressions, the heart rate is still less than 60 bpm, epinephrine may be given via either the ETT or the umbilical vein while compressions and ventilations continue (Table 133.5). Fewer than 0.2% of newborns will need epinephrine during resuscitation, and care must be taken when giving it, as the subsequent hypertension and increased cerebral

Table 133.3. Risk factors associated with birth of a depressed newborn**Antepartum factors**

Maternal diabetes	Significant maternal cardiac, renal, pulmonary disease Polyhydramnios
Maternal hypertension (chronic or pregnancy-induced)	
Maternal infection	Oligohydramnios
Fetal anemia	Multiple gestation
Fetal hydrops	Post-term gestation
Fetal anomalies	Premature or preterm rupture of membranes
Decreased fetal activity	Maternal substance abuse
Second- or third-trimester bleeding	No prenatal care Maternal age < 16 or > 35 years

Intrapartum factors

Chorioamnionitis	Placenta previa
Nonreassuring fetal heart rate tracing	Placental abruption
Emergent caesarian delivery	Uterine hyperstimulation
Use of general anesthesia	Prolapsed cord
Forceps or vacuum-assisted delivery	Breech or other abnormal presentation
Premature labor	Meconium-stained amniotic fluid
Precipitous labor	Significant intrapartum bleeding
Prolonged rupture of membranes	Opioids administered to mother within 4 h of delivery

Macrosomia
Prolonged labor
Prolonged second stage of labor

Figure 133.1. Chest compressions in the neonate. The preferred manner for chest compressions is the thumb-over-thumb technique with the fingers wrapped about the thorax for further support. This is preferred because it is considered to be more stable. The other acceptable technique is the two-finger technique with the other hand beneath the chest for further support. It is more useful for smaller hands and when an umbilical catheter is being placed.

blood flow may be associated with intracranial bleeding, especially in the fragile region of the germinal matrix.

Chest compressions should continue until the heart rate is >60 bpm; PPV should continue until the heart rate is >100 bpm and the baby is breathing. After 3 to 5 minutes, the dose of epinephrine may be repeated.

If the baby is not responding to resuscitation, consider that the neonate may be hypovolemic. Isotonic crystalloid or O-negative blood cross-matched with the mother's blood (10 ml/kg) should be given intravenously (IV) over 5 to 10 minutes. Albumin is no longer the fluid of choice for initial volume expansion and should not be considered. If hypovolemic shock is indeed the diagnosis, the neonate should respond quickly.

Sodium bicarbonate (2 mEq/kg) is sometimes given IV to correct metabolic acidosis, although no clear reduction of morbidity or mortality has been shown. This medication must be given slowly to reduce the risk of developing an intraventricular hemorrhage. It is also recommended that it not be given without an ETT in place. Refer to Table 133.4 for normal umbilical venous and arterial blood values.

Naloxone (0.1 mg/kg IV) may be given for severe respiratory depression if there is documented administration of an opioid to the mother within the past 4 hours. If the baby's mother is a chronic opioid user, however, naloxone should not be given because it may cause the baby to go into opioid withdrawal.

If ongoing resuscitative efforts have not resulted in clinical improvement, there are several unusual clinical problems

that should be considered. Pneumothorax may have occurred at some point during delivery and resuscitation. Hypoglycemia can be ruled out by checking the glucose level. Congenital diaphragmatic hernia can present with unequal breath sounds in the setting of unsuccessful resuscitation. If the infant has severe undiagnosed central nervous system (CNS) anomalies, resuscitation may not succeed.

After resuscitation

After a baby has been successfully resuscitated, ongoing care and monitoring should be provided to assess for complications as noted in Table 133.6. For instance, if meconium was present in the amniotic fluid, the newborn is at risk for development of meconium aspiration syndrome with respiratory distress, hypoxemia, hypercarbia, and pulmonary artery hypertension. In addition, complications may occur as a direct result of resuscitation efforts, such as a pneumothorax from broken ribs or a ruptured liver or spleen from improperly performed chest compressions.

Discontinuing resuscitation efforts is a difficult decision that involves all members of the team, including parents, physicians,

Table 133.4. Umbilical venous and arterial blood gas values

	pH	PO ₂	PCO ₂	Saturation (%)
Umbilical vein	7.30–7.35	30	40	70
Umbilical artery	7.24–7.29	20	50	28

Table 133.5. Medications for newborn resuscitation

Medication	Dose	Notes
Epinephrine IV	0.01–0.03 mg/kg	Can repeat q5min
Epinephrine ETT	Up to 0.1 mg/kg	Give with PPV
IV fluid	10–20 ml/kg	NS, LR, or blood
Naloxone	0.1 mg/kg IV or IM	Give in the setting of acute maternal opioid use after other considerations are eliminated
NaHCO ₃	2 mEq/kg IV	Give slowly

NS, normal saline; LR, lactated Ringer's; IM, intramuscularly.

Table 133.6. Potential complications in newborns

Pulmonary hypertension
Respiratory distress syndrome
Pneumonia
Hypotension
Acute tubular necrosis
Electrolyte imbalances
Syndrome of inappropriate antidiuretic hormone secretion
Feeding problems
Seizures
Necrotizing enterocolitis
Intracranial hemorrhage
Hypothermia
Hypoglycemia

and social workers. Some infants will not be able to be resuscitated. After 10 minutes of asystole, the chance of survival is slim, and, in those who survive, the incidence of severe disability is almost universal.

An intimate knowledge of the techniques of neonatal resuscitation is essential for the practicing anesthesiologist. Preparation, organization, and communication among team members will facilitate the best outcome for the baby.

Ambulatory and Remote Location Anesthesia

Beverly K. Philip, editor

Introduction to ambulatory anesthesia

McCallum R. Hoyt and Naila Moghul

Over the past three decades, anesthesia techniques and strategies for ambulatory surgery have grown considerably. Free-standing surgery centers have become common, and in some hospitals as many as 80% of all surgeries performed are on an ambulatory basis.

From a cost-based perspective, ambulatory centers are designed to offer improved case efficiency, better use of limited resources, and less expensive care. Choice of anesthetic technique and perioperative management play an important role in how the center functions, as do procedures and personnel appropriate to the center's marketplace strategy, available equipment, and facility design. Rapid induction and emergence as well as a thorough knowledge of anesthetic techniques to minimize common postoperative complications, such as postoperative nausea and vomiting (PONV), require a thorough understanding of the pharmacology and principles behind the choices made.

As the specialty has refined itself, cases of increasing complexity as well as patients with more significant medical issues are being considered for ambulatory settings. Precisely which cases are appropriate as well as what disqualifies a patient for procedures in an ambulatory setting remain to be fully defined, but the expectation is that the trend toward greater complexity will continue.

Patient selection

An ambulatory procedure can occur in either a free-standing center or as part of a hospital-based service. To categorize the procedures that match the facility resources and personnel expertise, some free-standing centers develop guidelines on appropriate procedures but also describe the suitable patient population that will match the abilities of the center's personnel. Guidelines may only propose which patients may be appropriate to the center, and, as the range and complexity of ambulatory surgical cases have increased over the years, so has the complexity of the patients being managed in such settings. As a result, appropriate patient selection remains an evolving concept.

The basic principles for preoperative patient evaluation are the same for ambulatory patients as they are for inpatients. Healthy patients or those with minor medical issues do not necessarily need to go through an on-site preoperative evaluation. They can fill out a form, partake in a phone screen, or fill out

an online form that is reviewed by someone from the preoperative clinic. For patients with more significant health issues that require active medical management, an evaluation at a preoperative clinic is usually recommended. This evaluation should be done several days in advance of the planned surgery as it often takes time to obtain records, review tests, or perform more assessment. It is also practical to discuss the probable anesthetic choices and initiate the informed consent process during this initial meeting so that patients have time to consider any questions they may have for the anesthesia provider on the day of surgery. Additionally, patients should be informed of the requirement that they will not be allowed to drive themselves home after surgery but will need to arrange for a responsible adult to take them home. Patients should understand that not having adequate arrangements before their surgery will likely disqualify them for ambulatory status, resulting in their surgery being rescheduled or plans made for an overnight stay.

Special considerations

There are some medical conditions or patient populations that raise questions as to their appropriate selection or require forethought unique to the ambulatory setting. These conditions and populations will be mentioned here. Although ambulatory centers may choose to include or exclude pediatric or pregnant patients, there is nothing about these populations that contraindicate their inclusion as ambulatory cases. Their basic management principles are discussed elsewhere.

Patients with significant comorbidities

No single factor determines whether a patient with significant health comorbidities requiring active medical management can be appropriately chosen for an ambulatory procedure in a free-standing center. Hospital-based centers may be better equipped both with personnel and facility resources to deal with the potential complications such a patient brings, making an unplanned inpatient admission far easier to address and manage. Regardless, cases should be decided within the context of facility and personnel capabilities. For instance, a stable American Society of Anesthesiologists (ASA) IV patient may have a cataract operation carried out safely in a free-standing ambulatory setting, yet a morbidly obese asthmatic for liposuction may not be appropriate for the same facility.

Elderly patients

There are no published guidelines on age limits for elderly patients, but rather each patient should be selected based on his or her medical status and the proposed procedure. Studies have not confirmed that advanced age alone is a risk factor, and elderly patients are scheduled for a broad range of procedures at most ambulatory centers. Although one study identified an age greater than 85 years as a predictor for hospital admission in the immediate postoperative period, pre-existing comorbidities and surgical length may have contributed to their results. Other studies have not confirmed this finding.

Morbid obesity

The percentage of patients who meet the body mass index (BMI) definition of morbid obesity is increasing at a rapid pace. Many of these patients have a comorbid history of cardiovascular, endocrine, pulmonary, or gastrointestinal disease. Difficulty with intravenous and airway access should be anticipated, and, when combined with the logistical considerations of proper equipment for higher BMIs, such patients may not be suitable for that facility. Although there is no evidence that adverse perioperative events leading to unplanned admissions are more frequent for patients with BMI greater than a particular number, centers may choose to set a limit above which patients are considered unsuitable candidates.

Obstructive sleep apnea syndrome

Obstructive sleep apnea (OSA) is estimated to be present in 2% of women and 4% of men, and is expected to increase severalfold over the next decade. Although OSA is almost always a consideration in the morbidly obese population, it can be present in persons with a normal body habitus, regardless of gender. Intraoperative airway management as well as postoperative somnolence, desaturation, hypertension, and dysrhythmias are more common complications encountered in this population. Although the literature acknowledges these complications, it does not exclude this population from the ambulatory setting. Current management strategies recommend matching the patient to the procedure, and suggest the use of neuraxial techniques, judicious use of opioids, both neuraxial and systemic, to avoid the potential respiratory depressant effects, and use of local field blocks and nonopioid analgesics for postoperative pain management. These patients should be placed in a nonsupine position while in recovery and discharge delayed until advancement into a nonmonitored environment is safe.

Respiratory disease

Patients with preexisting but well-controlled reactive airway disease are at low risk for postoperative respiratory complications and can routinely be managed at most ambulatory surgery centers. The risk for adverse postoperative events is higher if there are active symptoms and signs of bronchospasm preop-

eratively. If bronchospasm is present, any elective procedure should be rescheduled until it is adequately managed.

Cardiovascular disease

Patients with stable, preexisting cardiovascular disease routinely have procedures done at ambulatory centers. The literature does not suggest that well-managed patients are at increased risk. The patient's cardiac medication should be continued throughout the perioperative period, and there is no evidence that prolonged cardiac monitoring is required or beneficial. For laparoscopic procedures, there should be a clear understanding of the effects on the cardiovascular system, but these changes are resolved within an hour of the recovery period. Obviously, patients with unstable cardiovascular status or a history of a recent myocardial infarct are not considered suitable candidates.

Anesthetic options

Any anesthetic technique may be considered for the ambulatory patient as long as it is appropriate for the procedure and adheres to the goals of a rapid recovery.

General anesthesia

In selecting whether to use inhalational agents or avoid them by using a total intravenous anesthetic (TIVA), several concerns that apply to the ambulatory patient should be considered. As the pharmacologic properties of the medications discussed are covered elsewhere, only clinical considerations will be covered here.

Inhalation agents

The newer volatile agents of desflurane and sevoflurane work well for the ambulatory patient as the drug profiles show a fast onset and recovery with few side effects. Indeed, recovery indices are achieved more quickly when compared with popular TIVA agents, such as propofol. Randomized, controlled trials (RCTs), however, show that the use of volatile agents provides a risk factor for PONV, which may delay discharge of patients at risk despite the use of appropriate antiemetics. Nitrous oxide is also a popular adjunct to the inhalational technique, but systematic reviews also suggest that it may predispose the patient to PONV, if used.

A common practice is to try to achieve the benefits of one drug or method by combining techniques or switching volatiles; for example, using an isoflurane-based technique and then switching to desflurane to achieve the faster recovery profile it provides. This only serves to expose the patient to two agents unnecessarily as the observed recovery profile is that of an isoflurane-only technique. The same misconception is at play when propofol is used at the beginning and end of an anesthetic that uses a volatile in between – the so-called “propofol sandwich.” The goal is to achieve the antiemetic effects of the

propofol; however, the recovery profile more closely resembles that of the volatile agent.

Total intravenous anesthetics

Propofol provides the cornerstone for this technique, and opioids such as sufentanil or remifentanil are often added (see Chapter 49). By itself, propofol can provide antiemetic effects, but its recovery profile can be more prolonged when compared with profiles of the newer volatiles. Should an opioid be added, the risk of PONV increases and may delay discharge. Initial profiles suggest that opioid use in this manner may not be well-suited to the ambulatory patient; further research will be necessary to make that determination.

Neuraxial and regional anesthesia, field blocks, and pain management

One of the most common reasons for an unplanned hospital admission after ambulatory surgery is intractable pain. The use of neuraxial anesthesia (i.e., spinal, epidural, or a combined spinal epidural) in the ambulatory setting is somewhat controversial as it may delay discharge as the block recedes, but that does not mean that its use is not an appropriate choice if the patient and/or procedure are correctly selected. Regional blocks, as are used for surgery on the peripheral limbs, can correlate with a timely discharge and good pain management well into the postoperative period. Increasingly, continuous nerve blocks are being used to provide analgesia beyond the first 24 hours. Ambulatory patients receiving these techniques are often alert, comfortable, and discharged in a timely manner. A field block, which is the infiltration of local anesthetics along the incision by the surgeon, can also be an effective way to manage pain. Whether it is best to have the surgeon employ a field block before the incision, at the time of the closure, or both is unclear.

Whether some form of block is used or not, successful pain management is generally of a multimodal nature. Although the use of intraoperative opioids may be necessary, continuation of those same medications should not be the sole source of pain management. Intraoperative, but particularly postoperative, opioid use has been associated with PONV and is a specific risk factor. Attempts to reduce the use of opioids or avoid them altogether in the postoperative period can be achieved through the use of a multimodal analgesic approach. Medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase (COX)-2 inhibitors (a subset of NSAIDs), are reasonable choices, as is acetaminophen. An *N*-methyl-*D*-aspartate (NMDA) antagonist such as ketamine may also be a reasonable choice when used judiciously. The goal is to provide effective analgesic management that is comprehensive, of adequate duration, and with minimal side effects. Additionally, preemptive pain management with opioids has not been shown to reduce postoperative pain requirements. The preemptive use of nonopioid medications, such as the NSAIDs, has been

shown, however, to significantly reduce postoperative analgesic needs.

Discharge criteria

Established algorithms and predetermined protocols are frequently used during the recovery of patients in the postoperative unit. The nursing staff use these criteria to ensure that the patients are stable and ready for discharge. It is also their responsibility to make sure that the patients understand the discharge orders and have adequate transport and coverage for the required period. As outlined below, there are three distinct phases of recovery from anesthesia and surgery that apply to ambulatory patients.

Phase I

This phase immediately follows the removal of the patient from the operating area. Initial monitoring is intensive with one-to-one or two-to-one nursing coverage, and the patient is watched for maintenance of his or her own airway, stabilization of vital signs, and a return to baseline alertness. Blood pressure and oxygenation saturation are monitored as is the electrocardiogram (ECG). After the patient is considered to be stable and has met the defined criteria, he or she is moved to the second phase of recovery.

Phase II

When the patient is considered hemodynamically stable and alert and does not require the previous monitors, he or she advances to the second phase of recovery. Family members can now be present and often are in the ambulatory setting. Ambulation is monitored, voiding is encouraged, and, although liquids and solids may be offered, for ambulatory patients it is often prudent to not encourage intake because of the issues of PONV and travel. Analgesia should be achieved with nonopioid medications and ideally with over-the-counter analgesics. It is from this phase that the patient is discharged home, and patients must be discharged into the care of a responsible adult.

Fast-tracking

Fast-tracking is the term used for patients who are awake enough to bypass phase I recovery. Any variety of procedures may qualify a patient for this if he or she has had minimal anesthesia or any of a range of anesthetic techniques. Although the layout of the ambulatory recovery facility as well as nursing resources may impact the availability of such a program, the criteria used to fast-track a patient into phase II recovery directly from the operating room (OR) are the same criteria used to advance the patient from phase I into phase II recovery by the nursing staff. The exact criteria may vary slightly by facility, but generally the patient should be awake; with stable vital signs and minimal dizziness, pain, or nausea; and able to maintain a saturation of 92% or greater on room air. Patient

satisfaction surveys have shown that patients, families, and surgeons respond favorably to an early discharge as it contextualizes a well-conducted, well-tolerated, and well-planned anesthetic experience.

Postoperative issues

A true complication from anesthetics for ambulatory patients is rare, but side effects are common. Two issues, pain management and PONV, are the leading causes of an unplanned hospital admission when they occur to the extreme. Pain management principles have already been discussed. Emetic management involves patient hydration, limiting intake of solids postoperatively, recognizing the risk factors and minimizing them as much as possible, and giving appropriate antiemetics as indicated. Risk factors for PONV can be broken down into surgical, anesthetic, and patient-specific. Anesthetic factors have already been addressed. These involve the use of multimodal analgesics to reduce or avoid opioids in the intraoperative and especially the postoperative phase, the avoidance of volatiles and nitrous oxide, and the use of a regional technique or field blocks by the surgeon as appropriate. The surgical factors are less controllable and involve the type and duration of the surgery. The Apfel score, which is a simplified PONV risk score, applies one point for each of the following factors: female, nonsmoker, history of PONV, and use of postoperative opioids. With zero risk factors, the incidence for PONV is 10%. With each additional factor, the incidence increases to 20%, 40%, 60%, and 80%, respectively. Prophylactic treatment of PONV is also a multimodal approach, and some of the recommended antiemetics are selective serotonin 5-hydroxytryptamine type 3 (5-HT₃) receptor antagonists, steroids, anticholinergics, and butyrophenones. Dosing algorithms are beyond the scope of this chapter, but two rules to follow are (1) if the medication has not worked, do not give more but move to another class of antiemetic; and (2) if PONV returns ≥ 6 hours after treatment, the dose that was successful may be repeated.

Other side effects that may delay the discharge of the ambulatory patient or his or her return to normal activity are drowsiness, dizziness, headache, sore throat, and general aches. Although many of these side effects are difficult to avoid, the incidence of sore throat can be reduced by using a smaller endotracheal tube than is normally used for inpatients.

Anesthesia outside the operating room

Wendy L. Gross and Ramon Martin

Nonsurgical approaches to treatment outside the operating room (OR) often require the participation of anesthesiologists. Cases performed outside of the OR occur in areas that lack the infrastructure of the OR and are often unfamiliar to anesthesiologists. Medical practitioners and anesthesiologists practicing outside the OR are frequently faced with chronically or acutely ill patients whose medical conditions have not been or cannot be optimized. Existing comorbidities may go unnoticed and untreated unless an anesthesiologist points them out. Medical proceduralists are focused on getting the cases done and are likely to be unfamiliar with the risks of anesthesia in this environment. It is the task of the anesthesiologist to step back and evaluate the “big picture.”

Comorbidities such as obesity, (coronary artery disease [CAD], chronic obstructive pulmonary disease [COPD], hypertension [HTN], diabetes mellitus [DM], arthritis, etc.), significant opioid intake, solid tumors that compress and/or invade major organs, and psychosocial issues are some common complicating patient characteristics that are as important as airway evaluation in the anesthetic care of these patients. Consideration of these issues should be a component of ongoing discussions with participating medical interventionalists and constitute the key features of deciding how to take the best care of a patient during the procedure at hand.

A complete medical history is essential. Good communication skills and a thorough understanding of pathophysiology are required of any anesthesiologist practicing in a remote location because the OR support network may not be readily available and the procedure may be unfamiliar or new. Many interventionalists rely upon imaging modalities that anesthesiologists are unfamiliar with. Therefore, it is incumbent on the anesthesiologists outside the OR to establish an environment in which there is succinct, frequent, and clear communication between anesthesiologist and interventionalist regarding both the procedural plan and the progress of the intervention.

The change in venue creates technical, communication, and operational difficulties for anesthesiologists. This chapter addresses practice standards, problems encountered, and recommended approaches for procedures frequently performed in some common non-OR anesthetizing locations.

Non-OR standards of care

The OR model of care should be extended to all cases performed in non-OR locations and includes the following fundamental features:

1. Thorough preprocedure assessment and informed consent;
2. Standardized monitoring and anesthetic equipment consistent with maximal patient safety and comfort;
3. Clearly marked and readily available emergency equipment (code cart, defibrillator, and difficult airway cart);
4. Adequate backup (equipment and personnel) in case of emergencies and/or difficulties;
5. Available postoperative care in a postanesthesia care unit (PACU) setting with the oversight of an anesthesiologist and a dedicated nursing staff; and
6. A clear and understood procedure and anesthetic plan.

Any procedure performed in a non-OR area can degenerate into a complex or unmanageable situation for logistical or medical reasons. Adherence to the standards just mentioned is even more critical when an anesthetic is administered away from the support structure of the OR. The American Society of Anesthesiologists (ASA) guidelines for non-OR anesthesia care are summarized in Fig. 135.1.

Non-OR anesthetizing locations

In this section, we highlight seven commonly encountered non-OR locations where anesthetic care is provided regularly. Each of these will be discussed in terms of typical procedures performed and commonly encountered problems.

Angiography/interventional radiology

The angiography/interventional radiology (angio/IR) suite encompasses a wide range of procedures. Up to 70% of the procedures are urgent or emergent and are booked less than 48 hours ahead of time. Even though most of these cases are performed with a nurse providing sedation to the patient, there is a continual discussion between the anesthesiologists and angio/IR staff about how best to keep patients comfortable. Patient assessment before the procedure is critical to determine

GUIDELINES FOR NONOPERATING ROOM ANESTHETIZING LOCATIONS

(Approved by House of Delegates on October 19, 1994, and last amended on October 15, 2003)

These guidelines apply to all anesthesia care involving anesthesiology personnel for procedures intended to be performed in locations outside an operating room. These are minimal guidelines which may be exceeded at any time based on the judgment of the involved anesthesia personnel. These guidelines encourage quality patient care but observing them cannot guarantee any specific patient outcome. These guidelines are subject to revision from time to time, as warranted by the evolution of technology and practice. ASA Standards, Guidelines and Policies should be adhered to in all nonoperating room settings except where they are not applicable to the individual patient or care setting.

1. There should be in each location a reliable source of oxygen adequate for the length of the procedure. There should also be a backup supply. Prior to administering any anesthetic, the anesthesiologist should consider the capabilities, limitations and accessibility of both the primary and backup oxygen sources. Oxygen piped from a central source, meeting applicable codes, is strongly encouraged. The backup system should include the equivalent of at least a full E cylinder.
2. There should be in each location an adequate and reliable source of suction. Suction apparatus that meets operating room standards is strongly encouraged.
3. In any location in which inhalation anesthetics are administered, there should be an adequate and reliable system for scavenging waste anesthetic gases.
4. There should be in each location: (a) a self-inflating hand resuscitator bag capable of administering at least 90 percent oxygen as a means to deliver positive pressure ventilation; (b) adequate anesthesia drugs, supplies and equipment for the intended anesthesia care; and (c) adequate monitoring equipment to allow adherence to the "Standards for Basic Anesthetic Monitoring." In any location in which inhalation anesthesia is to be administered, there should be an anesthesia machine equivalent in function to that employed in operating rooms and maintained to current operating room standards.
5. There should be in each location, sufficient electrical outlets to satisfy anesthesia machine and monitoring equipment requirements, including clearly labeled outlets connected to an emergency power supply. In any anesthetizing location determined by the health care facility to be a "wet location" (e.g., for cystoscopy or arthroscopy or a birthing room in labor and delivery), either isolated electric power or electric circuits with ground fault circuit interrupters should be provided.*
6. There should be in each location, provision for adequate illumination of the patient, anesthesia machine (when present) and monitoring equipment. In addition, a form of battery-powered illumination other than a laryngoscope should be immediately available.
7. There should be in each location, sufficient space to accommodate necessary equipment and personnel and to allow expeditious access to the patient, anesthesia machine (when present) and monitoring equipment.
8. There should be immediately available in each location, an emergency cart with a defibrillator, emergency drugs and other equipment adequate to provide cardiopulmonary resuscitation.
9. There should be in each location adequate staff trained to support the anesthesiologist. There should be immediately available in each location, a reliable means of two-way communication to request assistance.
10. For each location, all applicable building and safety codes and facility standards, where they exist, should be observed.
11. Appropriate postanesthesia management should be provided (see Standards for Postanesthesia Care). In addition to the anesthesiologist, adequate numbers of trained staff and appropriate equipment should be available to safely transport the patient to a postanesthesia care unit.

Figure 135.1. Guidelines for non-OR anesthetizing locations. With permission from ASA.

what is needed for the patient to comfortably tolerate (i.e., hold still, breathe, and have no pain) a procedure. As a result, a member of the anesthetic team is often involved in evaluating even those patients who are not anticipated to require anesthesia. Such evaluation should begin with morning rounds in the angio/IR suite, when all the patients for the day are presented to the entire group of radiologists, nurses, and anesthesiologists. Discussion should continue during the day among providers.

Most of the procedures require that the patient lie supine. Pain from arthritis and surgical incisions; respiratory compromise from COPD, pneumonia, pleural effusions, or obstructive sleep apnea; and inability to cooperate because of dementia, language differences, or psychiatric disturbances can make a seemingly simple procedure extremely difficult or impossible. Some procedures (portal sclerotherapy, placement of a lumbar dialysis catheter, angiography and/or embolization for gastrointestinal (GI) bleeding in a hypotensive patient) clearly require the involvement of an anesthesiologist. Other procedures, such

as percutaneous nephrostomy tubes, biliary drainage catheters, hemodialysis catheters, arteriovenous (AV) graft declotting, and major vessel stenting, cause little pain after the placement of the intravascular catheter. The patient, however, does have to lie still and be able to cooperate when asked. Patient comorbidities and the scope of the procedure determine the choice of analgesia/anesthesia.

Increasing caseloads may make it cost-effective to have a nurse practitioner involved as a member of the anesthesia team to assist with patient assessments (from airway evaluations in patients with obstructive sleep apnea to comprehensive evaluations in complicated patients). The nurse practitioner interfaces with both the anesthesiologist assigned to angio/IR and the nurses and radiologists in the suite. This nurse practitioner assessment allows for timely and comprehensive patient-information gathering that might otherwise not occur and expedites implementation of treatment by both the radiologist and the anesthesiologist.

Particular issues of concern in the angio/IR area include temperature and radiation exposure. Elderly or chronically ill patients tolerate cold temperatures poorly. Hypothermia is a particularly serious complication of long procedures. Procedure rooms, traditionally kept at 60°F, are now maintained at 68°F. Longer procedures and a high acuity patient population make cold temperatures unacceptable. In addition, forced warm-air heaters are available in all rooms and are used for all patients. Several models that surround the patient but do not interfere with instrumentation are available. [Fig. 135.2](#) shows a typical interventional radiology procedure in the CT scanner.

Figure 135.2. Typical interventional radiology procedure in the CT scanner (Source: Brigham and Women's Hospital Web site).

The anesthesiologist should be educated about radiation exposure and the need to wear lead. In some cases, anesthesiologists who staff this area on a regular basis have been provided with their own lead because chronic use of lead that is too heavy or ill-fitting can lead to injury or exposure. There are often challenges related to maintaining a safe distance from the fluoroscopy equipment cone while still adequately monitoring the patient.

Endoscopy

Despite efforts by some insurers to curtail payment for anesthesia services provided in the endoscopy suite, there has been growing use of anesthesia care for those patients. This is due not only to patient requests, but more so to the increasing number of patients with multiple comorbidities, including obesity and chronic narcotic use. Esophagogastroduodenoscopy (EGD), retrograde endoscopy of the bile and pancreatic ducts (ERCP), and colonoscopies normally require only nurse-administered intravenous conscious sedation (IVCS), but medical comorbidities can make a patient an anesthetic candidate. The challenge has been to determine the need for anesthesia services well ahead of time. Because most of the procedures are scheduled electively, patients who are known to require anesthesia care are sent to the preadmitting test center for evaluation and then present on the day of their procedure with a preanesthetic evaluation and plan. The GI staff and the anesthesiologists assigned to the endoscopy suite should discuss individual outpatients and the plan for keeping them comfortable during their procedure. Sometimes outpatients who are scheduled to be cared for by an anesthesiologist have already unsuccessfully attempted the procedure with conscious sedation alone. Inpatients often present as add-on or emergent cases. A thorough preanesthetic assessment will determine what is needed. A patient with ischemic cardiomyopathy who is on the transplant list, a patient with complex congenital heart disease, or a patient with a left ventricular assist device may need to be cared for in the OR with a cardiac anesthesiologist either present for the case or available nearby for consultation. Anesthesiologists may be needed for unstable patients in either the medical intensive care unit (MICU) or the cardiac care unit (CCU) who cannot be moved but require endoscopy.

Most upper and lower endoscopies can be performed with mild to moderate sedation by anesthesiologists or properly trained nonanesthesiologists. Commonly used medications include benzodiazepines, short-acting opioids (such as fentanyl), and propofol. Intubation is rarely necessary and should be dictated by the patient's comorbidities. More complicated, lengthy, and painful procedures such as ERCP are more likely to require deep sedation or general anesthesia (GA).

Increasingly innovative procedures that are lengthy and require deep sedation also contribute to the increasing numbers of endoscopy cases requiring the involvement of anesthesiologists. Gastric bypass repair and double balloon enteroscopy are performed with GA. The anesthetic choice for other

procedures, such as laser treatment of Barrett's esophagus, percutaneous endoscopic gastrostomy (PEG) placement, or secretin test to assess bile and pancreatic duct function, are determined by the patient's overall condition.

Radiation oncology

The treatment of surgically unresectable cervical and uterine carcinoma has evolved from a 3-day tandem and ovoid application with continuous radiation therapy and the patient confined to bed, to short outpatient treatments over several days. GA is used for most of these cases. After induction of GA, the patient is placed in the lithotomy position for placement of tandem and ovoids. CT imaging confirms placement and provides the basis for the dosimetry calculations that take place next. Treatment is then carried out, the instrumentation is removed, and the patient is awakened and taken to the PACU. She is discharged later in the day. Some patients have undergone MRI for dosimetry planning. The magnetic resonance scanner being in a different location requires transporting the patient for the 20-minute scan. Occasionally, the authors have used epidural anesthesia with intravenous sedation for such cases, to minimize transport of intubated patients through the hallway.

Epidurals with either intravenous sedation or GA are used for interstitial implants. Because the radiation is given continuously for 48 to 72 hours after placement of the implants, epidurals are left in place and a continuous infusion of dilute local anesthetic and opioid (hydromorphone) is maintained until the course of radiation is completed and the instrumentation removed.

Prostate brachytherapy is a procedure chosen by men who wish to avoid surgical resection. After induction of GA, the patient is placed in lithotomy position and an ultrasound probe is used to guide the placement of needles that hold irradiated seeds. The CT scanner is used for dosimetry. After the seeds are placed and instrumentation removed, the patient is awakened and taken to the PACU. Discharge is usually the next morning.

GA is needed for patients who cannot hold still for conventional external beam radiation therapy. Severe tremors caused by Parkinson's disease or myotonic dystrophy can make external beam radiation impossible unless the patient can be immobilized. Each patient is handled individually with a meeting of all members of the care team as well as by a discussion with the patient and family to review all available options. Every attempt is made to find an alternative technique, distraction, or medication change before embarking on a lengthy course of a short anesthetic (5 days a week for 5–7 weeks).

Computed tomography

Diagnostic CT scans are quite quick and do not require sedation, analgesia, or anesthesia, with the exception of intubated patients from the OR or an ICU. CT-guided cryoablations of solid tumors require anesthetic support. Lesions of the liver and kidney can be accomplished with intravenous analgesia. Comorbidities that render the patient unable to lie flat or keep

relatively still for prolonged periods will occasionally necessitate the use of GA. Lung lesions require more careful consideration, and GA is used more frequently. If the lesion is close to a bronchus, a double-lumen tube is placed after induction of GA, and its position is confirmed with a fiber-optic bronchoscope prior to the start of a case. A pneumothorax is expected to some degree in most patients undergoing lung cryoablation, so close attention is paid to respiratory mechanics and the extent of the pneumothorax prior to extubation. If the pneumothorax is large enough to compromise pulmonary function, a chest tube is promptly inserted.

With rising patient acuity, the number of patients who cannot lie flat or hold still is increasing. As a result, the number of cases requiring anesthesia support is growing as well, even for simple procedures such as biopsies or placement of drainage catheters under CT guidance. As in other non-OR locations, the main goal is to screen patients to identify those who are not sedation candidates. We prefer, whenever possible, to schedule these patients for interview at our preoperative evaluation center prior to their procedure. In this way, patients undergo complete assessment and are booked electively with anesthesia care, which avoids the potential of a failed attempt to perform a procedure carried out with nurse-administered sedation only.

Magnetic resonance imaging

Magnetic resonance scanners are unique among non-OR locations because they are used solely for diagnostic testing. Patients who require anesthetic support to get through this imaging comprise a wide variety of patients who simply cannot lie still in the bore of the scanner for 25 minutes to 2 or 3 hours (depending on how much of the body is scanned). As with other non-OR areas, patient evaluation is of primary importance to determine the underlying causes of the MRI intolerance so that the intolerance can be effectively treated. Mental retardation, severe claustrophobia, anxiety disorders, pain from arthritis or physical injuries, and dementia or confusion from an intracerebral bleed are some of the underlying problems routinely seen. When paired with organ system dysfunction, these patients require thought and discussion before proceeding with intravenous analgesia or GA. It is sometimes necessary to discuss the risks and benefits of GA with the patient, family, and primary care team about when the possible information gained from the scan might not change the patient's outcome. This discussion must also include the MRI technicians who have a full schedule and are used to moving patients quickly through their scans.

MRI scanners present specific and unique challenges to anesthesiologists. First, all anesthesia equipment – including the anesthesia machine, laryngoscopes, pumps, and anesthesia cart – must be MRI compatible. In addition, the noise level in the 3-Tesla (3T) units is considerably higher than in 1.5T machines. It is so high that one cannot hear monitor signals and alarms. Remote monitoring from just outside the machine using a slave unit for vital signs and video images of the patient from ceiling-mounted cameras is therefore needed. It remains

to be seen whether this increased noise level will result in more patients being uncomfortable while lying in the scanner. With the advent of the 3T units, there are plans to begin performing procedures just as in CT: biopsies and cryoablation of solid tumors. This will generate more anesthetic cases in the MRI suite.

Unstable cardiovascular disease cannot be monitored with any precision in an MRI scanner and can possibly exclude some patients from having an anesthetic in that location. Although there have been improvements in the consistency of displaying the electrocardiogram (ECG) tracing, it is still not reliable when looking for changes in the ECG, particularly when the patient has been moved all the way into the bore of the magnet.

