#### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Brigham and Women's Hospital  
Boston, MA  
*Leukemia*

**C. Ryan Antolini, MD**

Physician  
Denver Arthritis Clinic  
Denver, CO  
*Acute Monoarticular Arthritis*

**Lindsey R. Baden, MD**

Associate Professor of Medicine  
Harvard Medical School  
Department of Medicine  
Division of Infectious Diseases  
Brigham and Women's Hospital  
Boston, MA  
*Immunizations*

**Ebrahim Barkoudah, MD, MPH**

Instructor in Medicine  
Harvard Medical School  
Associate Director, Hospital Medicine Unit  
Brigham and Women's Hospital  
Boston, MA  
*Occupational Medicine*

**Rebecca Marlene Baron, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Pulmonary and Critical Care Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Sepsis Syndrome*  
*Board Simulation: Critical Care*

**Elisabeth M. Battinelli, MD, PhD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Hematology  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Disorders of Platelets and Coagulation*

**Hasan Bazari, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of Nephrology  
Department of Medicine  
Massachusetts General Hospital  
Boston, MA  
*Hematuria and Proteinuria*

**Carolyn B. Becker, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of Endocrinology, Diabetes, and Hypertension  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Disorders of Calcium Metabolism*

**Rebecca A. Berman, MD, FACP**

Assistant Professor of Medicine  
Harvard Medical School  
Division of General Internal Medicine Primary Care  
Residency Director  
Marshall A. Wolf, MD Chair in Primary Care Medical  
Education  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Internal Medicine Summary*

**Bonnie L. Bermas, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of Rheumatology and Allergy-Immunology  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Systemic Lupus Erythematosus and Related Disorders*

**James D. Berry, MD**

Assistant Professor of Neurology  
Harvard Medical School  
Department of Neurology  
Massachusetts General Hospital  
Boston, MA  
*Neurology Summary*

**Tyler M. Berzin, MD, MS, FASGE**

Director, Advanced Therapeutic Endoscopy Fellowship  
Assistant Professor of Medicine  
Harvard Medical School  
Beth Israel Deaconess Medical Center  
Boston, MA  
*Peptic Ulcer Disease*

**Vanesa Bijol, MD**

Assistant Professor of Pathology  
Harvard Medical School  
Department of Pathology  
Brigham and Women's Hospital  
Boston, MA  
*Parenchymal Renal Disease*

**Erin A. Bohula, MD, DPhil**

TIMI Study Group  
Brigham and Women's Hospital  
Harvard Medical School  
Boston, MA  
*Acute Coronary Syndromes*

**Kari P. Braaten, MD**

Instructor in Obstetrics, Gynecology and Reproductive  
Biology  
Harvard Medical School  
Department of Obstetrics and Gynecology  
Brigham and Women's Hospital  
Boston, MA  
*Contraception*

**Jonathan D. Brown, MD**

Assistant Professor  
Vanderbilt School of Medicine  
Cardiovascular Division  
Department of Medicine  
Vanderbilt University Medical Center  
Nashville, TN  
*Cardiovascular Disease Prevention*

**Andrew E. Budson, MD**

Lecturer in Neurology  
Harvard Medical School  
Chief, Cognitive & Behavioral Neurology  
Associate Chief of Staff for Education  
VA Boston Healthcare System  
Professor of Neurology  
Boston University School of Medicine  
Associate Director and Education Core Leader  
Boston University Alzheimer's Disease Center  
Boston, MA  
*Dementia*

**Craig A. Bunnell, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Department of Medical Oncology  
Dana-Farber Cancer Institute  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Oncology Summary*

**Robert Burakoff, MD, MPH**

Vice Chair for Ambulatory Services  
Department of Medicine  
Weill Cornell Medical College  
New York, NY;  
Site Chief  
Division of Gastroenterology and Endoscopy  
New York–Presbyterian Lower Manhattan  
Hospital  
New York, NY;  
Visiting Scientist  
Harvard Medical School  
Boston, MA  
*Diarrhea and Malabsorption*  
*Board Simulation: Gastroenterology*

**Julie E. Buring, ScD**

Professor of Medicine  
Harvard Medical School  
Professor of Epidemiology  
Harvard T.H. Chan School of Public Health  
Division of Preventive Medicine  
Brigham and Women's Hospital  
Boston, MA

*Basic Principles of Epidemiology and Biostatistics*

**Flavia V. Castellino, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Rheumatology Unit  
Department of Medicine  
Massachusetts General Hospital  
Boston, MA

*Acute Monoarticular Arthritis*

**Mariana C. Castells, MD, PhD**

Professor of Medicine  
Harvard Medical School  
Division of Rheumatology, Immunology, and Allergy  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Allergy and Immunology*

**Wendy Y. Chen, MD, MPH**

Assistant Professor of Medicine  
Harvard Medical School  
Department of Medical Oncology  
Dana-Farber Cancer Institute  
Boston, MA

*Breast Cancer*

**Tracey A. Cho, MD**

Associate Professor of Neurology  
Harvard Medical School  
Department of Neurology  
Massachusetts General Hospital  
Boston, MA

*Neurology Summary*

**Sanjiv Chopra, MD**

Professor of Medicine  
Harvard Medical School  
Division of Gastroenterology  
Department of Medicine  
Beth Israel Deaconess Medical Center  
Boston, MA

*Liver Disease*

**Kenneth B. Christopher, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Assistant Program Director, Internal Medicine Residency  
Renal Division  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Approach to the Internal Medicine Board Examination*

**Jody C. Chuang, MD, PhD**

Medical Oncology Fellow  
Division of Oncology  
Stanford University  
Stanford, CA

*Lung Cancer*

**Raymond T. Chung, MD**

Associate Professor of Medicine  
Harvard Medical School  
Liver Center, Division of Gastroenterology  
Department of Medicine  
Massachusetts General Hospital  
Boston, MA

*Liver Disease*

*Cirrhosis*

*Hepatitis B and C*

**Jonathan S. Coblyn, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of Rheumatology, Immunology, and Allergy  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Rheumatoid Arthritis*

*Rheumatology Summary*

**Barbara A. Cockrill, MD**

Harold Amos Academy Associate Professor  
Harvard Medical School  
Pulmonary Vascular Disease Program  
Division of Pulmonary and Critical Care  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Evaluation of the Dyspneic Patient in Primary Care*

**Jean M. Connors, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Hematology  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Venous Thromboembolic Diseases*

**Shinjita Das, MD**

Instructor in Dermatology  
Harvard Medical School  
Department of Dermatology  
Massachusetts General Hospital  
Boston, MA

*Dermatologic Manifestations of Infectious Disease*  
*Dermatology for the Internist*

**Emily Choi DeCroos, MD**

Affiliated Assistant Professor of Neurology  
University of Tennessee College of Medicine  
Neurohospitalist, Erlanger Health System  
Chattanooga, TN

*Neurology Summary*

**Daniel J. DeAngelo, MD, PhD**

Associate Professor of Medicine  
Harvard Medical School  
Department of Medical Oncology  
Dana-Farber Cancer Institute  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Oncologic Emergencies*

**Paul F. Dellaripa, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of Rheumatology, Immunology, and Allergy  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Systemic Vasculitis*

**Bradley M. Denker, MD**

Associate Professor of Medicine  
Harvard Medical School  
Clinical Chief, Renal Division  
Beth Israel Deaconess Medical Center  
Renal Chief, Atrius Health  
Boston, MA

*Acute Kidney Injury*

*Board Simulation: Nephrology and Hypertension*

**Robert G. Dluhy, MD**

Professor of Medicine  
Harvard Medical School  
Division of Endocrinology, Diabetes, and Hypertension  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Adrenal Disorders*

**Benjamin L. Ebert, MD, PhD**

Professor of Medicine  
Harvard Medical School  
Division of Hematology  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Board Simulation: Hematology*

**Joshua A. Englert, MD**

Assistant Professor of Internal Medicine  
Division of Pulmonary, Critical Care, and Sleep Medicine  
The Ohio State University Wexner Medical Center  
Columbus, OH

*Mechanical Ventilation*

*Sepsis Syndrome*

**Lawrence J. Epstein, MD**

Clinical Instructor in Medicine  
Harvard Medical School  
Division of Sleep Medicine  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Sleep Apnea*

**Kenneth R. Falchuk, MD**

Associate Clinical Professor of Medicine  
Harvard Medical School  
Gastroenterology Division  
Department of Medicine  
Beth Israel Deaconess Medical Center  
Boston, MA

*Peptic Ulcer Disease*

**Christopher H. Fanta, MD**

Professor of Medicine  
Harvard Medical School  
Division of Pulmonary and Critical Care Medicine  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Asthma*

*Chest X-Ray Refresher*

*Board Simulation: Pulmonary Medicine*

**Sonia Friedman, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of Gastroenterology, Hepatology, and Endoscopy  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA

*Inflammatory Bowel Disease*

**Jacqueline S. Garcia, MD**

Instructor in Medicine  
 Harvard Medical School  
 Department of Medical Oncology  
 Department of Medicine  
 Dana-Farber Cancer Institute  
 Brigham and Women's Hospital  
 Boston, MA  
*Leukemia*

**Rajesh K. Garg, MD**

Associate Professor of Medicine  
 Harvard Medical School  
 Division of Endocrinology, Diabetes, and Hypertension  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Diabetes Mellitus*  
*Metabolic Syndrome*

**Elizabeth Gay, MD**

Member of the Faculty of Medicine  
 Harvard Medical School  
 Division of Pulmonary and Critical Care Medicine  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Pulmonary and Critical Care Medicine Summary*

**Hilary J. Goldberg, MD, MPH**

Assistant Professor of Medicine  
 Harvard Medical School  
 Division of Pulmonary and Critical Care Medicine  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Interstitial Lung Diseases*

**Norton J. Greenberger, MD**

Professor of Medicine, Part-Time  
 Harvard Medical School  
 Division of Gastroenterology, Hepatology, and Endoscopy  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Gastroenterology Summary*

**Kathleen J. Haley, MD**

Assistant Professor of Medicine  
 Harvard Medical School  
 Division of Pulmonary and Critical Care Medicine  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Essentials of Hemodynamic Monitoring*

**Florencia Halperin, MD**

Instructor in Medicine  
 Harvard Medical School  
 Division of Endocrinology, Diabetes, and Hypertension  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Pituitary Disorders*

**John D. Halporn, MD**

Instructor in Medicine  
 Harvard Medical School  
 Senior Physician  
 Department of Psychosocial Oncology and Palliative Care  
 Dana-Farber Cancer Institute  
 Associate Physician  
 Division of Palliative Medicine  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Palliative Care*

**Sarah P. Hammond, MD**

Assistant Professor of Medicine  
 Harvard Medical School  
 Division of Infectious Diseases  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Board Simulation: Infectious Disease*

**Robert I. Handin, MD**

Professor of Medicine  
 Harvard Medical School  
 Division of Hematology  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Disorders of Platelets and Coagulation*

**Simon Helfgott, MD, CM**

Associate Professor of Medicine  
 Harvard Medical School  
 Division of Rheumatology, Immunology, and Allergy  
 Department of Medicine  
 Brigham and Women's Hospital  
 Boston, MA  
*Common Soft Tissue Pain Syndromes*

**Galen V. Henderson, MD**

Assistant Professor of Medicine  
 Harvard Medical School  
 Department of Neurology  
 Brigham and Women's Hospital  
 Boston, MA  
*Stroke Prevention*

**Christina I. Herold, MD**

Instructor in Medicine  
Harvard Medical School  
Department of Medical Oncology  
Dana-Farber Cancer Institute  
Boston, MA  
*Breast Cancer*

**Li-Li Hsiao, MD, PhD**

Assistant Professor of Medicine  
Harvard Medical School  
Renal Division  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Urinalysis*

**Margo Hudson, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Endocrinology, Diabetes, and Hypertension  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Diabetes Mellitus: Control and Complications*

**Brian Hyett, MD**

Department of Gastroenterology  
Atlanta Digestive Specialists  
Portsmouth, NH  
*Liver Disease*

**Nicolas C. Issa, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Infectious Diseases  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Immunizations*

**Kunal Jajoo, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Gastroenterology, Hepatology, and Endoscopy  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Esophageal Disorders*

**David X. Jin, MD**

Fellow in Gastroenterology, Hepatology, and Endoscopy  
Harvard Medical School  
Division of Gastroenterology, Hepatology, and Endoscopy  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Pancreatic Disease*

**Jennifer A. Johnson, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Infectious Diseases  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*HIV Infection and AIDS*  
*Board Simulation: Infectious Disease*

**Ursula B. Kaiser, MD**

Professor of Medicine  
Harvard Medical School  
Chief, Division of Endocrinology, Diabetes, and Hypertension  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Pituitary Disorders*

**Joel T. Katz, MD**

Associate Professor of Medicine  
Harvard Medical School  
Director, Internal Medicine Residency  
Vice Chair for Medical Education  
Brigham and Women's Hospital  
Boston, MA  
*Pneumonia and Respiratory Infections*

**Shahram Khoshbin, MD**

Associate Professor of Neurology  
Harvard Medical School  
Department of Neurology  
Brigham and Women's Hospital  
Boston, MA  
*Seizure Disorders*

**Matthew Kim, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Endocrinology, Diabetes, and Hypertension  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Thyroid Disease*

**Yuli Y. Kim, MD**

Medical Director, Philadelphia Adult Congenital Heart Center  
Assistant Professor of Medicine  
Perelman School of Medicine at the University of Pennsylvania  
Penn Medicine and the Children's Hospital of Philadelphia  
Philadelphia, PA  
*Adult Congenital Heart Disease*

**Scott Kinlay, PhD, MBBS**

Associate Professor of Medicine  
Harvard Medical School  
VA Boston Healthcare System  
Brigham and Women's Hospital  
Boston, MA  
*Peripheral Vascular Diseases*

**Douglas B. Kirsch, MD, FAAN, FAASM**

Associate Professor  
University of North Carolina School of Medicine  
Medical Director, Sleep Medicine  
Carolinas HealthCare System  
Charlotte, NC  
*Sleep Apnea*

**Michael Klompas, MD, MPH**

Associate Professor of Medicine and Population Medicine  
Harvard Medical School  
Department of Population Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Infectious Disease Summary*

**Daniel R. Kuritzkes, MD**

Professor of Medicine  
Harvard Medical School  
Chief, Division of Infectious Diseases  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*HIV Infection and AIDS*

**Ann S. LaCasce, MD**

Associate Professor of Medicine  
Harvard Medical School  
Department of Medical Oncology  
Dana-Farber Cancer Institute  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Non-Hodgkin and Hodgkin Lymphoma*

**Michael J. Landzberg, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of Cardiovascular Medicine  
Children's Hospital Boston  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Adult Congenital Heart Disease*

**Meryl S. LeBoff, MD**

Professor of Medicine  
Harvard Medical School  
Chief, Calcium and Bone Section  
Director, Skeletal Health and Osteoporosis Center and  
Bone Density Unit  
Distinguished Chair in Skeletal Health and  
Osteoporosis  
Division of Endocrinology, Diabetes, and Hypertension  
Brigham and Women's Hospital  
Boston, MA  
*Metabolic Bone Diseases*

**I-Min Lee, MD, ScD**

Professor of Medicine  
Harvard Medical School  
Professor of Epidemiology  
Harvard T.H. Chan School of Public Health  
Division of Preventive Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Basic Principles of Epidemiology and Biostatistics*

**Eldrin Foster Lewis, MD, MPH**

Associate Professor of Medicine  
Harvard Medical School  
Cardiovascular Medicine Division  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Board Simulation: Cardiology*

**Darrick K. Li, MD, PhD**

Clinical Fellow in Medicine  
Harvard Medical School  
Division of Gastroenterology  
Department of Medicine  
Massachusetts General Hospital  
Boston, MA  
*Hepatitis B and C*

**Leonard S. Lilly, MD**

Professor of Medicine  
Harvard Medical School  
Chief of Cardiology  
Brigham and Women's Faulkner Hospital  
Boston, MA  
*Pericardial Disease*

**Kenneth Lim, MD, PhD**

Research Fellow in Medicine  
Harvard Medical School  
Renal Division  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Urinalysis*

**Joseph Loscalzo, MD, PhD**

Hersey Professor of the Theory and Practice of Physic  
Harvard Medical School  
Chairman, Department of Medicine  
Physician-in-Chief  
Brigham and Women's Hospital  
Boston, MA  
*Cardiac Examination*

**Julie-Aurore Losman, MD**

Assistant Professor of Medicine  
Harvard Medical School  
Department of Medical Oncology  
Dana-Farber Cancer Institute  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Board Simulation: Hematology*

**Ciorsti MacIntyre, MD**

Division of Cardiovascular Medicine  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Arrhythmias*

**James H. Maguire, MD, MPH**

Professor of Medicine  
Harvard Medical School  
Infectious Diseases Division  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Tropical Infections*

**Bradley A. Maron, MD**

Assistant Professor  
Harvard Medical School  
Associate Physician  
Division of Cardiovascular Medicine  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Pulmonary Hypertension*  
*Cardiology: Summary*

**Marie E. McDonnell, MD**

Lecturer in Medicine  
Harvard Medical School  
Director, Brigham and Women's Diabetes Program  
Division of Endocrinology, Diabetes, and Hypertension  
Brigham and Women's Hospital  
Boston, MA  
*Diabetes Mellitus: Control and Complications*

**Sylvia C.W. McKean, MD**

Associate Professor of Medicine  
Harvard Medical School  
Division of General Medicine  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Preoperative Evaluation and Management Before Major Noncardiac Surgery*

**Kathleen E. McKee, MD**

Partners Neurology Fellow in Movement Disorders  
MGPO Torchiana Fellow in Health Policy and Management  
Massachusetts General Hospital  
Brigham and Women's Hospital  
Boston, MA  
*The Neurologic Examination*

**Gearoid M. McMahon, MB, BCh, FASN**

Instructor in Medicine  
Harvard Medical School  
Associate Physician  
Renal Division  
Brigham and Women's Hospital  
Boston, MA  
*Acid-Base Disturbances*

**Julia McNabb-Baltar, MD, MPH**

Instructor in Medicine  
Harvard Medical School  
Division of Gastroenterology, Hepatology, and Endoscopy  
Department of Medicine  
Brigham and Women's Hospital  
Boston, MA  
*Pancreatic Disease*

**Jeffrey A. Meyerhardt, MD, MPH**

Associate Professor of Medicine  
Harvard Medical School  
Dana-Farber Cancer Institute

# Foreword

We are witnessing rapid change in all aspects of internal medicine. Within each specialty there is a deeper understanding of the mechanism of disease, how it should be treated, and the consequences of treatment. This breathtaking progress has been spanned by a course at the Brigham and Women's Hospital and Harvard Medical School that I founded in 1977 titled "The Intensive Review of Internal Medicine." The objectives of the course were to provide an in-depth review of the major areas of internal medicine both for practicing internists and for physicians preparing for the certifying examination for the American Board in Internal Medicine. Of course, more recently, physicians are expected to recertify every 10 years to update their knowledge, and this course serves this purpose as well. Our goal also included correlating pathophysiology with clinical presentation, something that I view as one of our strengths, because at Harvard Medical School we sit at the interface between practice and cutting-edge clinical science. Forty years later, I could hardly have envisioned that the IRIM course, as our course affectionately became known, would still be going strong and that there would be demand for a companion text. Its success has much to do with the outstanding faculty and my successors as chairs in the Department of Medicine, Victor Dzau and Joseph Loscalzo, who have strongly supported it.

The third edition of *The Brigham Intensive Review of Internal Medicine* builds on the success of the first edition.

It is amazing to see how rapidly internal medicine is advancing. This edition is again edited very capably by Drs. Singh and Loscalzo. They have selected outstanding authors, many drawn from the faculty at Harvard Medical School and its affiliated hospitals, in particular the Brigham and Women's Hospital. Each author is an authority in the particular area he or she covers. The book is superbly written and illustrated. It elegantly weaves together the many separate strands of internal medicine to provide a thorough understanding of the field. The editors have skillfully incorporated over 500 board-simulated questions and their answers into the book so that it is a "must have" for anyone preparing for board certification or recertification in internal medicine. In addition, the book will be a valuable resource for physicians who are in training and for practicing clinicians alike.

I am, therefore, very pleased to welcome the third edition of *The Brigham Intensive Review of Internal Medicine* and anticipate that this text will become the standard in internal medicine board review.

#### **Eugene Braunwald, MD**

Eugene Braunwald, MD, is the Distinguished Hersey Professor of Medicine at Harvard Medical School and Founding Chairman of the TIMI Study Group at the Brigham and Women's Hospital.

# Preface

Passing the boards for many readers of this book represents a “rite of passage.” In Lakota Sioux culture, *hembleciya* (ham-blai-che-ya) represents a Native American rite of passage. The word *hembleciya* translates to “crying for a dream.” The ceremony is frequently referred to as “going up on the hill,” because people often go to a nearby mountain for their rite of passage.

The certification by the American Board of Internal Medicine (ABIM), which was established in 1936, has become a rite of passage and is a “going up the hill” of sorts since years are spent acquiring knowledge, skill, and professionalism to achieve this goal. For many, however, preparing for the examination itself is a hard slog. Still, the many hours attending one or more courses tailored toward the boards and reading thick books like this one are worth the effort because of the validation ABIM certification provides. We

hope that this book continues to make a useful contribution in this endeavor.

Our book, now in its third edition, has been thoroughly updated, and new material has been added. Faculties from across Harvard Medical School have again participated, and we owe our deepest gratitude to them. A debt of gratitude and many thanks are also owed to Joan Ryan at Elsevier and to Michelle Deraney and Stephanie Tran at the Brigham and Women’s Hospital. Our understanding families remain, of course, our most steadfast supporters.

We hope that using this book to navigate the boards successfully is not where learning ends but, like the Native American ritual of *hembleciya*, represents a cry for a dream—one of lifelong learning.

**Ajay K. Singh, MBBS, FRCP, MBA**  
**Joseph Loscalzo, MD, PhD**

# Contents

## Section 1: Infectious Disease 1

# Pneumonia and Respiratory Infections

MARY W. MONTGOMERY AND JOEL T. KATZ

Respiratory symptoms are among the most frequent reasons for patients to seek medical attention. Seventy percent of patients presenting with a new cough will be diagnosed with acute bronchitis. Other common causes of a new cough include pneumonia, cough-variant asthma, congestive heart failure, postnasal drip, rhinosinusitis, and aspiration of oral contents. Among patients presenting to their primary care provider with a cough, clinical predictors of the 10% to 15% who will have pneumonia are advanced patient age (odds ratio [OR] 4.6), shortness of breath (2.4), fever (5.5), tachycardia (3.8), and localizing chest auscultation findings such as focal respiratory crackles (23.8) or rhonchi (14.6). The etiology, treatment, and prognosis of upper and lower respiratory tract infections are highly varied and are reviewed in this chapter.

## Acute Bronchitis

Acute bronchitis (AB) is a common seasonal (winter peak) infection of the upper respiratory tract that is generally viral in origin and does not require antibiotic therapy. The incidence of AB is 30 to 170 cases per 1000 persons per year. The most common causes are rhinoviruses, respiratory syncytial virus, influenza, parainfluenza, and adenovirus. These are highly contagious pathogens that spread rapidly through exposure to respiratory secretions or indirectly through shared environmental fomites. AB is generally a self-limited condition that lasts no more than 1 to 2 weeks. Over half the patients have purulent sputum, which is caused by sloughing of the tracheobronchial epithelial cells and is not indicative of a bacterial infection. When symptoms last more than 2 weeks, one should consider “atypical” bacteria, such as *Bordetella pertussis* or *Mycoplasma pneumoniae* infections, or alternative diagnoses such as postnasal drip syndrome from conditions of the nose and sinuses, asthma, gastroesophageal reflux disease, chronic bronchitis caused by cigarette smoking or other irritants, bronchiectasis, eosinophilic bronchitis, or the use of an angiotensin-converting enzyme inhibitor. At least nine randomized trials and a number of subsequent metaanalyses have addressed the benefit of antibiotics in AB. There is modest or no benefit to prescribing antibiotics in AB, and this must be weighed against the significant cost and adverse consequences of these medications.

Overtreatment of AB leads directly to increasing rates of antimicrobial resistance in the general population. Each year in the United States there are over 2 million illnesses and 23,000 deaths related to antibiotic resistant infections, which result in medical costs in excess of \$30 billion.

A small subset of patients with AB merit treatment, including those with episodes that occur during documented *B. pertussis* outbreaks or individuals with underlying lung disease (chronic obstructive pulmonary disease, asthma, or heavy tobacco use). The incidence of pertussis (whooping cough) and a clinically indistinguishable parapertussis have risen recently in the United States. In such settings, a second-generation macrolide, such as azithromycin or clarithromycin, is the ideal agent.

## Community-Acquired Pneumonia

Despite major advances in understanding its pathophysiology and management over the century since Sir William Osler declared it the “[c]aptain of the men of death,” pneumonia remains the leading infectious cause of death in the United States and in the world. Three major incremental reductions in community-acquired pneumonia (CAP) mortality have resulted from the introduction of antipneumococcal serum therapy (discovered in 1895, widely adopted by the 1920s), antibiotics (discovered in 1928, widely adopted by the 1940s), and mechanical ventilation (discovered in 1952, widely adopted in the 1960s). Pneumococcal vaccination has added only marginal survival benefit compared with these other advances. Annually, about 4 million cases of CAP are reported in the United States (approximately 6 cases per 1000 persons per year), leading to 1 million hospitalizations and 45,000 to 50,000 deaths. Mortality in all hospitalized patients with CAP ranges from 2% to 30%, and those patients who are assigned to the intensive care unit (ICU) for their initial care have a mortality as high as 40%. In contrast, mortality in outpatients ranges from <1% to 3%.

CAP is defined as an acute infection of the lung parenchyma accompanied by a new infiltrate on chest radiography or compatible auscultatory findings in a patient who is not hospitalized or living in a long-term facility for at least 2 weeks before the onset of symptoms. CAP symptoms

usually include at least two of the following features: fever or hypothermia, sweats, rigors, pleurisy, and new cough with or without sputum production or change in color of respiratory secretions. The absence of mucoid sputum production is associated with “atypical” pathogens (*M. pneumoniae*, *Chlamydia pneumoniae*, *Legionella* species, *B. pertussis*).

As was the case in Osler’s day, *Streptococcus pneumoniae* is still a leading identifiable cause of CAP although the incidence has declined likely in part because of pneumococcal vaccination (Table 1.1). “Atypical” pathogens are increasingly recognized as the cause of both outpatient and inpatient CAP, and these pathogens should be covered with empiric antibiotics in all cases. In clinical practice, the etiologic cause of CAP is not identified in most cases. One review of over 17,000 cases of CAP admitted to the hospital identified the pathogen in less than 10% of cases (see Barlett, 2011). Recent studies using specialized tests including broad range polymerase chain reaction (PCR) assays to detect pathogens increase the rate of microbiologic diagnosis to 38% to 87% of patients. In these studies, viruses were the most frequently detected pathogens and were found in approximately one-third of cases. The high rate of culture-negative CAP may be attributed to antibiotic pretreatment, inability to produce sputum for analysis, viral causes, or emerging pathogens that remain to be elucidated.