The magnet's impact on ferrous material precludes any patient with such material implanted from undergoing a magnetic resonance scan. Danger arises from dislodgement or malfunction of vascular clips, pacemakers, automatic implantable cardioverter-defibrillators (AICDs), mechanical heart valves, and implanted biological pumps. Shrapnel is another contraindication. The use of nonferrous materials such as titanium for vascular clips is considered MRI-safe. Some tattoo inks contain high amounts of ferrous oxide and have been reported to cause burn injury.

Interventional neuroradiology

The interventional neuroradiology suite is essentially an offshoot of the neurosurgical OR. Diagnostic cerebral angiograms are performed electively prior to aneurysm clippings. Vascular tumors or large meningiomas are imaged and embolized prior to surgical resection. The neuroradiology suite is also the main source of unplanned urgent cases. Patients often arrive with a subarachnoid hemorrhage for diagnostic angiography to look for a ruptured or leaking aneurysm or arteriovenous malformation (AVM) to determine whether it can be coiled or to map the vascular supply for clipping in the OR. After a craniotomy, if mental status changes ensue, patients are sent to the interventional neuroradiology suite for imaging to look for vasospasm and for possible treatment with intra-arterial verapamil.

Aside from the diagnostic cerebral angiograms (which are done with sedation only), all other procedures require GA, usually with arterial blood pressure monitoring. Because of the need to maintain cerebral perfusion pressure, blood pressure management is an important part of the anesthetic technique and requires communication with the IR staff about target blood pressure and whether anything is given by the proceduralist that might decrease blood pressure (i.e., intra-arterial verapamil). Communication must be maintained with the main OR anesthesia staff about any patients who might end up in the OR for open surgery.

Orphan non-OR cases

Not infrequently, anesthesiologists receive requests to provide “a little bit of propofol” to help get patients through procedures

in the MICU, the CCU, the emergency department (ED), or diagnostic areas (PET/CT and ultrasound). These requests are usually urgent or emergent, without prior warning. The patients are generally quite ill with multiple medical problems and no preprocedure assessment. The physicians making the requests are usually internists or radiologists who are not aware of the constraints that the patient's comorbidities place on the performance of the procedure or the administration of sedation or anesthesia. It is important for the anesthesiologist to ascertain that the procedure room has proper equipment, gas supply, and monitors for the safe provision of anesthesia.

The requests from the MICU, CCU, and ED present a dilemma because often these are truly emergencies. An anesthesiologist is sent to evaluate the patient and talk to the care team about what needs to be done. If the patient cannot be moved to the OR, then a limited amount of analgesia, with appropriate monitoring in place, is given to help get the patient through the procedure.

Cardioversions are sometimes necessary in intensive care units and in the electrophysiology (EP) or catheterization laboratories. Cardioversions require the presence of an anesthesiologist because the patient receives intravenous GA for the procedure, which can be short in duration but quite painful while the electrical shock is being delivered. Standard ASA monitoring should be used, including ECG, blood pressure cuff, pulse oximetry, and capnography. Equipment for emergency airway support must be immediately available at the bedside. Usually propofol or etomidate is administered for hypnosis while the patient is maintaining spontaneous ventilation. If the patient becomes apneic and requires ventilatory support, bag-mask ventilation is initiated. If the patient's airway is potentially difficult and minimal sedation is desirable, it is reasonable to give midazolam initially, so that the patient has amnesia for the event, and fentanyl for analgesia. The patient should be monitored postcardioversion for at least 30 minutes by a nurse until the vital signs return to baseline and the patient is fully awake.

Summary

Non-OR anesthetizing locations are a diverse, growing area that presents both challenges and opportunities for anesthesiologists. Non-OR procedures are becoming a significant aspect of hospital practice and patient care. As the perimeter of anesthesiology moves from the OR to encompass these new arenas, anesthesiologists must be involved in the planning of procedure rooms so that they are safe and are in compliance with basic ASA standards. We will need to expand the scope of preanesthetic evaluation to non-OR locations.

Transport of patients from ICUs to procedure areas and back is often more challenging than the procedure itself and may well become the routine responsibility of the anesthesiologist. In addition, transport requires good communication with nursing staff both in the procedure area and in the patient care unit. Transport monitoring should ensure that the anesthesiolo-

gist has all the information necessary to treat the patient should problems develop en route to the procedure area or back to the unit.

Each health care facility needs to create guidelines for the definition and administration of safe moderate and deep sedation and be able to clarify and discuss the risks and benefits of GA with nonsurgical medical practitioners. Anesthesiology has successfully spearheaded patient safety initiatives and advanced surgical practice in the OR, and it is critical to import those principles to the non-OR arenas.

Office-based anesthesia

Fred E. Shapiro

Office-based anesthesia (OBA) refers to the practice of ambulatory anesthesia in the office setting. OBA is a relatively new and growing field as the number of requests to provide anesthesia services by practitioners who have their own outpatient office-based operating facilities have grown at an exponential rate.

OBA marries convenience with financial incentive. It has attraction for both surgeon and patient; the former benefiting from greater control over schedule, operating costs, and revenue generation, and the latter gaining in comfort, convenience, and privacy. One need look no further than recent national statistics for evidence of the popularity of this emerging subspecialty. In 2005, The American Society of Anesthesiologists estimated that more than 10 million surgical procedures were performed in doctors' offices. This number has doubled since 1995 and continues to steadily grow. Today nearly 80% of all surgeries are currently performed in an outpatient facility, either connected to a hospital or in a separate surgical center, and approximately 1 in 10 surgeries are office-based. However, despite the large numbers of procedures, such facilities generally have little regulation at the local, state, or federal level – only 22 of 50 states have any regulations regarding OBA.

The most common procedures performed in the office include gastrointestinal (GI) endoscopy, ophthalmology, and cosmetic surgery. Other specialties (e.g., gynecology, urology, orthopedics, interventional pain, neurosurgery, pulmonary and cardiac procedures) are increasingly represented.

There has also been an increase in the complexity of the cases being performed in the office as well as an increase in the number of patients with major medical problems and risk factors undergoing these procedures. Therefore, the tremendous growth of OBA has been accompanied by concerns for patient safety. These concerns have been escalated by media reports of tragedies that may have been precipitated because the physician's office lacked the same resources (i.e., personnel, equipment, drugs, administrative policies, and facilities) that are present in an ambulatory surgical center or hospital. There must be one standard of care, no matter where the surgery is performed.

Advances in both surgical and anesthesia technology enable the office to be a very desirable place to perform numerous surgical procedures. In a properly accredited site with qualified,

licensed, and trained personnel, the office-based setting can provide a safe, pleasant, comfortable, and cost-effective experience for all.

The office-based anesthesia practice: creating a safe, pleasant, and comfortable experience

At this point one can easily see how anesthesia in the nonhospital setting is a unique subspecialty with its own particular challenges and concerns. This chapter is intended to familiarize the reader with the most crucial issues and to impart a knowledge basis for anyone delving into an OBA practice. We begin by discussing three key principles underlying OBA – to facilitate an experience that is safe, pleasant, and comfortable for both the patients and the personnel involved in the process.

How to keep it safe

Accreditation of office-based surgical facilities is currently performed by the following three organizations:

- The American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF);
- The Accreditation Association for Ambulatory Health Care (AAAHC); and
- The Joint Commission (TJC).

The commonly used classification of surgical facilities focuses on the level of anesthesia provided. The source of these classifications is the American College of Surgeons (ACS), as found in its booklet *Guidelines for Optimal Ambulatory Surgical Care and Office-based Surgery*. The ACS definitions are:

Class A (also known as Level I): Provides for minor surgical procedures performed under topical and local infiltration blocks with or without oral or intramuscular preoperative sedation. Excluded are spinal, epidural, stellate ganglion interscalene, supraclavicular, infraclavicular blocks, and intravenous regional anesthesia.

Class B (also known as Level II): Provides for minor or major surgical procedures performed in conjunction with

oral, parenteral, or intravenous sedation or under analgesic or dissociative drugs.

Class C (also known as Level III): Provides for major surgical procedures that require general or regional block anesthesia and support of vital bodily functions.

Safety features that are taken for granted or even unnoticed in an acute care hospital must be carefully built into a new office operating suite or retrofitted into an existing one.

To promote safety and encourage states to develop guidelines, the American Medical Association (AMA), with input from the ACS and the ASA, published a consensus list of principles. Entitled the “AMA Core Principles for Office-Based Surgery,” this list is summarized as follows (for full text, see <http://www.asahq.org/Washington/AMACorePrinciples.pdf>):

1. Guidelines or regulations for office-based surgery should be developed by states according to levels of anesthesia defined by the ASA.
2. Physicians should select patients for OBA by specified criteria including the ASA Physical Status Classification System.
3. Where available, offices that perform surgery should be accredited by a state-recognized entity.
4. Physicians involved in office-based surgery should have admitting privileges at a nearby hospital or maintain an emergency transfer agreement with a nearby hospital.
5. Informed consent guidelines should be followed.
6. Continuous quality improvement and adverse incident-reporting programs should be kept.
7. All physicians in an office-based setting should be board certified and fully trained.
8. Physicians performing office-based surgery may show competency by maintaining privileges at an accredited hospital or ambulatory surgical center for the procedures they perform in an office setting.
9. At least one physician who is credentialed in advanced resuscitative techniques (advanced trauma life support [ATLS], advanced cardiac life support [ACLS], or pediatric advanced life support [PALS]) must be present or immediately available with appropriate resuscitative equipment until the patient has met discharge criteria.
10. Physicians administering or supervising the anesthetic should have appropriate education and training.

How to make it pleasant

The next dictum for establishing a good OBA practice is to make the entire office-based perioperative experience pleasant. The ability to reinvent the traditional surgical experience is one of the most important reasons behind the emergence of anesthesia in the office setting. Office-based surgery can offer the

convenience of having procedures performed in a more comfortable setting with an expedient return home.

Advances in analgesic drugs and a growing awareness of complementary techniques, when carried out in the hands of skilled personnel, can help ease a patient smoothly into post-surgical recovery. The aim should be a pleasing experience for patient, family, and friends.

How to make it comfortable

The anesthesiologist plays an integral role in helping to make the perioperative experience pleasant for the patient. A well-conceived, well-structured office environment is essential. One would not want to walk into an office if the equipment and infrastructure are antiquated, cumbersome, or ill-functioning. Building an effectively functioning office-based practice can be a challenging business, but, when properly executed, the office-based environment can be the ideal place of work for an anesthesiologist.

Patient and procedure selection

There are two major issues that the anesthesiologist needs to address prior to initiating an anesthetic in the office: first, whether the patient would be an appropriate candidate for the proposed procedure, and second, whether the proposed surgical procedure would be appropriate for an office-based setting. The *ASA Guidelines for Office-Based Anesthesia* specifically address these issues.

In 2007, the ASA published the *Manual for Anesthesia Department Organization and Management* (MADOM; available from the www.ASAhq.org). Chapter 5 (Ambulatory Anesthesia) contains relevant TJC, AAAHC, and AAAASF accreditation standards, as well as the following additional ASA statements:

1. Guidelines for Ambulatory Anesthesia and Surgery
2. Statement on Qualifications of Anesthesia Providers in the Office-Based Setting
3. Guidelines for Nonoperating Room Anesthetizing Locations
4. Position on Monitored Anesthesia Care
5. Continuum of Depth of Sedation: Definitions of General Anesthesia and Levels of Sedation/Analgesia
6. Statement on Safe Use of Propofol
7. Statement on Granting Privileges for Administration of Moderate Sedation to Practitioners Who Are Not Anesthesia Professionals
8. Statement on Granting Privileges to Non-Anesthesiologist Practitioners for Personally Administering Deep Sedation or Supervising Deep Sedation by Individuals Who Are Not Anesthesia Professionals
9. Outcome Indicators for Office Based and Ambulatory Surgery

Sedation by non-anesthesiologists is addressed in *Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists*.

The administration of sedatives, hypnotics, analgesics, as well as anesthetic drugs commonly used for the induction and maintenance of general anesthesia is often, but not always, a part of monitored anesthesia care (MAC). In some patients who may require only minimal sedation, MAC is often indicated because even small doses of these medications could precipitate adverse physiologic responses that would necessitate acute clinical interventions and resuscitation. If a patient's condition and/or a procedural requirement is likely to require sedation to a deep level or even to a transient period of general anesthesia, only a practitioner privileged to provide anesthesia services should be allowed to manage the sedation. Due to the strong likelihood that deep sedation may, with or without intention, transition to general anesthesia, the skills of an anesthesia provider are necessary to manage the effects of general anesthesia on the patient as well as to return the patient quickly to a state of deep or lesser sedation.

In summary, MAC is a physician service that is clearly distinct from moderate sedation due to the expectations and qualifications of the provider who must be able to use all anesthesia resources to support life and to provide patient comfort and safety during a diagnostic or therapeutic procedure.

What types of drugs are used in the office?

Anesthesia for office-based surgery can be accomplished using a variety of approaches. Induction and maintenance of sedation or anesthesia can include intravenous and inhalational techniques. Short-acting agents are most appropriate. Central and peripheral regional anesthetic techniques can also be valuable.

More important than the choice of specific agents or techniques, the anesthesiologist must focus on providing an anesthetic that will provide for a rapid recovery to normal function, with minimal postoperative pain, nausea, or other side effects.

We might suggest a word of caution about using various drug combinations to accomplish adequate levels of sedation. It is reasonable to use drug combinations to provide synergy of effects, decrease the dose of each drug, and decrease the side effects. In the current environment, however, both the case complexity and patient comorbidities are increasing as well as the number of non-anesthesia personnel administering sedation in the office-based setting. We have to ask ourselves, "Are there any limits to this type of practice?"

In a recent article, Bhananker and colleagues performed a closed claims analysis of the injuries associated with MAC. These data refer to procedures performed in all kinds of health care settings, such as offices, ambulatory surgical centers, and acute care hospitals. The authors examined closed malpractice claims in the ASA Closed Claims Database since 1990 and found that more than 40% of claims associated with MAC

involved death or permanent brain damage similar to general anesthesia claims, and that respiratory depression was the most common (21%) mechanism of injury. They concluded that almost half (46%) of the claims could have been prevented by better monitoring, including capnography, improved vigilance, and audible alarms.

Which is the safest choice of anesthesia recommended for the office-based setting? Because the main focus of office-based anesthesia practice is to provide safety and comfort while facilitating a fast-track recovery, it is important to highlight the discharge criteria from the ASA–Society for Ambulatory Anesthesia (SAMBA) manual, *Office-Based Anesthesia: Considerations for Anesthesiologists in Setting Up and Maintaining a Safe Office Anesthesia Environment*. Here are a few excerpts:

The attention to patient safety issues provided by these standards and guidelines should apply to all postanesthesia care regardless of facility location.

Wherever the recovery of the patient is to occur, the area designated must provide an environment that ensures that space, equipment and staffing adequately meet the intent of current postanesthesia care guidelines and standards.

Policies and procedures specific to the postanesthesia care of the patient should be developed and routinely reviewed by all office staff members. Regardless of facility site, all patients shall be observed and monitored by methods appropriate to the patient's medical condition by appropriately trained staff. The qualifications of these staff are clearly delineated in the following documents: ASA Statement on the Anesthesia Care Team, Statement on Qualifications of Anesthesia Providers in the Office-Based Setting, Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists, Statement on granting Privileges for Administration of Moderate sedation to practitioners who are not Anesthesia Professionals.

Patient discharge is a physician responsibility. Appropriate written criteria for discharge should be applied and should conform to any specific state regulations that govern the provision of office anesthesia. Ambulatory Discharge Criteria require that the patient's vital signs be stable, the patient is fully oriented, is able to ambulate without dizziness, has minimal pain, nausea, vomiting, bleeding; and the patient must have a responsible "vested" adult escort. Personnel with training in advanced resuscitation techniques should be immediately available until all patients are discharged home. A standardized scoring system such as the Modified Aldrete Score may be used. Fast-Tracking Criteria may use the same scoring criteria with two additional assessments: postoperative pain and postoperative emetic symptoms.

Management Aspects of Anesthesia Practice

Ross J. Musumeci, editor

Patient safety, quality assurance, and risk management

Miriam Harnett and Jeffrey B. Cooper

Quality and safety – the concepts

Patient safety, quality assurance, and risk management are related concepts, but they differ in important ways. Patient safety is primarily concerned with the prevention of injury. Quality assurance includes safety, but it is a broader term that also includes measures of the failure and success of medical treatments at levels beyond safety. Modern risk management focuses on proactive prevention of adverse outcomes and managing potential liability in their aftermath. Prevention of injuries via error reduction and system improvements is a primary means to reduce the adverse events that would otherwise lead to malpractice or compensatory claims.

It is important to remember that anesthesia is not primarily therapeutic. Thus, it must be the goal of every anesthetic that *no patient should sustain an injury or complication from the anesthetic encounter.*

Dimensions of quality

Quality is an abstract concept. Numerous definitions of quality exist, but perhaps the most widely accepted definition is that of the Institute of Medicine (IOM) – quality is the “extent to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.”

Donabedian proposed that the quality of health care could be measured by observing its major components: structure, process, and outcomes. *Structure* involves the facilities and environment in which the care is delivered; *process* involves how care is actually delivered, including the interactions between clinicians and patients; and *outcomes* involves measuring the results of medical care. When making these observations, it is important to remember that it is the patient’s perspective on the quality of care that is most important.

Causes of preventable adverse events

The cause of accidents is almost always multifactorial and can include failures of the organization, the care team, the individual, technology, or process design. Poor communication is one of the most common root causes of major adverse events, and

it can have many underlying causes. Factors that contribute to failures by the individual practitioner are:

1. Production pressure
2. Fatigue or sleep deprivation
3. Failure to check equipment
4. Lack of supervision
5. Unfamiliarity with equipment or with drug
6. Failure to follow routine
7. Unawareness of a protocol
8. Failure to follow protocol
9. Distraction

Improving safety: from individual events to systems

Safety requires continual vigilance and a culture that makes safe practice the highest priority. It is not enough to consider individual actions. The organization must also consider working conditions, facilities, procedures, and work flow so that all aspects of anesthesia care are addressed.

The review of closed malpractice claims, peer review, clinical conferences, and incident reports can be helpful in identifying areas for improvement. These methods do not quantify the incidence of a particular event, but they may identify problems that can be corrected.

Historically, adverse events in medicine have been dealt with in a punitive fashion. There is now an increasing realization that these events are most frequently the result of bad systems and that blaming individuals is counterproductive. Attention is now being turned toward understanding the deeper causes of adverse events and correcting problems with the system of care in an attempt to reduce the likelihood of errors.

Practical elements for producing safe, high-quality patient care

Teamwork – Effective teamwork improves safety, so each individual must learn to work as a team member rather than as an individual.

Preparation of equipment and medication – Failure to adequately prepare for the administration of anesthesia often contributes to critical incidents. Preparation includes ensuring availability of emergency drugs and equipment, ensuring that equipment is functional, and having a plan in the event of an emergency.

A mnemonic (SOAP M) is an example of a checklist for setting up the operating room (OR).

- **Suction** – Make sure it is working.
- **Oxygen** – Do you have it? Can you measure it? Can you deliver it?
- **Airway** – Check laryngoscope and have an endotracheal tube ready even if you do not plan to use it.
- **Pharmacy** – Check vial before and after drawing up drugs, have emergency drugs ready, and make sure that vaporizers are full.
- **Machines/Monitors** – Perform negative and positive pressure checks and check ventilator function.

Preoperative assessment and planning

Preoperative assessment and planning include a thorough medical evaluation of the patient and development of the anesthesia care plan with attention to addressing any comorbidities or other issues that might contribute to an adverse event. The plan should include the anesthetic technique and requirements for monitoring and for postoperative care, all of which must be consistent with the wishes of the patient, the needs of the surgeon, and the resources of the facility.

Monitoring

The safe practitioner should follow the standards promulgated by the American Society of Anesthesiologists (ASA; see “Suggested readings”). Critical alarms must never be disabled.

Safety in care transitions

Transitions in care present special risks for adverse events because key information can easily be lost and practitioners may become distracted during this process. Transitions include handoffs for breaks during cases or transfers between the OR and the postanesthesia care unit (PACU) or intensive care unit (ICU). It is important to develop specific protocols for conducting handoffs and to be especially mindful at such times.

Control for human factors

It is imperative to be organized and consistent in the layout of your emergency airway equipment and emergency drugs so that they are easily accessible. Ritualizing simple safety routines is a good idea because it makes them instinctive and harder to forget. When drawing up a drug from a vial, the vial must be checked both before and after the drug is drawn, and syringes should always be labeled immediately. One of the most important routines that must be followed without exception is to

read the drug label three times before a drug is administered. Keeping lines well organized and drug infusions clearly and obviously labeled, maintaining an uncluttered workspace, and minimizing distractions are all important safety measures.

Applying systematic crisis management techniques

Anesthesia Crisis Resource Management (ACRM) is an organized set of principles for managing crisis situations in anesthesia. Adapted from CRM in aviation by Gaba and colleagues, it consists of the following principles:

- Seek assistance as soon as unusual circumstances are recognized, inform others on the surgical team, and call for extra assistance.
- Establish clear roles for each person involved in management of the event, and identify who will manage the event (the leader).
- Use effective communication processes, including reading back instructions before they are carried out, and clearly identifying who should carry out the instructions.
- Use resources effectively and identify what additional resources (people, supplies, equipment, transportation, etc.) are available to manage the situation.
- Maintain situational awareness and avoid fixations. One person should act as the event manager who observes the big picture rather than becoming immersed in details.

Following standards and practice guidelines

Standardizing practices is now widely accepted as a critical component for safety and reliability, and the ASA has established a large set of standards and guidelines. A list of common practice standards can be found on the ASA Web site listed in the “Suggested readings” section at the end of this chapter. Practitioners should be familiar with such guidelines and should know how and where to access them and apply them when necessary.

Periodic training

Because critical events are relatively rare, it is important to practice skills periodically. Schwid demonstrated that advanced cardiac life support (ACLS) skills are generally maintained for only approximately 6 months. Simulation is being used increasingly for such training in anesthesia, and in some specialties simulation has already become part of the evaluation processes of accrediting agencies.

Involving the patient in safety and quality

Anesthesia providers can involve patients in their own care, thus improving patient satisfaction and safety by

- Giving the patient information about the process of anesthesia care that he or she will experience;

- Encouraging the patient to speak up if he or she sees things that he or she does not understand or that may not seem appropriate (e.g., drugs that are being given, absence of hand washing or wearing gloves);
- Involving the patient's family members in care whenever practical;
- Giving the patient your contact information so he or she can notify you if he or she has any concerns or side effects after the anesthetic; and
- Encouraging a policy of disclosing errors and adverse events (a strategy that enhances trust and decreases skepticism in concerned patients).

Risk management

Background

In its 1999 report – “To Err Is Human” – the IOM declared that medical injury is a major cause of preventable deaths and called on the health care industry to make the reduction of medical errors a priority. The IOM emphasized evidence from other industries showing that faulty systems are the major cause of errors and accidents, and it strongly recommended that health care organizations focus their safety efforts in this area. In response, a major national movement has been launched to redesign health care systems.

In a subsequent report – “Crossing the Quality Chasm” – the IOM called on health care organizations to provide care that is safe, effective, patient-centered, timely, efficient, and equitable. There are two principles underlying the IOM recommendations for responding to incidents:

1. We must commit ourselves to relentless self-examination and continuous improvement.
2. Medical care must be patient-centered. After an incident, the primary objective should be to support the patient and maintain open communication by providing patients and families with the details of incidents and their implications.

How should an institution respond?

A serious incident should trigger a cascade of responses. The first concern should be the prevention of further harm and relief of suffering. Members of the health care team and appropriate administrative and clinical leadership should be promptly notified of the event. The patient and family should be told about the event as soon as possible and provided with only the facts that are known. They will probably need emotional and psychological support, so this should be readily available. Finally, the medical record should clearly document not only the event, but also the disclosure and all supportive measures that are provided to the patient and the family. It is important to note that caregivers may also require psychological support, depending on the type of event.

As soon as practical, all involved parties should participate in an analysis of the event, in which they search for the underlying systems failures. The goals of the analysis should be to gain

a full understanding of the circumstances involved in the event, identify contributing factors, and develop practical recommendations for systems changes designed to prevent a recurrence.

There are four essential steps in the full communication of adverse events:

1. Tell the patient and family *what* happened, but leave details of how and why for later. Determining the causes of an adverse event requires careful analysis and is time-consuming. Patients and their families are likely to want immediate answers when you disclose the event to them, but it is important to limit your discussion to known facts and avoid speculation.
2. Take responsibility. Taking responsibility for an adverse event is an essential step in the full communication of that event.
3. Apologize. When there has been an error, one of the most powerful things a caregiver can do to heal the patient and him-/herself is to apologize. Even when the caregiver is not at fault and system failures are responsible for the error, an expression of sorrow for the undesirable outcome can be helpful. Explaining the event, communicating remorse, and making a gesture of reconciliation can do much to defuse the hurt and anger that follows an injury.
4. Explain what will be done to prevent future events. After the investigation is completed and corrective changes are planned, it is important to inform the patient and family of these plans. Injured patients have a strong interest in seeing to it that what happened to them does not happen to someone else.

Reporting

Incidents should be reported promptly to supervisors, risk management, and other concerned parties to ensure appropriate treatment and communication with the patient and family and to facilitate institutional learning. Reporting is also necessary to comply with specific mandates established by various external regulatory agencies, such as the local department of public health, state board of registration in medicine, the US Food and Drug Administration, or the Joint Commission. Practitioners should be aware of such requirements in their area. Providers and hospitals also have an obligation to notify their liability insurance carriers of certain types of incidents, especially if there is a potential for future malpractice claims or compensation.

Summary and conclusions

The delivery of care should be recognized as a complex matrix of multiple providers, including both clinicians and facilities, all interacting with one another. There are many opportunities to improve patient care, and the pressure to improve the quality of perioperative care will continue to increase. The specialty of anesthesia is recognized as a leader in patient safety, and anesthesia providers can continue to provide leadership by

implementing the IOM recommendations and adopting a patient-centered approach to dealing with adverse events.

Operating room management: core principles

Richard D. Urman and Sunil Eappen

The operating room (OR) is an important part of the hospital because it is typically one of the biggest sources of revenue and one of the largest areas of expense. Until the 1980s, OR suites generated large profits and hospital administrators were able to allow them a great deal of autonomy despite their inefficiency. This situation has changed dramatically due to increasing requirements for cost containment in health care and a demand for accountability to the federal and state government, insurance companies, hospital administrators, surgeons, and patients. Whereas there was little centralized leadership in ORs of the past, OR management is now a critical feature of successful hospitals. A good management team must bring together many diverse components of the hospital to function together efficiently and effectively. [Figure 138.1](#) shows a typical hospital organizational structure and the parties involved in day-to-day OR management.

OR manager

There are at least four distinct stakeholders in the OR: hospital administration, nursing, anesthesiology, and surgery. Each of these stakeholders has its own interests, and the OR manager must be able to balance the needs of these different groups to maximize productivity and minimize conflict. The key characteristics of an effective OR manager are listed in [Table 138.1](#).

A more detailed job description of the OR manager can be found on the Web site of the American Association of Clinical Directors (AACD; www.aacdhq.org).

Anesthesiologists who have the characteristics listed in [Table 138.1](#) are particularly well-qualified to fill the OR manager position because they typically have a constant presence in the OR without the need for office hours, and they usually have a clear understanding of OR processes. Hospital administrators may prefer anesthesiologists or nurses for the OR manager position because their economic interests are often aligned with those of the hospital.

A successful OR manager must have the support of the hospital CEO and the chairpersons of the departments of surgery, nursing, and anesthesiology. It is necessary for all departments to give up some of their own authority and control so that the OR manager can run the OR in a manner that benefits everyone. The OR manager must also have the support of his or her own group, because the position will require time that could

otherwise be spent on group activities. For this reason, and also to emphasize the neutrality of the OR manager position among all departments, the OR manager and/or the manager's practice should be compensated by the hospital.

Scheduling and efficiency measures

The amount of revenue that an OR generates is dependent on the number of surgical cases that are performed, so a significant amount of time in OR management is spent on scheduling. Surgical scheduling rules must be established, and a daily schedule for both cases and OR staff must be generated. Both of these schedules are frequently modified to account for emergency cases and differences between booked and actual case times. The American Society of Anesthesiologists (ASA), The American College of Surgeons, and the American Organization of Registered Nurses have accepted the terminology presented by the AACD in their glossary of operating room measures. The complete glossary and standardized abbreviations are published on their Web site, and individuals interested in accurately measuring OR times should consult this comprehensive glossary. Many of the terms that are seen in the anesthesia literature are either AACD terms or are derived from AACD glossary terms. We have included an abbreviated list of commonly used terms in [Table 138.2](#).

OR utilization is a popular concept that can be used differently depending on the desired analysis. *Adjusted OR utilization* is defined as the amount of time an OR is used (in-OR

Table 138.1. Characteristics of an effective OR director

Has strong problem solving and organizational skills
Is even-tempered
Is able to commit a significant amount of nonclinical time
Is a strong clinician garnering respect of other clinicians
Has strong interpersonal and negotiation skills
Is able to understand business/financial concerns of institution and physicians
Understands perioperative processes
Understands scheduling systems and information technology
Understands organizational dynamics and is able to understand divergent needs and concerns of different stakeholders and bring them together
Is committed to overall performance of OR suite rather than individual department

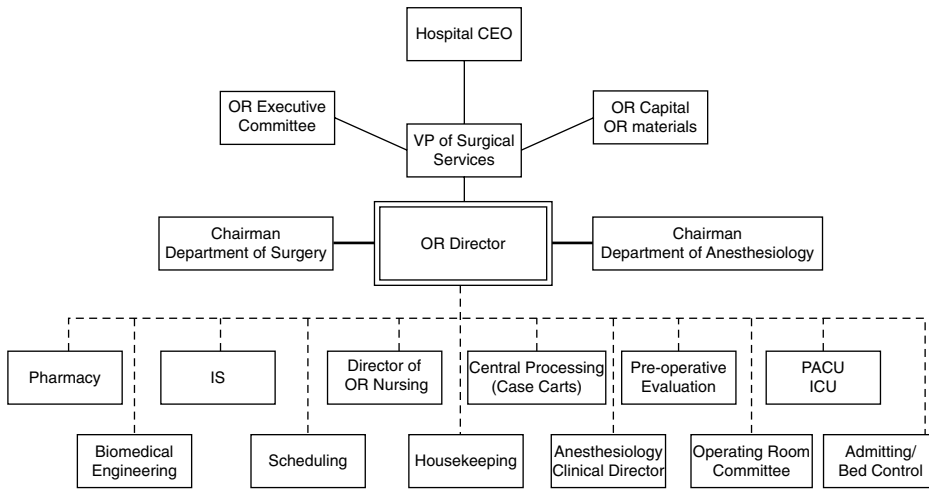

Figure 138.1. Typical organizational chart for management of OR.

time + turnover time) divided by the total amount of time the OR is staffed and available for the day (resource hours). The AACD term for adjusted OR utilization is “adjusted-percent utilized resource hours” (AURH). This measure tells you how much of the day has been filled with scheduled OR time. *Raw OR utilization* excludes turnover time in the calculation (in-OR time/resource hours). Raw OR utilization gives a ratio of billable to total OR hours, and either unbooked time or excessive turnover time will drive this value down. Decisions about the allocation of OR time for a surgeon or a service are often based on OR block utilization. *Block utilization* is defined as the amount of time that an OR is scheduled by a particular surgeon or service, divided by the total amount of block time

that this surgeon or service has been granted. This value may exceed 100% because it typically includes hours that services operate outside of their block time. A service that is consistently at greater than 80% block utilization will typically have trouble scheduling cases, so this number is frequently used as a guide as to when the service should be granted more OR time.

It is important to remember that factors other than block utilization may need to be considered for decisions regarding more or less OR time. For example, trauma services that are important to the community may require an unscheduled OR that is always ready for an emergency. The resulting low utilization rates will be acceptable if trauma is part of the hospital’s mission.

Table 138.2. Sample of OR efficiency terms

Resource hours or Allocated OR time	Time scheduled for OR to be staffed and available for performance of procedures
In-OR time	Total time that ORs have patients in them per day during resource hours
Raw OR utilization	$(\text{In-OR time} / \text{resource hours}) \times 100$
Adjusted OR utilization or Adjusted-percent utilized resource hours	$(\text{In-OR time} + \text{turnover time}) \times 100 / \text{resource hours}$
Block utilization or Adjusted-percent service utilization	$(\text{In-OR time} + \text{turnover time}) \text{ for day's cases} \times 100 / \text{block time}$
Induction complete or Anesthesia ready	Time when patient handed over to surgeon for positioning, surgical prepping, and draping
Induction time	Time from when patient enters OR to Induction complete
Surgical controlled time	Time from induction complete to when last dressing is placed
Emergence time	Time from last dressing is placed to when patient is ready to transfer
Anesthesia controlled time	Induction time + emergence time
Turnover time	Time from when one patient leaves the OR to when the next patient arrives into the OR
First case starts	Routinely measured as percentage of ORs in which the first scheduled patient arrives into the OR prior to or at scheduled start time

Open scheduling versus block scheduling

Traditionally, OR schedules were filled on a “first-come, first-served” basis that assumed that any case could be performed in any room and that all anesthesiologists and nurses could handle the different surgeries equally well. Increasingly complex cases with specialized equipment and teams have led to a more organized system of assigning rooms to specific surgeons or services and guaranteeing them specific time slots. This method of scheduling allows specialized equipment to remain in designated ORs (e.g., cardiopulmonary bypass circuits, laparoscopic equipment/displays) and for specific teams to work in these areas consistently. Block scheduling smoothes the variability in OR case volume by giving greater predictability to surgeons when booking their cases. It also creates more accountability when evaluating case volume expectations and targets for hospitals, surgeons, nurses, and anesthesiologists. In general, blocks appear to work more efficiently when they are assigned to specific services rather than to surgeons. Additionally, full day blocks are preferable to partial day blocks because they eliminate the possibility of delayed starts for a second service due to preceding cases running longer than expected. Block booking may not work well in ORs with high numbers of emergent cases that disrupt the schedule; in such situations, open scheduling for one or more rooms may lead to higher OR utilization and patient satisfaction.

A key part of block scheduling is having specific rules in place that govern how OR time is allocated. *Release time* is defined as the number of hours before the scheduled time of surgery when a block of time must be either booked or released for use by others. Release times for specific services should reflect the nature of their cases. For example, cardiac surgery typically has short release times due to the urgent nature of many of their cases, whereas plastic surgery has longer release times because their cases are almost exclusively elective.

Turnover time

Much energy and money has been expended on decreasing *turnover time*, which is defined as the time between when one patient has left the OR and the next one arrives. From a business perspective, it makes sense to reduce turnover time, because no revenue is generated while there is no patient in the OR. Unfortunately, a number of studies have revealed that even maximal improvements in turnover time will usually not open enough time in the schedule to allow additional case bookings later in the day. Efficient turnover during the course of the day, however, may lessen overtime in a busy OR leading to lower expenses and improved morale of the staff.

A number of functions need to be completed during turnover time:

- Room cleaning;
- OR table setup with sterile equipment;
- Anesthesia equipment cleaned and restocked;

Table 138.3. OR efficiency metrics to be measured

Overtime hours of OR staff
Scheduled start times to actual start time difference for all scheduled cases
Case cancellation rate
Contribution margin per hour or per OR per day
Turnover times
Prolonged turnover times (turnover times > 60 min)
PACU or ICU admission delays (cumulative number of minutes)
Scheduled case time to actual case time difference for all scheduled cases

- Patient taken to PACU/ICU, vital signs checked, patient signed off to PACU nurse;
- Medications reconciled and new ones checked out;
- Next patient greeted (anesthesiologist and OR nurse);
- Preoperative assessment including surgical and anesthesiology consent, surgical reassessment, review of plans, and site verification;
- Intravenous lines/block placed; and
- Anesthesia equipment checkout performed.