Epidemiologic clues can also help to determine less frequent causes of pneumonia, such as *Mycobacterium tuberculosis*, *Coxiella burnetii*, and endemic fungi (*Coccidioides* species, *Histoplasma capsulatum*, and *Blastomyces dermatitidis*) (see Table 1.5).

In the appropriate clinical situation, the diagnosis of CAP is established by demonstration of focal pulmonary findings, either by lung auscultation or by chest radiograph. Chest radiographs should be done in all patients with suspected CAP, because this test is useful in excluding complications (e.g., pleural effusions) and because associated findings may predict the pathogen (e.g., lymphadenopathy) or suggest alternative diagnoses (e.g., lung mass, lung abscess). When examined in a blinded fashion, the radiographic pattern does not reliably differentiate specific pathogens. This is particularly true among the elderly and immunocompromised patients, who may have unusual or no infiltrate in the setting of CAP. Radiographic improvement lags behind clinical response, and routine serial chest radiographs are not recommended unless the patient is not improving; however, all tobacco smokers and patients over the age of 65 years should have follow-up chest radiographs 3 to 6 months after an episode of pneumonia to exclude an underlying malignancy.

There are limited data to guide when patients should have a thorough microbiologic evaluation for the etiologic agent. It is currently advised when patients are immunocompromised, are admitted to the hospital or ICU, or have failed recent treatment. Hospitalized patients should have at least blood cultures and sputum Gram stain and culture. Any patients requiring an ICU admission will also require further diagnostic testing including *Legionella* and pneumococcus urinary antigen tests and multiplex PCR testing if available. If an etiologic agent is not discovered or there is clinical worsening, then many patients with

Modified from Marrie TJ, Poulin-Costello M, Beecroft MD, et al. Etiology of community-acquired pneumonia treated in an ambulatory setting. *Respir Med.* 2005;99:60–65; Cillóniz C, Ewig S, Polverino E, et al. Microbial aetiology of community-acquired pneumonia and its relation to severity. *Thorax* 2011;66:340–346; and Restrepo MI, Mortensen EM, Velez JA, et al. A comparative study of community-acquired pneumonia patients admitted to the ward and the ICU. *Chest* 2008;133:610–617.

severe pneumonia will undergo a bronchoalveolar lavage, which can be sent for bacterial, fungal, mycobacterial, and viral testing.

Various risk-stratification methods have been developed and validated to predict which patients are at sufficiently low mortality risk to justify home therapy, which costs 20-fold less than an inpatient stay. The easy-to-use CURB-65 risk score can be calculated based on five simple features, including the presence of confusion (1 point), blood urea nitrogen >30 mg/dL (1 point), respiratory rate  $\geq$ 30 breaths per minute (1 point), systolic blood pressure <90 mm Hg or diastolic blood pressure <60 mm Hg (1 point), and patient age 65 years or older (1 point). The risk of death or ICU admission increases with increasing CURB-65 scores (Table 1.2).

The pneumonia severity index is a validated risk stratification method that considers the risk contributions of patient demographic features (age having the greatest influence) and key physical examination and laboratory findings (Table 1.3). Of note, other than a measurement of arterial oxygenation, all laboratory testing is left up to the discretion of the health care provider. Patients in risk class I or II can be safely cared for at home. Risk class III can generally be cared for at home, but an inpatient observation is reasonable. Patients in risk classes IV and V should be admitted to the hospital (Table 1.4). All CAP patients with unexplained or a high degree of hypoxemia should be admitted to the hospital. Clinical judgment should supersede the recommendations of clinical prediction rules.

Key principles of pharmacotherapy for CAP include the following: (1) once the diagnosis is established, delays in administering antibiotics are associated with increased mortality; (2) all patients with CAP should be covered for “atypical” pathogens; and (3) recent antibiotic exposure should be considered when choosing empiric antibiotics. Clinicians should seek specific environmental exposures that may suggest an unusual pathogen (Table 1.5).

**TABLE 1.4 Pneumonia Severity Index Risk Classification and Recommendation**

Class	Points	Mortality (%)	Recommendation <sup>a</sup>
I	<sup>b</sup>	0.1	Home antibiotics
II	<70	0.6	Home antibiotics
III	71–90	0.9	Consider short hospitalization
IV	91–130	9.3	Hospitalize
V	>130	27	Hospitalize

<sup>a</sup>If the patient can be cared for at home (social).

<sup>b</sup>Risk class I requires age <50 years, lacking pneumonia severity index comorbidities and abnormal vital signs (see Table 1.3).

From Fine MJ, Auble TE, Yealy DM, et al. A prediction rule to identify low-risk patients with community-acquired pneumonia. *N Engl J Med*. 1997;336:243–250.

recommendations is given in Table 1.6. Once a specific organism has been identified, antibiotics should be narrowed to cover this agent with the least overlap in spectrum and additional cost. Treatment duration is on average 5 to 7 days, although a longer duration is recommended for pneumonia caused by certain pathogens including *Staphylococcus aureus*, *Legionella* species, and *Pseudomonas aeruginosa*. The IDSA guidelines recommend switching patients from intravenous to oral therapy when they are clinically improving, hemodynamically stable, and able to take and absorb oral medications. Antibiotics should then be stopped once patients have been clinically stable for 48 hours. Clinical stability is defined as a temperature  $\leq 37.8^{\circ}\text{C}$ , heart rate  $\leq 100$  beats per minute, respiratory rate  $\leq 24$  breaths per minute, systolic blood pressure  $\geq 90$  mm Hg, and arterial oxygen saturation  $\geq 90\%$  on  $\text{pO}_2$  on room air. Chest radiography is not used to define treatment duration because the radiographic resolution of pneumonia lags behind clinical improvement.

Most patients with pneumonia will improve in 3 to 5 days after starting treatment. A nonresolving pneumonia can be caused by an atypical pathogen that was not covered

by the standard therapy (i.e., *M. tuberculosis*, *Coccidioidomycosis*), an antibiotic resistant organism, the development of a loculated infection such as an empyema, an underlying malignancy, or a noninfectious cause such as cryptogenic organizing pneumonia. Certain factors have been identified that increase the overall risk of not responding to antibiotics. The risk factors include liver disease, leukopenia, and the presence of pleural effusions, multilobar infiltrates, or cavitations on chest imaging. The risk factors for *S. pneumoniae* drug resistance are listed in Table 1.7. Further imaging and microbiologic analyses are required for all patients with persistent or worsening symptoms after antibiotic therapy.

Increasingly, health care providers and facilities are being graded publicly on prespecified performance and outcome measures for certain diseases. The current Centers for Medicare and Medicaid Services performance measure for CAP is the use of a guideline-compliant antibiotic. The two outcome measures are 30-day mortality and 30-day readmission rate.

Finally, several vaccines are available for the prevention of *S. pneumoniae* and influenza virus infections. Every fall, all patients should be offered the influenza

**TABLE 1.5** Epidemiologic Conditions Related to Specific Pathogens in Patients With Selected Community-Acquired Pneumonia

Condition	Commonly Encountered Pathogen(s)
Alcoholism	<i>Streptococcus pneumoniae</i> and anaerobes
COPD and/or smoking	<i>S. pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> , and <i>Legionella</i> species
Nursing home residency	<i>S. pneumoniae</i> , gram-negative bacilli, <i>H. influenzae</i> , <i>Staphylococcus aureus</i> , anaerobes, and <i>Chlamydia pneumoniae</i>
Poor dental hygiene	Anaerobes
Epidemic legionnaires disease	<i>Legionella</i> species
Exposure to bats or soil enriched with bird droppings	<i>Histoplasma capsulatum</i>
Exposure to birds	<i>Chlamydia psittaci</i>
Exposure to rabbits	<i>Francisella tularensis</i>
HIV infection (early stage)	<i>S. pneumoniae</i> , <i>H. influenzae</i> , and <i>Mycobacterium tuberculosis</i>
HIV infection (late stage)	Above plus <i>Pneumocystis jiroveci</i> , <i>Cryptococcus</i> , and <i>Histoplasma</i> species
Travel to southwestern United States	<i>Coccidioides</i> species
Exposure to farm animals or parturient cats	<i>Coxiella burnetii</i> (Q fever)
Influenza active in community	Influenza, <i>S. pneumoniae</i> , <i>S. aureus</i> , <i>Streptococcus pyogenes</i> , and <i>H. influenzae</i>
Suspected large-volume aspiration	Anaerobes (chemical pneumonitis, obstruction)
Structural disease of lung (bronchiectasis, cystic fibrosis, etc.)	<i>Pseudomonas aeruginosa</i> , <i>Burkholderia (Pseudomonas) cepacia</i> , and <i>S. aureus</i>
Injection drug use	<i>S. aureus</i> , anaerobes, <i>M. tuberculosis</i> , and <i>S. pneumoniae</i>
Airway obstruction	Anaerobes, <i>S. pneumoniae</i> , <i>H. influenzae</i> , and <i>S. aureus</i>
From TB endemic part of world, history of incarceration or homeless	<i>M. tuberculosis</i>

COPD, Chronic obstructive pulmonary disease; HIV, human immunodeficiency virus; TB, tuberculosis.

**TABLE 1.6 Infectious Diseases Society of America/American Thoracic Society Treatment Guidelines for Community-Acquired Pneumonia**

Initial Triage	Treatment
Outpatients	Macrolides or doxycycline Fluoroquinolones may be preferred for older patients or in individuals with underlying chronic illnesses (heart, liver, renal, diabetes, alcoholism, malignancy, immunosuppressive medications) In general, avoid antibiotic classes that have been administered in the past 3 months
Hospitalized (general medical ward)	Extended-spectrum cephalosporin or beta-lactam/beta-lactamase inhibitor plus a macrolide; or fluoroquinolone (alone)
Hospitalized (ICU)	Extended-spectrum cephalosporin or a beta-lactam/beta-lactamase inhibitor plus either a macrolide or fluoroquinolone
Special considerations Individuals with structural lung disease	Antipseudomonal agents (piperacillin, piperacillin tazobactam, carbapenem, or cefepime) plus a fluoroquinolone
Beta-lactam allergy	Fluoroquinolone +/- clindamycin
Suspected community-associated MRSA	Add vancomycin or linezolid
Suspected aspiration	Fluoroquinolone +/- clindamycin, metronidazole, or a beta-lactam/beta lactamase inhibitor

*ICU*, Intensive care unit; *MRSA*, methicillin-resistant *Staphylococcus aureus*.  
From Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis*. 2007;44:S27–S72. vaccination. As of 2014, the Advisory Committee on Immunization Practices (ACIP) recommends all adults ≥65 years of age should receive the pneumococcal conjugate vaccine (PCV13) followed by the pneumococcal polysaccharide vaccine (PCV23). The ACIP also recommends PCV13 and PCV23 for patients with a cerebrospinal fluid leak, a cochlear implant, functional or anatomic asplenia, or an underlying immunodeficiency such as HIV or cancer. One adult pertussis vaccine dose (Tdap) is recommended by the Centers for Disease Control and Prevention for all adults, effective 2013. Hospitalization for other problems should not be overlooked as an opportunity to protect unvaccinated patients by administering these vaccines.

## Chapter Review

### Questions

1. A 45-year-old woman with hypertension and hyperlipidemia presents to an urgent care clinic with 10 days of fatigue and a productive cough with green sputum. On physical examination, she is afebrile with a respiratory rate of 12 breaths per minute and an oxygen saturation of 99% on room air. Auscultation of her lungs reveals few scattered wheezes bilaterally. Which of the following is the appropriate treatment of this patient?
  - A. Prescribe azithromycin
  - B. Prescribe amoxicillin-clavulanic acid
  - C. Withhold antibiotics at this time
  - D. Prescribe levofloxacin
2. A 63-year-old man with well-controlled diabetes, hypertension, and obesity presents to a clinic with 6 days of fevers, a productive cough, pleuritic chest pain, and dyspnea. On physical examination, he has a fever of 101.9°F, heart rate 99 beats per minute, blood pressure 140/80 mm Hg, respiratory rate 18 breaths per minute, and oxygen saturation 96% on room air. On lung examination, crackles are heard in the right lung base. Basic laboratory testing reveals normal electrolytes, creatinine, and liver function tests. The white blood cell count is elevated to 14,000 cells per microliter with a neutrophilic predominance. The hematocrit and platelets are normal. Chest x-ray reveals a right lower lobe

infiltrate with no pleural effusion. Should this patient be admitted to the hospital?