From the list above, it should be apparent that turnover time is dependent on many different factors.

OR efficiency

OR efficiency is a difficult concept to contain in any one single measurement. Macario and colleagues recently described a set of criteria and a scoring system that hospitals and OR managers may consider in determining the overall efficiency of their ORs. Table 138.3 lists the suggested metrics. All of these factors may not apply to every OR suite, but this is the first set of metrics that has met with some acceptance and uses measures that are readily available in most ORs. Hospital administrations are now beginning to benchmark their metrics against comparable institutions to identify opportunities and techniques that may improve efficiencies.

Additional cost-control measures

In 1994, the ASA formed an ad hoc committee on value-based anesthesia care to promote the best patient outcomes at the most reasonable costs. The committee wrote that the optimal choice of anesthesia management depends on maximizing the positive aspects of health, function, and satisfaction while minimizing the negative aspects of mortality, morbidity, and expense. Indeed, health care realities mandate that the costs of drugs, equipment, and time be incorporated into every anesthesiologist's decision-making process. Anesthesiologists control large amounts of expensive resources, and their decisions affect the finances of patients, hospitals, and insurers. It is important to practice evidence-based anesthesia, promote departmental discussions of costs and goals, define permissible activities for sales representatives, minimize waste, and develop practice guidelines for expensive drugs and technologies. Practitioners should also be provided with personalized anesthetic usage costs and patient outcomes feedback, including peer comparisons.

Physician credentialing

Diligence in physician credentialing and privileging is critical to high-quality care in the OR. The purpose of credentialing is to assure patients and third-party payers that the highest quality of health care is being provided by a professional staff selected according to a rigorous evaluation process based on qualifications and other objective criteria. Critical elements in the credentialing process include professional degrees conferred by accredited educational institutions, current and unrestricted professional licensure, postgraduate residency training, fellowship training, specialty board certification, professional standing as judged by peer review processes, physical health, and psychological well-being. Specific OR privileges for surgeons and anesthesiologists are determined by specialty training, certification, experience, and demonstrated competence. Recredentialing and reprivileging are required regularly and should be based on a critical appraisal of professional performance through peer review and continuous quality improvement (CQI) monitoring. The ASA Guidelines for Delineation of Clinical Privileges in Anesthesiology are referenced for the reader's convenience.

Practice management

Ross J. Musumeci

Introduction

Practice management includes the functions that are necessary to support the business and clinical operations of an anesthesia practice. The complexity of business operations that are required for each practice and the mix of physicians and non-physicians that fill those roles will vary depending on the size and objectives of the practice. This chapter describes the different components within practice management and acquaints the reader with important aspects of each one.

Contracting

Contracting is the process of negotiating a formal agreement with outside entities that defines the nature of your business relationship. Anesthesia practices typically negotiate professional service contracts with health care facilities, insurers, and employees. It is the role of the practice management team to negotiate these contracts with the aid of legal counsel.

Professional service agreements negotiated with a health care facility define the relationship between the anesthesia group and the facility. Among other things, these contracts usually describe the expectations that the hospital has of the anesthesia group, the methods that the anesthesia group will use to fulfill those expectations, the resources that the hospital will provide in support of the group's efforts, and the options that each side has if the other does not fulfill its side of the agreement. When structuring hospital contracts it is a good idea to carefully define which services the practice is obligated to provide and to clarify those services that are not included. Hospital contracts may also include an agreement about the level of financial support that the hospital will provide to the anesthesia group. The more time you spend up front creating a contract that is specific, the less likely it is that you will encounter a misunderstanding later.

Agreements must be secured with insurers to determine the level of reimbursement to which the practice will be entitled and the nature of the interaction among the insurer, its clients, and the practice. Collectively, these contracts define the level of income to which the practice is entitled, so a great deal of emphasis should be placed on securing the most favorable contracts possible.

Employment agreements form the basis for the relationship between the practice and its employees, and they typically specify compensation and the responsibilities of the employer and employee. It is worth spending some time to create good employment agreements to avoid misunderstandings after employment begins.

Billing and collections

Whereas contracting determines the level of revenue to which the practice is entitled, the billing and collections department performs the activities necessary to actually collect the money associated with the physician's services. The medical industry is unlike many others in that the actual amount received for a service is indeterminate at the time the service is rendered, making aggressive and thorough follow-up on claims important.

The typical activities within a billing and collections department are outlined in [Table 139.1](#). It is important to make sure that providers are credentialed with each insurer. If credentialing is not completed prior to providing services, the insurer may deny reimbursement.

Anesthesia records generated when services are rendered typically provide the basis for charges that are submitted to third-party payers. These records, along with any necessary supplemental documentation, are forwarded to the billing office for processing. There should be a mechanism to reconcile records that the billing office receives against cases that were actually performed on any given day to ensure that no charts are lost during transport. After charts are received by the billing office, patient demographic information is entered and the charts are then scanned for the relevant diagnoses and procedures.

Table 139.1. Billing and collections

Collections and follow-up
Reporting

The diagnoses and procedures must be “coded” by converting diagnoses and procedures to Current Procedural Terminology (CPT) codes, *International Classification of Diseases, 9th Revision, Clinical Modification* (ICD-9-CM) codes, and American Society of Anesthesiology (ASA) codes. CPT codes describe the medical, surgical, and diagnostic services that are performed by physicians and other health care providers. ICD-9-CM codes are used to code signs, symptoms, injuries, diseases, and conditions. The diagnosis indicated by the ICD-9-CM code must support the medical necessity of the procedure defined by the CPT code. CPT codes may be used when a flat fee is charged for services, such as arterial line placement, but all time-based billing requires that the CPT code be converted or “cross-walked” to a corresponding ASA code. The ASA updates and publishes ASA codes each year and structures them so that almost every CPT code has at least one corresponding ASA code, but in most cases ASA codes are further broken down to allow for greater anatomic specificity. It is extremely important to code accurately so that the practice can avoid rejections, which cause a delay in reimbursement. Prior to submission, charts should also be audited to ensure that they are in full compliance with documentation and billing guidelines as required by the American Medical Association and the Centers for Medicare and Medicaid.

After coding has been performed, claims processing can begin. This processing consists of charge capture, where information and coding are transferred from the chart to the actual billing instrument, and submission of the billing instrument to third-party insurers. Claims personnel should (1) have a mechanism for tracking the status of outstanding claims, and (2) follow up quickly on those that have either been rejected or have not received a timely response. Cash-posting personnel process all payments and match them to outstanding claims. They should ensure that payment amounts match the fee schedule agreed to by the insurer and should appeal any low or inaccurate payments. Given the varied ways in which claims are processed by different insurance companies, and the fact that many claims still require human intervention for processing, it is imperative that the practice have an effective way to monitor payer contract performance. Specifically, an allowable monitoring system is a required function of the billing department (with oversight from the finance department) in which all reimbursements are matched against contracted rates to ensure that there are not underpayments or overpayments made by payers. After a correct payment has been received, the claim is closed. In the event that payment is not received within a reasonable time frame despite appropriate follow-up, the claim is submitted to the collections department. Many groups outsource this function for older claims so that they can free resources to pursue more current claims that they are more likely to collect.

Billing and collections departments should also be able to provide the practice with reports of their activities. Some of the common reports that a billing department can provide are shown in Table 139.2. Basic performance of the billing and collections department can be readily ascertained by examining

Table 139.2. Reports and descriptions

Report	Description
Gross revenue	Gross charges prior to contractual allowances
Contractual allowances	Discounts given to insurers off of full rates
Net revenue	Charges net of contractual allowances
Net income	Excess of all revenues and gains over all expenses and losses for a period
Net collection ratio	Total collections divided by net charges
Bad debt	Uncollectible accounts
AR	Claims against payers (or other debtors) that are not yet collected
Average collection period	Average number of days from time of service to collection; also referred to as Days Outstanding in AR or Days Sales Outstanding (DSO)
Aging report	Breaks AR into buckets based on time since service provided
Payer mix ratio	Ratio of each payer’s gross charges to total gross charges; can also be calculated with net charges

the size of accounts receivable (AR), average collection period, the percentage of bad debt, and the age of AR. Upward trends in any of these metrics are undesirable and should prompt an investigation into the causes.

In general, an average collection period of less than 60 days is desirable, but it is not uncommon to see practices with average collection periods of more than 100 days. It is advisable to keep this value as low as possible. A typical aging report shows the amount of AR in the categories of up to 30 days, 60 days, 90 days, and older than 120 days. In general, the older the claim the harder it is to collect, so an increase in older claims is a significant finding that should be examined immediately.

It is advisable to evaluate the payer mix ratio of a hospital and to follow it over time. The significant disparity between governmental and nongovernmental payers that currently exists in reimbursement for anesthesia services makes it essential that the practice administrator knows exactly what this ratio is and understands its implications for profitability and the possible need for financial support from the hospital.

Scheduling

The scheduling department controls clinical personnel – the primary asset a practice uses to generate revenue and also its largest expense. It follows that this department has a major impact on expenses, revenues, and net income. In small practices, the scheduling function will be easier, but, as practice size increases, the complexity of scheduling can increase rapidly and can require significant resources.

There are several types of schedules that must be completed for the routine operation of an anesthesia practice. A daily schedule must be created to determine the personnel who are allocated to a given hospital each day and the locations to which they are assigned within that hospital.

Methods for creating on-call and vacation schedules must incorporate safeguards to ensure fairness. Aside from the

Table 139.3. HRM functions

Recruiting and hiring
Hospital credentialing
Maintaining a positive workplace environment
Personnel development and training
Ensuring that personnel and management practices conform to various regulations
Managing company's approach to compensation and benefits
Maintaining employee records and personnel policies
Performing employee evaluations
Dealing with employee relations, performance issues, and termination

obvious need to schedule these two items in a way that is consistent with safe and efficient practice operations, the most important aspect of the scheduling system is that it is perceived to be fair by the individuals that it affects. Anything that can be done to make the process and the results transparent to the involved individuals usually helps. A lack of transparency and perceived unfairness in these areas can cause a decrease in morale.

Human resources

The primary product of an anesthesia practice is the service that its personnel provide. Without good personnel, the product suffers. Good human resource management (HRM) is essential to a successful practice, especially in the competitive personnel market of today. An effective HRM department can improve employee retention leading to better customer service and a competitive advantage for the company. The essential functions of an HRM department are broad and include the items shown in [Table 139.3](#).

Shortages of both anesthesiologists and nurse anesthetists have made recruiting and hiring qualified personnel an increasingly difficult and important task, and a good HRM department will devote a significant amount of time to this task. It is important to remember that the cost of hiring a new employee and orienting and training him or her is usually greater than retaining existing employees. For this reason, the HRM department should also spend a significant amount of time on employee retention.

Development, training, and continuing education are a means to keep employees stimulated and interested and can lead to improved productivity and better morale. Retention is also dependent on maintaining a workplace that is pleasant and free of hostility. Issues of discrimination and harassment have implications for both employee retention and company liability, and it is the job of the HRM department to manage any issues that arise in this area.

Competing for personnel on the basis of salary alone is difficult and costly, but a flexible and creative benefits package may attract employees despite a lower salary offer. It is important that employees understand their total compensation, so the HRM department must both structure the benefits program well *and* communicate its contents and value effectively. Without good communication, the practice may be wasting its money on the program. Employee evaluations

provide an opportunity for the practice to improve the quality of the service its employees provide, but only if the process is managed in a professional and fair manner. Evaluations must be done as objectively as possible and with a means for appeal in the event that an unfavorable evaluation is delivered. Results should be delivered in a sensitive and confidential manner and with constructive intent. In the event that evaluations are not successful in altering poor performance and termination is considered, it is the job of the HRM department to ensure that (1) the employee is treated fairly and in accordance with all applicable laws, and (2) appropriate documentation is obtained prior to termination. For employees who self-terminate, HRM departments will frequently try to obtain competitive information by conducting exit interviews with departing employees. Issues related to termination, discrimination, or any type of harassment in the workplace should cause a practice's manager to consider early consultation with a labor attorney. The applicable law is complex, court decisions can result in treble damages, and the losses are not insurable. Furthermore, conflicts related to employment disagreements are usually fraught with emotion. For all of these reasons, issues related to termination, discrimination, and harassment in the workplace are dangerous to address without professional advice.

Human resource information systems are frequently used and can be helpful. When choosing a system, make sure that it is multifunctional and reduces redundant processing of information such as payroll and accounting. A good system should also track compliance items, such as the continuation of health insurance under Consolidated Budget Reconciliation Act (COBRA) or Family and Medical Leave Act (FMLA) issues, because noncompliance can be costly.

Finance

The finance department is responsible for managing all financial aspects of the practice, including accounts payable, payroll, expense reimbursement, revenue and expense tracking, creation of financial reports, and preparation of tax documents. This department is also responsible for helping to create and enforce financial controls, which are policies and procedures meant to safeguard assets within the company.

To understand financial reports, the practice manager must understand the difference between cash-based and accrual-based accounting. Cash-based accounting requires that revenue be recognized when money is received and expenses be recognized when payment is made. This idea is in contrast to that of accrual-based accounting, in which revenue is recognized when it is earned by providing a service, and expenses are recognized when they are incurred regardless of when money actually changes hands. Smaller practices may use cash-based accounting, but larger practices will almost exclusively use accrual-based accounting because it is considered to be more accurate and better able to give a clear picture of practice performance at any given time. Analysis of financial reports should be

undertaken with the intent of understanding past performance and finding ways to improve future performance. Reports should be analyzed on a regular basis, and attention should be paid to trends as well as to overall amounts in both expense and revenue line items. Good reports should be timely, accurate, and simple (but with enough detail to provide necessary information). The financial reports that are most commonly reviewed are the balance sheet, the income statement, and the statement of cash flows. The balance sheet is prepared on a single date, and it gives the reader a snapshot of the financial condition of the practice at that single moment in time. In contrast, the income statement reports revenues, expenses, and net income over a defined time period, so it provides a moving picture of the company's performance. Finally, the statement of cash flows reports on sources and uses of cash over a defined time period and tells the reader what the change in cash balances was during the time period. This statement is useful in accrual accounting because the other statements do not directly report on the cash status of the company.

The finance department is also responsible for assisting management in forecasting revenue and budgeting expenses. The process of budgeting and forecasting can be time-consuming, but it is time well spent. It requires thoughtful consideration of the current business environment, the resources that the practice will need, as well as existing opportunities and the likelihood that the practice will be able to capitalize on them. Considering all of these elements and their financial implications at a time when the information is actionable is far better than waiting to analyze financial data after the fact.

The creation of pro forma cash flow and income statements can also be useful if the practice is considering new hospital contracts or new investments of any kind. Pro forma statements are projected financial statements that are targeted to a specific initiative and are meant to show the expected cash flows, revenues, expenses, and net income from the project under consideration. Creation and analysis of these reports, along with a critical review of the assumptions that go into creating them, lessen the chance of the practice making an unprofitable decision on a new project or contract.

Risk management

Risk management is covered in another chapter, so comments here will be limited to those that apply directly to the business operations of the anesthesia practice. The risk management department is responsible for dealing with the possibility that future events may cause harm to the practice. Every anesthesia practice engages in some form of risk management, but the complexity of risk management activities varies widely based on the size of the practice and its organizational goals. Smaller practices tend to have simple structures with minimal personnel. They may have physicians perform many of the routine risk management activities and depend on their hospital's professional risk manager or the risk manager for their professional liability carrier in the event of an adverse outcome. Larger

practices are likely to have a more complex arrangement, up to and including employment of their own risk manager and the creation of a captive insurance company.

At its most basic level, risk management involves examining an organization to determine what can go wrong, what should be done to prevent adverse events, what should be done to manage adverse events after they occur, and how the practice will pay for adverse events that are compensable. This examination usually involves establishing and managing formal quality assurance–quality improvement programs, conducting analyses of adverse events, managing litigation, performing risk analysis of policy and procedure, and engaging in communication and education for the purposes of risk reduction. The key components of a properly structured risk management program include a user-friendly reporting system, a method for collection and review of data with the ability to identify trends and implement strategies to decrease risk, access to a risk manager and counsel, and strict attention to evidentiary protections when structuring the program. Some states provide limited protection for work products related to peer review or quality improvement, but this protection differs from state to state and is subject to judicial interpretation and balancing the plaintiff's interest in discovery against the public policy interest in peer review and quality improvement. The risk manager who is structuring your program should make sure that he or she is familiar with the particular evidentiary protections available in your state and must alter the program to keep up with any changes in these laws so that documents created as part of your risk management program will not be discoverable in a malpractice case.

Although not all risk managers work directly with brokers for the purpose of securing the organization's insurance, it is essential for the risk manager to play a role in this process. A broker will usually secure bids from multiple vendors to obtain cost-effective malpractice insurance and will present the bids to the risk manager and other designated individuals within the organization. When examining bids from malpractice insurers it is important to consider all aspects of the potential insurer including size, financial strength, reputation, length of time writing malpractice policies, and ratings by independent insurance rating organizations. It is also important to consider the level and quality of service they provide when claims are made. The best way to determine level and quality of service is to contact colleagues who have been sued while covered by the company. Additional weight should be given to bids from companies whose main product is professional liability insurance, particularly those that have provided at least 10 years of professional liability service in the same geographic area as the practice because experience with the local court system and defense attorneys is valuable when mounting a malpractice defense.

Some larger practices have attempted to gain more control over their malpractice costs and administration by self-insuring using on- or offshore captive insurance companies. Commercial malpractice insurance rates are partially dependent on the history of claims throughout the entire malpractice market.

Self-insuring can result in malpractice insurance rates being more dependent on the claims history of the practice being insured, so a practice with a good claims history may be able to lower malpractice insurance rates. It is important to note that setup and ongoing administrative costs are considerable and that a practice that is not already paying at least 1 million dollars in malpractice insurance premiums will probably not find it cost-effective to self-insure. The practice must also be large enough and have a long enough history for the actuarial analysis that determines its premiums to be reliable.

The Health Insurance Portability and Accountability Act of 1996

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) deserves special mention because it has a significant impact on many aspects of practice management. Title II of the act addresses the security and privacy of health data stating that “reasonable and appropriate” safeguards must be taken to protect the integrity and confidentiality of health information. Following from the requirements of Title II, the Department of Health and Human Services (DHHS) has created five rules: the Privacy Rule, the Transactions and Code Sets Rule, the Security Rule, the Unique Identifiers Rule, and the Enforcement Rule. These five rules apply to all covered entities, which include health plans, billing services or health care clearinghouses of other types, and health care providers.

The Privacy Rule requires covered entities to protect the privacy of certain individually identifiable health data called Protected Health Information (PHI). It also establishes regulations for the use and disclosure of PHI, which includes any part of a patient’s medical record or payment history. PHI must be disclosed to the patient on request, when required by law, or to facilitate treatment or payment or to third parties when consent has been given by the individual, but disclosure must be limited to the minimum amount necessary to achieve the required purpose. When PHI is disclosed, the disclosing entity is required to notify the individual and to keep track of any such disclosures.

The Security Rule deals specifically with electronic PHI and it requires the practice to institute administrative, physical, and technical safeguards. Administrative safeguards include policies and procedures that show how the practice will comply with the act. Physical safeguards protect against unauthorized access to hardware and software, and technical safeguards should protect against interception of PHI that is transmitted electronically.

The Enforcement Rule sets monetary penalties for noncompliance with any of the above rules. It is important that the prac-

tice manager be aware of all rules pertaining to the protection of PHI and to enact policies and procedures that will ensure compliance so that enforcement actions are avoided.

A full discussion of HIPAA is beyond the scope of this text, but practice managers should be fully versed in all aspects of Title II. All five of the above rules are relevant to practice management, and this chapter has only highlighted some of the major requirements of these rules. The reader is referred to the Centers for Disease Control and Prevention (CDC) and DHHS Web sites for further information.

Principles of medical ethics

Robert J. Klickovich and Rae M. Allain

Anesthesiologists are obligated to adhere to basic ethical principles in their practice. These principles primarily serve to protect the patient's interest, but are also applicable to other areas of professional conduct, including interactions with colleagues. This chapter will discuss basic medical ethics and describe common situations for the anesthesiologist in which ethical issues are paramount. Knowledge of ethical behavior is important given the anesthesiologist's role when patients are rendered unconscious and thus vulnerable due to either illness or intentionally administered medications.

Principles of consent

Autonomy, derived from the Greek roots *autos* (self) and *nomos* (rule), is widely accepted in our society, and it follows that patients have a right to self-determination. Patients may accept or refuse treatments after being presented with the necessary information, including the expected risks, benefits, and possible alternatives to a procedure. This dialogue between patient and physician is part of the informed consent process, which precedes the induction of anesthesia in elective circumstances. An inherent assumption of informed consent is that the patient understands the information and has the capacity for decision making. If the anesthesiologist questions whether a patient has this capacity (such as in the demented or delirious patient), then a formal assessment by a psychiatrist may be warranted. In such circumstances, a surrogate decision maker can be called on. This surrogate may be the patient's health care proxy (sometimes termed "durable power of attorney for health care") if the patient had designated such an individual previously. Alternatively, the patient's next of kin or close friend may be designated as the surrogate decision maker. It is incumbent on this individual to make decisions congruent with the patient's prior expressed wishes or values and not to choose based on what he or she would wish for him- or herself. If the patient has prepared advance directives (written documents describing what treatments or goals of care the patient would wish if incapacitated), these wishes should be respected by surrogates in the decision-making process. Advance directives may include a health care proxy designation and/or a "living will." The special circumstance of the pediatric patient mandates a surrogate decision maker for consent, usually a parent or legal guardian. Depending on the child's age, he or she may participate in the informed

consent discussion and render preferences. For example, a child may choose between an inhalation and an intravenous induction. Similarly, this dictum of involving patients in the explanation of the procedure and inviting their input where appropriate may be applied to patients lacking full capacity, such as the adult patient with developmental delay whose guardian provides consent for the procedure.

The informed consent process requires the anesthesiologist to disclose information regarding the anesthetic procedure. The consent process should meet the "reasonable person standard." This means that any reasonable person would be satisfied that the patient was fully informed of all material information prior to signing the consent form. The specifics of the level of disclosure and the amount of detail cannot be precisely defined and will vary with the individual patient and procedure. The anesthesiologist should be aware that informed consent is a process of communication between provider and patient and that no rote or standardized form can guarantee protection against legal recourse by the patient. A prudent approach seeks to offer the patient as much information as he or she wishes, with ample opportunity to answer the patient's questions at the conversation's conclusion.

Emergency circumstances may preclude the informed consent process. In such situations, both surgeon and anesthesiologist should agree that the procedure requires emergent intervention to prevent permanent harm to the patient, and this should be documented in the medical record. In the absence of known advance directives, full treatment options should be pursued until such time as the patient's directives become clear.

Religious and cultural beliefs

Modern medicine dictates respect for varying cultural and religious beliefs. For the anesthesiologist, a common situation is the refusal of blood transfusions by patients who are Jehovah's Witnesses. Members of this religion may interpret biblical scripture as prohibitive of transfusion, including the strict penalty of loss of eternal salvation. Interpretation of this prohibition of blood transfusion varies among Jehovah's Witnesses and, therefore, a careful and private discussion should take place between the anesthesiologist and the Jehovah's Witness presenting for surgery. The purpose of this discussion is to delineate the patient's wishes regarding transfusion. The discussion should

include preoperative preparation for blood conservation, consideration of deliberate hypotension or hypothermia, hemodilution, autologous donation, erythropoietin, and transfusion of synthetic colloid preparations (e.g., albumin). Many Jehovah's Witnesses will allow the use of red blood cell salvage, especially if the circuit is kept in continuity with the patient's circulation in a "closed" fashion. Finally, a frank discussion of the possible consequences of blood refusal, including death, is necessary. Legal precedent exists that allows the physician to administer a blood transfusion despite patient objections in some situations. Examples include the patient who is the sole parent of dependent children or the pediatric patient whose parents object to transfusion. It is prudent to involve legal counsel preoperatively in these circumstances whenever possible.

Cultural respect may require the anesthesiologist to make inquiries before interviewing the patient. For example, women of the Muslim faith may request a same-sex translator to discuss health-related issues. These patients may also require that the male head of household render health care decisions for them. To engender trust, enhance communication, and ensure understanding, it is beneficial to approach patients of different cultural backgrounds in an open-minded, nonjudgmental fashion.

Occasionally, the provision of care may provoke conflict with the anesthesiologist's personal ethics. For example, some practitioners object to providing anesthesia for procedures to terminate a pregnancy. There is controversy about the proper professional approach in this type of situation, but most ethical experts suggest that patients should be provided information about all legal and medically acceptable treatment options and that the practitioner has an obligation to help the patient find an alternate provider (e.g., anesthesiologist) if he or she cannot continue the physician–patient relationship due to ethical objections. A similar strategy may be invoked for the provider who is unwilling to respect a Jehovah's Witness patient's right to refuse blood transfusion. Open communication with the patient and with colleagues is usually the best approach in these situations, with the goal being adherence to the ethical principles of all involved parties. Emergency procedures that involve ethical conflict may be more difficult to resolve, but providing necessary care to the patient until an alternate provider is available is advisable.

Do not resuscitate (DNR) orders

The administration of anesthesia for a procedure frequently involves provision of measures that would be considered to be "resuscitation" in another setting. For example, hypnotic agents administered during the induction of general anesthesia commonly render a patient apneic, necessitating airway support to prevent imminent death. Similarly, muscle relaxants are commonly administered as part of an anesthetic to achieve optimal operating conditions for the surgeon, but the effects of these agents may require endotracheal intubation. In the past, these "resuscitative" measures were considered necessary for anesthesia care, and DNR orders were rescinded while a patient

underwent anesthesia. In today's increasingly complex medical environment, this approach no longer holds. The American Society of Anesthesiologists (ASA) recognizes that respect for patient autonomy requires an open discussion with the patient or patient's surrogate regarding do not resuscitate (DNR) orders prior to anesthetic care and suggests three possible approaches. First, the DNR orders may be revoked for the anesthetic and perioperative period, allowing full resuscitation. Second, limited resuscitation may be performed to include certain measures (e.g., endotracheal intubation) but not others, based on the patient's preferences. With this approach, the anesthesiologist may play a role in educating the patient, helping him or her to weigh the relative risks (or burdens) versus benefits of each intervention. Third, a goal-directed approach to resuscitation may be adopted for the anesthetic course. This approach seeks to define the goals of care and allows the anesthesiologist to use his or her judgment to determine if resuscitation is likely to achieve those goals. For example, a patient with end-stage cardiomyopathy may not wish to undergo treatment of dysrhythmias. If this patient were to develop a bradycardia judged easily reversible and directly attributable to the anesthetic, it might be treated with a drug, whereas development of ventricular tachycardia attributable to myocardial ischemia might not be treated at all. Regardless of the approach to resuscitation status under anesthesia, the anesthesiologist must participate in a discussion in advance with the patient or patient's surrogate to understand the patient's preferences, goals, and values. Involvement of the surgeon or proceduralist and/or the patient's primary physician in the discussion is ideal, and a detailed documentation of the discussion should be provided in the patient's medical record.

Death under anesthesia care

Advances in anesthesia care have made death related to anesthesia an uncommon event, with estimates ranging from 5 to 7 per 100,000 anesthetics. Mortality rates are higher for patients of ASA physical status III or greater. Although death in the operating room or procedure suite is rare, anesthesiologists who specialize in critical care medicine are more accustomed to caring for the dying patient. Approximately 10% to 25% of patients admitted to an intensive care unit (ICU) will not survive, so it is incumbent on the intensivist to be familiar with care of the dying patient. When the chance of a cure or meaningful recovery is poor, the patient or patient's surrogate may choose *comfort care* rather than further life-sustaining measures. The role of the physician at this time is to provide relief from pain, anxiety, or distress and to allow the patient to die in a dignified fashion. Optimal care under these circumstances involves the collaborative efforts of the patient, family, and an interdisciplinary health care team. Care should focus not only on the medical and psychological aspects of dying, but also on the emotional and spiritual needs of surviving family members.

Medications (e.g., opiates, hypnotics, benzodiazepines) commonly employed for anesthesia may be useful to treat symptoms in the dying patient. These medications should not

be withheld for fear of hastening death in such circumstances. To justify such treatment, some experts cite the ethical principle of *double effect*, where the intended good of the action (relief from pain) permits the potential harm (hastened death). Literature from the study of critically ill patients suggests that, despite clinicians' fears, medications administered to treat symptoms do not cause an earlier death.

Futility

Futility is a controversial topic that may arise in end-of-life discussions. Medical futility is perhaps best defined in the context of a particular treatment or intervention that scientific evidence shows will not achieve the goals of therapy. By this strict definition, physicians are not obligated to provide futile care. Sometimes futility is invoked as the reason to withdraw or limit life-sustaining treatments. This invocation may prove problematic because the wide variety of patient expectations, goals, values, and religious beliefs makes it difficult to define futility. In addition, society has provided no consensus definition of *futile care*. A more pragmatic approach to these situations is for the anesthesiologist to assist patients and their families in weighing the relative benefits and burdens of a given therapy within the context of the patient's beliefs and values. Using this approach, therapies that are likely to increase pain, suffering, or morbidity and those that diminish quality of life as appreciated by the patient are more likely to be refused.

Organ donation

The concept of organ donation is a medically and ethically acceptable option in our society but is one that may provoke ethical conflict. Most organ procurements derive from brain-dead donors (i.e., patients who are legally dead due to failure of whole brain function, but whose hearts are still beating). The exact criteria for determining brain death are locally determined and publicized in most hospital policy and procedure manuals; commonly, involvement of a physician specialized in neurologic illness is required. Although the legal concept of brain death is no different than death, this concept may be difficult for some families of religions or cultures that only recognize death as the cessation of the heartbeat. In such situations, efforts should be made to facilitate understanding in families who have a conflict with the withdrawal of care. A thoughtful, compassionate approach to the family may promote the consideration of organ donation in situations in which it would otherwise be refused.

Another option for organ donation is donation after cardiac death (DCD). This route may be considered by the patient or patient's surrogate if devastating injury or disease precludes an acceptable recovery and involves a controlled removal of the patient from life-sustaining treatments with the intention of organ procurement at some time interval (usually 2–5 minutes) following asystolic death. The withdrawal of life support (usually mechanical ventilation) may occur in the ICU or in

the operating room and requires careful orchestration of a multidisciplinary team to assure proper adherence to ethical principles. Specifically, there should be a clear distinction between the physician caring for the patient (often the intensivist) and the procuring transplant surgeons. Care for the dying patient should be paramount with the same attentiveness to treating pain and distress as would be provided to the non-organ donor patient. Because these patients die due to cessation of cardiopulmonary function, an anesthesiologist may not be required for the procurement. If the procurement of intrathoracic organs (heart, lungs) is planned, then reintubation and ventilation of the patient following pronouncement of death may be desirable and the attendance of an anesthesiologist may be requested. Finally, plans must be in place to treat the patient who does not die within the time frame (usually 2 hours) necessary for organ donation. Usually, the patient is then transported back to the ICU to continue treatment until death does occur.

Ethics consultation

Many hospitals offer clinicians and patients the assistance of a hospital ethics committee when confronting difficult ethical problems or a nonnegotiable conflict around ethical issues. An ethics consultation should provide a reasoned opinion and often recommends a specific course of alternative actions. The opinion offered by the consult is a recommendation and not a mandate, and acceptance is always voluntary. If a given dispute cannot be resolved, the anesthesiologist may inquire if the hospital has a resolution of conflict policy and follow the prescribed path. Finally, if a given dispute cannot be resolved, judicial involvement may be requested but often requires a great deal of time and expense. In general, US courts support the settlement of ethical conflicts within the medical environment.

The impaired anesthesiologist

Chemical dependence is a chronic, relapsing disease affecting individuals at all social levels. The impression that the disease is more common among anesthesiologists as compared to other health care providers has been disproved, but anesthesiologists are unique in administering drugs to patients themselves rather than entering an order for a medication to be administered by another professional. As a result, controlled substances are immediately available to the practicing anesthesiologist. If a colleague demonstrates the signs of addiction, including a loss of interest in activities, problems at home, problems at work, obvious changes in work habits (including the overadministration of opiates, frequent unexplained absences, inappropriate volunteering for extra work, or witnessed self-administration), then intervention is necessary.

Intervention should take place in a formal setting and should be conducted by an expert. It must include irrefutable documentation of the behavior, willingness of colleagues to describe events demonstrating the behavior, and a specific treatment plan. If the individual should deny the behaviors

despite irrefutable evidence, he or she should be informed that the state medical board will be advised of the suspected chemical dependence.

Anesthesiologists who have a history of addiction to opioids are statistically more likely to lapse than are those who have addictions to other substances. Legally, addiction is a disability. Recovering addicts who have been drug-free may not be refused employment solely on the basis of their disability, but state medical boards carefully weigh the risk to patients before allowing a recovered physician to return to practice and usually require that strict criteria for reentry be met. The anesthesiologist must have received treatment at a skilled facility with recommendations from treating providers stating that there is a low likelihood of relapse. A recovering provider must adhere to a detailed program of recovery, which may include the use of naltrexone, and he or she must abide by a written aftercare contract. The health care provider must be committed to a lifelong recovery. Family, partners, hospital staff, and administrators must accept the physician's return to work, and current recommendations suggest that a returning anesthesiologist should have 5 years of continuous monitoring.

While chemical dependence is an incurable disease, it may remain in long-term remission. Relapse is not a given, but may occur. Colleagues should provide the assistance and advocacy

necessary to reinstitute treatment, aftercare, and recovery in the event of relapse.

Risks in the operating room

Jie Zhou

The operating room (OR) contains safety risks for both patients and staff. This chapter discusses safety risks that are relevant to anesthesia providers.

Needle safety

The Centers for Disease Control and Prevention (CDC) estimates that there are approximately 1000 *sharps-related injuries* per day sustained by hospital-based health care personnel in the United States. Sharps-related injuries include those that are due to needles, scalpels, or invasive medical devices. Hollow-bore devices create more of a concern, because they are more likely to transmit pathogens. According to the CDC, hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV are the most commonly transmitted pathogens during patient care. Other pathogens include herpes, malaria, and tuberculosis.

The decrease in HBV infections, from approximately 12,000 in 1985 to 500 in 1997, is largely attributed to widespread immunization. Susceptible health care workers still have a 6% to 30% likelihood of HBV infection without postexposure prophylaxis, especially if the source patient is hepatitis B e antigen (HBeAg) positive. The number of transmissions of HCV to health care workers is unknown, but studies suggest that the transmission rate from an HCV-positive source to a healthy individual through a hollow needle ranges from 0% to 7%. HCV and HIV can also be transmitted through splash contamination of the conjunctiva or nonintact skin. The risk of HIV transmission following needlestick or mucous-membrane exposure is estimated to be 0.3% and 0.09%, respectively.

Data from the National Surveillance System for Health Care Workers (NaSH) suggest that 25% of hospital exposures to bloodborne diseases occur in the OR.