- A. Yes
  - B. No
  - C. Depends on the arterial blood gas result
  - D. Need more information
3. A 28-year-old male presents to the emergency room with fever, shortness of breath, and a dry cough. In the past 6 months he has lost 20 lbs of weight. His past medical history is significant for syphilis, which was treated with intramuscular penicillin 2 years ago. He has had multiple sexual partners and rarely uses protection. On physical examination, he is cachectic and chronically ill appearing. Temperature is 101°F, heart rate 100 beats per minute, blood pressure 100/60 mm Hg, respiratory rate 26 breaths per minute, and oxygen saturation 92% on room air and 83% with ambulation. He has multiple white plaques on his tongue and upper palate. Lung examination reveals bilateral and diffuse crackles. Chest radiography demonstrates diffuse interstitial infiltrates. A rapid screen for HIV is positive. What is the most likely pathogen causing his pneumonia?
- A. *Chlamydia psittaci*
  - B. *Streptococcus pneumoniae*
  - C. *Pneumocystis jiroveci*
  - D. *Coccidioides* species

4. An 82-year-old woman is brought by ambulance to the emergency room because of fever, a cough, and worsening confusion. She has known dementia, osteoporosis, and giant cell arteritis treated with 10 mg of prednisone daily. She also has frequent urinary tract infections treated with antibiotics. She resides in a nursing home. On physical examination, she has a fever of 102°F, heart rate 120 beats per minute, blood pressure 90/60 mm Hg, respiratory rate 26 breaths per minute, and oxygen saturation 92% on room air. Lung examination reveals crackles in the left lower lobe, and egophony is noted. Serum electrolytes, creatinine, liver function tests, complete blood count, blood cultures, and sputum Gram stain and culture are sent and are pending. Which empiric antibiotic regimen would be appropriate to start at this time?
- A. Azithromycin
  - B. Vancomycin + cefepime + levofloxacin
  - C. Clindamycin
  - D. Doxycycline

#### Answers

## HIV Infection and AIDS

JENNIFER A. JOHNSON AND DANIEL R. KURITZKES

According to the Centers for Disease Control and Prevention (CDC), more than 1.2 million persons with HIV infection were estimated to be living in the United States by 2012, 13% of whom were unaware of their HIV diagnosis. Internists often provide medical care both to patients with as-yet undiagnosed HIV infection and to those with known infection. Without appropriate treatment, patients may develop a variety of potentially fatal infectious and noninfectious complications of HIV infection. Through early diagnosis and prompt initiation of antiretroviral therapy (ART), patients with HIV can live long and healthy lives, with life expectancy approaching that of the general population. Early diagnosis and appropriate management of patients with HIV is also an important public health measure because those with known HIV infection can take highly effective measures to avoid transmitting the virus to others. In recent years, our resources for HIV prevention have expanded significantly; many of these tools are best implemented by internists in primary care and other settings.

### History and Epidemiology

HIV and AIDS first entered public consciousness with the CDC's *Morbidity and Mortality Weekly Report* (MMWR) published on June 5, 1981, discussing five cases of *Pneumocystis carinii* (now known as *P. jiroveci*) pneumonia (PCP) among previously healthy gay men living in Los Angeles.

By the late 1980s it appeared that the initial education efforts and activism focusing on disease awareness among men who have sex with men (MSM) were having an appreciable impact on curbing AIDS incidence within this high-risk group. By the end of the 1990s, however, the trend toward decreasing incidence among MSM had reversed and has since been rising steadily.

In 2014 there were more than 44,000 new HIV diagnoses in the United States; approximately 67% of these were among MSM. Incidence among MSM is uneven by race/ethnicity. HIV incidence declined significantly from 2005 to 2014 in most risk groups, except among African-American MSM; new diagnoses among African-American MSM have increased 22% over the past decade. Only 24% of new infections in 2014 were attributed to heterosexual contact

and only 6% to injection drug use. Among other risk groups incidence is also uneven by race/ethnicity. There were more than four times more new HIV infections among African-American women than among white women in 2014. Hispanic/Latina men and women are also disproportionately affected by HIV.

### Signs and Symptoms

Primary HIV infection typically presents as a mononucleosis-like syndrome with nonspecific symptoms that can be confused for many other infections. In one series, approximately 75% of persons acutely infected with HIV experienced symptoms attributable to an acute retroviral syndrome. Symptoms can occur from a few days to 10 weeks after exposure. The severity of the illness can range from a mild flu-like illness that resolves promptly to a severe multisystem disease requiring hospitalization. The most common symptoms of acute HIV infection include fever, maculopapular rash, mucocutaneous ulcers, lymphadenopathy, arthralgias, pharyngitis, malaise, weight loss, aseptic meningitis, and myalgias (Table 2.1). The symptoms of fever, rash (especially in combination), oral ulcers, and pharyngitis are highly predictive for the diagnosis of acute HIV infection.

Because of a precipitous drop in CD4 lymphocytes that may occur during acute HIV infection, some individuals can present during this phase with opportunistic infections, such as PCP or thrush.

After the acute retroviral syndrome resolves, patients may be asymptomatic during a plateau period in the infection, which can last for years. Later symptoms vary depending on disease stage and the degree of immunologic dysfunction. Table 2.2 lists AIDS-defining clinical conditions associated with significant immune suppression.

Conditions commonly seen by internists in the outpatient setting that are not AIDS-defining but should prompt consideration of HIV testing include herpes zoster virus reactivation (shingles), seborrheic dermatitis, thrush, and recurrent vaginal candidiasis; all occur commonly in those without HIV infection but with higher incidence and increased severity among patients with HIV. Any new testing, diagnosis, or treatment of other sexually transmitted

infections (genital herpes simplex, syphilis, gonorrhea, chlamydia) should also prompt HIV testing given mutual risk factors. Tuberculosis can present in HIV-infected individuals even with a relatively high CD4 count, and all persons diagnosed with tuberculosis should be tested for HIV. Many HIV-infected persons will be asymptomatic, however, underscoring the need for routine screening.

**TABLE 2.1 Signs and Symptoms of Acute HIV Retroviral Syndrome**

Sign/Symptom	Frequency (in 209 Cases)
Fever	96%
Adenopathy	74%
Pharyngitis	70%
Rash	70%
Myalgia/arthralgia	54%
Thrombocytopenia	45%
Leukopenia	38%
Diarrhea	32%
Headache	32%
Nausea/vomiting	27%
Transaminitis	~20%
Thrush	12%
Neuropathy	6%
Encephalitis/meningitis	6%

Modified from Niu MT, Stein DS, Schnittman SM. Primary human immunodeficiency virus type 1 infection: review of pathogenesis and early treatment intervention in humans and animal retrovirus infections. *J Infect Dis.* 1993;168(6):1490-1501.

## Establishing the Diagnosis

The CDC guidelines for HIV testing published in the September 2006 MMWR recommend one-time routine opt-out testing for patients age 13 to 64 years in all health care settings unless the patient declines. CDC guidelines also recommend annual testing among those who engage in high-risk behavior. It is important to recognize that the notion of high-risk groups has been replaced by that of high-risk behavior and that many people who engage in high-risk behaviors do not disclose these behaviors. A study of MSM in New York City found that about 40% of those engaging in high-risk behaviors had not disclosed attraction to or having had sex with men to their health care providers.

In 2014 the CDC updated their guidelines for HIV diagnostic testing. Current guidelines recommend initial testing with a US Food and Drug Administration (FDA)-approved antigen/antibody combination (fourth generation) immunoassay that detects HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen to screen for established infection with HIV-1 or HIV-2. The inclusion of the p24 antigen capture allows for diagnosis before seroconversion, shortening the “window” period (recent infection but negative serology) to approximately 10 to 13 days after the appearance of viral RNA (Fig. 2.1). Samples that are non-reactive on initial screening immunoassay are determined to be negative. Samples that are reactive on initial screen undergo differentiation HIV-1/HIV-2 antibody immunoassay, and subsequently HIV-1 nucleic acid testing if necessary to confirm. This new testing algorithm provides the most sensitive and specific HIV testing, detects HIV infection earlier than previous algorithms and resolves some of the confusion with indeterminate HIV-1 Western blot results. Although this testing algorithm shortens the

**TABLE 2.2 AIDS-Defining Conditions in HIV-Infected Persons**

Infectious	Oncologic	Other
Candidiasis of bronchi, trachea, lungs, esophagus	Cervical cancer, invasive	Encephalopathy, HIV-related
Coccidioidomycosis, disseminated or extrapulmonary	Kaposi sarcoma	HIV-attributed wasting syndrome
Cryptococcosis, extrapulmonary	Lymphoma, Burkitt (or equivalent)	
Cryptosporidiosis, chronic intestinal	Lymphoma, immunoblastic (or equivalent)

window period, some patients with acute retroviral syndrome may still have negative serology even with the combination antigen/antibody immunoassay. A high suspicion for acute HIV infection based on signs and symptoms should prompt HIV-1 RNA polymerase chain reaction (viral load) testing concurrent with the antigen/antibody combination immunoassay.

The CDC no longer recommends use of the previous HIV testing algorithm of initial screening for HIV-1/HIV-2 antibody by enzyme-linked immunosorbent assay (ELISA) followed by confirmatory Western blot assay for those with reactive ELISA, although this may be the only serologic test available at some practice sites.

Rapid HIV testing can be performed on both blood specimens and oral secretions. A negative test carries the same implications as a negative ELISA; a positive rapid test must be confirmed with standard serologic testing, preferably by the recommended combination antigen/antibody immunoassay.

Rapid testing has been associated with a relatively high number of false-positive results when performed in low-prevalence settings. Hence reactive results should be communicated as “preliminary” or “inconclusive” with a need for confirmatory testing. Despite this drawback, rapid

point-of-care HIV testing may be advantageous in some patient care settings.

The CDC recommends opt-out HIV screening as a part of the routine panel of prenatal screening tests for all pregnant women without a special written consent being required. Repeat screening in the third trimester should be performed in geographic areas with an elevated HIV incidence.

### Initial Evaluation

The initial evaluation of an individual with HIV infection should consist of a complete history including a detailed social history, physical examination, and laboratory evaluation. In addition to making the diagnosis, the stage of HIV illness should be determined, and the presence of other possible concurrent infections should be determined.

Initial laboratory evaluation should include HIV antigen/antibody testing (if the original laboratory test is not available for review), CD4 count, plasma HIV RNA (viral load), and genotypic HIV resistance testing. Basic blood work including complete blood count with differential, chemistry, and liver function tests should be obtained. Fasting glucose and fasting lipid panel are also recommended

Note. Units for vertical axis are not noted because their magnitude differs for RNA, p24 antigen, and antibody.

• **Fig. 2.1** Laboratory testing for HIV infection. (Modified from Centers for Disease Control and Prevention and Association of Public Health Laboratories. Laboratory testing for the diagnosis of HIV infection: updated recommendations. <http://dx.doi.org/10.15620/cdc.23447>; June 27, 2014.)

at baseline. A urinalysis should be obtained (to evaluate for HIV-associated nephropathy).

Initial evaluation should also include screening tests for syphilis (by treponemal test if available), toxoplasmosis IgG, cytomegalovirus IgG, and viral hepatitis serologies (hepatitis A antibody, hepatitis B surface antigen and antibody, hepatitis B core antibody, and hepatitis C antibody). In addition, a tuberculin skin test (TST) or interferon- $\gamma$  release assay (IGRA) (unless there is a history of prior tuberculosis or positive TST or IGRA) should be obtained. If a TST is performed when the patient's CD4 is  $<200$  cells/mm<sup>3</sup>, it should be repeated when the CD4 rises to  $>200$  cells/mm<sup>3</sup> after initiation of ART. If the TST or IGRA is positive or there are pulmonary symptoms, a chest x-ray (CXR) should be obtained. Women should undergo a Papanicolaou (Pap) smear, and one should consider baseline testing for gonorrhea and chlamydia. Although there are no formal CDC recommendations for performing annual anal Pap smears for MSM, many experts in the field support this practice. New York State has issued formal guidelines for anal dysplasia screening that include baseline and annual anal Pap smear testing for HIV-positive MSM and women, and high-resolution anoscopy for patients with evidence of dysplasia on Pap smear.

Many factors can powerfully affect the outcome of treatment by influencing adherence and access to care, including substance use, mental illness, social support, economic stressors, ongoing high-risk behaviors, and family-planning issues; all should be assessed during initial evaluation and regularly during care. Given the stigma that still surrounds the diagnosis of HIV, it is important to discuss disclosure and family support with patients with newly diagnosed HIV. Education about HIV risk behaviors and prevention of HIV transmission to others should be provided initially and then subsequently at each patient visit.

## Initiation of Therapy

Mounting evidence of the benefits of early initiation of ART from multiple large clinical trials has led to the most recent the Department of Health and Human Services (DHHS) recommendations for timing of initiation of ART. Since 2012 the DHHS guidelines in HIV-infected adults and adolescents have recommended initiation of ART for all persons with HIV infection, regardless of CD4 count. Early initiation of ART has been shown to decrease morbidity and mortality for persons with HIV infection. Recently two large clinical trials, START (Strategic Timing of Antiretroviral Therapy) and TEMPRANO, documented a significant decrease in morbidity and mortality with immediate initiation of ART even at CD4 cell count  $\geq 500$  cells/mm<sup>3</sup>. In addition, ART for persons with HIV infection effectively prevents transmission of infection to others. Prior concerns about long-term toxicities of ART and potential for drug resistance have diminished with newer less-toxic antiretroviral agents, coformulated tablets with increased ease of dosing, and medications with high barriers to drug resistance.

Currently, the benefits of early ART clearly outweigh any potential risks. In 2016 the World Health Organization updated its HIV treatment guidelines and now also recommends initiation of ART for all persons with HIV infection regardless of CD4 count or stage of HIV infection.

ART is most successful as continuous lifelong treatment, so adherence is essential. Deferred initiation of ART may be considered on a case-by-case basis if clinical or psychosocial factors warrant management before initiation. Conversely, ART should be initiated urgently for persons with opportunistic infections, pregnancy, coinfections with hepatitis B or C, HIV neurocognitive disorders, or HIV nephropathy.

## Hepatitis Coinfection

Those at risk for HIV infection are also at risk for other chronic infections with similar modes of transmission. Coinfections of particular clinical interest in the HIV-infected person include hepatitis B virus (HBV), hepatitis C virus (HCV), and syphilis.

Chronic HBV infection develops more frequently in HIV-coinfected patients than in those with HBV alone. Although HIV infection affects the natural course of HBV infection, HBV coinfection does not appear to have an effect on CD4 depletion or progression to AIDS. Many agents used to treat HBV are also active against HIV. Treating only HBV may lead to drug-resistant HIV. For this reason, coinfecting patients requiring treatment for HBV should be started on a standard ART regimen that includes two agents active against both HIV and HBV (such as tenofovir and emtricitabine [FTC]).

HIV and HCV coinfection can accelerate the clinical course of both infections. Immunologic decline from HIV may be more rapid, and HCV RNA levels are increased in these patients; patients with HIV and HCV are more likely to develop cirrhosis or decompensated liver disease. Previously, management of chronic HCV infection with interferon-based therapy was difficult and often unsuccessful. However, current treatments with directly acting agents for chronic HCV are well tolerated and result in cure of HCV in  $>90\%$  to  $95\%$  of cases.

## Regimens for Initial Antiretroviral Therapy

Preferred initial ART consists of a three-drug regimen: two nucleos(t)ide reverse transcriptase inhibitors (NRTIs) and a third drug from one of two classes: an integrase strand transfer inhibitor (INSTI) or a protease inhibitor (PI) combined with a pharmacokinetic booster (either ritonavir [RTV] or cobicistat). Regimens that include a nonnucleoside reverse transcriptase inhibitor (NNRTI) may be considered as an alternative. All of the preferred regimens for initial ART are dosed once daily, and many are available as coformulated single-tablet once-daily regimens. Medication regimens with low pill burden and low dosing frequency have been associated with increased medication adherence, decreased pharmacy costs, and decreased rates of complications including

hospitalizations. Other regimen options may be appropriate on a case-by-case basis. The preferred and alternative regimens for initial ART are outlined in [Box 2.1](#). The recommended regimens for initial ART are updated frequently; updated guidelines and additional information regarding ART for special populations (including children and pregnant women) are available at <http://aidsinfo.nih.gov>.

## Nucleos(t)ide Reverse Transcriptase Inhibitors

All preferred and alternative initial ART regimens include either tenofovir with FTC or abacavir (ABC) with lamivudine (3TC). Tenofovir disoproxil fumarate (TDF) can cause renal dysfunction and bone demineralization. The recent advent of tenofovir alafenamide (TAF), which offers the same antiviral efficacy as TDF with lower risk of nephrotoxicity and bone demineralization, has led to expanded recommendations for initial ART. Both TDF and TAF

### • BOX 2.1 Preferred and Alternative Regimens for Initial Antiretroviral Therapy

#### Preferred Initial Antiretroviral Therapy Regimens

##### INSTI-Based Regimens

- Dolutegravir/abacavir/lamivudine<sup>a</sup>
- Dolutegravir plus tenofovir alafenamide/emtricitabine or tenofovir disoproxil fumarate/emtricitabine
- Elvitegravir/cobicistat/tenofovir alafenamide/emtricitabine or elvitegravir/cobicistat/tenofovir disoproxil fumarate/emtricitabine
- Raltegravir plus tenofovir alafenamide/emtricitabine or tenofovir disoproxil fumarate/emtricitabine

##### Protease Inhibitor–Based Regimen

- Darunavir/ritonavir plus tenofovir alafenamide/emtricitabine or tenofovir disoproxil fumarate/emtricitabine

#### Alternative Initial Antiretroviral Therapy Regimens

##### NNRTI-Based Regimens

- Efavirenz/tenofovir disoproxil fumarate/emtricitabine
- Efavirenz plus tenofovir alafenamide/emtricitabine
- Rilpivirine/tenofovir alafenamide/emtricitabine or rilpivirine/tenofovir disoproxil fumarate/emtricitabine<sup>b</sup>

##### Protease Inhibitor–Based Regimens

- Atazanavir/cobicistat or atazanavir/ritonavir plus tenofovir alafenamide/emtricitabine or tenofovir disoproxil fumarate/emtricitabine
- Darunavir/cobicistat or darunavir/ritonavir plus tenofovir alafenamide/emtricitabine or tenofovir disoproxil fumarate/emtricitabine
- Darunavir/cobicistat or darunavir/ritonavir plus abacavir/lamivudine<sup>a</sup>

<sup>a</sup>Abacavir-containing regimens only for patients who are human leukocyte antigen-B\*5701 negative.

<sup>b</sup>Only when HIV viral load <100,000 c/mL and CD4 count >200 cells/mm<sup>3</sup>. *INSTI*, Integrase strand transfer inhibitor; *NNRTI*, nonnucleoside reverse transcriptase inhibitor.

From *Panel on Antiretroviral Guidelines for Adults and Adolescents*.

Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents. Department of Health and Human Services. <http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf>; updated July 2016.

are available coformulated with FTC and as components of single-tablet ART regimens. ABC does not carry a risk of nephrotoxicity, but ABC use has been associated with increased risk of cardiovascular events in some studies so it may not be the optimal choice for persons with preexisting cardiovascular disease or risk factors. ABC may cause life-threatening hypersensitivity in persons who carry the human leukocyte antigen (HLA)-B\*5701 allele; as such, all patients should be tested for HLA-B\*5701 before receiving this medication, and ABC allergy should be listed in a patient's medical record if he or she tests positive. ABC is available coformulated with 3TC in a once-daily tablet; both are also coformulated into a single-tablet ART regimen with dolutegravir (DTG). Other NRTIs, including zidovudine (AZT), didanosine (ddI), and stavudine (d4T) are no longer recommended because of toxicities.

## Nonnucleoside Reverse Transcriptase Inhibitors

Efavirenz (EFV) was coformulated with TDF and FTC into the first single-tablet once-daily regimen for HIV treatment, which became available in 2006. EFV use is associated with a number of side effects including rash and central nervous system symptoms such as dizziness, somnolence, depressed mood, and vivid dreams. EFV was previously thought to be a teratogen, but recent data suggest there is no increased risk of teratogenicity; most treatment guidelines no longer proscribe EFV use during pregnancy. Rilpivirine (RPV) is an alternative NNRTI that is available as a coformulated single-tablet regimen together with TAF and FTC, and one with TDF and FTC. RPV should not be used in those with a baseline viral load >100,000 copies/mL or baseline CD4 count <200 cells/mm<sup>3</sup> because of higher rates of virologic failure in this population. Absorption of RPV is dependent on simultaneous consumption of a high-fat meal and can be diminished by concurrent use of antacids. Nevirapine is no longer recommended in the United States because of significant toxicities, including hepatotoxicity.

## Protease Inhibitors

All currently recommended PIs require pharmacologic boosting with a CYP3A4 inhibitor, either RTV or cobicistat. Of the many PIs, only boosted darunavir is currently recommended as part of a preferred initial ART regimen; boosted atazanavir is now considered an alternative for initial ART. Darunavir has slightly fewer toxicities in some clinical trials and slightly increased efficacy in some populations. Atazanavir absorption can be diminished by concurrent use of antacids, similar to RPV. Atazanavir use is also associated with indirect hyperbilirubinemia and rare nephrolithiasis. PIs afford a high barrier to resistance even in patients with nonadherence and virologic failure. Although RTV is also a PI, its side effects are dose-limiting, and it is now used exclusively as a booster for other PIs. The boosting effect comes from the potent inhibitory effect of RTV

on the cytochrome P450 system, which is advantageous for increasing the levels of other PIs but a potential problem for the dosing of many other medications. For this reason, providers must carefully screen for drug-drug interactions with RTV. Some of the most commonly prescribed medications that interact with RTV are statins, warfarin, amiodarone, oral contraceptives, methadone, benzodiazepines, and corticosteroids. RTV use concurrent with use of peripherally administered corticosteroids (such as joint injections and inhalers) can cause systemic corticosteroid effects, in some cases resulting in iatrogenic Cushing syndrome and subsequent adrenal insufficiency. Cobicistat is a newer CYP3A4 inhibitor that was first approved as part of a single-tablet ART regimen in 2012. Cobicistat is currently used to boost PIs (darunavir and atazanavir) and the integrase inhibitor elvitegravir. The drug-drug interactions of cobicistat are similar to those seen with RTV.

### Integrase Strand Transfer Inhibitors

Since the FDA approval of the first INSTI (raltegravir [RAL]) in 2007, ART has been transformed by this class of drugs. Integrase inhibitors offer highly potent antiviral activity with low pill burden, minimal adverse events and (for some INSTIs) minimal drug-drug interactions. Twice daily RAL has been replaced in recent years by once-daily elvitegravir (EVG) and DTG. EVG requires boosting with cobicistat; a fixed-dose combination of EVG/cobicistat is available as part of two single-tablet once-daily regimens: one with TAF and FTC, the other with TDF and FTC. Cobicistat inhibits renal excretion of creatinine, resulting in an increase in serum creatinine. Although not itself nephrotoxic, the creatinine increase associated with cobicistat administration results in an artifactual decrease in estimated glomerular filtration rate, which is challenging to distinguish from true nephrotoxicity in certain clinical settings. For this reason, it is not recommended for persons with significant renal disease. DTG is a once-daily highly potent antiretroviral agent with a high barrier to the development of drug resistance. DTG does not require pharmacologic boosting for once-daily dosing and is available in a small tablet that can be taken with TAF/FTC or TDF/FTC for a full regimen. A single-tablet once-daily regimen of DTG with ABC and 3TC is also available.

### Goals of Therapy

The goal of HIV therapy is to suppress the replication of HIV as demonstrated by an undetectable viral load from serum. CD4 cell count recovery will be variable and dependent on many factors. Once begun, treatment should not be interrupted without a compelling reason because those on intermittent therapy have been shown to have a poorer prognosis. Frequency of monitoring (CD4 and HIV viral load) depends in part on the clinical course, but generally it is performed every 3 to 4 months and every 6 to 12 months in stable patients with long-term virologic suppression. In

this era of highly effective and often coformulated ART, nonadherence is by far the most common cause of virologic failure (detectable viral load despite prescribed ART). Still, genotypic resistance testing should be performed in most instances of virologic failure to rule out the development of new drug resistance (see [Box 2.1](#)).

### Monitoring and Routine Follow-Up Care

After patients enter care and begin ART, ongoing clinical and laboratory monitoring depends on the clinical scenario. Patients with adherence difficulties, ongoing viremia, adverse reactions to medications, opportunistic infections, or other complications require close clinical and laboratory monitoring. Patients who are stable on ART with successful virologic suppression for a prolonged period of time may only require clinical and laboratory monitoring every 6 to 12 months. Primary preventive care is critically important for patients with HIV because HIV infection is associated with increased risk of non-AIDS-defining malignancies and cardiovascular disease. Age-appropriate cancer screening (e.g., cervical and breast cancer screening, colon cancer screening) and cardiovascular risk evaluation/modification (e.g., smoking cessation, lipid and glucose monitoring, diet and exercise programs) are important facets of primary care for patients with HIV.

### HIV Prevention

Despite the declining incidence of HIV infection in the United States over the past decade, incidence has declined more slowly in recent years; more than 44,000 new HIV infections were diagnosed in the United States in 2014. There is still a great need and opportunity for advances in HIV prevention and implementation of prevention techniques to curtail the epidemic within the United States and throughout the world. Certain populations have a startlingly high incidence of HIV in the United States. In 2016 the CDC calculated the estimated lifetime risk of HIV for many risk groups and race/ethnicity groups. Most notably at current infection rates an estimated one in six MSM and one in two African-American MSM will be diagnosed with HIV infection within their lifetime. Comprehensive HIV prevention strategies should target these high-risk vulnerable populations ([Figs. 2.2 and 2.3](#)).

Many methods of HIV prevention are currently in use, and many more are currently under investigation. Risk reduction education and traditional barrier methods, such as male and female condoms, are important tools for HIV prevention but may not be sufficient in some settings. Needle exchange testing/treating programs have been effective at decreasing HIV incidence among injection drug users. Male circumcision decreases sexual HIV transmission from women to the circumcised male partner by approximately 60% and does not require ongoing patient adherence to any drug or behavior, but efficacy in preventing transmission among MSM has not been tested. Perinatal transmission can

• **Fig. 2.2** Lifetime risk of HIV diagnosis by transmission group. MSM, Men who have sex with men. (From Centers for Disease Control and Prevention. <http://www.cdc.gov/nchhstp/newsroom/2016/croi-2016.html#Graphics>.)

• **Fig. 2.3** Lifetime risk of HIV diagnosis among men who have sex with men (MSM) by race/ethnicity. (From Centers for Disease Control and Prevention. <http://www.cdc.gov/nchhstp/newsroom/2016/croi-2016.html#Graphics>.)

be lowered to <1% to 2% with the implementation of prevention of mother-to-child transmission programs, which include fully suppressive combination ART to the mother during pregnancy and postnatal ART for the newborn, as well as exclusive formula feeding in developed countries.

Patients who have had a recent (within 72 hours) occupational or nonoccupational exposure that carries the possibility of HIV transmission (e.g., needlestick, occupational mucosal exposure, unprotected anal intercourse, sexual assault) should be screened for and offered antiretroviral postexposure prophylaxis (PEP). PEP consists of a combination ART regimen (usually tenofovir and FTC with either RAL or DTG) taken for a 28-day course. The limited available data on PEP suggests that this treatment decreases the risk of HIV transmission by at least 80%.

In 2014 the CDC published guidelines for the use of preexposure prophylaxis (PrEP) for prevention of HIV transmission. These guidelines were developed from review of a number of clinical trials of use of antiretroviral agents among HIV-negative individuals at high risk for HIV acquisition caused by a variety of risk factors (most commonly MSM but also heterosexual persons and injection drug use) for prevention of HIV acquisition. PrEP is now

recommended as one option for HIV prevention for MSM and heterosexual men and women at substantial risk of HIV infection and should be considered for persons with injection drug use and for decreasing potential for HIV transmission in serodiscordant couples during conception. PrEP consists of daily treatment with fixed-dose combination tenofovir and FTC; episodic dosing around times of sexual activity has also been shown to be effective in some populations. Baseline evaluation includes screening for HIV infection, anemia, renal/hepatic dysfunction, hepatitis B and C infections, and sexually transmitted infection (STI) screening (gonorrhea, chlamydia, and syphilis). PrEP is then prescribed for 3-month intervals punctuated by in-clinic visits for risk reduction counseling, laboratory monitoring, and screening for HIV and other STIs. Efficacy of PrEP has been closely linked to adherence, which has been low in some studies.