Several injury prevention strategies have been deployed over the past two decades, including the use of barrier-focused universal precautions for all OR personnel, the Bloodborne Pathogens Standard published by the Occupational Safety and Health Administration (OSHA), and the Needlestick Safety and Prevention Act of 2000. In addition, many engineering controls, such as retractable needles or blunt needles, have been developed, but work-practice controls are the most effective means of preventing blood exposure. The CDC recommends the following procedures in the OR:

- Using instruments, rather than fingers, to grasp needles, retract tissue, and load/unload needles and scalpels;
- Giving verbal announcements when passing sharps;
- Avoiding hand-to-hand passage of sharp instruments by using a basin or *neutral zone*;
- Using alternative cutting methods, such as blunt electrocautery and laser devices, when appropriate;
- Substituting endoscopic surgery for open surgery when possible; and
- Using round-tipped scalpel blades instead of sharp-tipped blades.

Anesthesia gases

There are two current classes of inhaled anesthetic agents: nitrous oxide and halogenated gases, including sevoflurane, desflurane, halothane, and enflurane. A US Food and Drug Administration (FDA) review in 2005 associated methoxyflurane with serious, irreversible, and even fatal nephrotoxicity and hepatotoxicity in humans, so it has been withdrawn from the market.

The National Institute for Occupational Safety and Health (NIOSH) issued “Criteria for a Recommended Standard. Occupational Exposure to Waste Anesthetic Gases (WAGs) and Vapors.” The NIOSH criteria are highlighted in [Table 141.1](#).

The 2007 update of the NIOSH criteria that is listed at the end of this chapter encourages raising awareness of WAG hazards among health care workers and suggests strategies to minimize exposure. OSHA published the “Guideline for Workplace Exposures” (GWE) in 2000. This guideline lists operational procedures, engineering controls, and work practices for WAGs in the OR. Its Web address is also listed at the end of this chapter.

More recently, the Task Force on Trace Anesthetic Gases (TFTAG) of the American Society of Anesthesiologists (ASA) issued “Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit.” TFTAG analyzed the literature on WAGs regarding their mutagenicity, carcinogenicity, organ toxicity, and reproductive effects. TFTAG concluded that there is not adequate evidence to prove adverse health effects caused by exposure to trace levels of WAGs in the OR. However, TFTAG does support the use of scavenging systems for WAGs,

Table 141.1. The NIOSH criteria

No worker is exposed to halogenated anesthetic agents at concentrations > 2 ppm when used alone or > 0.5 ppm when used in combination with nitrous oxide over a sampling period not to exceed 1 h.

No worker is exposed to nitrous oxide when used as the sole anesthetic agent exceeding a time-weighted average concentration of 25 ppm during anesthetic administration.

Anesthetic gas machines, non-rebreathing systems, and T-tube devices shall have an effective scavenging device that collects all WAGs.

WAG disposal systems are in place prior to starting an anesthetic.

Low-pressure leaks shall be < 100 ml/min at 30-cm water pressure.

High-pressure leaks from the gas supply (cylinder or pipeline) to the flow control valve should be a maximum of 10 ml/min.

Anesthetic gas flows shall not be started prior to induction of anesthesia.

Anesthetic flow meters shall be turned off or the Y-piece sealed when the breathing circuit is disconnected from the patient after administration of the anesthetic agent has started.

Before the reservoir bag is disconnected from the anesthetic delivery system, it shall be emptied into the scavenging system.

Comprehensive medical and occupational histories shall be obtained on each employee prior to employment and maintained in the employee's medical record.

Employees shall be provided with information and training on hazardous chemicals.

Any abnormal outcome of pregnancies of employees or of the spouses of employees exposed to WAGs shall be documented as part of the employee's medical records, and these records shall be maintained for the period of employment plus 20 years.

Upon employment and at least yearly thereafter, each worker shall be informed of possible health effects of exposure to WAGs.

Air monitoring shall be performed in all locations with the potential of worker exposure to WAGs.

Results of air sampling methods, locations, dates, and concentrations measured and results of leak tests shall be maintained for at least 20 years.

not only in the OR, but also in other locations where inhaled anesthetic gas is administered.

Chemical hazards

Latex

Latex has become a common source of allergic reactions in OR personnel, and it is estimated that 8% to 12% of health care workers are latex-sensitive. Latex can trigger an IgE-mediated cutaneous, respiratory, and systemic reaction, ranging from irritant contact dermatitis (Type IV) to immediate, life-threatening sensitivity (Type I). The prevalence among anesthesiologists is reported to be approximately 12.5% to 15.8%. Latex allergy is associated with allergies to avocado, potato, banana, tomato, chestnut, kiwi fruit, and papaya. People with spina bifida are also at increased risk for latex allergy.

Latex allergy should be suspected in anyone who develops allergic symptoms after latex exposure. Irritant or contact dermatitis is the most common reaction from a latex encounter. Certain medications may reduce the allergy symptoms, but complete latex avoidance is the most effective approach.

Halothane

There are two distinct forms of liver damage from halothane. Type I hepatitis occurs commonly and presents with minor elevations of liver enzymes. Type II hepatitis, which is thought to

be immune-mediated, is rare and unpredictable and can result in severe, fulminant hepatitis with a high mortality.

Hepatitis induced from occupational exposure to halothane has been reported in pediatric anesthesiologists. There is also a reported case of isoflurane hepatotoxicity in a patient with a previous history of halothane-induced hepatitis. This case suggests that personnel with a history of liver injury from one haloalkane should not be exposed to another. Occupational safety and health guidelines for halothane are available at the OSHA Web site.

Methyl methacrylate

Methyl methacrylate (MMA) is an organic compound used to cement prostheses in orthopedic surgery. The most common effect of overexposure to MMA is irritation of the skin, eyes, nose, throat, or lungs, but it can also affect the nervous system. OSHA has established a permissible exposure limit of 100 ppm, 410 mg/m³ time-weighted average (TWA).

Severe cardiopulmonary complications, such as hypotension, bradycardia, and cardiac arrest, have been reported in patients with the use of MMA. The direct myocardial depressant effect of MMA seems to be caused in part by depression of Ca²⁺ influx across the cardiac membrane. MMA may also cause direct relaxation of venous and arterial smooth muscle.

Fire safety

OR fires are rare but potentially disastrous. Current literature estimates that there are approximately 100 surgical fires in the United States each year, but the real incidence may be higher.

Most surgical fires involve the airway. For a fire to occur, three components, known as the "fire triad," must be present: an oxidizer, an ignition source, and a fuel. In the OR, oxidizers include oxygen and nitrous oxide; ignition sources include lasers, drills, electrocautery sets, and fiber-optic light sources; and fuels include endotracheal tubes, flammable solutions, sponges, and drapes.

In May 2008, ASA issued a Practice Advisory for the Prevention and Management of Operating Room Fires. The advisory recommends providing fire safety education and training to anesthesiologists, and it lists the methodology for preparation, prevention, and management of OR fires. The ASA Operating Room Fires Algorithm contained within the full advisory summarizes important aspects of fire prevention and fire management. Recommendations for prevention include keeping ignition sources away from oxidizer-enriched atmospheres, configuring surgical drapes to minimize the accumulation of oxidizers, and allowing sufficient drying time for flammable skin-prepping solutions. They also recommend that the surgical team determine preoperatively whether the procedure is high risk and that appropriate precautions be identified and put in place prior to the start of surgery. The fire management section calls for immediate evaluation if an "early warning sign of fire" is identified, and discusses the management of both airway and nonairway fires. The full ASA advisory is listed at the end of the

Figure 141.1. Radiation scale. From <http://www.osha.gov/SLTC/radiation>.

chapter; all anesthesia practitioners should be familiar with its contents.

Radiation safety

Radiation is used in a variety of areas in the OR. In general, there are two types of radiations: non-ionizing radiation and ionizing radiation. Non-ionizing radiation comprises electromagnetic radiation ranging from extremely low frequency (ELF) to ultraviolet (UV). Ionizing radiation consists of particulate (alpha, beta, neutrons) and electromagnetic (x-rays, gamma rays) radiation. Anesthesiologists may be exposed to any of them (see Fig. 141.1).

Non-ionizing radiation

Laser safety

Laser is the acronym for “light amplification by stimulated emission of radiation.” The four major properties of laser light are monochromaticity, spatial coherence, high energy, and focusability (directionality).

Clinical usefulness of each laser is determined by the degree of thermal effect when it strikes the tissue, which in turn is determined by three variables: the absorptive and reflective properties of the tissue at the laser wavelength, the power density, and the duration of exposure. The absorption of laser energy is determined by the wavelength of the light and the physical characteristics (pigmentation, hemoglobin, and water content) of the tissue. There are four types of lasers that are used clinically: the carbon dioxide (CO₂) laser, the argon laser, the neodymium:yttrium–aluminum–garnet (Nd:YAG) laser, and the potassium titanyl phosphate (KTP) laser (green laser).

The CO₂ laser has a wavelength of 10,600 nm, which is in the invisible infrared region. A low energy helium–neon (HeNe) 633-nm laser was added to provide visibility during clinical use. CO₂ laser emissions are completely absorbed by cellular water and produce tissue destruction to a depth of 100 to 200 microns, which is approximately half the thickness of the epidermis.

The argon laser emits at a wavelength of 488 nm and 514 nm, which carries a visible blue-green color. It is absorbed by hemoglobin and pigmented tissue and is poorly absorbed by water. It can be used to effectively coagulate vessels.

The Nd:YAG laser is in the near-infrared range with a wavelength of 1064 nm. It is commonly used for eye, bladder, and synovial capsule surgery.

The KTP laser is generated by passing the Nd:YAG laser through a potassium titanyl phosphate crystal. The beam is at a wavelength of 532 nm and has a green color. It is commonly used in prostate surgery.

Risks of laser use include thermal burns, eye injuries, electrical hazards, fires, and explosions. Ophthalmic safety is one of most common concerns with laser use because a reflected laser beam could create significant ocular trauma. Protective eyewear should be worn by all OR personnel any time that the laser is in use. Effective protection from laser injury requires a unique lens that absorbs the particular wavelength of the laser in question, so there is no universal eyewear that provides protection against all lasers. Eyewear is rated for optical density (OD), which is the base-10 logarithm of attenuation. For example, eyewear with OD 3 will reduce the beam power in the specified wavelength range by a factor of 1000.

Smoke plumes resulting from the thermal destruction of tissue by laser and electrocautery devices have received increased attention as a safety concern in recent years. Research studies have confirmed that this smoke plume can contain toxic gases and vapors such as benzene, hydrogen cyanide, and formaldehyde; bio-aerosols; dead and live cellular material (including blood fragments); and viruses. At high concentrations, the smoke causes ocular and upper respiratory tract irritation in health care personnel and creates visual problems for the surgeon. NIOSH released a Health Hazard Alert on the danger of smoke plumes in 1996.

UV safety

Studies of indoor UV-emitting fluorescent lamps have demonstrated a 3.9% increase in the risk of skin malignancies over solar UV exposure. The level of risk is associated with the specific frequency within the UV range. UVB (290–320 nm) radiation directly damages DNA and is highly mutagenic and carcinogenic in animal experiments compared to UVA (320–400 nm) radiation, which indirectly damages DNA through the formation of reactive oxygen radicals.

No OSHA standard exists for UV radiation (UVR), but both NIOSH and the International Commission on Non-Ionizing

Radiation Protection (ICNIRP) have made varying recommendations for UV light within the spectral region of 200 to 400 nm with the most restrictive limits on the UVB region between 200 and 315 nm. Exposure limits are dependent on both the frequency and intensity of the radiation and must be determined using tables that can be found in the NIOSH or ICNIRP information at the end of this chapter.

Ionizing radiation

Anesthesiologists may encounter various types of ionizing radiation, including particulate radiation with alpha, beta, or neutrons in a radiology oncology treatment suite, gamma rays at a Gamma Knife center, or x-rays in a fluoroscopy or neuroradiology suite.

Ionizing radiation is carcinogenic at high doses. Its effects include direct chromosomal changes, indirect free radical formation, and cataract formation. Total radiation exposure is determined by three factors: (1) intensity and time of exposure, (2) distance between the anesthesiologist and the source of radiation, and (3) the use of shielding. The latter two factors can be modified by the anesthesiologist. Radiation exposure is inversely proportional to the square of the distance from the source, so increasing distance is an effective way of decreasing exposure.

Common lead aprons leave several vulnerable spots of the human body, including both the thyroid and the eyes. Thyroid shields and eye protection should be worn along with lead aprons to minimize the risk of thyroid cancer or cataract formation.

The U.S. Nuclear Regulatory Commission (NRC) has established the current occupational exposure limits for both shallow and deep doses in adults:

- (1) An annual limit, which is the more limiting of
 - (i) the total effective dose equivalent being equal to 5 rems (0.05 Sv) or
 - (ii) the sum of the deep-dose equivalent and the committed dose equivalent to any individual organ or tissue other than the lens of the eye being equal to 50 rems (0.5 Sv).
- (2) The annual limits to the lens of the eye, to the skin of the whole body, and to the skin of the extremities, which are
 - (i) a lens dose equivalent of 15 rems (0.15 Sv) and
 - (ii) a shallow-dose equivalent of 50 rem (0.5 Sv) to the skin of the whole body or to the skin of any extremity.

The limits for fetal radiation exposure vary between agencies from 100 mrem/y (1 mSv/y) to 500 mrem/y (5 mSv/y) or less during the gestational period.

Statistics for anesthesiologists and researchers

Samuel M. Galvagno Jr. and Kamal K. Sikka

An elementary understanding of statistics is essential to help the evidence-based practitioner address common problems encountered throughout the vicissitudes of daily anesthetic practice.

The medical literature has an abundance of studies that use statistics, but there are few available books devoted to the use of statistics in anesthesiology. Because statistical techniques are complicated, researchers and practitioners of anesthesia should be aware of the misuse of statistics to promulgate flawed conclusions. The data in the numerical examples described in this chapter are adapted from Jensen, Wernberg, and Andersen.

This chapter is not a comprehensive dissertation on statistics. For more comprehensive studies, the reader is referred to two excellent texts: one by Freedman, Pisani, and Purves and the other by Dawson and Trapp.

Basic math review

Logarithms

Logarithms are used to describe the power to which a number must be raised to get another number. For example, the Henderson–Hasselbalch equation describes how plasma partial pressure of carbon dioxide (PCO_2), plasma bicarbonate concentration ($[HCO_3^-]$), the negative logarithm of the apparent dissociation constant (pK) for plasma carbonic acid (H_2CO_3), and the solubility (S) of CO_2 in plasma interact to determine plasma pH.

$$pH = pK_1 + \log[\text{bicarbonate}]/0.03 \times PCO_2$$

A logarithmic scale is a scale of measurement that uses the logarithm of a physical quantity instead of the quantity itself. Presentation of data on a logarithmic scale can be helpful when the data cover a large range of values. The logarithm reduces this range to a more manageable range. On most logarithmic scales, *small* values, or ratios of the underlying quantity, correspond to *small* values of the logarithmic measure. Well-known examples of such scales are:

- Richter scale for earthquake magnitude,
- Decibel for acoustic power, and
- Logit for odds in statistics.

One example of the use of logarithms is Lagasse's depiction of the trend of anesthesia-related deaths from 1954 through 2001. The death rate was extrapolated from either a power or logarithmic fit of these figures (1/5000–1/10,000). By using logarithmic methods, the death rate from anesthesia for plastic surgery can be more accurately estimated because previous nonlogarithmic methods cited the risk to be falsely low – 1/300,000.

Graphs of simple equations

It is a frequent practice in anesthesiology and critical care medicine to estimate the human body surface area (BSA). BSA is one example of a linear regression equation that can be applied clinically. Linear regression is a statistical method that involves determining an equation to predict a value based on other known values. The determination of BSA is useful in several areas related to the body's metabolism, such as ventilation, fluid requirements, extracorporeal circulation, and drug dosages. The following formula estimates BSA and is demonstrated in Fig. 142.1.

Basic exponential functions are depicted as hyperbolic or parabolic curves. These mathematical functions are used to determine the value of y when x is known, or vice versa. Fig. 142.2 demonstrates a basic exponential function ($y = b^x$).

Figure 142.1. An example of linear regression.

Figure 142.2. An example of an exponential function.

Table 142.1. Blood glucose levels of 25 preoperative children undergoing anesthesia

Patient	mg/dl	Patient	mg/dl	Patient	mg/dl
1	36	11	70	21	86
2	47	12	72	22	88
3	52	13	74	23	93
4	56	14	75	24	97
5	61	15	76	25	106
6	63	16	77		
7	66	17	79		
8	67	18	83		
9	68	19	83		
10	69	20	83		

Two common graphical representations of data, the histogram and the percentage cumulative frequency distribution, are shown in Fig. 142.3 for the data from Table 142.1.

The histogram graphically represents the type of distribution exhibited by the data, whether they are balanced around the mean or skewed to one side. The percentage cumulative frequency represents the percentage of data occurrences below a given percentage value. The percentage cumulative distribution in Fig. 142.3 shows that only 4% of the children undergoing preoperative starvation had a blood glucose level less than 40 mg/dl, which can be classified as hypoglycemic.

Table 142.2. Examples of interval and categorical data

Type of data	Description	Example
Interval	Discrete: Integer-only scale	Number of toes, number of nostrils
Interval	Continuous: Constant scale interval	Temperature, weight, blood pressure
Categorical	Dichotomous: Binary data	Male/Female, Alive/Dead
Categorical	Nominal: Qualitative; cannot be ranked	Eye color, type of surgery
Categorical	Ordinal: Data that are ranked but do not have a consistent scale interval	ASA class, Mallampati class, VAS pain score

Basic statistics

Data classification

Samples of populations are described with different terms. Interval data are composed of discrete and continuous variables. Categorical variables refer to observations the values of which are categories. Examples are provided in Table 142.2. Classification of data becomes important when choosing the correct statistical test.

Probability

The probability (Pr) of an event (A) is the proportion of times it occurs in a long sequence of trials. Probabilities always lie between 0 and 1.

$$\text{Pr}(A) = N_A/N$$

N = mutually exclusive outcomes

N_A = equally likely outcomes

p value

The p value is the probability of obtaining a test statistic that is as extreme or more extreme as the one actually observed, assuming that the null hypothesis is true. The p value is a measure of the probability that a difference between groups during an experiment happened by chance. For example, a p value of

Figure 142.3. Histogram and percentage cumulative frequency distribution of blood glucose levels of preoperative children undergoing anesthesia.

Table 142.3. Ways to prevent Type I and Type II errors

Raise the level of alpha (not commonly done)
 Reduce population variability
 Make the difference between the conditions greater
 Increase the sample size (most common method used)

.01 ($p = .01$) means that there is a 1 in 100 chance that the result occurred by luck. The lower the p value, the more likely it is that the difference between groups was caused by the experimental intervention.

Type I (α) and Type II (β) error

Type I (α) error is the probability that the data will indicate that the null hypothesis is wrong. Stated another way, Type I error is the probability that a difference will be found between two groups when none actually exists. Type I error (α) is usually set at .05, which means that there is a 5 in 100 chance that a given result occurred purely by chance.

Type II (β) error is the probability that a difference actually does exist between two conditions but the data erroneously indicate that no difference exists. By convention, Type II (β) is usually set at .2. (See Table 142.3.)

Statistical power

The power of a test is $1 - \beta$, which usually equals 80%. Statistical power is the probability that one will detect a meaningful difference, or effect, if one were to occur. Ideally, studies should have power levels of .80 or higher, which means that there will be an 80% chance or greater of finding an effect if one is really there.

Measures of central tendency and dispersion

Given a population of data, there are several numeric measures for characterizing the information represented by the data. The population of data can be represented by measures representing the central tendency or dispersion of the data.

Mean (or average) represents the central tendency of the data, defined as

$$\bar{x} = \sum_{j=1}^N x_j$$

where x_j is the j th sample in a total population of N samples. For the sample size of $N = 25$ in Table 142.1, the mean is 73.1 mg/dl.

The median is the central sample when the data are ordered in an ascending or descending order. For $N = 25$, the 13th sample of the data from Table 142.1, when arranged in an ascending or descending order, is the median and is equal to 74 mg/dl. For distributions that are composed of an even number of samples, the median is the arithmetic average of the two central samples. For example, when $N = 20$, the median is the arithmetic average of the 10th and 11th sample.

The mode is the most frequently occurring sample in the population. The mode of the data in Table 142.1 is 83 mg/dl.

The standard deviation is a measure of dispersion and is the root mean square (RMS) deviation of values from their arithmetic mean. It is expressed as

$$\sigma = \sqrt{\frac{1}{N} - 1 \sum_{j=1}^N (x_j - \bar{x})^2}$$

The standard deviation of the population in Table 142.1 is 15.78 mg/dl.

The range is another measure of dispersion and is the difference between the maximum and minimum values in a distribution. The range in Table 142.1 is 70 mg/dl.

The variance is the square of the standard deviation.

Standard deviation and standard error of the mean

The standard deviation is a measure of spread, scatter, or dispersion of a sample. When data are distributed normally, 1, 2, and 3 standard deviations from the mean encompass 68%, 95%, and 99% of the population, respectively (Fig. 142.4).

The standard error of the mean is a measure of the precision with which the population center (mean) is known. If the data from a sample are distributed in the standard bell-curve fashion (normal distribution), a formula can describe the spread of the data around the mean. The standard error of the mean is calculated by dividing the standard deviation by the square root of the sample size. It is always smaller than the standard deviation. The choice between using the standard deviation or the standard error of the mean is controversial.

Figure 142.4. Standard deviations.

Figure 142.5. Normal distribution of blood glucose levels of preoperative children undergoing anesthesia superimposed over the histogram from Fig. 142.3.

Normal statistical distribution

Also known as the Gaussian distribution, or the bell curve, the normal distribution is commonly used in statistical analyses. It is characterized by the mean and variance of the data. When the distribution is normalized to a mean of 0 and a variance of 1, it is termed as the standard normal distribution. The probability distribution for the normal distribution is represented as

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x - \bar{x})^2}{2\sigma^2}\right).$$

In Fig. 142.5, the normal distribution is superposed on the histogram from Fig. 142.3. It can be observed that the normal distribution accurately represents the data in Table 142.1.

Confidence intervals

Confidence intervals (CIs) define a range of values within which the population mean is likely to lie. A CI is the probability that a number will be between an upper and lower limit. CIs are usually reported as a 95% CI, which is the range of values within which one can be 95% sure that the true value for the whole population lies. The 95% (p value = .05) and 99% (p value = .01) CIs are the most commonly used.

Figure 142.6 demonstrates 50 realizations of a CI for μ . A CI can be considered as the range, or interval, of results in which the researcher has confidence. As seen from the figure, there is a fair chance that an interval that actually contains μ will be picked; however, there is still a chance that the wrong interval may be picked.

Statistical techniques

Student's t test

The Student's t test can be used to examine the effect of a controlled experiment on a population distribution by a comparison of the means. If each subject in a study has one measurement (blood pressure, heart rate, temperature), as in before and after some event, than a *one sample* or *paired* t test should

Figure 142.6. Fifty realizations of a CI for μ . See text for explanation.

be used. This pairing of measurements reduces variability and increases the power of the test. When two separate groups are compared to each other (one group gets one drug, another group gets a placebo or standard treatment), a *two sample* or *unpaired* t test should be used. Unpaired t tests have less power than do paired t tests due to increased variability.

Nonparametric tests

When data are *not* normally distributed or when they are on an *ordinal* level of measurement (i.e., American Society of Anesthesiologists [ASA] class, visual analog scale [VAS] pain score), nonparametric tests should be used. A common mistake in medical research is using the wrong class of statistical test, such as a parametric test in place of a nonparametric test. The basic rule is to use a parametric test (t test) for data normally distributed and a nonparametric test for skewed data. The Mann–Whitney U test is the nonparametric equivalent of the unpaired t test. It is used to compare two groups, but unless the data are skewed or ordinal, it is best to use a t test. The Wilcoxon rank-sum test is almost identical to the Mann–Whitney U test (see Table 142.4).

Analysis of variance

An analysis of variance (ANOVA) is a parametric statistical test that is used when there is more than one group that requires analysis. The t test tells one if the variation between two groups is significant. When multiple groups require analysis, multiple t tests are not the answer because, as the number of groups grows, the number of needed paired comparisons grows quickly. For seven groups there are 21 pairs. If 21 pairs were compared, one would not be surprised to observe that events happen only 5% of the time. Thus, in 21 pairings, a p value of .05 for one pair

Table 142.4. Commonly used parametric and nonparametric tests

Parametric	Nonparametric
Student's t test	Mann–Whitney U test
One-way ANOVA	Kruskal–Wallis H test
Paired t test	Wilcoxon signed-rank test
Correlated F ratio	Friedman ANOVA by ranks

Figure 142.7. Examples of correlation coefficients.

cannot be considered significant. An ANOVA puts all the data into one number (F) and provides one probability for the null hypothesis.

Chi-square

The chi-square test (χ^2) is a statistic used to compare the frequencies of two or more groups. Researchers often use chi-squares to test *nominal* data (e.g., eye color, type of surgery). This nonparametric test provides a rough estimate of confidence; it accepts as input data that are weaker and less accurate than are the data accepted by parametric tests (e.g., t tests and ANOVAs). Therefore, it has less status in the hierarchy of statistical tests.

Regression analysis

It is often important to relate the effect of an input parameter to the output parameter of an experiment. The correlation between input and output parameters is achieved through regression analysis. The correlation can be used for prediction of the output parameter through interpolation for input parameters within the range of the experiment or by extrapolation outside the range of the experiment. Regression can be single variable or multivariable, linear or nonlinear.

Linear regression

Linear regression analyzes the relationship between two variables, X and Y . In general, the goal of linear regression is to find the line that best predicts Y from X . The term *regression*, like many statistical terms, is used in statistics quite differently than it is used in other contexts.

The value r^2 is a fraction between 0 and 1.0, and has no units (see Fig. 142.7). An r^2 value of 0.0 means that knowing X does not help predict Y . There is no linear relationship between X and Y , and the best-fit line is a horizontal line going through the mean of all Y values. When r^2 equals 1.0, all points lie exactly on a straight line with no scatter, and knowing X allows one to predict Y perfectly.

A simple linear regression between the blood glucose levels (B) and the ages (A) in Fig. 142.3 can be represented as

$$B = mA + c,$$

where m is the slope and c is the intercept of the solid line in Fig. 142.3. The slope m and intercept c are obtained from the formulae

$$m = \frac{\sum (B_j - \bar{B})(A_j - \bar{A})}{\sum (B_j - \bar{B})^2} \quad \text{and}$$

$$c = \bar{B} - m\bar{A},$$

where the subscript j represents a patient, \bar{B} is the mean blood glucose level, and \bar{A} is the mean age of all patients in Table 142.2. If a limit of 40 mg/dl is used, it can be observed that children younger than 4 years would be susceptible to hypoglycemia and an intervention would be required. (See Fig. 142.8.)

Multiple regression

In multiple regression, there is more than one variable. For example, in predicting a difficult airway, a study might look at Mallampati classification, thyromental distance, and mouth opening. Some board questions may ask one to choose between an ANOVA or multiple regression given the scenario presented. All ANOVA models can be solved using multiple regression, but the reverse is not true. ANOVA is used for independent variables that are *categorical* (e.g., male/female, alive/dead, blue/brown eyes), whereas multiple regression models can be used with categorical, continuous, or a mix of both types of variables.

Figure 142.8. Blood glucose levels correlated to age of preoperative children undergoing anesthesia.

Regression draws a line that relates changes in one variable to changes in another. On the left-hand side, multiple regression also has one variable, but the right-hand side can have more than one. For two independent variables, multiple regression draws a plane, and for more than two a *surface* or *hyperplane*.

The data showed a correlation among the systemic vascular resistance index (SVRI), hematocrit, and MFV in the MCA. As SVRI increased and hematocrit decreased, MFV appeared to increase. Multiple regression analysis showed that SVRI and hematocrit explained 46% of the variance of MFV in patients without vasospasm. These results suggest that, in addition to already accepted variables (a hematocrit of 33%–38%, a central venous pressure of 10–12 mm Hg, a pulmonary wedge pressure of 15–18 mm Hg, and a systolic arterial pressure of 160–200 mm Hg), SVR/SVRI might be of value to more appropriately adjust triple-H-therapy.

Odds ratios

Odds are a ratio of events to non-events. For example, if the event rate for a disease is 0.2 (20%), the non-event rate is 0.8 (80%), and its odds are $0.2/0.8 = 0.25$. The odds ratio is the odds of an experimental patient suffering an event relative to the odds of a control patient.

The odds ratio can be defined as the ratio of the odds of an event occurring in one group to the odds of it occurring in another group. These groups might be men and women, an experimental group and a control group, or any other dichotomous classification. An odds ratio of 1 indicates that the condition or event under study is equally likely in both groups. An odds ratio greater than 1 indicates that the condition or event is more likely in the first group; an odds ratio less than 1 indicates that the condition or event is less likely in the first group. The odds ratio must be greater than or equal to zero. As the odds of the first group approaches zero, the odds ratio approaches zero. As the odds of the second group approaches zero, the odds ratio approaches positive infinity.

For example, in a study of 185 adult patients who had retromastoid craniectomy with microvascular decompression of cranial nerves, use of desflurane was an independent predictor for postoperative nausea and vomiting (PONV). The odds ratio was 2.8; therefore, patients who received desflurane were 2.8 times more likely to have PONV than were patients who did not receive desflurane.

Risk ratios

The risk ratio is the ratio of the risk in the experimental group (EER: experimental event rate) to the risk in the control group

(CER: control event rate). The risk ratio is equal to the EER divided by the CER. Risk ratios are used in randomized trials and cohort studies.

Miscellaneous statistical definitions

Sensitivity: True positives / (true positives + false negatives). The probability of the test finding disease among people who have the disease or the proportion of people with disease who have a positive test result.

Specificity: True negatives / (true negatives + false positives). The probability of the test finding NO disease among those who do NOT have the disease or the proportion of people free of a disease who have a negative test.

Positive predictive value (PPV): True positives / (true positives + false positives). The percentage of people with a positive test result who actually have the disease.

Negative predictive value (NPV): True negatives / (true negatives + false negatives). The percentage of people with a negative test who do *not* have the disease.

Neurophysiology of pain

Edgar L. Ross

The ability to sense, interpret, and modulate pain is vital to survival. René Descartes proposed one of the first descriptions of the sensory system more than 300 years ago. Descartes' theory envisioned a direct, single-channel system that coursed via nerves to the spinal cord with a direct synapse in the brain. This theory implied that our central nervous system is hard-wired and unchanging. This approach adversely impacted our approach to pain management for centuries. Descartes' approach to pain was unquestioned and not critically examined until the second half of the 20th century. This theory did not take into account our understanding of various other influences in pain, such as the psychological, environmental, biological, social, and genetic factors in an individual, and suggested treatment approaches, such as neurolytic procedures, which were believed to be universally curative and were widely practiced without an understanding of the possible consequences. Improvement in our understanding of chronic pain now provides evidence that this approach was to the detriment of the patients. With the publication of the gate theory of pain by Melzack and Wall in 1965, research was rekindled, leading to a complete reexamination of perception and modulation of pain. This research has significantly improved our understanding of treatment approaches and opened entire new vistas of potential treatment options.

Definition

What has become apparent from our new insights and understanding is that pain as a sensation is a complex phenomenon. The two basic terminologies that are needed to explain this clinical phenomenon include nociception and pain. The International Association for the Study of Pain (IASP) defines these two different terms as follows:

- *Nociception* is a noxious stimulus or a stimulus that would become noxious if prolonged. Activity induced in a nociceptive pathway by a noxious stimulus triggers pain.
- *Pain* is an unpleasant sensory and emotional experience, which we primarily associate with tissue damage or describe in terms of such damage, or both.

These two terms speak to both the complexity of our nervous system and its perception of pain. Most important, what is implied by this definition is that nociception is not equivalent

to pain. Nociception can take place without the patient experiencing pain, and perception of pain is understood as a protective response from our body required for survival. In fact, under certain circumstances, we all have a profound ability to suppress nociception to the point that we would not even sense pain, even in the presence of significant injuries. There are times, however, when pain would be distracting and even detrimental to survival. Patients can have severe, unremitting pain without significant pathology that explains their pain. Centrally originating inhibitory systems are thought to have evolved for these situations. With the increased understanding of these inhibitory systems, treatment approaches have been developed that take advantage of and enhance this inhibition to manage pathologically painful states.

Neuronal plasticity

Normal sensation, which is the absence of pain, requires a balance between both the inhibitory and excitatory pathways of the central and peripheral nervous systems. This balance is changed in a process called *sensitization*. Sensitization leads to increased sensitivity of all stimuli. Two clinical phenomena that can be noted clinically are considered the hallmarks of this process (Fig. 143.1).

Figure 143.1. Sensitization leading to change in responsiveness of stimulus.

Figure 143.2. Steps leading to central sensitization.

- Hyperalgesia – an increased response to what is usually a painful stimulus
- Allodynia – a painful response to what is ordinarily a non-painful stimulus, such as light touch

Various specialized sensory receptors including free nerve endings are located at the end of the peripheral nervous system. Injuries to tissue can release numerous substances that sensitize these receptors leading to a decreased threshold and increased responsiveness to all stimuli, such as light touch instead of just pain (Fig. 143.2).

The peripheral sensory nervous system is composed of two distinct classes: larger rapid conducting myelinated A delta and beta fibers and slower smaller unmyelinated C fibers. Under normal circumstances, the larger rapid conducting fibers responding to cold sensations are able to localize pain sensation quickly and precisely. The C fibers, which are normally stimulated by heat or mechanical stimuli, poorly localize the site of pain. They are connected to both the sympathetic nervous system and the spinal cord. These two nerve classes are responsible for pain transmission and stimulation of a protective reflex arc.

Pain-processing mechanisms

Sensory nerve fibers course into the dorsal horn where multiple different mechanisms have been found to modulate noxious stimuli. Three important types of modulating influences are

1. Nonpainful sensory inputs,
2. Descending inhibitory inputs, and
3. Central processing.

The ascending sensory information is transmitted up the spinal cord to the supraspinal processing areas. The spinothalamic tracts are the primary but not the only tracts responsible for this. Wall and Melzack's gate theory proposes that this ascending, nonpainful sensory input helps to gate the painful stimulus and forms the basis for the spinal cord stimulator's mechanism of action.

Inhibiting descending pathways are primarily based on noradrenergic, opioid, and serotonergic neurotransmitters and exert their inhibitory action on the lamina II of the dorsal horn. This inhibitory influence acts either directly through neural connections from higher centers, such as rostral ventral

medulla or nucleus raphe magnus, or by the release of endorphins and other inhibitory neurotransmitters. There also appear to be descending facilitatory pathways that serve to enhance transmission of nociceptive impulses in the spinal cord. The origins of these pathways are found in the rostral ventral medulla. This pathway is active during peripheral tissue injury and produces hyperalgesia. This effect is achieved through maintenance of central sensitization and enhancement of active neurons. Glutamatergic neurotransmitters appear to be important in this process. With persistent injury, repeated C fiber stimulation leads to increased sensitivity of the dorsal horn to further stimulation. This phenomenon is known as the *windup*. This process contributes to initiation and perpetuation of central sensitization. Glutamate plays a major role in this process as well. Activation of these pain inhibitory processes, either from higher centers or through the use of medications such as opioids, tricyclic antidepressants, *N*-methyl-D-aspartate (NMDA) receptor antagonists, α -adrenergic antagonists, or electrical stimulation using a transcutaneous electrical nerve stimulation (TENS) unit or a spinal cord stimulator, helps in shutting down the nociceptive gate.

From the dorsal horn, the ascending pathways consist of the spinothalamic, spinoreticular, and spinomesencephalic tracts. These tracts synapse in supraspinal modulatory centers. Neurons found in selected centers of the cerebral cortex respond to and process the nociceptor input. These centers include the somatosensory cortex, thalamus, cingulate gyrus, and the insular cortex. These multiple areas are involved in the central processing of the pain experience, including affective responses, responsiveness to stress reduction (such as hypnosis), and stress management approaches.