Multiple studies have now demonstrated that treatment of HIV-infected persons effectively prevents transmission to others, with efficacy approaching 100%. This concept, known as *treatment as prevention*, can be optimized by early diagnosis of HIV via increased routine testing and universal treatment of all HIV-infected persons.

## Chapter Review

### Questions

1. A 42-year-old man presents to primary care physician with complaint of progressive cough and shortness of breath over the past few weeks. Upon further questioning he reports weight loss, malaise, and diarrhea over the past 6 to 12 months. On examination, he is mildly tachycardic and tachypneic, oxygen saturation is 90% on room air, and he has scattered rales on lung auscultation and seborrheic

dermatitis on the face. CXR shows patchy bilateral infiltrates. Sputum culture is negative for bacteria. Serum lactate dehydrogenase is 295 U/L, and serum 1,3-beta glucan is >500 pg/mL. HIV Ag/Ab test is screen positive, and differentiation is positive for HIV-1. The most likely explanation for the current clinical situation is:

- A. Acute retroviral syndrome complicated by pneumonia

- B. Acute retroviral syndrome complicated by tuberculosis
  - C. Established HIV infection, now AIDS, complicated by PCP
  - D. Atypical pneumonia with false-positive HIV test
2. Additional testing reveals HIV viral load >1 million copies/mL, CD4 count 98. The patient is admitted to the hospital and initiates high-dose sulfamethoxazole/trimethoprim for PCP. The most appropriate plan for initiation of ART is:
- A. Start TAF/FTC plus DTG during hospitalization, and then schedule for follow-up in the clinic within 1 to 2 weeks of hospital discharge for close monitoring.
  - B. Complete 21-day course of sulfamethoxazole/trimethoprim, and then initiate TAF/FTC plus DTG in outpatient follow-up after hospital discharge.
  - C. Complete 21-day course of sulfamethoxazole/trimethoprim, and then continue on once-daily prophylactic sulfamethoxazole/trimethoprim for 3 months to demonstrate adherence to medications and clinic visits before initiation of ART.
  - D. Start TAF/FTC plus DTG during hospitalization, and then schedule for follow-up in clinic at 6 months after hospital discharge for monitoring on stable ART.
3. Before beginning ART, which of the tests following is not indicated?
- A. Serum creatinine
  - B. Urine toxicology
  - C. Genotypic HIV resistance test
  - D. Hepatitis B surface antigen
4. A 23-year-old man presents to primary care clinic with new penile discharge and dysuria for the past 7 to 10 days. Urethral gonorrhea is diagnosed by urine nucleic acid amplification test. The patient is treated with intramuscular ceftriaxone injection and oral azithromycin. Which of the following is the most appropriate next step for HIV prevention?
- A. Initiation of tenofovir/FTC plus RAL for 28-day course for PEP
  - B. Initiation of daily tenofovir/FTC for PrEP at that visit, without further laboratory testing
  - C. Baseline HIV Ag/Ab screening, give condoms, follow up annually for HIV screening and risk reduction counseling
  - D. Baseline HIV Ag/Ab screening, discussion of risks and benefits of PrEP and initiation of tenofovir/FTC for PrEP if HIV screening negative and patient amenable

### Answers

1. C
2. A
3. B
4. D

## Infective Endocarditis

ANJU NOHRIA

**I**nfective endocarditis (IE) is an infection of the endocardial surface of the heart. It is characterized by one or more vegetations comprising a mass of platelets, fibrin, microorganisms, and inflammatory cells. IE primarily involves the heart valves (native or prosthetic). Other structures may also be involved, including the interventricular septum, the chordae tendineae, the mural endocardium, or intracardiac devices such as a pacemaker. The most common infective causes are bacterial; however, fungal endocarditis can be seen in patients who are immunocompromised (Table 3.1). Valvular involvement in IE may lead to congestive heart failure (CHF), conduction abnormalities, and myocardial abscesses. Systemic complications in IE include embolization of both sterile and infected emboli, abscess formation, and mycotic aneurysms.

IE should be distinguished from nonbacterial endocarditis or marantic endocarditis. The latter is most commonly found on previously undamaged valves, and, unlike IE, the vegetations are usually small and sterile. Nonbacterial endocarditis does not cause a systemic illness, but systemic embolization may occur. Causes of nonbacterial endocarditis include a hypercoagulable state, cancer (usually mucinous adenocarcinoma), Libman-Sacks endocarditis, or pregnancy.

The incidence of IE based on hospital admissions in the United States is approximately 15 cases per 100,000 persons per year and is increasing by 2.4% annually. The mean age of patients with IE in the United States is 60.8 years of age, with more than one-third being 70 years of age or older. IE is more than twice as common in males than in females. There is no racial predilection. Untreated, IE has a very high morbidity and mortality. Antibiotic therapy is the mainstay of treatment. Surgery may be required under certain circumstances.

### Pathophysiology

IE develops because of local adherence and invasion of bacteria onto the valvular leaflet. Normal endothelium is resistant to colonization and infection by circulating bacteria. Disruption of the endothelium exposes the underlying matrix and promotes the production of tissue factor

and the deposition of fibrin and platelets as part of the normal healing process. Such nonbacterial thrombotic endocarditis facilitates bacterial adherence and infection. Endothelial damage can result from mechanical lesions provoked by turbulent flow, catheters, electrodes, inflammation (such as in rheumatic heart disease), or degenerative changes.

Endothelial inflammation without valvular lesions can also promote IE. In these circumstances, local inflammation leads to the expression of beta-1 integrins that bind circulating fibronectin. Pathogens such as *Staphylococcus aureus* contain fibronectin binding proteins on their surface, allowing them to be internalized by the endothelial cell where they can hide from host defenses, multiply, and spread to distant organs. IE develops most commonly on the mitral valve, closely followed in descending order of frequency by the aortic valve, the combined mitral and aortic valve, the tricuspid valve, and, rarely, the pulmonic valve. Mechanical prosthetic and bioprosthetic valves exhibit equal rates of infection.

Bacteremia may occur during dental treatment as well as invasive procedures involving the gastrointestinal (GI) and genitourinary (GU) tracts. However, there are other potential causes for bacteremia including the presence of colon cancer, urinary tract infections, and intravenous drug abuse (IVDA).

### Predisposing Factors for Infective Endocarditis

Risk factors for IE are shown in Box 3.1. Whereas in the past, rheumatic fever was the most common predisposing factor for native valve IE, degenerative valve disease (significant mitral and/or aortic regurgitation) currently represents the most common underlying abnormality. Mitral valve prolapse (MVP) is the most common lesion, and the risk of IE is increased in the presence of thickened mitral leaflets or mitral regurgitation. Although rheumatic heart disease remains a major cause of IE in the developing world, it constitutes <5% of IE cases in the Western hemisphere.

**TABLE 3.1 Microbiologic Causes by Type of Infective Endocarditis Among 2781 Patients With Definite Infective Endocarditis**

Causative Organism	% Patients			
	Native Valve IE		Intracardiac Device IE	
	IVDA	Non-IVDA	PVE	Other Devices
<i>Staphylococcus aureus</i>	68	28	23	35
Coagulase-negative <i>Staphylococcus</i>	3	9	17	26
Viridans group streptococci	10	21	12	8
<i>Streptococcus bovis</i>	1	7	5	3
Other streptococci	2	7	5	4
<i>Enterococcus</i>	5	11	12	6
HACEK	0	2	2	0.5
Fungi/yeast	1	1	4	1
Polymicrobial	3	1	0.8	0
Negative cultures	5	9	12	11
Other	3	4	7	6

IVDA; Intravenous drug abuse; HACEK, *Haemophilus*, *Aggregatibacter*, *Cardiobacterium*, *Eikenella*, and *Kingella* species; IE, infective endocarditis; PVE, prosthetic valve endocarditis.  
Modified from Murdoch DR, Corey GR, Hoen B, et al. Clinical presentation, etiology, and outcome of infective endocarditis in the 21st century: The International Collaboration on Endocarditis-Propective Cohort Study. *Arch Intern Med*. 2009;169(5):463-473.

Approximately 12% of patients have congenital heart disease as a predisposing factor for IE, with bicuspid aortic valve being the most common abnormality. Other contributing congenital abnormalities include ventricular septal defect, patent ductus arteriosus, transposition of the great arteries, and tetralogy of Fallot. Atrial septal defect (secundum variety) is rarely associated with IE.

Prosthetic valves continue to be an important predisposing factor for IE and are present in approximately 20% of cases. It is estimated that 5% of mechanical and bioprosthetic valves become infected, with valves in the mitral position being more susceptible than those in the aortic position. Mechanical valves are more likely to be infected within the first 3 months of implantation and bioprosthetic valves after 1 year.

The proportion of IE patients with chronic intravenous access (9%) and intracardiac devices (11%) is rising. Devices commonly become infected within a few months of implantation. Infection of pacemakers includes that of the generator pocket (the most common), the proximal leads, and the portions of the leads in direct contact with the endocardium.

IVDA remains an important risk factor in approximately 10% of patients with IE. The majority of patients with IVDA IE have no underlying valvular abnormality, and one-half of IVDA-associated IE cases involve the tricuspid valve.

Patients with conditions such as diabetes mellitus, chronic hemodialysis, and immunocompromised states as

a result of cancer and HIV also demonstrate an increased susceptibility for IE.

## Clinical Features

IE can present as a rapidly progressive acute febrile illness or as an indolent subacute illness with low-grade fever, malaise, anorexia, and weight loss. Fever is the most common sign and symptom of IE and is present in 96% of patients. Valvular involvement can give rise to a new murmur (48%) or worsening of a preexisting murmur (20%). Other clinical manifestations relate either to intracardiac extension of infection or to extracardiac consequences of systemic infection or embolic disease (Box 3.2).

CHF is the most common complication of IE (32%). The clinical features can include dyspnea, pulmonary edema, and cardiogenic shock. Acute regurgitation caused by native valve IE is the most common cause of CHF and can occur because of mitral chordal rupture, flail leaflet, leaflet perforation, or interference of leaflet closure by the vegetation. Perivalvular extension in prosthetic valve IE can lead to valvular dehiscence and CHF.

Perivalvular extension can also lead to abscess formation (14%), pseudoaneurysms, and fistulae. These should be suspected in cases of persistent fevers despite antibiotics or new atrioventricular block. These are most commonly seen with IE involving the aortic valve and are more frequent in patients with prosthetic valve infection.

### • BOX 3.1 Characteristics of Patients at Risk for Infective Endocarditis

#### Cardiac Abnormalities

##### High Risk

- Prosthetic valve
- Prior infective endocarditis
- Patients with congenital heart disease
  - a. Cyanotic heart disease without surgical repair, or with residual defects, palliative shunts, or conduits
  - b. Repaired with prosthetic material within the last 6 months
  - c. Residual defect at site of prior repair with prosthetic material or device

Cardiac transplant recipients who develop cardiac valvulopathy

##### Moderate Risk

- a. Noncyanotic congenital heart disease
- b. Mitral valve prolapse with mitral regurgitation or thickened mitral leaflets
- c. Hypertrophic cardiomyopathy
- d. Acquired valvular dysfunction

##### Low Risk

- a. Isolated secundum atrial septal defect
- b. Atrial septal defect, ventricular septal defect, and patent ductus arteriosus >6 months post-repair
- c. Innocent, physiologic, or functional heart murmurs without structural heart disease

#### Patient Characteristics

- Current intravenous drug use
- Intracardiac device
  - a. Pacemaker
  - b. Implantable cardioverter defibrillator
- Chronic IV access
- Hemodialysis
- Diabetes mellitus
- Human immunodeficiency virus
- Cancer

Embolic events are frequent complications related to migration of vegetations to distal sites. The brain and spleen are the most frequent sites of embolism in left-sided IE, whereas pulmonary embolism is common in patients with right-sided IE. Other sites of embolic disease include the kidney, liver, and iliac, mesenteric, and coronary arteries. Neurologic complications include stroke (17%), mycotic aneurysms, or central nervous system (CNS) infections. Mycotic aneurysms result from septic emboli to the vasa vasorum with subsequent spread through the vessel wall. They can leak slowly, leading to headache and meningeal symptoms, or rupture acutely without prior warning. Risk factors for embolization include vegetations >10 mm in diameter; mobile vegetations; vegetations on the mitral valve; particular organisms such as *S. aureus*, *Streptococcus bovis*, and fungi; previous embolism; and multivalvular IE. Embolic events, especially stroke and myocardial infarction, are associated with increased mortality. The risk of embolization decreases significantly after the initiation of appropriate antibiotic therapy.

### • BOX 3.2 Clinical Findings in Infective Endocarditis

#### Findings

- Fever >38°C
- New or worsening cardiac murmur
- Congestive heart failure
- Conduction system abnormalities

#### Vascular Phenomena

- a. Arterial emboli (such as stroke, myocardial infarction, septic pulmonary embolism, and other peripheral emboli)
- b. Neurologic complications (mycotic aneurysm, intracranial hemorrhage)
- c. Conjunctival hemorrhages
- d. Splinter hemorrhages
- e. Janeway lesions

#### Immunologic Phenomena

- a. Osler nodes
- b. Roth spots
- c. Glomerulonephritis
- d. Elevated erythrocyte sedimentation rate
- e. Elevated C-reactive protein
- f. Elevated rheumatoid factor
- g. Splenomegaly

Other stigmata of systemic and embolic disease are seen less commonly in the antibiotic era. These include:

1. **Petechiae:** These may occur on the palpebral conjunctivae, the dorsa of the hands, feet, and toes, the anterior chest and abdominal walls, the oral mucosa, and the soft palate.
2. **Splinter hemorrhages:** Subungual hemorrhages that are linear and red. Hemorrhages that do not extend for the entire length of the nail are more likely the result of infection rather than trauma.
3. **Janeway lesions:** Irregular erythematous and painless macules (1–4 mm in diameter) that are located on the thenar and hypothenar eminences of the hands and feet. They usually represent an infectious vasculitis of acute IE resulting from *S. aureus* infection.
4. **Osler nodes:** Tender nodules that range from red to purple, usually observed in patients with subacute IE, and primarily located in the pulp spaces of the terminal phalanges of the fingers and toes, soles of the feet, and the thenar and hypothenar eminences of the hands. Neuropathic pain often precedes their appearance. They last from hours to several days. They remain tender for a maximum of 2 days. Osler nodes likely reflect circulating immune complex deposition subcutaneously. They have also been described in various noninfectious vasculitides.
5. **Clubbing of fingers and toes:** Observed in <10% of patients, clubbing primarily occurs in those patients who have an extended course of untreated IE.
6. **Arthritis:** This is associated with subacute IE, is asymmetric, and is limited to one to three joints. Clinically, it resembles the joint changes found in patients with rheumatoid arthritis, reactive arthritis, or Lyme disease. The fluid is usually sterile. Acute septic monoarticular

arthritis can occur in patients with acute IE, most often caused by *S. aureus* infection.

7. Splenomegaly: This is observed more commonly in patients with long-standing subacute disease. It may persist long after successful therapy.
8. Roth spots: Retinal hemorrhages with pale centers. The Litten sign represents cotton-wool exudates. Roth spots arise from immune-mediated vasculitis.
9. Renal: Regional infarcts in the kidney from peripheral embolization cause painless hematuria and infarction of the kidney. Patients with subacute IE may also develop a postinfectious glomerulonephritis.

## Specific Infective Endocarditis Syndromes

### Intravenous Drug Abuse Infective Endocarditis

The incidence of IE among IVDA in the United States ranges from 0.15% to 2% per year. The incidence of IE is higher among HIV-infected than HIV-seronegative IVDA. Other risk factors include female gender, increased frequency of injection use, and prior IE. Overall, methicillin-sensitive *S. aureus* is the most common etiologic agent (60%–70%). The remainder of cases is caused by coagulase-negative staphylococci,  $\beta$ -hemolytic streptococci, fungi, aerobic gram-negative bacilli, and including *Pseudomonas aeruginosa*. Polymicrobial infection occurs in 2% to 5% of cases. The tricuspid valve is the most frequently affected (70%), followed by the mitral and aortic valves (20%–30%); pulmonic valve infection is rare (<1%). More than one valve is infected in 5% to 10% of cases. The usual manifestations are fever, bacteremia, and septic pulmonary emboli. Right heart failure can occur because of elevated pulmonary pressures or severe tricuspid regurgitation. The prognosis of right-sided endocarditis is generally good; overall mortality is <5% and, with surgery, <2%. Tricuspid vegetations >2 cm and presentation with acute respiratory distress are associated with increased mortality. The prognosis of left-sided IE, especially with involvement of the aortic valve, is less favorable; mortality is 20% to 30%, and even with surgery it is 15% to 25%. IE caused by gram-negative organisms or fungi has the worst prognosis.

### Prosthetic Valve Endocarditis

Prosthetic valve endocarditis (PVE) accounts for 20% of all cases of IE and affects mechanical and bioprosthetic valves equally. Of all prosthetic valves, 1% to 6% develop IE, and the rate increases after revision or resection of the valve (15%). Early PVE is defined as infection within 60 days of valve implantation, and late PVE occurs after 1 year. The causative organisms for early PVE tend to be coagulase-negative staphylococci, *S. aureus*, gram-negative bacilli, fungi, *Corynebacterium*, and *Legionella* whereas late PVE tends to have coagulase-negative staphylococci, *S. aureus*, viridans group streptococci, enterococci, fungi, and *Corynebacterium* as the common causative organisms. Of note, some

have suggested that *S. aureus* is the most common infecting organism in both early and late PVE. Early PVE is often difficult to diagnose, because fever and inflammation are common in the postoperative period even in the absence of IE. Clinical features of late PVE closely resemble those of native valve endocarditis (NVE). New prosthetic valve regurgitation resulting in CHF is the most common consequence of PVE. In early PVE, the infection usually involves the junction of the sewing ring and annulus, leading to valve dehiscence, perivalvular abscess, pseudoaneurysms, and fistulae. In late PVE, the infection frequently involves the valve leaflets, resulting in vegetations, cusp rupture, and perforation. Occasionally, the vegetation can be large enough to cause valvular obstruction. Systemic emboli occur in 40% of patients, and stroke and neurologic complications are also frequently seen in patients with PVE (40%). PVE is associated with an increased risk of in-hospital mortality. Patients with early PVE, staphylococcal PVE, fungal PVE, and complicated PVE (severe prosthetic dysfunction, heart failure, abscess, or persistent fever) have the worst prognosis and should be managed aggressively with surgery. Uncomplicated, nonstaphylococcal, nonfungal, late PVE can be managed medically with close follow-up because of the increased risk of late complications.

### Cardiac Device Infective Endocarditis

Cardiac device IE constitutes approximately 7% of all IE cases in the United States and is rapidly growing in frequency. The majority of cardiac device infections affect the subcutaneous generator pocket (either from skin contamination at the time of implantation or later), and 10% to 23% of these progress to cardiac device IE involving the electrode leads, valve leaflets, or endocardial surface. Cardiac device IE is one of the most difficult forms of IE to diagnose and must be suspected in the presence of unexplained fever in a patient with a cardiac device. It often presents indolently with local signs of infection and respiratory or rheumatologic symptoms. Approximately one-half of all cases of cardiac device IE result from health-care-associated infections. *S. aureus* (35%) and coagulase-negative staphylococcus (31.6%) are the predominant causes of cardiac device IE, followed by fungi, gram-negative organisms, and *Corynebacterium*. Cardiac device IE results in vegetations on the electrode leads and causes coexisting valve infection in one-third of cases. The tricuspid valve is most commonly affected (67%), followed by mitral, aortic, and pulmonic valves, respectively. This can lead to valvular regurgitation, right-sided heart failure, pulmonary and systemic embolism, and persistent bacteremia. Cardiac device IE is associated with an in-hospital and 1-year mortality of 14.7% and 23.2%, respectively. Health-care-associated infection and concomitant valvular involvement are associated with increased in-hospital mortality. Early device removal during the index hospitalization does not affect in-hospital mortality but improves 1-year survival.

## Diagnosis and Workup of Infective Endocarditis

The modified Duke criteria are generally used for the diagnosis of IE (Box 3.3). To make a definite diagnosis of IE, either two major criteria, one major and three minor criteria, or five minor criteria are required. A diagnosis of possible IE is made in the presence of one major and one minor criterion or three minor criteria. The diagnosis of IE is rejected if there is a firm alternative diagnosis for the manifestations of IE, the manifestations resolve within 4

### • BOX 3.3 Modified Duke Criteria for Diagnosis of Infective Endocarditis

#### Major Criteria

##### Blood Culture Positive for Infective Endocarditis

Typical microorganisms consistent with infective endocarditis from two separate blood cultures:

- Viridans streptococci, *Streptococcus gallolyticus* (*bovis*), HACEK group, *Staphylococcus aureus*; or
- Community-acquired enterococci in the absence of a primary focus; or

Microorganisms consistent with infective endocarditis from persistently positive blood cultures; defined as follows:

- At least two positive cultures of blood samples drawn more than 12 hours apart; or
  - All of three or a majority of greater than four separate cultures of blood (with first and last sample drawn at least 1 hour apart)
  - Single positive blood culture for *Coxiella burnetii* or antiphase 1 IgG antibody titer >1:800
- Evidence of endocardial involvement

##### Echocardiogram Positive for Infective Endocarditis

- Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative explanation; or
- Abscess; or
- New partial dehiscence of prosthetic valves
- New valvular regurgitation

#### Minor Criteria

- Predisposition, predisposing heart condition, or injection drug use
- Fever >38°C
- Vascular phenomena (as in Box 3.2)
- Immunologic phenomena (as in Box 3.2)
- Microbiologic evidence: positive blood culture that does not meet a major criteria or serologic evidence of an active infection with an organism consistent with infective endocarditis.

From Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/ American Heart Association Task Force on Practice Guidelines (Writing Committee to revise the 1998 guidelines for the management of patients with valvular heart disease). Endorsed by the Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol*. 2008;52(13):e1-142.

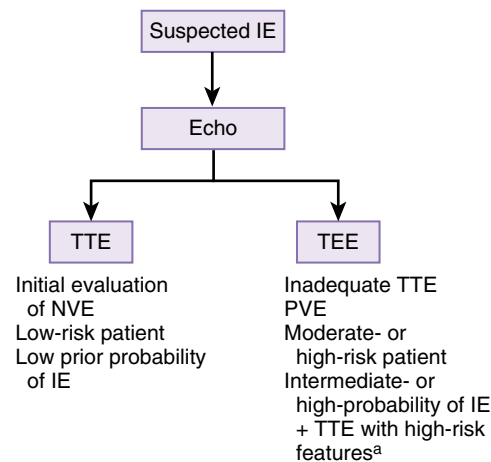

HACEK, *Haemophilus*, *Aggregatibacter*, *Cardiobacterium*, *Eikenella*, and *Kingella* species; IgG, immunoglobulin G.

days of antibiotic treatment, and there is no pathologic evidence of IE at surgery or autopsy  $\leq 4$  days after antimicrobial therapy.

Blood cultures are the key to making the diagnosis of IE; however, echocardiography has become essential for the workup and diagnosis of IE and should be performed in all suspected cases. Echocardiographic evidence of an oscillating intracardiac mass or vegetation, an annular abscess, prosthetic valve dehiscence, and new valvular regurgitation are major criteria in the diagnosis of IE. Echocardiography is also useful for evaluating and predicting the potential complications of IE. By contrast, the diagnosis of IE can never be excluded based on negative echocardiogram findings, either transthoracic (TTE) or transesophageal (TEE).

TTE can detect vegetations in approximately 40% to 63% of patients with suspected NVE, whereas the sensitivity of TEE approaches 90% to 100%. In fact, a negative TEE virtually rules out a diagnosis of NVE. PVE is much more difficult to detect with TTE and has a sensitivity of 36% to 69%, whereas that of TEE approaches 86% to 94%. Therefore TEE should be performed in all patients with suspected PVE. TTE, on the other hand, is easily able to identify tricuspid vegetations; TEE does not increase the accuracy of detection in these cases. However, TTE has a very low sensitivity compared with TEE in evaluating cardiac device IE (23% vs. 94%), particularly in its ability to assess concomitant lead and valve involvement. TEE also has a much higher sensitivity for the detection of complications of IE including endothelial erosion, perivalvular abscesses, mycotic aneurysms, and intracardiac fistulae (90% vs. 43%). A potential algorithm for the use of echocardiography in the detection of IE is shown in Fig. 3.1.

Radionuclide scans, such as gallium-67 and indium-111 tagged white cell scans, are of marginal use in diagnosing IE. Catheterization of the heart is rarely required for the diagnosis

• **Fig. 3.1** Algorithm for transthoracic (TTE) versus transesophageal (TEE) in patients with infective endocarditis (IE). NVE, Native valve endocarditis; PVE, prosthetic valve endocarditis. <sup>a</sup>Large/mobile vegetations, valvular insufficiency, suggestion of paravalvular extension, or secondary valve dysfunction.

of IE or any of its complications. A CT scan of the head should be obtained in patients who exhibit CNS symptoms or findings consistent with a mass effect (e.g., macroabscess of the brain).

## Treatment of Infective Endocarditis

Treatment of IE comprises antimicrobial therapy to address the bacterial infection and medical and surgical strategies to deal with complications. In patients at high risk of endocarditis, based on either the clinical picture or the patient's risk factor profile, such as IVDA or a history of previous IE, the presumption of endocarditis is often made before blood culture results are available.

### Antimicrobial Therapy

Antibiotics remain the mainstay of treatment for IE. Antibiotic therapy should be started as soon as possible after taking multiple sets of blood cultures drawn at least 30 minutes apart (usually three to five sets). Initial antibiotic choice is empiric and intravenous until culture and sensitivity data become available. Patients should generally be hospitalized for treatment. The empiric antibiotic regimen should be based on the presence of NVE or intracardiac device–related IE (early vs. late) and knowledge of local microbial epidemiology. In general, NVE and late PVE regimens should cover staphylococci, streptococci, HACEK (*Haemophilus* species, *Aggregatibacter* species, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species), and *Bartonella*. Early PVE should cover methicillin-resistant *S. aureus* and gram-negative organisms. The definitive antibiotic regimen is based on identification of the causative organism (Table 3.2).

Relapse, or a repeat episode caused by the same organism as the previous episode of IE, usually occurs within 6 months of the initial episode. This is usually related to an insufficient course of antibiotics, suboptimal choice of antibiotics, or persistent focus of infection. In these instances, an additional 4 to 6 weeks of antibiotics are required. Reinfection refers to a repeat episode of infection with a different microbe. Patients with IVDA, prosthetic valves, previous IE, on chronic dialysis, and those with multiple risk factors for IE are at increased risk for developing reinfection and should receive appropriate prophylaxis.

### Medical Treatment of Infective Endocarditis Complications

Mild CHF resulting from valvular insufficiency or myocarditis may be managed with standard medical therapy. Often this is progressive, and despite achieving a microbiologic cure, requires valvular surgery. Anticoagulation is controversial, despite the embolic complications encountered with IE. Patients who are anticoagulated have a higher rate of intracerebral bleeding.