Other factors that affect pain processing include central nervous system immune responses initiated by endothelial and glial cells. This immune response serves to enhance production of a variety of inflammatory mediators and sustain pain and hypersensitivity found in acute injuries as well as to perpetuate chronic pain states. Gender differences in pain have been well documented. Multiple studies have suggested that women have greater pain sensitivity compared to men. In addition, cyclical changes found in women change pain perceptions as well. Responsiveness to analgesics, including receptor differences and responsiveness, has also been documented. Continued research into gender differences, including genetic factors, will likely lead to differences in treatment approaches.

Types of pain

There are three different etiologies of pain that can be described. These include:

1. Nociceptive pain without tissue damage or sensitization. In this model, a noxious stimulus is detected, but no physiologic change occurs to change the nervous system (Fig. 143.3a).
2. Inflammatory pain from tissue damage leading to sensitization. In this situation, tissue damage releases

Figure 143.3. Types of pain: (A) nociceptive pain; (B) inflammatory pain; and (C) neuropathic pain without nociception.

factors that lead to sensitization in both the peripheral and central nervous systems. This sensitization leads to a physiologic change, which decreases the discriminatory ability of peripheral nociceptors as well as heightens sensitivity to all stimuli, including spontaneous pain. These changes are usually temporary and part of the healing process. In small numbers of patients, these changes are permanent and lead to chronic pain (Fig. 143.3b).

- Neuropathic pain results from damage to either the peripheral or central nervous system. This damage could come about from unchecked sensitization or physical damage. Many chronic pain syndromes are neuropathic in nature. In addition, this neuropathic process points to the fact that pain can be reported without any nociception or tissue damage. Neuropathic pain is commonly not reversible and is often considered to be much more severe and resistant to treatment (Fig. 143.3c).

Summary

Pain physiology is much more complex than the original René Descartes idea. With the growing understanding of how pain is modulated and perpetuated, new therapeutic targets are now understood with the promise of improvement in treatment.

Postoperative acute pain management

Darin J. Correll

The Joint Commission mandates that all patients have the right to adequate assessment and management of pain. Better pain control, depending on the agent(s) and modalities used, leads to benefits not only in terms of cardiovascular and respiratory complications but also in endocrine, immunologic, gastrointestinal, and hematologic outcomes. Other reasons to control pain in the postoperative setting are that patients are often more concerned about being in pain than they are about the primary reason for being in the hospital, quality of recovery is improved, and acute pain may become persistent if not treated properly.

Basic pain management guidelines

Listen to and believe the patient: Pain is always subjective, and the provider must accept the patient's report of pain. Assess the patient's level of pain and degree of pain relief using appropriate tools on a regular basis. A multimodal approach for managing pain is always better than using a single modality to its limit. This approach may include both pharmacologic and non-pharmacologic measures and allows for the best possible analgesia with the lowest incidence of side effects. Always discuss the analgesic plan with the patient and family, understand the patient's expectations of pain management, and offer reasonable goals for the therapy. If pain is present most of the time or expected to last for an extended period of time (e.g., longer than a few weeks), dose around-the-clock or with long-acting agents. As-needed (PRN) dosing of immediate-release agents is also needed for breakthrough pain. If pain is intermittent or expected to last a short time (e.g., less than a couple of weeks) then PRN dosing of immediate-release agents can be used. Communication with the patient's primary care provider regarding the discharge analgesic plan is helpful, especially if there has been an alteration to a chronic analgesic regimen. Ensure that the patient has adequate follow-up for the effectiveness of the analgesic regimen and the development of possible side effects on discharge from the hospital, as well as a plan for a taper off of analgesics; if the patient was not on chronic analgesics before.

Pain assessment and mechanism of pain

It is important to ask the patient about his or her prior analgesic history, what therapies have either worked or not worked in the

past, as well as if he or she was taking any analgesic agents prior to admission, and, if so, the exact doses. Ask about all the locations where the patient is experiencing pain and any radiation from the primary location(s). Have the patient rate the intensity of the pain using scales appropriate to the patient and situation.

The most commonly used measurement tools for intensity of pain in the postoperative setting are the single-dimension scales. A frequently used variation of this scale is the verbal numeric scale. Patients are asked to verbally state a number between 0 and 10, where 0 is "no pain at all" and 10 is "the worst pain imaginable," to correspond to their present pain intensity. Variations of the single-dimension scales that may be of benefit in elderly or cognitively impaired populations are scales that use drawn faces ranging from a content-looking smiling face to a distressed-looking face (e.g., Faces Pain Scale or Wong-Baker Faces Scale) instead of relying on the patient choosing a number for his or her pain.

The benefits of single-dimension scales are that they are quick and easy to use – this is important in the acute setting, where repeated measures are needed over a brief period of time. One disadvantage of single-dimension scales is that they attempt to assign a single value to a complex, multidimensional experience. Another disadvantage is that patients can never know if the present experience is the "worst." A final disadvantage is that these scales have a ceiling at the uppermost end, so if a value of "10" is chosen and the pain worsens, the patient officially has no way to express this change.

To choose the correct therapy for treating pain, the underlying mechanism or generator of the pain needs to be determined (Table 144.1). One of the best ways to make this determination is to have the patient use adjectives to describe the character of the pain (e.g., aching, burning, dull, electric-like, sharp, shooting, stabbing, tender, throbbing). In the postoperative period it is still important to determine the impact of the pain on the patient's functional ability. Specifically, does the pain affect the patient's ability to cough, get out of bed, and ambulate while in the hospital?

Analgesic modalities

It is important to remember that pain can be helped with non-pharmacologic measures. In general, the scientific data on the

Table 144.1. Mechanisms of pain

NSAIDs, nonsteroidal anti-inflammatory drugs; GI, gastrointestinal. (From Correll, DJ, *Pain Management in Hospital Medicine: Just the Facts*, McKean, Bennett, Halasyamani.)

use of these measures are limited; however, most of the measures have little risk, and, if the patient believes that the therapy is going to help, then it is likely to be of at least some benefit, due to the cognitive and affective nature of pain. In terms of pharmacologic measures, many different agents are available in three basic categories: non-opioid analgesics, opioids, and adjuvant analgesics. There is no one correct way to treat a patient in pain. It is best to individualize therapy for each patient, developing a regimen that uses a multimodal approach with the addition or alteration of agents when pain control is inadequate and an adjustment or diminishing of agents as the pain resolves.

Nonpharmacologic measures

Application of cold (to reduce inflammation) or heat (to reduce spasms) to muscles or joints is a commonly employed technique, but the evidence for an actual analgesic benefit is mixed. Hypnosis has been shown to reduce pain associated with medical procedures; however, it requires specific training and

time to administer. Transcutaneous electrical nerve stimulation (TENS) has shown conflicting results in terms of an analgesic benefit in the acute setting, but it has been shown to reduce the need for pharmacologic analgesics. There is limited evidence of a benefit in the acute setting for relaxation and guided imagery. Acupuncture and electro-acupuncture have been shown to be of benefit in the acute setting both to improve pain and to reduce common side effects of opioid analgesics; however, they require specific training and time to administer.

Pharmacologic measures

The various pharmacologic options have been discussed in other chapters. Table 144.2 lists some of the available non-opioid analgesics. Ketorolac is available in the intravenous (IV) form for patients who are unable to take anything by mouth.

A detailed discussion on opioids for management of pain can be found in other chapters. Other than asking the patient if a particular agent has worked or not worked in the past, it is not possible to determine which opioid may work best

Table 144.2. Select nonopioid analgesics

Agent	Adult dosing	Maximum dose	Comments
Acetaminophen	650–1000 mg q 6 h PO/PR	4000 mg	Single doses > 1000 mg do not improve analgesia
Choline magnesium trisilicylate	1000–1500 mg BID PO	3000 mg	Caution in liver disease, avoid in severe liver disease
Diclofenac	50 mg BID–QID PO	200 mg	Low GI effect incidence, but possible increased renal effects; recent data suggest increased negative CV effects
Etodolac	200–400 mg q 6–8 h PO	1000 mg	Low GI and renal effect incidence; safest NSAID in liver disease
Ibuprofen	400–600 mg q 4–6 h PO	3000 mg	< 1,500 mg QD has low risk of GI effects, possible increased renal effects, inhibits CV benefits of aspirin when given concomitantly
Ketorolac	30 mg q 6 h IV	120 mg	High risk of renal and GI complications; use for no more than 5 days; 15 mg q 6 h in renal impairment, age > 65 y, weight < 50 kg
Nabumetone	750–1500 mg QD or BID PO	1500 mg	Low GI effect incidence
Naproxen	250–500 mg q 6–12 h PO	1500 mg	Possible increased liver and renal effects, probably least negative CV effects
Celecoxib	100–200 mg QD PO	200 mg	Use 100-mg dose if possible; long-term use has increased negative CV effects

CV, cardiovascular; PO, oral; PR, rectal. (From Correll, DJ, *Pain management in Hospital Medicine: Just the Facts*, McKean, Bennett, Halasyamani.)

Table 144.3. Recommended starting doses of opioids for adults over 50 kg

^b Maximum recommended 24-hour dose: 400 mg in adults \leq 75 years; 300 mg in adults $>$ 75 years old.

^c Recent US Food and Drug Administration (FDA) approval of oral form; therefore, limited clinical experience. (From Correll, DJ, *Pain management in Hospital Medicine: Just the Facts*, McKean, Bennett, Halasyamani).

for a given patient. Whenever possible, the enteral route of administration is best as it is the easiest route and offers the most stable pharmacokinetics. If the enteral route is not available or if adequate analgesia is not able to be obtained in a timely manner, then IV administration should be used. Intramuscular administration is not recommended because it is painful and has variable pharmacokinetics. With a competent patient, the use of an IV patient-controlled analgesia (PCA) has been demonstrated to offer the best overall pain management option (see sections on PCA later in this chapter).

The pronounced individual variability in opioid response, combined with changes in responsiveness over time, mandates individualization of opioid doses based on a continuing process of assessment (analgesia and adverse effects) and dose titration. Table 144.3 lists the recommended starting doses for moderate to severe pain in the opioid-naïve patient.

There are, however, some agents that should not be used, at least first-line, in the postoperative setting. Codeine is not a good first choice because it is possible that approximately 10% to 20% of the population does not have an active form of the enzyme (i.e., cytochrome P450 2D6) necessary to convert codeine into the active drug, morphine. Morphine is relatively contraindicated in patients with severe renal insufficiency due to the accumulation of the metabolite morphine-6-glucuronide, which can lead to sedation and respiratory depression. Meperidine is not recommended as its active metabolite, normeperidine, can accumulate in a day or two to levels that cause nervous system excitation (tremors, muscle twitching, convulsions). In addition, it causes a strong euphoric feeling, especially when given as an IV push, and it usually causes more nausea than do other agents. Hydrocodone use needs to be monitored closely because of the acetaminophen component in the available preparations that can lead to acetaminophen toxicity. Also, non-medical uses of hydrocodone combination preparations lead to emergency department visits more frequently than any other pharmaceutical agent.

If a patient is not receiving enough pain relief at a given dose, increase the dose by 25% to 50%. If a patient is having pain before the next dose is due, reduce the interval and/or increase the dose.

Rotation from one opioid to another may be necessary in several circumstances. The first situation is when a few attempts have been made at increasing the dose of an opioid and the patient is still not receiving any pain relief, in this case, rotation to a different opioid may provide better analgesia. A second situation is one in which a patient is having intolerable side effects; again, rotation to a different opioid may provide a better side effect profile. A third situation occurs when a particular opioid is not available by the route of administration required in a given patient. A fourth situation would occur if a patient has been on an opioid for an extended period of time and is demonstrating signs of tolerance to the analgesic effects, again, rotation to a different opioid may provide better analgesia, usually at less than the expected equianalgesic dose due to incomplete cross-tolerance, which means that the patient will not be “as tolerant” to the new opioid agonist as he or she was to the one previously taken. Thus, when converting between opioids, for any of the reasons mentioned above, the calculated equianalgesic dose of the new agent must be reduced by 25% to 75% to prevent oversedation and/or respiratory depression.

Sustained-release formulations should generally only be initiated in the acute setting if pain is present most of the time and it is assumed that the pain generator will last for an extended period of time (e.g., $>$ 2 weeks). If the pain is more incident-related or expected to be of a brief duration, then immediate-release agents should be employed. When using a sustained-release opioid, also provide doses of an immediate-release opioid equivalent to 10% to 15% of the 24-hour total, to be used every few hours for breakthrough pain. While on a sustained-release opioid, if the need for breakthrough pain medications is high (e.g., if more than four rescue doses are needed in 24 hours) then increase the dosage of the sustained-release agent by 50% to 100% of the total 24-hour breakthrough dose used.

Transdermal fentanyl is not appropriate for acute pain, especially in opioid-naïve patients. There is a black box warning against its use in the acute setting due to the risk of severe respiratory depression from the delayed peak effect of the drug as the pain level decreases. It is intended for use in patients who are already tolerant to opioids of comparable potency.

Methadone is not appropriate as the first-line agent in the acute setting, especially in opioid-naïve patients. Its use requires an understanding of the unique pharmacology of the drug, especially its extended duration of action and its dose-dependent potency. Also, as it takes a few days to reach a stable plasma concentration, patients will need to be followed closely to monitor for effectiveness and side effects. It must also be realized that methadone is a racemic mixture of a μ -agonist and an *N*-methyl-D-aspartate (NMDA) antagonist, which makes patients have a lesser degree of analgesic tolerance development.

A detailed discussion of the various adjuvant medication in pain management will be discussed in additional chapters.

Acute pain in the opioid-tolerant patient

In patients with chronic pain on opioids, post-surgical pain adds to the pain burden, thus opioid use can be expected to be higher than just replacement of what the patient was on before coming in to the hospital, and can be significantly higher than in opioid-naïve patients. More pain complaints and higher pain scores should be expected. Discussion of reasonable goals and expectations of analgesic therapy with the patient is crucial. These patients often know what agents have either worked or not worked for them in the past. The use of multimodal therapy in this patient population is especially important.

IV patient-controlled analgesia

IV PCA is an excellent therapy for the maintenance of already established analgesia. Therefore, if a patient is in moderate to severe pain, health care provider-delivered doses of an opioid must be used to reach an acceptable level of analgesia first because the incremental dosing of a PCA will not allow patients to achieve comfort in a reasonable period of time.

PCA may be used in any patient requiring IV opioids provided that he or she is alert, oriented, and able to understand how to use the equipment appropriately.

PCA parameters

All PCA machines allow for the setting of the following parameters: demand (bolus) dose, lockout interval, hourly limit, continuous (basal) infusion, and rescue (loading) dose.

Demand (bolus) dose

The demand dose is the amount of opioid that the patient receives each time he or she activates the machine. The appropriate choice for the amount of the demand dose should be small enough so that side effects are minimized yet large enough to provide effective analgesia.

Lockout interval

The lockout interval is the amount of time following a successfully delivered demand dose during which the patient can administer no further opioid even if the system is activated. Lockout intervals between 5 and 10 minutes are commonly used. Even though the time to peak effect for certain opioids may be longer, there do not appear to be any data suggesting that any specific time is more or less effective or safe, regardless of the opioid chosen.

Hourly limit

An hourly limit sets the maximum amount of opioid that can be administered in the given time period. The proposed purpose for this setting is to add a level of safety to the system; however, no data support this claim. An hourly limit is automatically

determined by the setting of a demand dose and lockout interval. The use of an hourly limit less than the predetermined limit based on bolus dose and lockout interval does not make logical sense, as the patient would be able to get a dose of opioid on schedule for only a part of every given time period and then not be able to receive anything for the remainder of the time period.

Continuous (basal) infusion

A continuous infusion delivers a set amount of opioid every hour without the need for the patient to activate the system. Continuous infusions are not commonly used, as no documented benefits have been shown for most patients. Continuous infusions are not recommended in high-risk populations such as elderly patients, opioid-naïve patients, patients concomitantly using other sedatives, and patients with obstructive sleep apnea or morbid obesity. The use of continuous infusions increases the overall opioid consumption and has been identified as an independent risk factor for respiratory depression. Continuous infusions have not been shown to improve patient satisfaction or pain rating scores, and they do not decrease the frequency of demand dose use.

It may appear to make sense to use a continuous infusion at night when the patient is sleeping and therefore unable to activate the PCA; however, studies have shown that nighttime basal infusions do not improve sleep or analgesia.

Continuous infusions may be needed in opioid-tolerant patients, especially those who are chronically taking continuous-release agents. If the patient cannot take his or her usual doses of opioid enterally, then a continuous infusion should be used. Determine an IV equivalent for the amount of opioid that the patient takes in a day (taking into account incomplete cross-tolerance if switching to a different agent), divide this amount by 24 hours, and administer as the hourly continuous infusion rate.

Rescue (loading) dose

Rescue doses are specific amounts of opioid delivered by a health care provider that are generally in excess of the patient's demand dose given when the level of analgesia from the PCA is inadequate. These doses can also be administered at the initiation of PCA therapy to initially achieve an adequate level of analgesia at which point they are more commonly referred to as *loading doses*.

Patients may require a rescue dose for a variety of reasons while they are on a PCA. There may be brief periods of increased nociceptive input beyond the ability of the demand dose to be effective (e.g., dressing changes). If patients forget to or cannot use the PCA for a period of time (e.g., long period of sleep) they may get behind on their analgesia and require a larger amount of opioid to catch up.

PCA opioid choices

There does not appear to be a clearly superior opioid for use in PCA devices. Because morphine has an active metabolite

Table 144.4. Initial PCA demand doses in opioid-naïve patients

Opioid agonist	Demand dose
Morphine	1–2 mg
Fentanyl	20–30 µg
Hydromorphone	0.2–0.3 mg
Methadone	1–2 mg
Sufentanil	2–5 µg
Meperidine	10–20 mg

there can be an accumulation of effects, especially in elderly patients and/or patients with renal failure, so it is generally best to avoid in these patients. Fentanyl has a shorter duration of action than morphine, which is good if one is concerned about accumulating effects, but bad in that patients must frequently activate the PCA. Meperidine should be used only in rare cases in which a patient has documented intolerance to all other opioid choices, and then it is recommended to limit the total dose to 600 mg in a 24-hour period for no more than 3 days. Methadone is especially useful in patients who take methadone chronically, whereas it is not appropriate as a first-line agent in others because the conversion from methadone to another agent when the patient is taking oral analgesics is difficult given the dose-dependent potency of methadone.

Table 144.4 lists the recommended starting demand doses to be used in opioid-naïve patients. In the opioid-tolerant patient, these doses will need to be individualized based on the amount of opioid the patient takes per day leading to higher initial demand doses and possibly the initial use of continuous infusions (see the Continuous (basal) infusion section.) High-risk patients – identified as elderly (age 70 or older), morbidly obese, or with a history of obstructive sleep apnea – should have lower initial demand doses (e.g., one half the usual demand dose).

PCA management

If the patient does not receive adequate pain relief with a given demand dose, increase the dose of opioid per activation using the parameters suggested in Table 144.5.

A small subset of opioid-naïve patients may prove that they need and can be safe with a continuous infusion. For example, if, following several demand dose increases over several hours, a patient continues to need to use the PCA frequently to maintain analgesia without evidence of side effects (i.e., sedation or respiratory depression) and repeatedly gets behind, because he or she falls asleep, and then awakens in severe pain not adequately treated with the demand doses or easily treated with

Table 144.5. Usual PCA demand dose changes for inadequate analgesia

Opioid agonist	Demand dose increase
Morphine	0.5–1 mg
Fentanyl	5–10 µg
Hydromorphone	0.1 mg
Methadone	0.5–1 mg
Sufentanil	2 µg
Meperidine	5–10 mg

rescue doses, then a low-dose continuous infusion may be appropriate. The starting continuous infusion for the opioid-naïve patient should generally not be more than a single demand dose per hour (e.g., 1–2 mg/h for morphine).

If a continuous infusion is being used in any patient, one must be cautious if the amount of pain is assumed to be decreasing with time (e.g., continued healing following surgery). If a patient has a continuous infusion and does not need to activate the PCA, or if side effects (i.e., pruritus, nausea, sedation) begin to increase, then the basal rate should be decreased or discontinued. This downward adjustment or discontinuation of the basal rate allows for the maintenance of the inherent safety of the PCA device in that the patient controls the amount of opioid received as opposed to it being on an opioid infusion, to help reduce the chance of respiratory depression.

PCA safety and efficacy

One of the major benefits of PCA is that it helps overcome the wide interpatient variation in opioid requirements by allowing each individual patient to titrate the amount of opioid that he or she receives based on the response experienced. In addition, there is some degree of a placebo effect imparted by the use of a PCA enhancing the overall pain control. The patient-controlled aspect is also one of the major safety features of the PCA in that it is assumed that if a patient is getting sedated, he or she will not activate the PCA, thereby limiting the possibility of respiratory depression.

Based on the results of several meta-analyses, when PCA is compared to conventional nurse-administered opioids on a PRN basis it has been shown to provide slightly better pain control and improved patient satisfaction and is preferred by patients. Patients with PCA use slightly more opioid and experience a higher incidence of pruritus but have similar rates of other opioid-related side effects (e.g., nausea, vomiting, sedation, and respiratory depression). There is also a slight (non-significant) reduction in the length of hospital stay in patients using PCA. Finally, there appears to be a lower incidence of pulmonary complications in patients using PCA.

The reason that PCA is proposed to be more effective than nurse-delivered opioid administration is termed the *PCA paradigm* (Fig. 144.1). Analgesia is obtained when the plasma concentration of an opioid is within a certain range, which is specific to each individual. The lowest value of this range is known as the minimum effective analgesic concentration (MEAC). When the concentration of opioid goes above this range no further analgesia is obtained and side effects (i.e., sedation and respiratory depression) occur. When the opioid plasma concentration falls below the MEAC, the patient experiences pain. The assumed course of events is that patients will be able to maintain their own plasma opioid concentration around the MEAC by administering a demand dose every time they experience pain, which is in contrast to conventional nurse-administered boluses that result in much larger fluctuations in opioid plasma concentration with time spent above

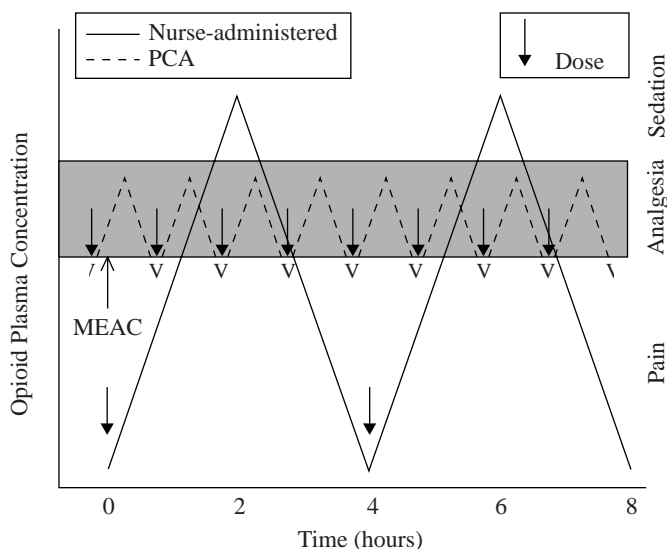

Figure 144.1. Intermittent nurse-administered opioids versus PCA-administered opioids. Shaded area: analgesic plasma concentration range. Adapted from: Ferrante FM, Orav EJ, Rocco AG, Gallo J. A statistical model for pain in patient-controlled analgesia and conventional intramuscular opioid regimens. *Anesth Analg* 1988; 67:457–461.

the analgesic range as well as significant time spent below the MEAC.

PCA monitoring

Although there are no actual guidelines for how to monitor patients on PCA, a recent statement by the Anesthesia Patient Safety Foundation (APSF) offered recommendations. The APSF advocates the use of continuous monitoring of oxygenation (i.e., pulse oximetry) and ventilation in patients receiving PCA. The reason for monitoring both oxygenation and ventilation is that pulse oximetry has reduced sensitivity as a monitor of hypoventilation when supplemental oxygen is administered. Therefore, when supplemental oxygen is used, monitoring of ventilation should be undertaken with a technology designed to assess breathing or estimate arterial carbon dioxide concentrations. Continuous monitoring is most important for high-risk patients (e.g., patients with obstructive sleep apnea, morbidly obese patients) but likely should be applied to all patients.

Patient-controlled epidural analgesia

Although this section focuses on the use of patient-controlled epidural analgesia (PCEA) for the postoperative patient, the concepts can be used in other settings as well (e.g., women in labor, cancer patients). A PCEA may be used in any patient requiring epidural analgesia provided that he or she is alert, oriented, and able to understand how to use the equipment appropriately.

PCEA parameters

All PCEA machines allow for the setting of the same parameters as described for a PCA.

Demand (bolus) dose

The optimal demand dose for PCEA is not known but is usually set at 2 to 4 ml. There is no information that a particular demand dose works best with a certain analgesic regimen.

Lockout interval

Lockout intervals between 10 and 20 minutes are commonly used. These times are more in line with the peak effect of the analgesics than are the lockout intervals used for PCA.

Hourly limit

If an hourly limit is used it should be the amount mathematically determined by the choice of demand dose, lockout interval, and continuous infusion rate. This determination will ensure that the patient receives analgesics continuously.

Continuous (basal) infusion

Continuous infusions are commonly used for PCEA management. Continuous infusions are usually started at 4 to 6 ml per hour with the usual upper limit of 14 ml per hour. Height of the patient does not appear to be a determinant of the correct infusion rate. There are some data to suggest that weight is positively correlated and age is negatively correlated with PCEA requirements. It is the location of the surgery, however, that appears to have the strongest correlation with PCEA requirements in that thoracoabdominal operations need higher rates than do lower extremity surgeries. This increased anesthetic requirement is likely a function of the number of dermatomes that need to be covered.

Rescue (loading) dose

The amount of a rescue dose to be used will be determined by a number of factors including the specific analgesics being used, the number of dermatomes that need to be covered, and potentially the hemodynamic status of the patient (see “PCEA management” section later in text).

PCEA analgesic agents

There does not appear to be a clearly superior regimen for use in PCEA devices. Local anesthetics are the most commonly used analgesic agents. Classically, bupivacaine is the most commonly used local anesthetic due to its relative resistance to tachyphylaxis. The cardiotoxicity of bupivacaine has led some practitioners to the use of levobupivacaine or ropivacaine instead. The usual ranges of concentration for the various local anesthetics are listed in Table 144.6. Often the higher range of concentrations is used for lower extremity orthopedic procedures and the less concentrated solutions used for thoracic surgery; however, there are no conclusive data to support this practice.

The next most common agents used for PCEA therapy are the opioids. They are commonly used in combination with a local anesthetic. There seems to be no benefit of administering

Table 144.6. Local anesthetic choices for PCEA

Local anesthetic	Concentration range
Bupivacaine	0.0625%–0.2%
Levobupivacaine	0.0625%–0.2%
Ropivacaine	0.1%–0.2%

lipophilic opioids (i.e., fentanyl or sufentanil) solely via the epidural route. The site of action of lipophilic opioids when given epidurally is not clear. Studies looking at the efficacy of fentanyl and sufentanil given epidurally versus IV are contradictory. Most studies measuring the plasma concentrations of these opioids when given via an epidural or IV have shown no difference in levels, thus suggesting that the major site of action is not at the spinal cord but rather due to systemic absorption.

Hydrophilic opioids (i.e., morphine or hydromorphone), in contrast, maintain high cerebrospinal fluid levels for an extended period of time and therefore can act at the opioid receptors in the spinal cord. Table 144.7 lists concentrations documented in the literature for the various opioids when administered via the epidural route; the “correct” dose is not known. The total 24-hour dose of opioid must be kept in mind if high, continuous-infusion rates or large, frequent-demand doses are used, especially for high-risk patients. When used in combination with local anesthetics, the lower end of the concentration ranges are suggested.

Other agents have been studied as adjuvant medications added in combination with local anesthetics and/or opioids for epidural use; however, they are not used extensively in most clinical practices. This is likely because the studies are limited and show equivocal results. The major proposed benefits are improved analgesia and an analgesic sparing effect (i.e., the ability to use lower concentration of the other agents, specifically local anesthetics and opioids). Table 144.8 lists the adjuvant agents and offers suggested concentrations from the literature as the “correct” doses have not been determined.

A major concern with the addition of clonidine has been an increased incidence of hypotension and sedation. Use of epinephrine has shown improved analgesia with activity, although it may lead to an increased incidence of motor block. Epinephrine use also has been shown to reduce plasma concentrations of lipophilic opioids by allowing them to remain in the neuraxis for long enough to actually bind to the opioid receptors in the spinal cord. The concern with neostigmine is that, when used for intrathecal administration, a dose-dependent incidence of nausea and vomiting occurs as well as sedation,

Table 144.7. Opioid choices for PCEA

Opioid	Concentration range
Fentanyl	1–4 µg/ml
Hydromorphone	10–50 µg/ml
Morphine	20–100 µg/ml
Sufentanil	0.5–1 µg/ml

Table 144.8. Other agents for PCEA

Analgesic	Concentration range
Clonidine	1–3 µg/ml
Epinephrine	2–5 µg/ml
Neostigmine	1–7 µg/ml

but epidural use does not seem to have the same increased incidence of nausea and vomiting, and only minimal sedation occurs, if at all. Also, when neostigmine is started preoperatively it may provide some degree of a preemptive analgesic effect.

PCEA complications/side effects

Epidural infusions are associated with complications related to the placement of epidural catheters and medications used. The incidence of serious, permanent neurologic complications is exceedingly rare, and data comprise mostly a handful of case reports. The incidence of spinal hematoma has classically been thought to be 1:150,000 in the presence of normal coagulation, although recent studies have suggested that it may be more common. The incidence of epidural hematoma formation in a patient who is anticoagulated is not known, but it is estimated at 1:3000 in patients receiving therapeutic low-molecular-weight heparin. A full discussion of epidurals and anticoagulation is beyond the scope of this chapter; the most recent guidelines can be found on the American Society of Regional Anesthesia and Pain Medicine Web site (www.asra.com). Epidural abscess incidence is not known but is considered rare (at most 0.05%). Risk factors for abscess formation may be longer times of having the epidural in place (possibly > 6 days) as well as use in immunocompromised patients. Intrathecal or intravascular migration of an epidural catheter is estimated at approximately 0.2%, although it is likely much less frequent. The incidence of premature catheter dislodgement is estimated at approximately 6%.

The major side effects due to local anesthetics in epidurals are hypotension, central nervous system (CNS) toxicity, and motor block. The probability of hypotension from an epidural does not rise above 1% to 2% until the spread of the epidural is beyond 14 sympathetic dermatomes. In most instances, the band of analgesia, plus another 6 dermatomes for the spread of the sympathetic blockade beyond the analgesic level, is less than 14 dermatomes. The major mechanism by which an epidural might cause hypotension is through decreased venous return (preload) from reduced venous capacitance; therefore, the most appropriate treatment is increasing cardiac preload by increasing intravascular volume. Hence, hypotension is rarely seen in the supine normovolemic patient. Thus it is often the fluid status of the patient that is more of a causative factor than the epidural itself. This is evidenced by the fact that stopping the epidural infusion in a patient often does not improve blood pressure unless the pain becomes so great that a large sympathetic response occurs.

CNS toxicity (seizures) from systemic accumulation of local anesthetics is obviously based on the total amount of the drug used over time and has an estimated incidence of 0.01% to 0.1%. Motor block of the lower extremities is estimated at less than 3% when lower concentrations of local anesthetic are used and greater than approximately 25% with higher concentrations. In addition, the level of epidural insertion has much to do with the actual incidence in that lumbar epidurals are more likely than thoracic epidurals to cause motor block.

The incidence of nausea and/or vomiting with opioid-containing PCEA therapy is estimated at between 4% and 15%, although higher incidences have also been reported. The incidence of severe pruritus is between 2% and 17%, with the incidence of any degree of pruritus likely being well over 50%. Sedation is reported to occur in approximately 15% of patients. Respiratory depression is estimated to occur in 0.1% to 0.4% of patients. A higher incidence (approaching 1.5%) of respiratory depression is seen in some studies using morphine.

The respiratory depression seen with epidural opioids is biphasic. Early respiratory depression (within an hour of epidural initiation) is thought to be due to systemic absorption of the opioids via epidural veins and is thus more likely with the lipophilic opioids. Delayed respiratory depression (occurring 4–8 hours after epidural initiation) is seen especially when using the hydrophilic opioids and is thought to be due to the cephalad spread of the opioids in the cerebrospinal fluid.

PCEA management

Inadequate pain relief with an epidural can be due to a number of reasons, and an evaluation of the patient needs to be done to determine the best course of action. When a local anesthetic is part of the epidural solution, this evaluation should entail a determination of where the band of analgesia is located, either by testing for pinprick sensation or temperature differentiation. If the level of analgesia is more, or completely, one-sided the epidural catheter can be pulled out of the epidural space in 0.5- to 1-cm increments in an attempt to make the block bilateral. The optimal depth of multiorifice catheters is 3–5 cm in the epidural space. If the level of analgesia is not adequate to cover the entire extent of the surgical incision, then the rate of the continuous infusion can be increased, usually in increments of 2 ml/h, or the concentration of the local anesthetic can be increased. Either change will increase the number of dermatomes covered as the total quantity of local anesthetic, in milligrams, is the major factor in the amount of spread. If the patient has an adequate number of dermatomes covered but is still having pain, then the block is not dense enough. In this case, change the epidural solution to a more concentrated local anesthetic and/or add other agents (i.e., opioid and/or adjunct). If at any point the patient is in severe pain, a rescue dose of either the epidural infusion (4–8 ml) or a more concentrated local anesthetic bolus (e.g., 3–6 ml of 0.25% bupivacaine) can be used to achieve comfort faster.

Lower-extremity motor block can be of any degree from mild to complete. If the level of analgesia does not need to cover the lumbar nerves and it more than adequately covers the surgical incision, then the rate of the continuous infusion can be decreased (usually in increments of 2 ml/h). If the level of analgesia needs to cover the lumbar nerves or if the level of analgesia is just covering the extent of the surgical incision, then the local anesthetic concentration should be decreased to attempt to make the motor block less pronounced. If the patient is not going to be getting out of bed, for reasons other than the motor block from the epidural, then no change in therapy is really necessary, especially if the motor block is not bilateral and complete.

The concern with a complete motor block, especially one that occurs after the epidural has been running for some time with normal motor function previously, is that it may be a sign of the development of an epidural hematoma. Motor block, the most common presenting symptom of epidural hematomas, is seen in 46% of cases, followed by back pain in 38% of cases. If an epidural hematoma is suspected, the epidural should be stopped and motor function evaluated over the next 2 hours. If no resolution of the motor block occurs in this time, the patient should be sent for an MRI to rule out hematoma formation. The best chance for recovery of neurologic function from an epidural hematoma is to undergo a decompression laminectomy within 8 hours of the onset of symptoms.

As stated in the PCEA complications /side effects section, if hypotension is seen it is usually best to treat with intravascular volume expansion. If this is not possible, then the analgesic level should be established to ensure that the spread is not too excessive for the surgical incision; if it is, then a reduction in the continuous infusion rate can be made. If the hypotension is so severe that the epidural infusion needs to be turned off, one should ensure that the patient has another means of analgesia (e.g., IV PCA). In addition, if the blood pressure does not increase significantly after approximately 2 hours, then it is not likely that the epidural was contributory to the hypotension and the infusion can be restarted.

If the patient is having the opioid-related side effects of nausea and/or vomiting or pruritus, the options are to treat the particular side effect with a specific therapy or remove the opioid from the epidural solution. To treat nausea and/or vomiting, any of the available antiemetics can be tried as none has been proven to be the most effective. The pruritus caused by epidural opioids is generally not due to histamine release, instead being a central μ -receptor-related phenomenon. Thus it is best treated with a medication that has μ -receptor antagonist properties (e.g., 5 mg of IV nalbuphine every 4 hours PRN) – not an antihistamine.

Sedation or respiratory depression from epidural opioids definitely requires at least the removal of the opioid from the solution. If either is severe, especially respiratory depression, then naloxone administration may be necessary. Careful titration of naloxone (40- μ g increments every couple of minutes) is

necessary to minimize the chance of complete reversal of analgesia and the development of hypertension, tachycardia, and pulmonary edema. Naloxone has a relatively short duration of action (about 1 hour); therefore, patients should be monitored for return of respiratory depression as the opioid effects can last as long as 12 hours after discontinuation. Therefore, repeat doses of naloxone may need to be given. Another option is to begin a naloxone infusion.

PCEA efficacy versus parenteral opioids

Based on the results of several studies and meta-analyses, epidural analgesia is better than PCA with opioids in a number of ways. Pain control is improved for general surgery, orthopedic, and gynecologic patients. All epidural regimens (except hydrophilic opioids alone) when compared to PCA provide improved analgesia. There is statistically better analgesia at rest and during activity for all types of surgery (through postoperative day 4), as well as clinically appreciable differences in pain with activity through postoperative day 1. Greater improvements in analgesia are seen when epidurals contain a local anesthetic and when the insertion level is matched to the surgery (i.e., epidural insertion site around the mid-dermatome of the incision).

There is a reduction in pulmonary and cardiac complications (including postoperative myocardial infarction) in major vascular surgery and in high-risk patient populations with the use of thoracic epidurals. In addition, there is a reduction in the time of postoperative ileus (by 1–1.5 days) following abdominal surgery with the use of epidural regimens that contain local anesthetics. There has also been the suggestion that epidurals decrease the time to mobilization, duration of intensive care unit stay, and time to discharge. In lower-extremity revascularization, epidurals have been shown to improve the incidence of graft survival. Historically, epidurals have reduced the incidence of deep vein thrombosis (DVT) and pulmonary embolism (PE); however, no studies have been done recently comparing epidural infusions to newer pharmacologic thromboprophylaxis. Epidural therapy is more expensive than PCA therapy. In terms of side effects, PCA therapy has a higher incidence of nausea and sedation, whereas epidurals have a higher incidence of pruritus, urinary retention, and motor block (although this will vary with the agents and concentrations chosen).

PCEA efficacy versus continuous epidural infusions

It has been suggested that PCEA compared with continuous epidural infusion (CEI) optimizes pain control by allowing the

patient to top-up him- or herself when there is an increase in pain or in anticipation of a painful event (e.g., prior to getting out of bed or having physical therapy) as opposed to having to wait for a health care provider. Some studies have shown that PCEA compared to CEI provides improved analgesia, whereas others have only shown a decreased requirement for provider-administered boluses. Some data are contradictory in terms of whether PCEA or CEI provides improved analgesia, but PCEA has been suggested to improve patient satisfaction, and PCEA does reduce the total amount of analgesics required. Additionally, PCEA has a decreased risk of motor block and nausea but an increased incidence of pruritus when compared to CEI.

PCEA safety and monitoring

Tubing that is clearly marked and differentiated from IV tubing (e.g., different color) is essential to prevent medications other than the intended epidural solution from being injected into the epidural space. Although there are no actual guidelines for how to monitor patients on a PCEA, the APSF does offer some recommendations if the infusion contains an opioid as described in the section PCA monitoring.

Multidisciplinary approach to chronic pain management

Pradeep Dinakar and Edgar L. Ross

Pain is the most common presenting symptom and accounts for the majority of visits to the physician's office. Acute pain can usually be treated with oral, intravenous, or epidural administration of analgesics, both opioid and non-opioid. Unlike the treatment of acute pain, that of chronic pain is usually more complex given the bio-psycho-socio-genetic influences on the development of chronic pain. A common mistake and reason for treatment failure is the tendency to simplify the treatment of chronic pain by trying these approaches individually and sequentially rather than simultaneously. A multimodality approach addressing these complex interrelated factors leads to the best possible outcome. Several other treatment barriers have been identified that lead to these poor outcomes (Table 145.1).

The evaluation process should identify the various problems, and the treatment plans formulated must address these problems concurrently. Individual treatment plans addressing all of the problems maximize the potential for improved outcomes. Treatment plans for chronic pain should consist of the following components tried concurrently:

- Pharmacologic management;
- Interventional pain management;
- Pain-related psychological symptom management along with behavioral therapy; and
- Rehabilitation directed toward improving the patient's function and endurance.

Table 145.2 enumerates the various treatments available for chronic pain.

Pharmacologic management

Many different classes of medications have been used in the treatment of pain. Given the varying pain physiologies, rarely can one single medication be completely effective in all types of pain. The most common approach is to try various different classes of medications, both individually and in combination, until optimal pain relief is obtained. Polypharmacy can lead to both synergistic analgesic effects as well as a reduction in individual medication side effects due to dose reduction. Good knowledge of the pharmacodynamics, pharmacokinetics, and adverse effects of these medications is essential in the treatment of these conditions.

Analgesics can be classified as either primary or adjuvant medications based on the pain etiology. In most of the nociceptive pain conditions the primary medications are usually opioid or nonopioid drugs, and adjuvants are anticonvulsants, antidepressants, *N*-methyl-D-aspartate (NMDA) antagonists, muscle relaxants, or topical medications. In neuropathic pain syndromes, these adjuvants serve as the primary medications and the opioid and nonopioid medications work as adjuvants given their lack of efficacy in neuropathic pain. Table 145.3 lists some of the more common classes of medications used in pain management.

Opioid analgesics

Opioid analgesics are μ -receptor agonists, which are the oldest class of medication used in the management of both cancer and noncancer pain. Multiple routes of administration include oral,

Table 145.1. Chronic pain management treatment barriers

Treatment barrier	Solution
Inadequate or wrong type of analgesics	Defining the types of pain and using appropriate agents are important for successful treatment.
Allowing patients to overuse analgesics	Use treatment contracts for controlled substances, and monitor effects of medication and improvement in the patient's function with the use of these analgesics.
Failure to use polypharmaceutical approaches	Often no single analgesic can be effective by itself. The use of multiple pharmaceutical agents enhances analgesia and can decrease individual side effects.
Failure to recognize patient's psychological symptoms, such as depression and anxiety	Psychological symptoms are common and enhance pain perception.
Failure to recognize a patient's loss or lack of a social support system	Social isolation and loss of a job is common. Distraction is an easy and effective approach for chronic pain.
Failure to recognize deconditioning and other rehabilitative needs	Deconditioning and muscle weakness lead to further pain if activity is inappropriate for ability. Energy conservation principles are important for successful treatment.

From Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

Table 145.2. Multidisciplinary modalities for pain treatment

Treatment modality	Description
Medications	Medication management for different types of pain and associated symptoms; see Table 146.3 for more specific management discussion.
Nerve blocks	Interventional treatments that can be helpful even when patients have not responded to noninvasive therapies.
Surgery and implantable devices	In certain well-selected patients, implantable devices, such as spinal cord stimulators and intrathecal pumps, can be helpful as part of a comprehensive treatment plan.
Relaxation training	Anxiety and unmanageable stress enhance a patient's pain perception.
Biofeedback	These approaches can provide patient-initiated nonpharmacological treatment and help to give patient a sense of control.
Support and education, groups and individual	Using groups and individual approaches, learning about what chronic pain is and how a patient can restore self-control can be helpful.
Psychotherapy	Depression and other comorbid psychological conditions can stand in the way of meaningful progress in chronic pain management.
Vocational counseling	Helpful for treatment plans that call for return to work; should be obtained early in the treatment course to facilitate goal-directed treatment.
Occupational and physical therapies	A must for almost all chronic pain patients to restore function.
Transcutaneous electrical nerve stimulation (TENS)	Noninvasive device that can be helpful for select patients where electrical energy is applied to the skin through electrodes.
Acupuncture and other alternative medicine approaches	Alternative medicine therapies have been helpful for relaxation and analgesia in well-selected patients as part of the treatment plan.
Nutrition counseling	Many chronic patients are obese and require weight loss as part of a treatment plan.

Modified from Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

intravenous, epidural, intrathecal, topical patch, buccal, rectal, and inhalational. Given the inherent risk of abuse and dependence, these drugs are classified as Schedule II and III drugs. Tolerance and dependence are common among all opioid medications. Reducing analgesia due to tolerance can be countered by opioid rotation. The initial management of nociceptive pain is with noncombination or combination short-acting opioids. Long-acting opioids are useful when the short-acting opioids fail to effectively control pain. These long acting opioids provide a baseline pain control, and short-acting opioids are used for breakthrough pain. These short-acting opioids are dosed at 10% to 15% of the total opioid dose. Breakthrough doses should ideally not exceed four doses per day. Opioid side effects are common with increasing doses and in more sensitive patients. The first strategy is opioid rotation, which can often improve

a patient's tolerance to this therapy. The more common side effects and their treatments are listed in Table 145.4.

Nonopioid analgesics

Nonopioid medications include the nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and acetaminophen. NSAIDs are the most commonly prescribed medications for pain. They work by inhibiting cyclooxygenase (COX) 1 and 2. This COX1 inhibition also forms the basis for their gastrointestinal (GI) side effects. COX2 inhibitors are selective in controlling inflammation and have minimal GI side effects. Acetaminophen is now thought to work on a recently identified COX3 receptor. Both classes of NSAIDs should be used with caution in patients with a history of hypertension,

Table 145.3. Medication classes useful in management of chronic pain

Drug class	Pain treated
Opiates (oxycodone, OxyContin, Percocet, hydrocodone, morphine, methadone)	Used for nociceptive pain; helpful with appropriate adjuvants for neuropathic pain.
NSAIDs (aspirin, naproxen, ibuprofen, celecoxib)	Mainly useful for nociceptive pain; the COX2 inhibitors have increased the variety of clinical settings where they can be used with reduced GI discomfort.
TCAs (amitriptyline, nortriptyline, doxepin, imipramine)	Neuropathic pain, can improve sleep and mood.
SSRIs (citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline)	Some studies have suggested that these might be helpful in neuropathic pain syndromes. They are helpful for depression, which is common in chronic pain.
Anticonvulsants (gabapentin, pregabalin, tegretol, valproic acid, valium, topiramate, levetiracetam, zonisamide, lamotrigine)	Primarily used for neuropathic pain syndromes; can be useful as adjuvant for opiates and improvement in quality of sleep.
NMDA receptor antagonists (ketamine, memantine dextromethorphan)	Useful as opiate adjuvants, might help to improve responsiveness of neuropathic pain to opiates; might be helpful to manage opiate tolerance
Muscle relaxants (baclofen, valium, cyclobenzaprine)	Myofascial pain from muscle spasms and headaches.
μ -2 agonists (tizanidine, clonidine)	Useful for opiate withdrawal, can be helpful for neuropathic pain.
Topical medications (lidocaine patch, desipramine cream, capsaicin)	Localized neuropathic pain or dysesthesias.

Modified from Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

Table 145.4. Opioid-induced complications and their treatments

Side effect	Treatment approach	Comments
Nausea Sedation	Antiemetics or pro-peristaltic agents Psychostimulants such as methylphenidate or modafinil	Ensure that the patient is not constipated. Use low doses and administer in AM to avoid sleep difficulties. Consider depression with this side effect.
Euphoria Constipation Loss of libido Loss of appetite	Trial of methadone Laxatives, stool softeners, oral naloxone Hormone replacement therapy Anabolic steroids or dronabinol (Marinol; Abbott Laboratories)	This can be a troubling side effect for many patients. Use prophylactic measures to avoid this routine side effect. High-dose opiates cause suppression of the hypothalamic pituitary axis. Also a symptom of depression
Dizziness Urinary retention	Consider scopolamine patch. Trial of bladder muscle stimulant such as bethanechol (Urecholine; Duramed Pharmaceuticals)	Opioids can have an effect on the inner ear balance mechanism. If using a tricyclic or other anticholinergic, consider stopping or changing medication.
Respiratory depression Myoclonus	Usually not needed, tolerance builds rapidly GABA agonists, such as baclofen, benzodiazepines	If respiratory depression is noted, look for new developing pathology. Rare with oral routes; consider reducing opioid doses if able, opioid rotation or alternate routes such as epidural or intrathecal route

From Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

concurrent use of prednisone, coronary artery disease, pre-existing renal disease, peptic ulcer disease, or concurrent use of other highly protein-bound drugs, such as coumadin. The routes of administration include oral, intravenous, rectal, and topical.

Antidepressants

Antidepressants are used in the management of pain and depression in chronic pain. Their use is limited by debilitating side effects as seen in [Table 145.5](#). When using these medications, the effective approach is to pick the drug with the side-effect profile that may be a secondary benefit to the patient. Tricyclic antidepressants (TCAs) exert their analgesic effect

by restoring inhibitory controls through blockade of norepinephrine and serotonin reuptake. Unfortunately, the tricyclics are limited by significant anticholinergic side effects that many patients find intolerable. Newer antidepressants, such as the selective serotonin reuptake inhibitors (SSRIs) and selective norepinephrine reuptake inhibitors (SNRIs), lack anticholinergic side effects.

Anticonvulsants

The various generations of anticonvulsants have neuropathic pain action ([Table 145.6](#)). They are commonly used as adjuvants in nociceptive pain and as primary agents in neuropathic pain unless limited by side effects or lack of efficacy. Carbamazepine

Table 145.5. Side effects of TCAs

Side effect	Drug class and examples	Comments
Cardiovascular effects	TCAs cause postural hypotension, nortriptyline and doxepin less than imipramine, amitriptyline, desipramine, clomipramine TCAs have also been shown to increase the incidence of cardiac arrhythmias in patients with existing cardiac disease.	Most serious in elderly patients with increased risk of falling and hip fractures There might even be a risk of this side effect in patients without evidence of cardiovascular disease.
Sedation	Common with all TCAs; nortriptyline less common and the SSRIs and desipramine can produce insomnia	The sedating TCAs are often used at night to take advantage of their sedation. To avoid falling, care should be taken with patients who frequently get up at night.
Anticholinergic effects	Imipramine, amitriptyline, and doxepin show strong effects, less so with nortriptyline, desipramine; SSRIs lack this effect	Manifested by dry mouth, constipation, and urinary retention
Weight change	TCAs cause increased appetite, SSRIs can lead to anorexia and some weight loss.	Consider drug class based on weight goals for patient
Sexual dysfunction	TCAs and SSRIs have all been reported to have sexual side effects.	Consider dose reduction or plan sexual activity with trough levels of drug.
Psychiatric complications	Use TCAs with caution in suicidal patients; can trigger mania in bipolar patients.	Seek psychiatric help for patients with complicated psychological history.
Withdrawal symptoms	Both SSRIs and TCAs	Wear all antidepressants; avoid abrupt discontinuation.
Central serotonin syndrome	Can be caused by combinations of SSRIs and TCAs	Use these combinations with caution.
Analgesic effects	Strong analgesics include imipramine, amitriptyline, nortriptyline, and desipramine. Less analgesic are the SSRIs. Venlafaxine and bupropion might have some analgesic activity.	Balance dose, side effects, and analgesic activity; consider adding anticonvulsant to lower antidepressant doses when partial response to antidepressant alone

From Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

Table 145.6. Types of anticonvulsants used in pain management

Drug	Dose	Frequency	How supplied, mg	Comments
First-Generation Anticonvulsants				
Carbamazepine (Tegretol, Novartis Pharmaceuticals)	100–1000	BID to QID	100, 200, 20 mg/ml suspension, also 200 and 300 CR tablets	Requires monitoring for liver toxicity and anemia
Phenytoin (Dilantin, Pfizer Pharmaceuticals)	100–300	QD	50, 100, also 100 CR capsule, 25 mg/ml suspension	Not helpful for neuropathic pain; significant side effects
Valproic acid (Depakote, Abbot Laboratories)	150–1000	TID	125, 250, 500 coated tablets	Not helpful for neuropathic pain; indicated for third-line migraine prophylaxis
Clonazepam (Klonopin, Roche Laboratories)	.25–2 mg/d	TID	0.5, 1.0, and 2.0 tablets	Limited evidence for efficacy as an analgesic; must be weaned off slowly because of potential of seizures
Second-Generation Anticonvulsants				
Gabapentin (Neurontin, Pfizer Pharmaceuticals)	900–3600	TID	100, 300, 400 capsules, 600 and 800 tablets	Indicated for PHN; doses should be titrated upward to 3600 mg at least before determining to be ineffective
Lamotrigine (Lamictal, Glaxo SmithKline)	150–500	BID	25, 100, 150, 200 tablets and 5, 25 mg dispersion tablet	Slow titration at 25 mg/wk to avoid Stevens–Johnson syndrome; also associated with nausea, vomiting, and visual disturbances
Topiramate (Topamax, Ortho-McNeil Pharmaceuticals)	25–200	BID	15, 25 capsules, 25, 100, 200 tablets	No consistent evidence for neuropathic pain; good support for headache management; associated with weight loss Monitor sodium levels
Oxcarbazepine (Trileptal, Novartis Pharmaceuticals)	150–300	BID–QID	150, 300, 600 tablets	
Levetiracetam (Keppra, UCB Pharma)	1000–4000	BID–QID	250, 500 tablets	Well tolerated, little evidence for efficacy
Zonisamide (Zonagran, Elan Biopharmaceuticals)	100–400	QD	100, 200, 300, 400 tablets	Titrate slowly, to avoid sedation; little evidence for efficacy
Tiagabine (Gabitril, Cephalon)	2–32 mg	BID–QID	2, 4, 12, 16 tablets	Small trials show some efficacy

CR, Controlled release; PHN, Post-herpetic neuralgia.

From Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

may produce bone marrow depression, phenytoin causes undesirable cosmetic effects (gum hyperplasia, hirsutism) and ataxia at high doses, valproate can produce hepatotoxicity, and neurontin causes weight gain and sedation.

NMDA antagonists

The various medications in this class are ketamine, memantine, dextromethorphan, and methadone. Ketamine has shown considerable efficacy in treating neuropathic pain. Methadone is effective in weaning heroin and other narcotic abusers in detoxification.

Muscle relaxants

Muscle relaxants are a varied group of medications that involve depression of the central nervous system (CNS). The various classes of muscle relaxants are shown in Table 145.7. The γ -aminobutyric acid (GABA) agonists and other CNS depressants have been shown to have analgesic effects in both chronic and acute pain. The mechanism of action is thought to be through the depression of the descending reticular activation system and not peripheral inhibition. Benzodiazepines and carisoprodol have long-term dependency liability. Sedation is a common side effect with most of the muscle relaxants. Clonidine acts by potentiating the effects of opioids. It is most commonly used intrathecally along with opioids. Cyclobenzaprine is related to

TCA. Its mechanism of action is through a reduction in activity of both the gamma and alpha motor systems.

Topical medications

Topical medications have the potential advantage of providing effective therapy without the side effects of systemic absorption. Topical medications would have the promise of being effective adjuvants against peripheral sensitization, which is a significant

Table 145.7. Types of muscle relaxants

Drug class	Trade name	Generic name
GABA agonists	Lioresal (Novartis Pharmaceuticals)	Baclofen
	Valium (Roche Laboratories)	Diazepam and other benzodiazepines
CNS depressants	Soma	Carisoprodol
	Parafon Forte	Chlorzoxazone
	Skelaxin (King Pharmaceuticals)	Metaxalone
	Robaxin (Schwarz Pharmaceuticals)	Methocarbamol
Antihistamines	Norflex (3M Pharma)	Orphenadrine
Central μ_2 -adrenergic agonists	Catapres	Clonidine
	Zanaflex	Tizanidine
TCA-like drug	Flexeril	Cyclobenzaprine

From Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

Table 145.8. Behavioral therapy for chronic pain

Therapy	Description
Hypnosis and visualization	The patient is taught to visualize relaxing mental images, such as a secluded beach or a peaceful meadow. This helps to decrease anxiety, and facilitates deep relaxation.
Guided imagery	Directed visualization focuses on specific psychological issues using pain-decreasing images.
Biofeedback	Relaxation technique measures a physiologic phenomenon, such as muscle tension, and provides audible or visual feedback indicating a state of relaxation.
Cognitive-behavioral therapy	This teaches various techniques, such as distraction training, cognitive restructuring, role-playing, or mental imagery.
Group therapies	When well planned and with appropriate patient dynamics, group therapy is helpful. The interaction is planned to share important breakthroughs in insight, discuss progress with treatment, and different strategies for overcoming everyday obstacles to improvement.
Family therapy	Patients and their families often feel angry at each other. The family can be a significant stressor but is an important source of support that is needed for progress. This approach attempts to bring insight into how to provide support without enabling continued disability.

From Ross EL. *Pain Management. Hot Topics*. 1st ed. Philadelphia: Hanley & Belfus; 2003.

mechanism for the maintenance of a chronic pain condition. Limitations of topical agents include (1) the ability to treat only relatively small areas and (2) systemic absorption. Examples of topical medications include NSAIDs, local anesthetics (EMLA cream: eutectic mixture of lidocaine and prilocaine), and capsaicin, a vanilloid agonist that causes conduction analgesia not associated with suppression of motor or sensory function unrelated to pain.

Interventional pain management

Interventional approaches to pain management and their complications are described in detail later. They are almost always used in conjunction with other conservative modalities of treatment.

Psychological approach

Coexisting psychological problems including depression, anxiety, mood disorders, personality disorders, anger, and history of abuse are commonly associated with chronic pain. [Table 145.8](#) lists some of the psychotherapy approaches to deal with these problems.

Rehabilitation

Rehabilitation is as important as medical management and psychological therapy in the successful management of chronic pain. It helps in restoring better daily function and quality of life, reducing psychological comorbidities, and even discontinuing pain medications. Without rehabilitative therapies, the likelihood of improvement is low and the chance of reoccurrence for disability is high. Patients are taught that pain should not dictate the level of activity and the same level of activity should be maintained irrespective of the level of pain. The basics of the rehabilitative strategies described in [Table 145.9](#) include general aerobic conditioning and focused therapy directed at the injured part of the body. Given that therapy is difficult in this patient population, maintaining motivation is key to a better outcome. Group activities, keeping logs of progress, and involvement in miscellaneous recreational activity can be of help to improve compliance. The initial part of acute rehabilitation involves 3 to 5 days of intense therapy. Aggressive therapy can result in noncompliance due to worsening of pain. After patients start meeting the initial goals, visits can be gradually decreased in frequency and intensity. An overview of the treatment of chronic pain is presented in [Fig. 145.1](#).

Table 145.9. Rehabilitative therapies for chronic pain

Rehabilitative therapy	Description of treatment and goals
Modalities such as heat, ice, ultrasound	These are temporary, short-lasting therapies and therefore should only be used as adjuvant to an active rehabilitation.
Stretching	Mild and controlled stretching prepares the patient for further activity. Care should be taken to avoid injuring tight muscles that have not been active for a long period of time.
Cardiovascular exercise	Chronic pain patients are often deconditioned. A general aerobic program can increase endurance and activity tolerance. Aerobic exercise has antidepressant effects.
Work conditioning	This is a specific program that is used to prepare for a return to work. A job description is obtained, and the goals of therapy should lead to the physical demands of that type of work.
Strength training	This is usually focused on the portion of a chronic pain patient that is significantly weakened by the original insult. This approach is also used to train alternate muscle to supplement the site of original injury. Care should be taken to keep the goals realistic and avoid further injury.
Orthotics and prosthetics	Adaptive aids are often useful for return to function. The benefits of truly understanding a patient's impairments and creatively designing adaptive aids can be extremely helpful in enhancing function.

Psychological evaluation and treatment of chronic pain

Robert N. Jamison

Introduction

The International Association for the Study of Pain defines *pain* as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.” This definition recognizes that pain is an emotional as well as a sensory phenomenon. Pain is the most common reason to see a physician, and epidemiologic studies have independently documented that chronic noncancer pain is seen as an international problem of immense proportions.

Chronic pain influences every aspect of a person’s functioning. Profound changes in quality of life are associated with intractable chronic pain. Significant interference with sleep, employment, social function, and daily activities is common. Chronic pain patients frequently report depression, anxiety, irritability, sexual dysfunction, and decreased energy. Family roles are altered, and worries about financial limitations and future consequences of a restricted lifestyle abound. Patients with chronic back pain generally present with a history of multiple medical procedures yielding minimal physical findings.

Psychological assessment of chronic pain

Important components of chronic pain that must be evaluated as part of a psychological assessment include pain intensity, functional capacity, mood and personality, coping and pain beliefs, and medication usage. In addition, a behavioral analysis should be conducted, and information on psychosocial history, adverse effects of treatment, and health care utilization should be obtained.

Semistructured interview

The most popular means of evaluating the psychological state of the patient is a semistructured interview. Pertinent information acquired during an interview is frequently given significant weight when a decision regarding treatment is made. Before meeting with the patient, the interviewer should review all referral information, including discharge summaries, psychological testing results, previous physicians’ notes, and medical history reports. Each of the following categories should be assessed during the interview: (1) pain description; (2) aggravating factors; (3) daily activity level; (4) relevant medical history; (5) past and current treatments; (6) education and

employment history; (7) compensation status; (8) history of drug or alcohol abuse; (9) history of psychiatric disturbance; (10) current emotional status and social support; and (11) perceived directions for treatment. These areas have been identified as important in assessing candidacy for medical interventions for pain. Whenever possible, the spouse, the significant other, or a close family member of each patient should be interviewed.

Pain intensity measures

One of the primary goals of treatment for chronic pain is to decrease the intensity of the pain. As a result, it is important to monitor pain intensity both for a period before treatment and throughout the course of treatment. There are a number of ways to measure pain intensity, including numeric pain ratings, the visual analogue scale (VAS), and verbal rating scales (Table 146.1).

Numeric pain ratings often involve the patient’s rating of his or her pain on a scale of 0 to 10 or 0 to 100. Descriptive anchors that help the patient understand the meaning of each numeric value improve the measure. Another popular means of measuring pain intensity is the VAS, which uses a straight line (often 10 cm long) with extreme limits of pain at either end (e.g., “no pain” to “worst pain possible”). The pain patient is instructed to place a mark at the point on the line that best indicates present pain severity. Scores are obtained by measuring the distance from the end labeled “no pain” to the mark provided by the patient. The disadvantages of this method are that it is time-consuming to score and that its validity for older patients is questionable. Handheld computers enable VAS entry by screen touch with a stylus, and electronic diaries can aid in more complete and timely collection of patient diary data.

There are a number of verbal rating scales, which consist of words (as few as four or as many as 15, often ranked in order of severity from “no pain” to “excruciating pain”) that are chosen by the patients to describe their pain. Verbal scales not only measure pain intensity but also assess sensory and reactive dimensions of the pain experience. Verbal scales can be used to measure the descriptive nature of pain; the patient chooses words from a list that best describe the pain experience (e.g., piercing, stabbing, shooting, burning, throbbing).

Of all of the self-report measures, numeric rating scales are most popular among professionals. There is no evidence to

Table 146.1. Pain rating scales*

Example of numeric pain rating scale										
0	1	2	3	4	5	6	7	8	9	10

					15. Excruciating			15. Excruciating		

* Karoly P, Jensen MP. *Multimethod Assessment of Chronic Pain*. New York: Pergamon Press; 1987.

suggest that the VAS or verbal rating scales are any less sensitive to treatment effects, however. All of these measures have been shown to be acceptable in the quantification of clinical pain. The McGill Pain Questionnaire (MPQ) is a frequently used comprehensive questionnaire that includes 20 subclasses of descriptors as well as a numeric pain intensity scale and a dermatomal pain drawing. A short form of the MPQ is also popular. The MPQ measures various aspects of the pain experience and is sensitive to treatment effects and differential diagnosis.

Mood and personality assessment

Pain patients often show signs of depression and anxiety. Psychopathology and/or extreme emotionality have been seen as a contraindication for certain therapies. There is ongoing debate among mental health professionals about the best way to measure psychopathology and/or emotional distress in chronic pain patients. Most measures are helpful in ruling out severe psychiatric disturbance. Unfortunately, no measure can boast validity in predicting treatment outcome. The measures most commonly used to evaluate personality and emotional distress include the Minnesota Multiphasic Personality Inventory (MMPI-2), the Symptom Checklist-90-Revised (SCL-90-R), the Millon Behavioral Health Inventory (MBHI), the Illness Behavior Questionnaire (IBQ), and the Beck Depression Inventory (BDI).

Functional capacity and activity interference measures

Some clinicians consider pain reduction meaningless if there is no noticeable change in function. Thus, some reliable measurement of functional capacity should be used before the onset of therapy. A noticeable increase in level of activity helps to justify continued therapy and supports treatment efficacy. A

number of self-report measures can be used to assess activity level and function: the Sickness Impact Profile (SIP), the Short-Form Health Survey (SF-36), the Multidimensional Pain Inventory (MPI), and the Pain Disability Index (PDI). Automated measurement devices, such as the portable up-time calculator and the pedometer, are useful in obtaining accurate measures of activity. These devices should be used in conjunction with self-monitoring assessment techniques.

Performance measures of function include the Modified Symptom Limited Treadmill Test and the Fingertip to Floor Distance Test. The first test has much in common with the 6-minute treadmill walking test, where distance is measured by how fast a patient is able to walk on a treadmill in 6 minutes. In the latter test, patients are asked to bend forward as far as possible without bending the knees and the distance from the tip of the middle finger to the floor is measured. These tests assess aerobic capacity and range of motion in the lumbar spine but are not always highly correlated with pain or disability.

Pain beliefs and coping measures

Pain perception, beliefs about pain, and coping mechanisms are important in predicting the outcome of treatment. Unrealistic or negative thoughts about an ongoing pain problem may contribute to increased pain and emotional distress, decreased functioning, and greater reliance on medication. Certain chronic pain patients are prone to maladaptive beliefs about their condition that may not be compatible with the physical nature of their pain. Patients with adequate psychological functioning exhibit a greater tendency to ignore their pain, use coping self-statements, and remain active to divert their attention from their pain.

Because efficacy expectations have been shown to influence the efforts that patients will make to manage their pain, measures of self-efficacy or perceived control are useful in

assessing a patient's attitude. A number of self-report measures assess coping and pain attitudes. The most popular tests used to measure maladaptive beliefs include the Coping Strategies Questionnaire (CSQ), the Pain Management Inventory (PMI), the Pain Self-Efficacy Questionnaire (PSEQ), the Survey of Pain Attitudes (SOPA), and the Inventory of Negative Thoughts in Response to Pain (INTRP). Newer instruments currently being tested include the Pain Beliefs and Perceptions Inventory (PBPI), and the Chronic Pain Self-efficacy Scale (CPSS). Patients who catastrophize, who are passive in coping with pain, who demonstrate low self-efficacy regarding their ability to manage their pain, who describe themselves as disabled by their pain, and who report frequent negative thoughts about their pain are at greatest risk for poor treatment outcome. It is suspected that patients who have unrealistic beliefs and expectations about their condition are also poor candidates for pain treatment.

Monitoring of medication and adverse effects

Compliance is an important component in decisions about whether to continue, discontinue, or modify treatment for chronic pain. Clinicians ask patients to comply with their treatment protocol but rarely come up with a way to monitor compliance, particularly medication usage. A patient's retrospective report of use of medication, although of value, is subject to inaccuracies. Recall can be enhanced if the patient continuously monitors usage. In addition, both compliance and accuracy in reporting are improved if a family member assists with the monitoring. Medication records kept by patients should include the name of the medication, the date and time when it is taken, and the dosage.

Adverse effects should be monitored regularly during treatment for chronic pain. The monitoring of side effects related to medication use is often neglected in clinical practice, yet can be as important as the monitoring of pain intensity. Periodic monitoring of adverse effects by means of a checklist can provide relatively objective criteria useful in the assessment of treatment. Such a checklist may include drowsiness, dizziness, coordination impairment, irritability, depression, headache, memory lapse, dry mouth, visual distortions, nausea or vomiting, sweating, constipation, heart palpitations, itching, breathing problems, nightmares, and difficulty urinating. Although patients frequently report adverse reactions to medication during the initial stage of treatment, many of these reactions diminish over time.

Portable monitors using customized software have made the collection and storage of serial data about health behaviors both convenient and affordable. Electronic diaries allow two-way communication between patients and providers and may be an efficient means of evaluating and tracking medication use and associated symptoms. With the advent of palm-top computers (PTCs) and the ability to capture time-stamped data and store them for uploading to a larger computer, more investigators are exploring options of capturing data throughout the

day. Ecologic momentary assessment (EMA) refers to frequent data captured from subjects in their natural environment. Studies have shown that natural data are less prone to fabrication and may be a truer indicator of patient responses in the environment. Patients are shown to demonstrate remarkably high compliance with electronic diary monitoring.

Neuropsychological testing

As part of a comprehensive psychological assessment, a patient's neuropsychological status must first be determined. In cases of physical trauma (such as head injury) or in cases of decreased cognitive functioning, neuropsychological assessment may be indicated. Such an assessment is important in the evaluation of potential organic pathology that may limit the usefulness of cognitive interventions. A number of neuropsychological assessment tools exist for such evaluations.

Substance abuse assessment

Structured interview measures have been published for the assessment of alcoholism and drug abuse. Whenever possible, the patient's family members and/or significant other should also be interviewed. The Structured Clinical Interview for the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV), SCID, is a semistructured diagnostic interview that assigns current and lifetime diagnoses based on DSM-IV criteria. For each positive identification of a symptom, the SCID follows a question sequence to determine whether the symptom meets severity criteria for diagnosis. Other substance abuse measures include the CAGE Questionnaire, the Michigan Alcoholism Screening Test (MAST), and the Self-Administered Alcoholism Screening Test (SAAST).

Psychological approaches to pain management

Goals of psychological interventions

Patients with chronic pain who consult their primary care physicians, pain specialists, pain services, or pain management programs are usually experiencing a significant degree of psychological distress that requires intervention. Regardless of the setting, a number of treatment goals are relevant to the care of the chronic pain patient: reduction of pain intensity; increased physical functioning; control of medication use; improvement in sleep, mood, and interaction with others; and eventual return to work or to normal daily activities.

Reduction of pain intensity

A persistent pain problem is the reason most patients enter a pain management program. In such a program, however, patients are taught not to set pain reduction as their primary treatment goal. Instead, they are encouraged to focus on other, more attainable goals. Although the elimination of pain is rarely reported, patients often describe a reduction in the intensity of their pain by the conclusion of a structured pain program.

Increased physical functioning

Most interventions support regular exercise, including stretching, cardiovascular reconditioning, and weight training. Patients are encouraged to exercise regularly and to increase their activity at a progressive rate while under supervision. The goal is to gradually increase function without exceeding predetermined limits of pain and discomfort.

Control of medication use

Through education and daily monitoring, most patients are able to use prescription pain medication responsibly. Patients are frequently requested to monitor and record their daily medication use as a way to become aware of patterns and any associated side effects.

Improvement in sleep, mood, and interaction with others

Most patients report depression, problems relating to other people, and difficulties with memory and attention. Techniques aimed at decreasing emotional distress and increasing self-esteem should be considered in these instances.

Return to work or to normal daily activities

Patients who set as their goal an eventual return to work often are successful. Follow-up helpfulness ratings indicate that patients who have a positive experience in a pain management program tend to return to work and/or maintain an active, productive lifestyle.

Psychological interventions and program components

Education

Most people with chronic pain have an inadequate understanding of the nature of their painful condition. It is important for them to be knowledgeable about their pain and the treatments designed for them. Information can be conveyed through patient manuals on chronic pain, video presentations, handouts, or individual sessions. An optimal way to educate patients is through didactic groups; however, individual psychoeducational training may be useful as well. Topics for these educational sessions may include the physiology of pain, medication for chronic pain, exercise and pain, stress management, sleep disturbance, assertiveness training, posture and body mechanics, problem solving, weight management and nutrition, vocational rehabilitation, sexual issues, positive thinking, and relapse prevention. In general, patients who understand their condition and who have been exposed to relevant management techniques maintain a perception of control over their pain and show higher rates of success in meeting their goals. Active learning techniques, including the completion of homework such as periodic surveys, checklists, diaries, or questionnaires and brainstorming, should be emphasized.

The ultimate goal of any intervention is to increase the patient's perceived control over pain. Several themes critical to a

pain management approach should be highlighted throughout a structured program:

1. You will most likely not be "cured."
2. You need to expect ups and downs.
3. Rarely does pain intensity remain exactly the same over time.
4. You need to have a fall-back plan for those times when you have a flare-up of pain.
5. What you do about your pain may be as beneficial as anything that is done to you.
6. You need to work toward gaining control over your condition with the help of medical treatments and psychological pain management strategies.

Repetition will ensure that patients leave with an understanding of these important principles.

Relaxation training

Chronic pain patients tend to experience substantial residual muscle tension as a function of the bracing, posturing, and emotional arousal often associated with pain. Such responses, maintained over a long period, can exacerbate pain in injured areas of the body and can increase muscular discomfort. For example, it is common for patients with low back pain or limb injuries to develop neck stiffness and tension-type headaches. Relaxation training has been recommended as a way to reduce pain through the relaxation of tense muscle groups, the reduction of symptoms of anxiety, the use of distraction, and the enhancement of self-efficacy. In addition, this training can increase the patient's sense of control over physiologic responses. In a pain management intervention, patients are taught and encouraged to practice a variety of relaxation strategies, including diaphragmatic breathing, progressive muscle relaxation, autogenic relaxation, self-hypnosis, and cue-controlled relaxation. Biofeedback training may also be employed. Live demonstrations of these techniques are preferable to verbal explanations. All patients should be encouraged to practice each technique at home. Compact discs can be made or purchased for practice purposes.

Cognitive/behavioral therapy

Pain patients frequently show signs of emotional distress, with evidence of depression, anxiety, and irritability. Therapy with a cognitive/behavioral orientation is designed to help patients gain control of the emotional reactions associated with chronic pain. Specific problem-solving strategies can be offered during therapy sessions, including (1) identifying maladaptive and negative thoughts, (2) disputing irrational thinking, (3) constructing and repeating positive self-statements, (4) learning distraction techniques, (5) working to prevent future catastrophizing, and (6) examining ways to increase social support. Personal relationship issues can also be explored. The patient's strengths and positive coping mechanisms should be emphasized.

Cognitive/behavioral therapy has a number of objectives. The first is to help patients change their view of their problem

from overwhelming to manageable. Patients who are prone to catastrophize benefit from examining the way they view their situation. What might otherwise be perceived as a hopeless condition can be reframed as a difficult yet manageable condition over which the patient can exercise some control.

The second objective is to help convince patients that treatment is relevant to their problem and that they need to be actively involved in their own treatment and rehabilitation. Patients need to understand how relaxation training, cognitive restructuring, adaptive coping skills, and pacing behaviors can help decrease their pain. They also need to reorient their view away from that of passive victim and toward that of proactive, competent problem solver. When individuals are successful in managing difficult painful episodes, their views change. They eventually begin to believe themselves capable of overcoming any acute flare-up of pain.

The third objective is to teach patients to monitor maladaptive thoughts and substitute positive thoughts. Persons with chronic pain are plagued, either consciously or unconsciously, by negative thoughts related to their condition. These negative thoughts have a way of perpetuating pain behaviors and feelings of hopelessness. Demonstrating how and when to attack these negative thoughts and when to substitute positive thoughts and adaptive management techniques for chronic pain is an important component of cognitive restructuring. Patients are encouraged to attribute success to their own efforts; they need to know that they are responsible for the gains they make. Finally, future problems and lapses need to be discussed so that the patient will have a “game plan” to manage short-term setbacks.

Group therapy

Group therapy presents an opportunity to discuss concerns or problems that patients have in common. The specific problem-solving strategies used may be the same as in individual supportive therapy and cognitive behavioral therapy. Unlike psychotherapists in traditional group sessions, group therapists in a pain management program are encouraged to be active facilitators. They may need to redirect the discussion so that every member has an opportunity to speak and no one individual monopolizes the session. Participants should be offered individual therapy sessions in which to deal with personal issues.

Certain group members may initially be reluctant to discuss personal problems related to their pain. The group therapist must prevent other group members from being overly judgmental and negative. Group members should be told that they are there to learn from one another and to support one another in gaining control over their pain.

Family therapy

Chronic pain significantly impacts all members of a family. Family members need to be educated about the goals of therapy and should have an opportunity to share their concerns. Moreover, active involvement of family members helps to ensure the patient's long-term success. Therefore, both patients and mem-

bers of their families should be invited to attend family therapy sessions during which the facilitator encourages them to ask questions about the pain management program, to discuss their concerns and expectations, and to express their feelings. Besides enhanced communication, important outcomes of these sessions are that family members learn how to help the person in pain to achieve and maintain goals and that they come to understand that they are not alone in dealing with the person in pain.

Physical activity and exercise

Most patients are deconditioned because of their reluctance to exercise and because of a perceived need to protect themselves. Some patients have been medically advised to restrict activity when pain increases. Patients with chronic pain need to know that exercise is important. Some stretching, cardiovascular activity, and weight training should be encouraged. Each patient should be asked to keep track of his or her activity in an exercise record. It is important to set an exercise quota so that the patient will work to meet a weekly goal. The exercise plan should initially be determined by the patient and reviewed and supervised by a physical therapist or exercise physiologist. Patients should be instructed to stretch before and after each exercise session.

Any attempt by chronic pain patients to exercise is bound to entail some disappointment and perceived failure. Patients may make excellent gains, only to experience a flare-up of their condition. These setbacks should be anticipated so that the patient does not become excessively disappointed. Behavioral research suggests that compliance with exercise is best in a structured setting where each person is monitored and given encouragement for his or her accomplishments. Unfortunately, many persons with chronic pain tend to discontinue a regular exercise regimen within 6 months after a treatment program is concluded. Ways to encourage perseverance, such as organizing an exercise period with others, joining a health club, or combining exercise with another everyday activity, should be explored.

Vocational counseling

The goal of vocational rehabilitation is a return to work. After an extended period out of work, patients become both physically and psychologically deconditioned to the demands and stresses of the workplace. Together, a vocational rehabilitation counselor and the patient can develop a plan that incorporates both long-range employment goals and short-term objectives based on medical, psychological, social, and vocational information. Vocational rehabilitation counselors are specialists in the assessment of aptitudes and interests, transferable skills, physical capacity, modifications in the workplace, skills training, and job readiness.

Many chronic pain patients receive workers' compensation benefits or social security disability income. Patients may fear that their benefits will be jeopardized if they return to work. A vocational rehabilitation counselor can help a patient negotiate with an employer a return-to-work trial that will not

jeopardize the patient's income. Through counseling strategies and assessment tools, a patient's suitability for returning to work or retraining can be determined. Patients should be familiar with the Americans with Disabilities Act to know their rights regarding discrimination due to a pain-related disability.

Relapse prevention

Most chronic pain patients need continued support if they are to maintain their gains. Patients should be encouraged to identify and anticipate situations that place them at risk for returning to previous maladaptive behavioral patterns. They should also be encouraged to rehearse problem-solving techniques and behavioral responses that will enable them to avoid a relapse. The goals of relapse prevention are to help the patient (1) maintain a steady level of activity, emotional stability, and appropriate medication use; (2) anticipate and deal with situations that cause setbacks; and (3) acquire skills that will decrease reliance on the health care system.

Follow-up has been shown to be a vital factor in the prevention of relapse. A specific written follow-up plan should be made for each patient before the end of treatment. The participant should be offered structured follow-up services, such as participation in a monthly support group session and/or in individual sessions.

Multidisciplinary team

Chronic pain involves a complex interaction of physiologic and psychosocial factors, and successful intervention requires the coordinated effort of a treatment team with expertise in a variety of therapeutic disciplines. Although some clinics offer a single treatment approach, most pain programs use a blend of medical, psychological, vocational, and educational techniques. Treatment modalities for chronic pain generally include medical assessment, medication management, pain-reduction treatments, didactic instruction, relaxation training, biofeedback, physical therapy, psychotherapy, and vocational counseling.

An interdisciplinary staff coordinates efforts to rehabilitate the pain patient and provides a comprehensive discharge and follow-up plan designed to meet the patient's short- and long-term needs. The patient's active participation in the treatment plan is strongly encouraged. Among the predictors of success in a multidisciplinary pain program are the patient's motivation to cope with pain and his or her external support systems.

Benefits of a pain management program

Pain programs are cost-effective. Patients who complete a multidisciplinary pain program return to work or undergo voca-

tional rehabilitation more often than do patients who do not enter a pain program. Multidisciplinary pain programs also produce marked subjective and functional improvements in chronic pain patients: Pain ratings decrease from admission to discharge, reliance on medication decreases, and physical functioning increases. These positive treatment outcomes are often maintained 2 to 3 years after discharge.

Future studies

There has been a rapid change in the way health care services are offered in the United States. More and more decisions about treatment are made by employees of insurance carriers on the basis of financial resources rather than need. An increasing need for accountability and efficacy has encouraged the implementation of cost-saving measures and program evaluation. Preference is given to programs that are tailored to the individual rather than to programs in which all group participants receive every treatment.

In light of the attention given to these changes, the economic efficiency of treatment for chronic, nonmalignant pain is worthy of discussion. Although evidence exists for the cost-effectiveness of therapy for chronic pain, such treatment may not meet the criterion of increased benefit with little cost. Prior classification of patients may help in identifying those individuals who will most benefit from pain therapy. No reported studies have satisfactorily addressed this issue, and outcome data are needed. Documentation of increased function and decreased health care utilization among certain patients as a result of pain therapy would support the continuation of pain management programs. The field of remote data entry through personalized technology holds much promise for clinicians in the future. Currently available technologic methods of tracking can address the need for improved evaluation and treatment of persons with chronic pain.

Interventional pain management I: epidural, ganglion, and nerve blocks

John C. Keel and Alina V. Bodas

General patient care considerations

Patients who undergo interventional procedures for pain, such as single-shot epidural steroid injections (ESIs), or ganglion or nerve blocks, should be instructed in advance to prepare for the procedure. They should not have the procedure in the event of recent febrile illness or if there is risk of bacteremia because of the risk of bacterial seeding of the epidural space and other structures. They should take only clear liquids for 4 hours prior to the procedure, to avoid aspiration in the event of loss of airway protection. For neuraxial procedures, any anticoagulant use must be stopped according to established guidelines, under the supervision of the prescribing physician, to reduce risk of bleeding and epidural hematoma. Standard guidelines regarding anticoagulants include the consensus statement of the American Society of Regional Anesthesia and Pain Medicine. An escort must be available on the day of injection. Written, informed consent must be carefully documented. During neuraxial procedures, the patient will generally be monitored with a blood pressure cuff and pulse oximeter. Certain patients will require a peripheral intravenous (IV) line. Sedation is generally not recommended for elective pain procedures, as it is important for the patient to be able to provide feedback and cooperation.

Pharmacology

Injectates typically include local anesthetic and adrenocortical steroids (glucocorticoids). Local anesthetics are reversible sodium channel binders, and they produce varying degrees of neural blockade. Most often used are the amino amides lidocaine 1% to 2% and bupivacaine 0.25% to 0.5%. Higher concentrations of lidocaine can be associated with neurotoxicity. Lidocaine for anesthetizing skin can be mixed in a 9:1 ratio with 0.9% bicarbonate to enhance onset speed and reduce discomfort. Bupivacaine should not be mixed with bicarbonate because of resulting precipitate formation. Epinephrine is generally not included in chronic pain procedures, as it could exacerbate sympathetically mediated pain (SMP).

Glucocorticoids reduce inflammation by stabilizing leukocytes, inhibiting macrophages, decreasing edema, and reducing scar formation. Steroids also decrease the activity of irritated nerves. In interventional pain medicine, long-acting depot

steroid is used, such as triamcinolone or methylprednisolone. Interestingly, such agents are US Food and Drug Administration (FDA) approved for intramuscular use, so they are usually used “off-label” for chronic pain procedures. The typical dose is 40 mg (1 ml) for transforaminal epidural injections, and 80 mg (2 ml) for interlaminar and caudal injections. At these doses, four to six ESIs per year can be administered, if appropriate. ESIs performed in series, however, are not routinely indicated (e.g., “series of three”). As little as 40 to 80 mg of intramuscular triamcinolone acetonide can suppress the hypothalamic–pituitary–adrenal axis for 2 to 4 weeks. All glucocorticoids have systemic effects, such as fluid retention and increased insulin requirement in diabetes, but the degree of systemic effect in neuraxial pain procedures is not well understood. Although rare, even *single doses* of injected steroid have been reported to cause Cushing’s syndrome its devastating sequelae such as avascular necrosis, e.g., in patients who take ritonavir for HIV.

Neurolytics are most often used in patients with cancer pain. Alcohol 50% to 95% and phenol 6% to 10% produce long-lasting neurolysis by protein denaturation, coagulation, and precipitation. Phenol acts as an anesthetic at lower concentrations, is more viscous, and is less painful on injection than is alcohol. Alcohol is hypobaric in cerebrospinal fluid (floats on top), whereas phenol is hyperbaric (sinks) in cerebrospinal fluid. Neurolysis of peripheral nerves with a cutaneous sensory distribution should be avoided, as this can result in neuropathic pain.

Fluoroscopy

In blind techniques, using only surface landmarks, 30% of lumbar and 50% of cervical ESIs may miss the intended target. Controversy exists regarding outcomes of ESI, in part because earlier studies did not include fluoroscopic guidance. Fluoroscopy greatly enhances accuracy of needle placement, and is now the standard of care in the performance of ESI. Contrast agents are often used with fluoroscopic imaging. Contrast can be injected under live fluoroscopy to visualize potential unintended intra-arterial injection. The method of aspirating and looking for blood return should not be used alone, as it has up to a 50% false-negative rate. Contrast can detect intrathecal or subdural placement. Contrast can demonstrate location and extent of intended injectate distribution. Non-ionic monomeric contrast agents are used for interventional pain procedures, as these

are stable in solution and are less toxic. Gadolinium can be used in patients at risk of allergic reaction.

Epidural steroid injections

Interventional pain practitioners use fluoroscopically guided ESIs to place steroid in this space near the nerve roots to suppress local inflammation that is thought to be the cause of radicular pain. Radicular pain is neuropathic pain in the distribution of spinal nerve roots, whereas radiculopathy involves conduction block in the spinal nerve, with resulting neurologic deficit, with or without pain. Radiculitis is inflammation of the nerve root. Radicular pain can arise from mechanical or chemical irritation due to a herniated nucleus pulposus or spondylosis with stenosis of nerve pathways. Varieties of ESI include interlaminar, transforaminal, selective spinal nerve block, and caudal.

Evidence-based indications for ESI include treatment of pain radiating in the distribution of spinal nerves. Spinal stenosis and neurogenic claudication may also be treated with ESI. Axial back pain is usually not an indication for ESI, except in discogenic back pain, which may be mediated by the sinuvertebral nerves. Interlaminar and transforaminal ESI are indicated to treat cervical and lumbar radicular pain. Selective nerve root blocks (SNRBs) are used as diagnostic procedures to determine if a specific nerve root is the source of pain, in the setting of inconclusive or inadequate imaging, often in anticipation of surgery. Caudal ESIs can treat lumbosacral radicular pain and back pain attributed to failed back surgery syndrome. The various complications of ESIs are described in subsequent chapters.

Interlaminar epidural steroid injections

Interlaminar ESIs are performed in the cervical and lumbar spine using the loss of resistance (LOR) technique. The patient is placed prone on the fluoroscopy table. In anteroposterior (AP) view, the 22-gauge Touhy needle tip is directed just lateral to the spinous process, toward the interlaminar space. As the tip nears the ligamentum flavum, lateral views are used to check depth, as the LOR indicates the exact place of the epidural space

(Fig. 147.1). Non-ionic contrast is used to confirm epidural flow before injecting steroid (Fig. 147.2). Typical injectate is 80 mg (2 ml) of triamcinolone. Injectate in the lumbar region may include a small amount of local anesthetic, but local anesthetic is usually not used in the cervical spine (Fig. 147.3). This interlaminar ESI technique cannot be performed if there has been a laminectomy at that level, as there are no reliable landmarks for

(A) **(B)**

the interlaminar epidural space. In such cases, transforaminal or caudal approaches should be used.

Transforaminal epidural steroid injections

Transforaminal ESIs are most commonly performed in the lumbar spine. For lumbar transforaminal ESIs, the patient is placed prone on the fluoroscopy table. Oblique views are used to identify the pedicle over the target nerve root and the superior articular process of the vertebra below the nerve. The tip of a 25- to 22-gauge spinal needle is directed at the “six o’clock” position of the pedicle, within the “safe triangle,” outlined by the inferior border of the pedicle, the spinal nerve itself, and the lateral border of the vertebral body (Fig. 147.4). AP views are used to check the medial extent of the needle, then lateral views are used to guide the needle transforaminally (Fig. 147.5). Non-ionic contrast under live fluoroscopy is used to confirm epidural flow and to rule out intravascular uptake before injecting steroid. Typical injectate is 40 mg (1 ml) of triamcinolone, with or without a small amount of local anesthetic. The transforaminal approach has a much greater chance of delivering injectate to the anterior epidural space, the site of presumed pathology in disc herniations. Cervical, thoracic, and sacral transforaminal ESIs are sometimes performed. Cervical and thoracic transforaminal injections have high complication rates and are not as commonly used. Sacral transforaminal ESIs, most often accomplished at S1, are similar to lumbar ESIs. During the sacral transforaminal ESI, the spinal needle is advanced through the posterior sacral foramen until it is in proximity to the exiting S1 nerve root. Contrast is used to confirm the position and

the steroid is injected around the nerve root with an epidural spread.

Selective spinal nerve blocks

A selective spinal nerve block – an SNRB – is similar to a transforaminal ESI. An SNRB is used as a diagnostic procedure to

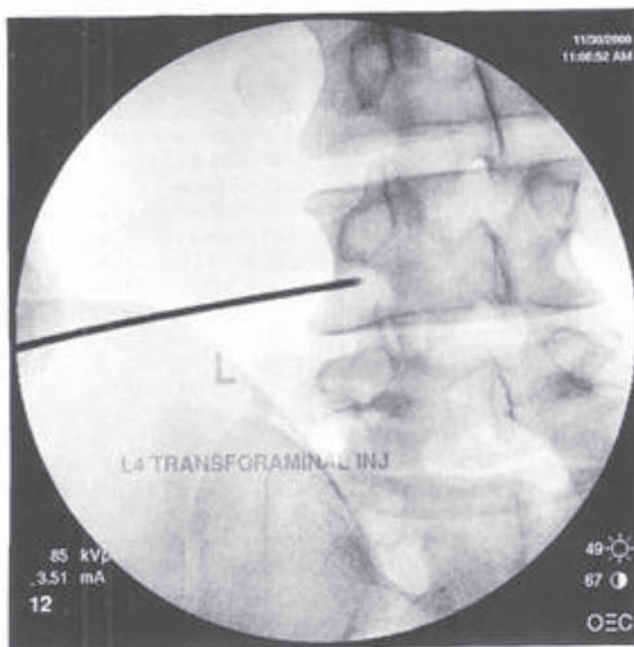

Figure 147.4. Lumbar transforaminal epidural steroid injection. (Adapted from Waldman SD. *Atlas of Interventional Pain Management*. 2nd ed. Philadelphia: Elsevier; 2004.)

A

B

determine if a specific root level is the source of pain. The needle tip is placed just outside of the neural foramen, lateral to the position for transforaminal ESIs. There should not be epidural spread of injectate. This procedure is often performed to locate a target for surgery (Fig. 147.6).

Figure 147.6. SNRB. (From Waldman SD. *Atlas of Interventional Pain Management*. 2nd ed. Philadelphia: Elsevier; 2004.)

Caudal epidural steroid injections

Caudal ESIs are performed by introducing a needle through the sacral hiatus, past the sacrococcygeal ligament. The patient is placed prone on the fluoroscopy table. Using lateral views, the needle is advanced, not past the lower aspect of S3 (avoiding dural puncture). Non-ionic contrast under live fluoroscopy is used to confirm epidural flow and to rule out intravascular uptake before injecting steroid (Fig. 147.7).

Ganglion blocks

Sympathetic blocks have utility in the diagnosis and treatment of pain that is mediated by the sympathetic nervous system. Positive response to sympathetic block may be diagnostic of SMP. The therapeutic effect of blocks may be due to interruption of central sensitization. The effect of sympathetic blocks may even predict outcomes with implanted spinal cord stimulators.

Sympathetic nervous system anatomy

The cell bodies of the preganglionic nerve fibers of the sympathetic nervous system arise in the intermediolateral cell column from T1 through L2. After exiting the spinal cord, these fibers either synapse or pass through the sympathetic chain. The sympathetic chain is composed of ganglia containing the cell

Figure 147.7. Caudal epidural steroid injection.

bodies of sympathetic postganglionic fibers, and is located on both sides of the vertebral column. Anatomic variation exists in the preganglionic pathways. For example, preganglionic sympathetic axons may travel up to 12 segments intraspinally before exiting the spinal cord. Axons of the thoracic ganglia remain ipsilateral, but axons in the lumbar ganglia take both ipsilateral and contralateral pathways. The cervical sympathetic ganglia include the superior, middle, and inferior cervical ganglia. The inferior cervical ganglion is often fused with the first thoracic ganglion (82% of cases) to form the stellate ganglion. Sympathetic afferent and efferent innervation of the head, neck, and upper limbs travels through this stellate ganglion. Eleven sympathetic ganglia lie in the thoracic region juxtaposed to the necks of the ribs. In both of these regions, the sympathetic chain lies in close proximity to the somatic nerves. Sympathetic innervation of the abdominal viscera is supplied by the celiac plexus. The preganglionic sympathetic nerves pass through the paravertebral sympathetic chain without synapsing. They then synapse at the celiac plexus, anterolateral to the abdominal aorta at T12–L1. Postganglionic fibers follow branches of the aorta to respective visceral structures.

Efficacy of sympathetic blocks

A number of methods have been devised to determine the effectiveness of a sympathetic block. One example is surface temperature monitoring. For upper limb blocks, temperature change can be monitored on the shoulder, forearm, and dorsum of hand or digit (preferably the thumb). For lower limb blocks, temperature can be monitored along the anterior thigh, dorsum of the foot, or the great toe. After a sympathetic block, the skin temperature should increase by at least 1°C to 2°C. Other methods involve psychogalvanic response, or sweat testing, wherein various chemicals that detect the presence of sweat are used to test a limb postblock. If a sympathetic block is successful, no sweat should be detected.

Stellate ganglion block

The stellate ganglion lies in front of the neck of the first rib with the vertebral artery passing over it. The sympathetic innervation to the head and neck arise from T1 and T2 and passes through the stellate ganglion on its way to more cephalad ganglia. The sympathetic innervation to the upper extremity arises from T2 through T8. Some of these fibers may synapse at the second thoracic ganglion and therefore may not be fully affected by a stellate ganglion block. Stellate ganglion blocks are indicated for pain, vascular spasm, and other various conditions of the head, neck, and upper extremities (Table 147.1).

To perform a stellate ganglion block, first position the patient supine with a roll under the shoulder for extension of the head and neck. This position draws the cervical spine more superficially, making it easier to reach while drawing the esophagus behind the trachea. Next, palpate the space between the carotid pulsation and the lateral trachea as low as possible in the neck. Another method is to retract the sternocleidomastoid muscle laterally and palpate the transverse process of the sixth cervical vertebra, called Chassaignac's tubercle. Generally, the sixth cervical vertebra is located at the level of the cricoid cartilage. Then make a skin wheal with local anesthetic over the medial border of the carotid pulsation. Direct a 22- to 25-gauge, 1.5-inch needle caudally and medially toward the junction of the lateral portion of C7 through T1 (Fig. 147.8). When bone is encountered, withdraw the needle 1 mm and inject 1 ml of contrast medium. Confirm contrast spread with fluoroscopy. Inject

The great vessels of the neck are gently retracted laterally, and the needle is placed on the anterior tubercle of the transverse process of C6 (Chassaignac's tubercle). Note the position of the vertebral artery within the foramen transversarium, the spinal nerve root and dural cuff, and the carotid artery and jugular vein.

5 to 10 ml of local anesthetic. Use of fluoroscopy in the performance of stellate ganglion blocks is the standard of care. Prior to the use of fluoroscopy, larger volumes of local anesthetic were injected because the exact location of injection could not be assessed. Larger volume insured wider spread but increased risk of adverse events. Signs of a successful block include ipsilateral Horner syndrome along with nasal congestion, venodilation of the limb, and increase in temperature of the limb by at least 1°C to 2°C (Table 147.2).

Celiac plexus blocks

Sympathetic innervation to the abdominal viscera is composed of preganglionic axons from the T5 through T12 level that leave the spinal cord, pass through the sympathetic chain, and synapse at distal sites. A network of ganglia, including the celiac ganglia, superior mesenteric ganglia, and the aorticorenal ganglia compose the celiac plexus. This plexus is located at the T12 through L1 level, anterior to the aorta, epigastrium, and crus of the diaphragm.

Celiac plexus block is indicated for treatment and diagnosis of pain from visceral structures innervated by the celiac plexus. These structures include the pancreas, liver, gallbladder, omentum, and mesentery and alimentary tract from the stomach

to the transverse colon. Use of celiac plexus block for chronic relapsing pancreatitis is controversial, but there may be some role, including the use of celiac plexus steroid injection. Neurolytic celiac plexus block is indicated as a palliative measure in upper abdominal malignancies, such as pancreatic carcinoma, where there is intractable pain. Celiac plexus neurolysis may lead to some diarrhea due to unopposed parasympathetic activity. It may, however, also decrease nausea and vomiting in these patients.

Current practice involves the use of fluoroscopy or CT for guidance of celiac plexus block. The block can also be performed using ultrasound, gastroscopy, or direct visualization intraoperatively. All approaches have the goal of depositing injectate anterior to the aorta, at the location of the plexus. For example, a fluoroscopically guided diagnostic block can be accomplished with a transcrural approach (crosses the diaphragmatic crura) or a retrocrural approaches (Fig. 147.9). In the transcrural approach, the patient is positioned prone with a pillow under the epigastrium. For the left side, an 18-gauge introducer needle is inserted 2 to 3 cm lateral to the L1 spinous process and aimed at the upper lateral margin of the L1 body. A 22- to 25-gauge needle with a curved tip is inserted through introducer and advanced medially to the celiac plexus. In the lateral view, the needle is then passed 2 to 3 cm beyond the edge of the L1 vertebral body. Continuous aspiration is maintained. Blood aspirate indicates penetration of the aorta, in which case a transaortic approach should be used. In this approach, needle advancement is simply continued through the anterior wall of the aorta. Contrast should indicate a pulsatile pattern anterior to the aorta. If bilateral spread is not seen, for the right

Figure 11-1, p. 124.)

side, a 20-gauge, 15-cm needle tip is directed to the upper lateral border of L1, then directed 2.5 cm anterolaterally and caudad. Contrast is injected again to assess spread. If spread is adequate, the 10 to 15 ml of local anesthetic is injected intermittently (e.g., 0.5% lidocaine or 0.25% bupivacaine). If a neurolytic block is being considered, a diagnostic celiac plexus block must be performed well in advance, using local anesthetic, to determine if a neurolytic block would be effective. The splanchnic nerve block is essentially the retrocruial approach to a celiac plexus block. The needles are directed toward mid-T12 (versus cephalad L1). This technique avoids the aorta, and has similar effects as the celiac plexus block.

Lumbar sympathetic blocks

The lumbar sympathetic chain is located along the anterolateral border of the lumbar vertebral bodies. There are a variable number of ganglia, with blockade of the second and third ganglia resulting in close to complete sympathectomy of the lower limb.

Lumbar sympathetic block is indicated for several SMP and neuropathic pain conditions (Table 147.3). The patient is positioned prone with a pillow beneath the epigastrium. Fluoroscopy is used to identify L2 transverse process and vertebral body. A 20-gauge, 5-inch needle is placed roughly 4 to 8 cm lateral to the L2 spinous process and advanced until it is 1 to 2 mm posterior to the vertebral body. Contrast medium is

injected to confirm spread prior to injection of local anesthetic. A large volume (15–20 ml) is injected incrementally. Successful block is indicated by venodilation and temperature increase in the involved lower limb. This procedure can be performed bilaterally (Fig. 147.10).

Hypogastric plexus block

The superior hypogastric plexus, just below the aortic bifurcation, anterior to the L5 vertebral body, innervates organs in the pelvis and pelvic floor. The hypogastric plexus carries sympathetic and parasympathetic fibers. Hypogastric plexus block is performed for diagnosis of pain from pelvic viscera and for treatment of pain from pelvic malignancies. With the patient prone, a 22-gauge long needle is directed to the inferior anterolateral aspect of L5. Contrast should spread just anterior to

Figure 12-2, p. 137.)

L5 through S1 (Fig. 147.11). Bilateral, unilateral, diagnostic, or neurolytic blocks can be performed. For a diagnostic block, 5 to 10 ml of local anesthetic is injected incrementally, per side.

Ganglion impar block

The ganglion impar represents the termination of the sympathetic chain. It rests anterior to the sacrococcygeal junction. Various techniques are described to block this ganglion, including a bent needle technique during which the needle enters at the level of the anococcygeal ligament. Given the close proximity of the rectal canal to this entry site, however, the easiest and safest approach is to traverse the sacrococcygeal ligament itself. Injection of contrast agent under fluoroscopy confirms proper needle placement. The technique can be performed with local anesthetic and steroid for nonmalignant pain conditions, such as coccygodynia, or perirectal pain from tumor involvement. Neurolytic blockade should probably be performed only for malignant pain conditions, and only after a diagnostic block is performed. The advantage of the ganglion impar block over other neurolytic procedures for rectal pain is that bowel and bladder function is generally unaffected. A local anesthetic

Figure 147.11. Sagittal view of the superior hypogastric block.

block should be done prior to a more permanent neurolytic blockade.

Peripheral nerve blocks

Single injections to block peripheral nerves can be used for diagnosis and treatment in chronic pain conditions. Local anesthetic can provide several hours of relief and can aid in diagnosis or the ability to participate in physical therapy. Steroids can provide lasting relief in entrapment syndromes where pathology includes inflammation. Some of the common peripheral nerve blocks for chronic pain are described in this section.

Trigeminal nerve block

Trigeminal nerve blocks help reduce pain in trigeminal neuralgia. The trigeminal nerve and Gasserian ganglion are accessed via a similar approach for diagnostic and neurolytic blocks, as well as via radiofrequency ablation. With the patient supine, a long 20-gauge needle is inserted 2.5 cm lateral to the corner of the mouth. The needle is directed to the pupil of the eye, into the foramen ovale. Fluoroscopy and contrast are used to confirm position (Fig. 147.12).

Greater and lesser occipital nerve blocks

These blocks are usually performed using surface landmarks. The posterior occipital protuberance and the mastoid process are identified, and the injection sites are sites at the one-third and two-thirds points on the line between these landmarks. The greater occipital nerve (mostly C2) is medial,

Figure 147.12. Trigeminal nerve block. Sagittal view of the Gasserian ganglion block.

and the lesser occipital nerve (C2 or C3) is lateral. Care is taken to avoid the occipital artery by entering medial to the artery. Steroid and local anesthetic are typically injected. This procedure is performed to treat occipital headaches or occipital neuralgia. Tension-type headache may not respond to occipital nerve blocks (Fig. 147.13).

Cervical plexus block

Cervical plexus block provides analgesia to the head and neck region. Both superficial and deep cervical plexus can be blocked. The deep cervical blocks help with surgeries such as carotid endarterectomy and thyroid surgeries. These blocks also have a role in pain management of the upper extremity, including postoperative pain, pain from trauma, complex regional pain syndrome (CRPS), and neuropathic pain (Fig. 147.14).

Suprascapular nerve block

This block can be performed with landmarks or with fluoroscopy. A short, 22-gauge needle is directed to the suprascapular notch, at the location of the nerve. Steroid and local anesthetic are typically injected. This injection can be used for any painful condition of the shoulder, such as arthritis or adhesive capsulitis (Fig. 147.15).

Intercostal nerve block

An intercostal nerve block is an injection of a steroid or local anesthetic around the intercostal nerves that are located under each rib (Fig. 147.16). It is used to treat neuropathic chest pain

Figure 147.13. Occipital nerve blocks.

secondary to postthoracotomy syndrome, postherpetic neuralgia, and other neuropathic chest pain syndromes. This procedure can be performed blindly, under ultrasonography and fluoroscopy. Pneumothorax is a possible complication of which the physician should be cognizant during and after the procedure.

Figure 147.14. Cervical plexus block.

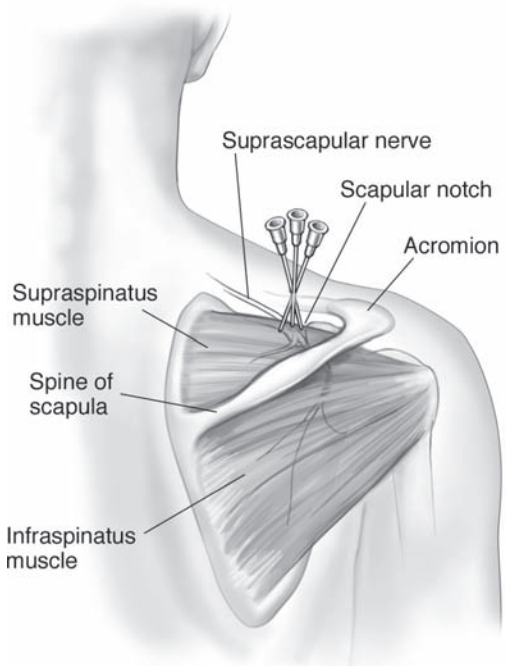

Figure 147.15. Suprascapular nerve block. Posterior view of blocking the suprascapular nerve.

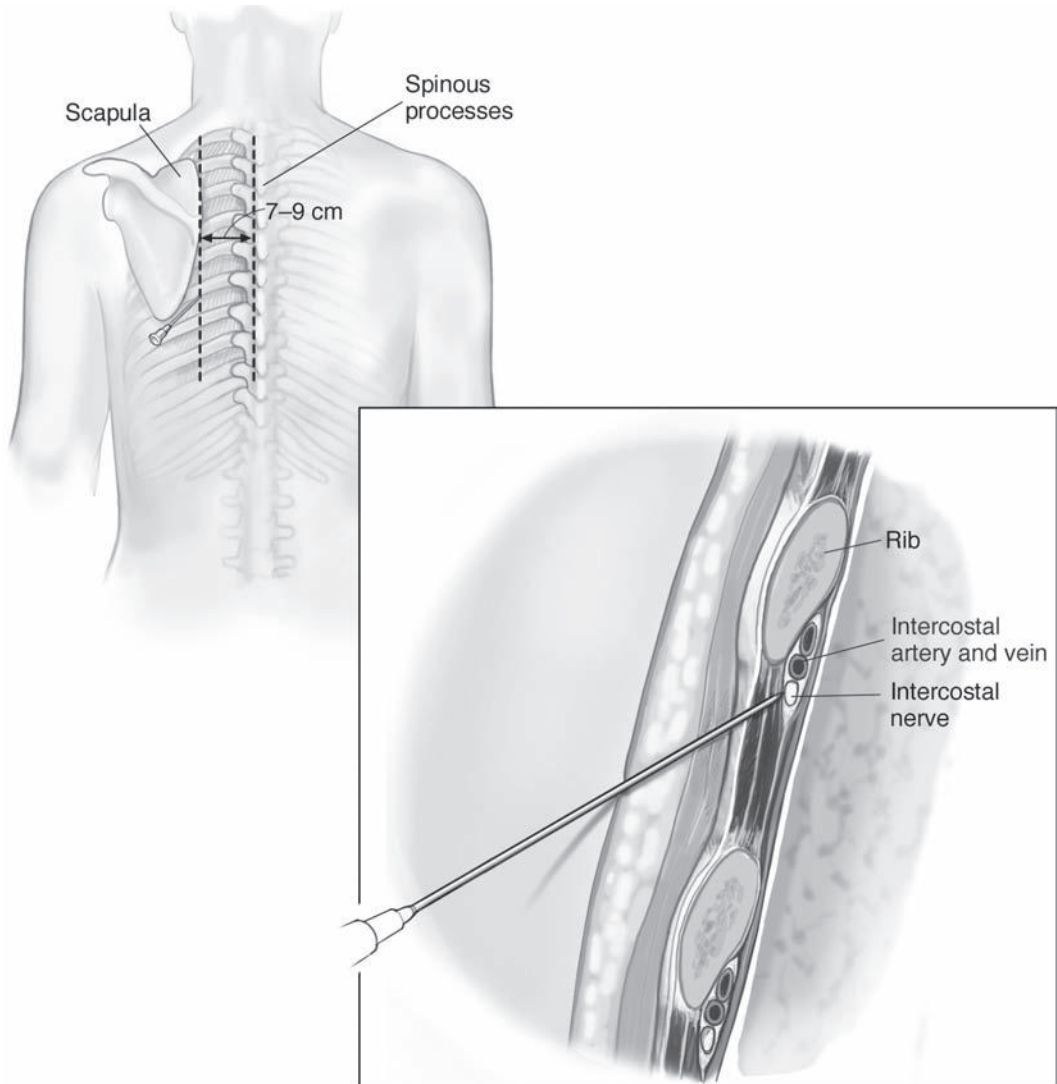

Figure 147.16. Intercostal nerve block.

Figure 147.17. Lateral femoral cutaneous nerve block. Anterior view of the nerve block 2 cm below and medial to the anterior superior iliac spine.

Paravertebral nerve block

Paravertebral block is an injection of local anesthetic adjacent to the vertebral body close to the exit of the spinal nerves from the intervertebral foramina. This injection causes both an ipsilateral somatic and sympathetic nerve blockade in multiple contiguous thoracic dermatomes above and below the site of injection. Indications include postoperative and surgical analgesia in breast, thoracic, renal, and abdominal surgeries. Other indications include fractured ribs and postherpetic neuralgia. The advantages include avoidance of thoracic epidural injection, low risk of pneumothorax, and multiple levels of analgesia with a single injection.

Lateral femoral cutaneous nerve block

With the patient supine, a 25-gauge short needle is directed 2 cm medial and 2 cm inferior to the anterior superior iliac spine, deep to fascia. A 10-ml volume of steroid and local anesthetic is injected in a field block pattern. This block is used to treat meralgia paraesthetica (Fig. 147.17).

Ilioinguinal and iliohypogastric nerve blocks

With the patient supine, a 25-gauge, 1.5-inch needle is inserted 2 inches medial and inferior to the anterior superior iliac spine, directed toward the symphysis pubis. When the needle enters the external oblique fascia a mixture of steroid and local anesthetic is injected in a field block pattern without violating the peritoneal cavity (Fig. 147.18). This block may be used in posthernia pain secondary to ilioinguinal neuropathy. Ilioypo-

Figure 147.18. Ilioinguinal nerve block. Anterior view of the nerve block 2 inches below and medial to the anterior superior iliac spine over the inguinal ligament.

gastric block is done in a similar fashion, but the needle entry point is 1 inch medial and below the anterior superior iliac spine (Fig. 147.19). The iliohypogastric and ilioinguinal nerves have overlapping cutaneous distributions (Fig. 147.20).

Figure 147.19. Ilioypogastric nerve block. Anterior view of the nerve block 1 inch below and medial to the anterior superior iliac spine over the inguinal ligament.

Figure 147.20. Overlapping dermatomes of the ilioinguinal, iliohypogastric, and genitofemoral nerves.

Genitofemoral nerve block

With the patient supine, the genital branch is injected at the junction of the inguinal ligament and pubic tubercle. The femoral branch is injected below the midpoint of the inguinal ligament after avoiding the femoral artery. A mixture of local anesthetic and steroid is injected. This is typically done in post-hernia or scrotal pain (Fig. 147.21).

Pudendal nerve block

Pudendal nerve block provides analgesia to the S2 through S4 dermatomes supplying the anal, perineal, and genital areas. It can be performed transvaginally or transperineally by fluoroscopy, ultrasound or CT-guided approaches. The indications include chronic pelvic or perineal pain secondary to pudendal nerve entrapment or compression by sacrospinous ligament or in the pudendal canal. The pudendal nerve terminates in the right and left dorsal nerve of the penis. Penile nerve blocks

Figure 147.21. Genitofemoral nerve block. Anterior views of the nerve block at both the femoral and genital branches are shown.

provide analgesia in release of paraphimosis, dorsal slit of the foreskin, penile lacerations, and circumcisions.

Interventional pain management II: implantable and other invasive therapies

Christian D. Gonzalez, Pradeep Dinakar, and Edgar L. Ross

Interventional techniques were developed to interrupt the transmission of pain. It makes the healing process more tolerable. The fundamentals of interventional pain medicine can be traced as far back as the American Civil War. During that time, Silas Weir Mitchell performed amputations of limbs that were extremely painful after nerve injury, a phenomenon he termed *causalgia*. In Europe it would be René Leriche who would follow Mitchell's steps during World War I. He based his hypothesis on sympathetic dysfunction as an etiology for causalgia.

Scientific advancements have allowed for the development of newer techniques to treat pain. The use of fluoroscopy and its advancements have created a more effective and safer practice. This chapter is dedicated to the discussion of more invasive and implantable techniques in the management of pain.

Medial branch nerve blocks

Medial branch nerve blocks (MBBs) are a diagnostic tool for the pain physician (Refer to figure in [Chapter 147](#)). With age, we develop arthritic changes of the spine. These changes are accelerated by trauma, obesity, weight lifting, and work-related stress on the facet joints. We start seeing degenerative changes in the spine by the third and fourth decade of life. The loss of cushion from the disc causes the facets to bear more weight. The end result is hypertrophied facets that can be painful. MBB is performed using just a local anesthetic or in combination with steroids to determine if the patient obtains pain relief. If the block is positive (there is pain relief), the patient is scheduled for radiofrequency lesioning (RFL) of the medial branch nerves. RFL gives a longer lasting pain relief than the block. The need to perform diagnostic blocks and the number of diagnostic blocks, if any, prior to the RFL are controversial. There are no adequate data to support either practice.

Intra-articular facet blocks

Intra-articular facet block involves the deposition of medications inside the facet joint (Refer to figure in [Chapter 147](#)). The drawback of performing these injections is the repetitive use of corticosteroids. Some practitioners argue, however, that it is a therapeutic injection and only requires one step. Others consider a positive finding enough of a criterion to performing RFL when the pain returns.

Sacroiliac joint injection

The sacroiliac joint is a major culprit of axial back pain, especially in the elderly population. These joints become degenerative and cause pain as the degeneration progresses. Imaging of the joint is not accurate in determining if the changes observed correlate with pain. Also, physical examination has been under debate to determine the most accurate test to diagnose sacroiliac joint pain. Most practitioners will agree that combinations of examinations, with or without imaging, are the best tool for the diagnosis. New studies show that tenderness to palpation over the sacroiliac joint may be the single most accurate examination. Others argue that, if it is suspected, a diagnostic/therapeutic block can be performed ([Fig. 148.1](#)). If the pain worsens, then it can be repeated as necessary versus consideration of an RFL of the joint.

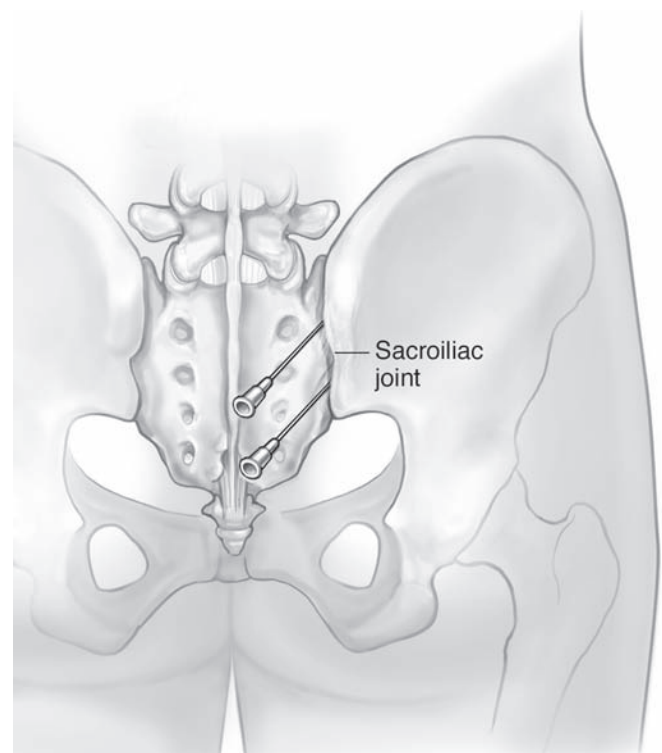

Figure 148.1. Sacroiliac joint injection.

Radiofrequency lesioning

Conventional RFL is used for many different therapies in the management of pain. Today it is mostly used for the treatment of axial back pain produced by facet arthropathy and sacroiliac joint arthropathy. After obtaining a positive diagnostic block, which is a reported pain relief of greater than 50% to 75%, the decision is made as to whether to proceed to RFL. This procedure is therapeutic and (at least in theory) gives pain relief for greater than 6 months, which is the nerve regeneration time. RFL causes the lesion by the passage of current from an active electrode in the tissue (insulated cannula with a bare tip) to the dispersive electrode (grounding pad/cannula). Voltage on the cannula generates an electric field around its tip. Heat is then generated in the tissue. The lesion size is dependent on the time, temperature, and tip diameter. The radius of the lesion increases until thermal equilibrium is reached. Monitoring the tip temperature enables control of the lesion size. The nervous tissue withstands temperatures up to 42.5fC, whereas temporary cessation of neural functions occurs at 42.5fC to 44fC. In conventional RFL, we cause permanent damage to the nerve by increasing the temperature to 80°C, thus causing thermal injury.

Pulsed RFL, in contrast, is used to treat facet joints, sacroiliac joints, dorsal root ganglion, stellate ganglion, Gasserian ganglion, and intervertebral discs. Pulsed RFL causes voltage fluctuations, but there is no heating of the tissue or tissue damage. Even though the exact mechanism of action of pulsed RFL is unknown, a presumed theory states that persistent increase of c-Fos expression in the dorsal horn neurons causes possible inhibition of the synaptic activation of the C fibers.

Vertebral body augmentation therapy

Indications are recent vertebral body compression fractures secondary to osteoporosis or malignancies that have failed conservative therapy. In both conditions there is skeletal disease that is characterized by low bone mass and architectural deterioration of bone tissue. These changes lead to an increase in bone fragility and increased susceptibility to fractures. It is estimated that approximately 44 million people in the United States are at high risk for vertebral body compression fractures. Ten million are related to osteoporosis, whereas the other 34 million are related to low bone mass. The vast majority of osteoporotic cases are in women, with a predominance of a 4:1 ratio. Fifty-five percent of this population at risk is older than 55 years. In 2002, the National Osteoporosis Foundation estimated that osteoporosis-related expenditures in the United States account for more than 20 billion dollars per year. Silverman and colleagues showed that approximately 20% of osteoporotic patients who have suffered a vertebral fracture in the past will present with another fracture within 1 year.

Evaluating the patient for vertebral body compression fracture involves a thorough history and physical examination.

Most patients can tolerate the acute period of the fracture and require no therapy. The first step in patient care is to allow 6 weeks of conservative therapy. The patient is given analgesics, usually opioids, and placed on minimal exercise recommendations. However, if after 2 weeks the patient is bedridden, in severe pain, or not tolerating the analgesics, then the therapy is recommended to prevent adverse outcomes. It is important to rule out any contraindications for treatment, including allergies, severe spinal stenosis, retropulsion of fracture fragments, or nerve root compromise. It is also important to obtain appropriate imaging. MRI with a STIR sequence is the imaging modality of choice. Acute inflammatory processes will be bright, whereas normal tissue and fat will be dark. This allows us to best determine the approximate time of injury (old vs. new fracture) and also the extent of inflammation in the area. If MRI is contraindicated, then a bone scan study would be the next option.

There is a debate between the use of a balloon to create a cavity for the injection of cement (kyphoplasty; Fig. 148.2) versus injection of the cement without a cavity (vertebroplasty; Fig. 148.3). The major difference between the two is the extravasation of cement, which is less common with the creation of a cavity. Also, a major advantage of using the balloon and creating the cavity is the thickness of the cement that can be injected. If no cavity is created, thin, liquefied cement is injected. Extravasation of cement intravascularly can cause unwanted major complications, including pulmonary embolism and death. Studies have shown that both procedures are effective in treating the fracture and pain. Recent randomized, controlled trials (RCTs) have not shown a significant long-term improvement between patients undergoing vertebroplasty and those undergoing sham procedures.

Discography

Discography is a study performed for the diagnosis of a suspected painful disc. It also serves as an anatomical study of the disc by using contrast and imaging the disc afterward. The main reason to use this study is to help determine which disc is causing the pain before the patient undergoes further therapy. Most practitioners use this technique prior to the patient having fusion surgery of the spine. Outcome studies show a better outcome from fusion surgery if the affected disc was first identified with the use of discography.

Some institutions inject a determined volume, some follow a pressure-guided study, and others inject until a painful response is obtained and compared this at other levels. With the development of newer technology, we can assess the opening disc pressure, volume injected, and changes in pressure during the study at different levels. If no concordant pain is achieved, it is a negative study. If there is concordant pain, it is a positive study and the level(s) affected is identified (Fig. 148.4). The outcomes from fusion surgery or other therapies improve if one single level is affected (vs. multiple level involvement).

Figure 148.2. Kyphoplasty.

Intradiscal electrothermal therapy

Approved by the U.S. Food and Drug Administration (FDA) in 1998, more than 50,000 intradiscal electrothermal therapy (IDET) procedures have been performed to date. Periprocedural costs are less than one-fifth of those for fusion surgery. IDET works by causing thermal modification of the annular collagen fibers (Fig. 148.5). It is used for chronic discogenic back pain. Discogenic pathology must be established prior to performing the therapy. Candidates should (1) have failed at least 6 months of comprehensive conservative therapy and (2) be facing surgery as the sole therapeutic option. Two major RCT studies have shown that IDET is beneficial for patients who are

younger than 50 years, have a lesser than 30% disc height loss, have no major disc herniation (>4 mm), do not have central canal stenosis, and have only one disc affected with a positive-concordant discogram.

Implantable therapies for pain

Implantable therapies have long held a role in the treatment of the most refractory pain patients. These therapies hold the promise of relief in well-selected patients, even when all other approaches have not been helpful. There are several different approaches that are selected based on clinical circumstances.

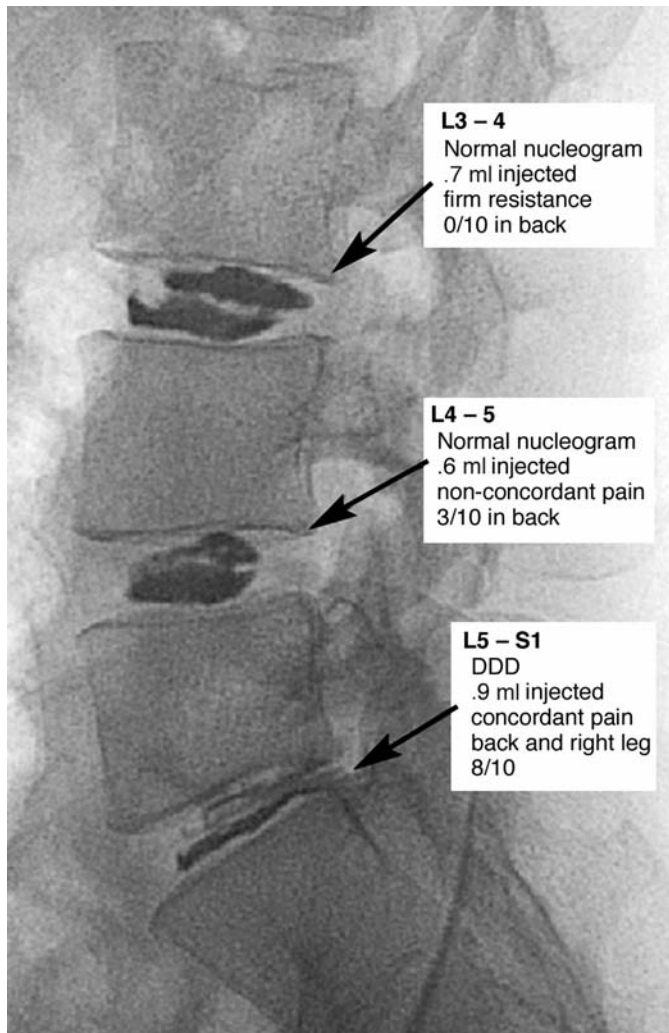

Figure 148.4. Discography.

Figure 148.5. IDET.

Epidural catheters

There are two types of epidural catheters and multiple techniques for implantation and anchoring. This is usually used in conditions requiring short-term analgesia. These catheters are tunneled subcutaneously a distance from the insertion site. Some epidural catheters have Dacron sleeves that reduce the incidence of infection migrating to the epidural space.

Subcutaneous reservoir or port-a-cath

This device consists of two parts: (1) a subcutaneous port attached to (2) a catheter, which is placed into either the epidural or intrathecal space. This procedure is indicated for either malignant or nonmalignant pain states after oral medications have proven ineffective. This procedure is generally reserved for intermediate-length therapy, particularly for patients with malignancies and less than 3 months of life expectancy. This procedure can also be used in the treatment of complex regional pain syndrome (CRPS), and can facilitate aggressive rehabilitation. The device can subsequently be removed after treatment has concluded. The procedure for catheter placement is identical to the one used for epidural or intrathecal catheter placement. The catheter is tunneled subcutaneously to a silicone access port, which is placed in a pocket over the anterior of the rib cage. This reservoir can be accessed percutaneously to provide either intermittent injections or continuous infusions of analgesics.

Intrathecal infusion pump implantation

There are two types of pumps: fixed flow and programmable. Fixed flow pumps are usually less costly and can hold more medication; however, dosing changes require pump refills. Programmable pumps can provide various programming options, including complex infusion programs. Dosing changes are easily done, with programmed increases in the pump's infusion rate. The indications for these pumps are refractory pain secondary to either malignant or nonmalignant pain in a patient who is not a candidate for surgical approach or has not responded to oral medications. Psychological screening is recommended. The placement of these infusion pumps is similar to catheter placements as described earlier in text. An additional step is required to surgically create a pocket, usually on the anterior abdominal wall. The spinal catheter is tunneled subcutaneously from the posterior site to the pump pocket and attached to the pump. Radiographs of pump and catheter are shown in Fig. 148.6.

Neurostimulation

Electrical stimulation of the central nervous system (CNS) has long been used for analgesia in neuropathic pain states. Electrodes can be used for both peripheral and central stimulation. Epidural placement of multielectrode arrays can be effective for a variety of conditions, including neuropathic pain syndromes and pain from vascular insufficiency. Electrodes have also been

implanted along peripheral nerves, such as the median, radial, sciatic, tibial, and peroneal nerves. More recent approaches have used a suboccipital approach for occipital neuralgia and transsacral approaches for pelvic pain and bladder dysfunction. Deep brain stimulation has been used to a limited extent for various central pain syndromes and Parkinson's disease. To be effective, spinal cord electrodes must be placed in the epidural space. Intrathecal placement is painful and causes unwanted motor stimulation. The location of peripheral nerves determines placement of stimulating electrodes. Suboccipital electrodes are placed transversely in the subcutaneous tissue at the C1 or C2 level. Transsacral placement of electrodes relies on the visualization of sacral foramen.

Peripheral nerve stimulator placement requires visualization of the affected nerve. Either a percutaneous approach using a needle or a direct approach using a cut down to the nerve to allow the placement of a flat or paddle lead alongside the desired nerve is used. Fascial grafts in the open approach are often used to protect the nerve. For epidural stimulation, the placement of the electrode is similar to the placement of epidural catheters. Trial stimulation determines efficacy prior to implantation of the system. Fixation of the electrode is important to avoid movement. Two types of pulse generators exist: an external system that relies on radiofrequency current for power or a battery-operated implantable pulse generator (IPG). Recently, rechargeable systems have been introduced that have largely

replaced radiofrequency units. The IPG is usually implanted in the buttock, over the greater trochanter, or in the abdominal wall (see Figs. 148.7–148.10).

Complications associated with interventions in pain medicine

Christopher J. Gilligan and James P. Rathmell

Overview

As with virtually all medical treatments, interventions used to treat acute and chronic pain may result in complications. To prevent adverse outcomes during these treatments, it is essential to have detailed knowledge of the anatomy of the structures that lie near the target site for each intended treatment and a clear understanding of technical aspects of the procedure that are devised to minimize the risk of harm to these structures. The widespread use of fluoroscopy has increased both the precision and the safety of many techniques. When complications do arise, prompt recognition and treatment can often prevent serious sequelae. This chapter will review complications that may arise from common treatments used in pain medicine.

Complications associated with epidural, transforaminal, facet joint, and sacroiliac joint injections

Direct injection of local anesthetic, with or without long-acting corticosteroid suspensions, is widely used in the diagnosis and treatment of pain arising from spinal structures. Among the most common procedures are epidural steroid injections and transforaminal injections for radicular pain associated with acute lumbar disc herniation and spinal stenosis, zygapophysial (facet) injections aimed at treating axial back pain associated with facet arthropathy, and sacroiliac (SI) joint injections for treatment of SI-related low back pain. The American Society of Anesthesiologists (ASA) maintains an ongoing surveillance of malpractice claims that have been settled through the ASA Closed Claims Project. A recent report stemming from this project detailed 114 complications associated with chronic pain treatment (Table 149.1). Neurotoxicity, direct neurologic injury, and the pharmacologic effects of corticosteroids have all been reported.

Neurotoxicity

The intrathecal injection of radiographic contrast, anesthetics, or steroids for meningeal inflammation from the breach of the spinal canal during surgery with or without direct neural injury can result in arachnoiditis or cauda equina syndrome. The typical signs and symptoms of arachnoiditis are shown in

Table 149.2. There is little evidence that any of the components of the available long-acting corticosteroid preparations are neurotoxic. Following the appearance of arachnoiditis during the intrathecal injection of methylprednisolone acetate, polyethylene glycol was suggested as the offending agent, which was subsequently disproved. It is important for practitioners to realize, however, that, despite their widespread use for epidural injection, these steroid preparations are not labeled for epidural use by the US Food and Drug Administration or any other regulatory agency. The concern regarding arachnoiditis appears to be limited to intrathecal administration (e.g., following inadvertent dural puncture in the course of attempted epidural placement). Thus, it is advisable to use all available means to avoid intrathecal injection of corticosteroid.

Neurologic injury

Direct mechanical injury to the spinal nerves or the spinal cord itself can occur during needle placement for epidural injection. The most common presentation of such nerve injuries is persistent paresthesia. Surprisingly, needle penetration into the cord is not always catastrophic and may even occur without the patient reporting symptoms. More significant injury occurs if there is subsequent bleeding into the spinal cord or if anything is injected through the needle into the parenchyma of the spinal cord. The risk of direct injury to the spinal cord is greatest when epidural injection is carried out at the high lumbar, thoracic, or cervical level with deep sedation; these patients are unable to report symptoms on needle contact with the cord. Large disc herniations at the level of the injection, which narrow or obliterate the epidural space anteriorly, displace the spinal cord

posteriorly, predisposing the cord and dorsal root ganglion to injury (Fig. 149.1). Immediate neurosurgical consultation and diagnostic imaging are warranted in cases where injury to the spinal cord is suspected; consideration should be given to administration of a course of high-dose intravenous corticosteroids, as this approach has proven somewhat beneficial in reducing neuronal injury following blunt traumatic spinal cord injury.

Vascular injury

The most concerning risk of transforaminal injection is unintentional vascular injection of the steroid suspension.

Intravenous injection is an innocuous event during transforaminal injection; particulate steroid injected intravenously will simply be carried away from the site of inflammation, thus reducing any local anti-inflammatory effect. In contrast, intra-arterial injection is far less common, but may cause catastrophic neurologic injury. In the cervical spine, the vertebral artery, the ascending cervical artery, and the deep cervical artery all furnish spinal branches that enter the intervertebral foramina. These spinal branches supply the vertebral column but also give rise to radicular arteries that accompany the dorsal and ventral roots of the spinal nerves (Fig. 149.2). Frequently, anterior radicular arteries are of significant caliber and reinforce the anterior spinal artery. Such reinforcing arteries can occur at any cervical level, but appear to be more common at lower cervical levels. If particulate steroid is injected into a reinforcing radicular artery during transforaminal injection, infarction of the cervical spinal cord could ensue. Radicular arterial branches arising from the vertebral artery can also join the arterial supply that reaches the anterior spinal artery; it is possible that injectate placed within a radicular artery during

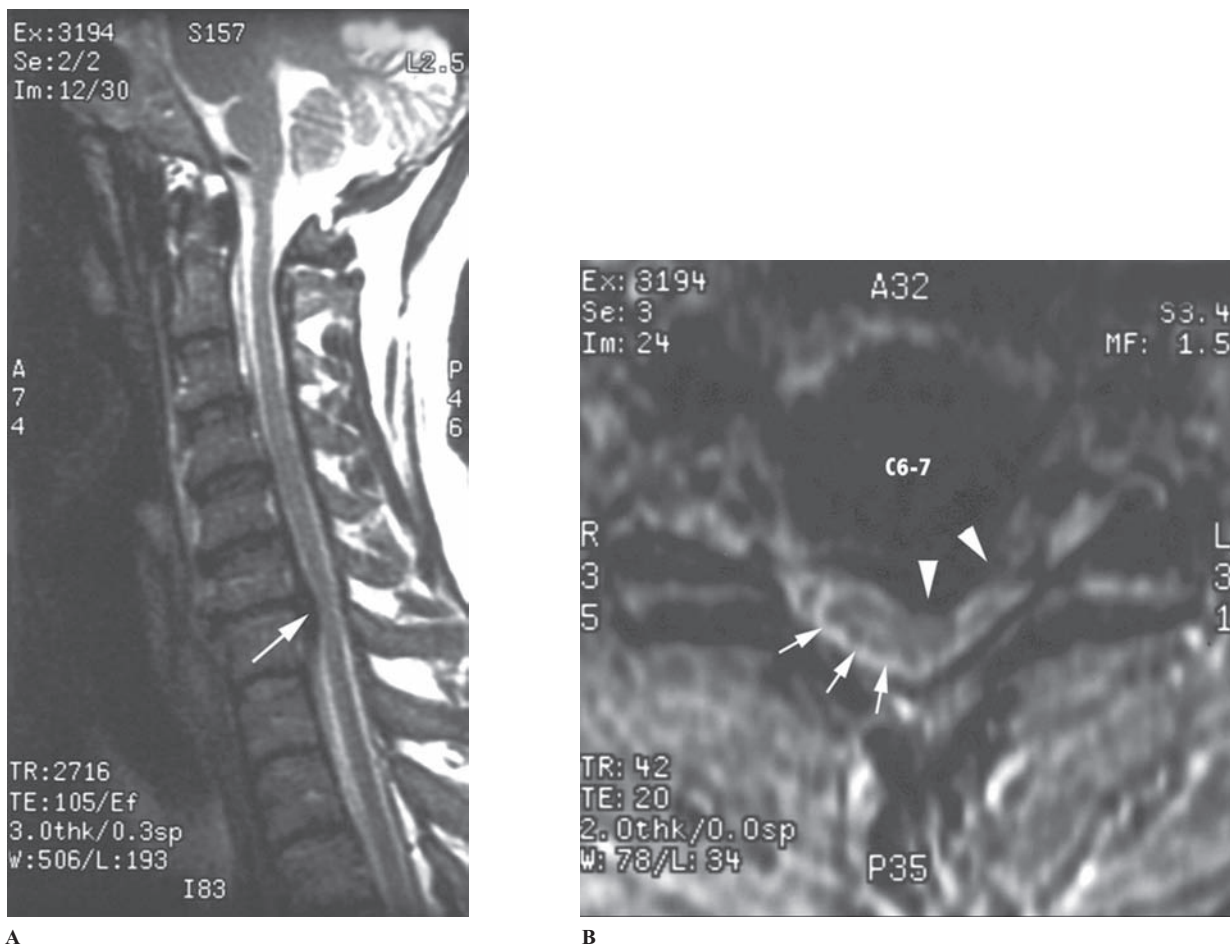

Figure 149.1. Cervical MRI of large disc herniation causing effacement of the epidural fat and CSF surrounding the spinal cord. (A) Midline sagittal, T2-weighted MRI showing large disc herniation at the C6/7 level (arrow) that effaces the epidural fat and CSF signal both anterior and posterior to the spinal cord. (B) Axial, T1-weighted MRI, showing a large central and left-sided disc herniation (arrowheads) displacing the spinal cord (arrows) to the right posterolateral limits of the spinal canal. Figure 149.2. Axial view of cervical transforaminal injection at the level of C6. The needle has been inserted along the axis of the foramen and is in final position against the posterior aspect of the intervertebral foramen. Insertion along this axis places the needle behind the spinal nerve and behind the vertebral artery, which lies anterior to the foramen. *Inset:* A spinal artery arises from the vertebral artery. It supplies the vertebral column. Another spinal artery enters the intervertebral foramen from the ascending cervical artery or deep cervical artery. It furnishes radicular branches that accompany the nerve roots and ultimately reach the anterior and posterior spinal arteries of the spinal cord. (Modified with permission from: Rathmell JP. *Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine*. 1st ed. Philadelphia: Lippincott Williams & Wilkins; 2006, Figure 6–1, p. 54.)

transforaminal injection could reach the vertebral artery via retrograde flow through an arterial anastomosis. If particulate steroid reaches the vertebral artery during transforaminal injection, infarction of the posterior circulation of the brain, including the cerebellum, could result. Published guidelines for performing cervical transforaminal injections are designed to prevent these complications (Table 149.3).

Epidural catheters are usually used in conditions requiring short-term analgesia. The major vascular complication with lumbar transforaminal injections involves the reinforcing radicular artery, known as the artery of Adamkiewicz, which typically arises at thoracic levels but in 1% of individuals it arises as low as L2, and more rarely as low as the sacral levels. In patients with a low-lying radicular artery, the artery can be entered during lumbar transforaminal injections. The more frequently reported minor complications include transient headaches, increased back pain, facial flushing, increased leg pain, and vasovagal reaction.

Table 149.3. Preventing complications during cervical transforaminal injection

- Advance the needle using fluoroscopic guidance from an anterior oblique approach.
- Ensure that the needle remains over the superior articular process along the posterior aspect of the intervertebral foramen. The vertebral artery lies anterior to the foramen. Keeping the needle posterior avoids risk of penetrating the vertebral artery.
- Use anteroposterior radiography to adjust final needle depth. Do not advance the needle more than 50% across the medial-lateral dimension of the foramen to avoid penetrating the dural sleeve.
- Once the needle is in final position, inject a small volume of radiographic contrast under “live” or “real-time” fluoroscopy to ensure that injection into an artery does not occur. Digital subtraction angiography is a fluoroscopic technique that offers advantages over conventional fluoroscopy by subtracting out the overlying radiodense structures and improving visualization of contrast spread.

Rathmell JP, Aprill C, Bogduk N. Cervical transforaminal injection of steroids. *Anesthesiology* 2004; 100(6):1595–1600.

Pharmacologic effects of corticosteroids

The administration of exogenous corticosteroids can lead to both hypercortisolism and suppression of the adrenal cortex’s normal production of endogenous glucocorticoids. The long-acting corticosteroid preparations used for epidural steroid injection slowly release the active steroid over 1 to 3 weeks. Fluid retention, weight gain, increased blood pressure, congestive heart failure, and Cushingoid side effects have been reported after epidural steroid injections. Glucocorticoid administration reduces the effect of insulin and results in increased blood glucose levels and insulin requirements in diabetics for 48 to 72 hours. Although rare, allergic reaction to systemic administration of corticosteroid has also been documented.

Bleeding complications

Epidural injection for pain treatment carries the risk of epidural or subdural bleeding in patients without any apparent coagulopathy. Significant bleeding within the epidural space can cause compression of neural structures, potentially resulting in paraplegia or quadriplegia. The risks of neuraxial injections for pain treatment in patients taking anticoagulants are similar to those in such patients receiving perioperative epidural analgesia. Epidural injection of steroids should be avoided in patients receiving systemic anticoagulants (e.g., coumadin or heparin) or potent antiplatelet agents (e.g., clopidogrel or ticlopidine). Nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, do not appear to increase the risk of epidural hematoma formation due to epidural injection.

Infectious complications

Injection therapy for pain treatment carries a small risk of both superficial and deep infection, including neuraxial infection, such as epidural abscess, which has potentially devastating complications, including permanent sensory and motor deficits and bladder and bowel dysfunction. Table 149.4 shows a recent review of epidural abscess following various types of epidural steroid injections. Other complications include meningitis, osteomyelitis, and septic arthritis of the facet joints. Considerations regarding sterile technique and use of disinfectant solutions are similar to those recommended for single-shot regional anesthetic techniques performed in the perioperative period. Most experts recommend the use of an iodine-based skin

Table 149.4. Data regarding cases of epidural abscess following epidural steroid injections

preparation solution, routine use of sterile drapes and gloves, and strong consideration of use of face masks and hats. Routine use of preprocedure antibiotics does not appear to be warranted in the majority of single-shot spinal and perispinal injections. Pain practitioners should establish written post-procedural instructions for their patients that provide a clear description of the signs and symptoms of evolving infection and a clear process for contacting pain clinic personnel in the event of any worrisome signs or symptoms. Whereas some isolated paraspinal infections have been treated with needle aspiration, most will require open surgical incision and drainage along with the administration of systemic antibiotics.

Complications associated with sympathetic blocks

Sympathetic blocks, including stellate ganglion, celiac plexus, and lumbar sympathetic blocks, have been used for more than half a century. The various complications described earlier in this chapter, including neurotoxicity, neurologic injury, vascular injury, bleeding, and infectious complications, also apply to sympathetic blocks. The specific complications that are associated with these blocks are described in the following sections.

Stellate ganglion block

Complications from stellate ganglion block can arise from vascular complications, unintended nerve blocks, epidural or intrathecal injection, or inadvertent injury to the surrounding structures.

Several arteries and veins lie in close proximity to the intended injection site, the anterior tubercle of C6 or C7. Intravenous injections into the neck veins do not commonly result in sequelae because the low volume and concentration of local anesthetic do not produce a toxic effect. In contrast, intra-arterial injections can give rise to catastrophic complications. Vertebral artery injections can occur when the needle is inserted too medially and posteriorly. The practitioner typically contacts