## Surgical Indications in Infective Endocarditis

Approximately one-half of patients with IE require surgery. Indications for surgery for NVE are depicted in Box 3.4. The indications for surgery in patients with PVE are shown in Box 3.5. In general, surgical consultation should be obtained in all patients presenting with PVE. Routine surgery is not indicated in a first episode of PVE caused by a sensitive organism.

Removal of a pacemaker and its wires is recommended for the treatment of intracardiac device–related infection, especially if lead-associated or valvular vegetations are found. Device removal should be strongly considered if there is no clear source of bacteremia other than the presence of an intracardiac device. Occasionally, local debridement and administration of appropriate antibiotics may be sufficient to cure an uncomplicated pacemaker pocket infection. After removal of the infected device, immediate reimplantation should be avoided until completion of an adequate course of antibiotic therapy because of the risk of new infection. If reimplantation is necessary, a new transvenous system is usually implanted on the contralateral side.

## Antibiotic Prophylaxis for Infective Endocarditis

The American Heart Association (AHA) recommends that prophylaxis should be provided to reduce the risk of IE. This rests on three principles: (1) certain underlying cardiac conditions predispose patients to a high risk of IE; (2) bacteremia with organisms known to cause IE occurs commonly in association with invasive dental, GI, or GU tract procedures; and (3) antimicrobial prophylaxis is thought to be effective in reducing IE associated with dental, GI, or GU tract procedures. However, the recent change in antibiotic prophylaxis recommendations attempts to balance the risk of IE with the risk of promoting resistant microorganisms through unnecessary and widespread use of antibiotics. Therefore the AHA no longer recommends IE prophylaxis based solely on an increased lifetime risk of acquisition of IE. In particular, this applies to MVP. The AHA no longer recommends routine prophylaxis for MVP because IE is extremely rare with MVP, and the consequences of IE in these patients, who often do not have associated comorbidities, are generally mild. Only patients deemed to be at the highest risk of IE should receive antibiotic prophylaxis (see Box 3.1). These patients should receive antibiotic prophylaxis targeted at *Streptococcus viridans* species for dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa (scaling or root canal procedures). A suggested antibiotic regimen is shown in Table 3.3. The antibiotic dose should be administered in a single dose before the procedure. If the dosage of antibiotic is inadvertently not administered before the procedure, the dosage may be administered up to 2 hours after the procedure. The administration

**TABLE 3.2 Recommended Antimicrobial Therapy for Infective Endocarditis**

Organism	Recommended Treatment <sup>a</sup>
Adult NVE caused by penicillin-susceptible <i>S. viridans</i> , <i>S. gallolyticus</i> ( <i>bovis</i> ), or other streptococci	Penicillin G at 12–18 million U/d <i>or</i> Ceftriaxone 2 g/d for 4 weeks <i>or</i> Penicillin G or ceftriaxone + gentamicin 3 mg/kg/d for 2 weeks  In patients who are allergic to penicillin, use vancomycin 30 mg/kg/d
For NVE caused by relatively resistant <i>S. viridans</i> and <i>S. gallolyticus</i> ( <i>bovis</i> )	Penicillin G at 24 million U/d for 4 weeks + gentamicin 3 mg/kg/d for 2 weeks If isolate is ceftriaxone susceptible, may use ceftriaxone 2 g/d for 4 weeks  In patients who are allergic to penicillin, use vancomycin 30 mg/kg/d for 4 weeks
IE caused by <i>A. defectiva</i> , <i>Granulicatella</i> species, enterococci, and resistant <i>S. viridans</i> (MICs of penicillin G of $\geq 0.5$ $\mu\text{g/mL}$ )	Ampicillin 12 g/d or penicillin G at 18–30 million U/d intravenously, combined with gentamicin at 3 mg/kg/d with duration determined by infectious disease consult In patients who are allergic to penicillin, use vancomycin
PVE caused by penicillin-G–susceptible <i>S. viridans</i> , <i>S. gallolyticus</i> ( <i>bovis</i> ), or other streptococci	Penicillin G at 24 million U/d or ceftriaxone 2 g/d for 6 weeks $\pm$ gentamicin 3 mg/kg/d for 2 weeks In patients who are allergic to penicillin, use vancomycin 30 mg/kg/d for 6 weeks
NVE caused by methicillin-sensitive <i>S. aureus</i>	Nafcillin or oxacillin at 12 g/d for 6 weeks In patients who are allergic to penicillin, use ceftazolin 6 g/d for 6 weeks
PVE caused by methicillin-sensitive <i>S. aureus</i>	Nafcillin or oxacillin at 12 g/d for $\geq 6$ weeks + rifampin 900 mg/d for $\geq 6$ weeks + gentamicin 3 mg/kg/d for 2 weeks  In patients who are allergic to penicillin, use vancomycin 30 mg/kg/d for $\geq 6$ weeks + rifampin 900 mg/d for $\geq 6$ weeks + gentamicin 3 mg/kg/d for 2 weeks
NVE caused by methicillin-resistant <i>S. aureus</i>	Vancomycin 30 mg/kg/d for 6 weeks or daptomycin for 6 weeks with dose determined by infectious disease consult
PVE caused by methicillin-resistant <i>S. aureus</i>	Vancomycin 30 mg/kg/d for $\geq 6$ weeks + rifampin 900 mg/d for $\geq 6$ weeks + gentamicin 3 mg/kg/d for 2 weeks
NVE or PVE caused by penicillin-susceptible <i>Enterococci</i>	Ampicillin 12 g/d or penicillin 18–30 million U/d + gentamicin 3 mg/kg/d for 4–6 weeks <i>or</i> Ampicillin 12 g/d + ceftriaxone 4 g/d for 6 weeks
NVE or PVE caused by penicillin-resistant <i>Enterococci</i>	Vancomycin 30 mg/kg/d + gentamicin 3 mg/kg/d for 6 weeks
NVE or PVE caused by penicillin, aminoglycoside, and vancomycin-resistant <i>Enterococci</i>	Linezolid 1200 mg/d for $>6$ weeks <i>or</i> Daptomycin 10–12 mg/kg/d for $>6$ weeks
NVE or PVE caused by HACEK organisms	Ceftriaxone 2 g/d <i>or</i> Ampicillin 12 g/d <i>or</i> Ciprofloxacin 800 mg/d for 4 weeks if NVE and 6 weeks if PVE

<sup>a</sup>Antibiotics to be administered intravenously in divided doses and adjusted according to renal function as necessary.

From, Baddour LM, Wilson, WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A scientific statement for healthcare professionals from the American Heart Association: endorsed by the Infectious Diseases Society of America. *Circulation*. 2015;132(15):1435-1486.

of prophylactic antibiotics solely to prevent IE is no longer recommended for patients who undergo GU or GI tract procedures, including diagnostic TEE, esophagogastroduodenoscopy, or colonoscopy.

Perioperative antibiotic prophylaxis should be considered in patients undergoing implantation of a prosthetic valve

or intracardiac device. The prophylaxis should be aimed at staphylococcal species and should be started immediately before the procedure and terminated 48 hours later. All potential sources of dental sepsis should be evaluated and eliminated before implantation of prosthetic valves and intracardiac devices if possible.

### • BOX 3.4 Indications for Surgery in Native Valve Endocarditis (NVE)

#### Class I Recommendations

Acute NVE with valve dysfunction resulting in heart failure  
 NVE caused by fungal or highly resistant organisms  
 NVE complicated by heart block, annular or aortic abscess, or destructive penetrating lesions  
 NVE with persistent bacteremia/fever lasting >5–7 days after appropriate antibiotic therapy

#### Class IIa Recommendations

NVE with persistent vegetations and recurrent emboli despite appropriate antibiotic treatment  
 NVE with severe valve regurgitation and mobile vegetation >10 mm

#### Class IIb Recommendations

NVE with mobile vegetation >10 mm with or without emboli

### • BOX 3.5 Indications for Surgery in Prosthetic Valve Endocarditis (PVE)

#### Class I Recommendations

PVE with heart failure caused by valve dehiscence, intracardiac fistula, or severe valve dysfunction  
 PVE with persistent bacteremia despite appropriate antibiotics for 5–7 days  
 PVE complicated by heart block, annular or aortic abscess, or destructive penetrating lesions  
 PVE caused by fungi or other resistant organisms

#### Class IIa Recommendations

PVE with recurrent emboli despite appropriate antibiotic treatment  
 PVE with relapsing infection  
 PVE with mobile vegetation >10 mm

**TABLE**  
3.3

**Suggested Regimens for Antibiotic Prophylaxis in Patients Undergoing Dental Procedures**

Patient Considerations	Antimicrobial Agent	Regimen
Not allergic to penicillin	Amoxicillin	2 g orally or IM/IV 30–60 minutes before procedure
Allergic to penicillin	Clindamycin	600 mg orally or IM/IV 30–60 minutes before procedure

*IM, Intramuscularly; IV, intravenously.*

## Chapter Review

### Questions

- Infective endocarditis prophylaxis is only routinely recommended for which of the following procedures?
  - Cystoscopy
  - Vaginal hysterectomy
  - Esophageal dilatation
  - Flexible bronchoscopy with biopsy
  - Tooth extraction in a patient with a prosthetic heart valve
- Which of the following statements regarding endocarditis in intravenous drug abusers (IVDAs) is false?
  - Right-sided (tricuspid valve) endocarditis is most common.
  - Polymicrobial infections are observed most commonly.
  - Data support the use of short-course (2-week) therapy for right-sided endocarditis caused by methicillin-sensitive *Staphylococcus aureus* in IVDAs.
  - Fungi account for <5% of cases of endocarditis in IVDAs.
  - Candida* species are the most common fungal organism causing endocarditis in IVDAs.

3. Which of the following clinical features should not raise the suspicion of infective endocarditis?
- A new regurgitant murmur
  - Embolic events of unknown origin
  - Fever
  - Hematuria
  - Erythema marginatum

### Answers

## Immunizations

NICOLAS C. ISSA AND LINDSEY R. BADEN

Childhood immunizations are responsible for the control of many infectious diseases once common in the United States including polio, measles, mumps, rubella, diphtheria, pertussis, and *Haemophilus influenzae* type b. Vaccine-induced immunity, however, may decrease with time, and adult immunization recommendations consider both waning immunity and age-related risks of exposure and infection. Benefits of immunization are not limited to the vaccinated individual but also include herd immunity for the population at large, including nonimmunized persons and those with weakened immune systems, waning immunity, or those who may not have fully responded to prior vaccinations. Immunizations, however, also carry risks that can range from common minor local skin reactions to rare, life-threatening adverse reactions. These risks are carefully weighed in the creation of immunization schedule recommendations, balancing the individual's risk of exposure with the earliest timing that immunizations can be safely and effectively administered.

This chapter reviews the recommendations for adult immunizations in the United States as promoted by the Centers for Disease Control and Prevention (CDC) and the Advisory Committee on Immunization Practices (ACIP) and provides information regarding the basic principles underlying immunization and specific contraindications to vaccination. Immunization recommendations for travelers to other parts of the world require specific information regarding the infectious risks endemic to each area and are beyond the scope of this chapter. Further detailed information for both recommended immunizations in the United States and travel vaccines can be obtained from the CDC website: <http://www.cdc.gov/vaccines>.

### Basic Principles of Immunizations

Protection against infectious organisms may be via induction of either passive or active immunity. Passive immunity results from the transfer of preformed antibodies, whereas active immunity requires the generation of an antigen specific cellular and/or humoral immune response. Although passive immunity provides immediate protection, the effects are short-lived (usually 3–6 months). Conversely, active vaccination strategies

provide longer-lasting immunity through the induction of a memory response, although this response may wane with age and require intermittent vaccination “boosters.” Halting community spread of wild-type infections, however, may decrease natural boosting. This poses a potential challenge to successful vaccination strategies and highlights the importance of maintaining up-to-date booster schedules.

A variety of different types of antigens or immunogens have been used as vaccines to induce active immunity. Vaccines comprised of live attenuated infectious agents are generally the most efficacious in stimulating longer-lasting immunity, although their use is contraindicated in certain populations, such as individuals with severe immune impairment and pregnant women. Polysaccharide vaccines generate a T-cell-independent immune response, and their immunogenicity is generally poorer in infants and children younger than 2 years of age. Polysaccharides conjugated to protein carriers increase their overall antigenicity and elicit T-cell help, thus facilitating the induction of a memory response. Toxoid vaccines typically consist of deactivated toxins and may be used to generate immunity against specific toxins produced by infectious agents rather than against the causative organism.

Passive immunization is produced through the administration of specific or pooled immunoglobulins (Ig). These preformed antibodies are typically administered following recent exposure to an infectious agent or just before possible exposure. In the United States, only plasma that has tested negative for certain infectious agents such as hepatitis B virus (HBV), HIV, and hepatitis C virus (HCV) is used to produce Ig. Available specific Ig products include tetanus Ig, rabies Ig, hepatitis A Ig, and hepatitis B Ig. Passive and active immunizations may be combined to provide both immediate and sustained protection. For example, following a bite from an animal potentially infected with rabies, both rabies Ig and the rabies vaccine should be given. When this type of combined strategy is used, the preformed Igs and the active vaccine must be administered at separate sites.

### Precautions and Contraindications

In general, severely immunocompromised individuals should not receive live vaccines because of the theoretical concern

**TABLE 4.1** Live Vaccines

Live Viral Attenuated Vaccines	Live Bacterial Vaccines
Measles, mumps, rubella (MMR) Varicella (for both chickenpox and shingles) Oral polio virus Yellow fever	Typhoid (Ty21a, oral) Bacille Calmette-Guérin (BCG)

for infection despite the agent's attenuated status (Table 4.1). Owing to the theoretical risk to the fetus, pregnant women should also not receive live vaccines. The only contraindication applicable to all vaccines is a history of a severe allergic reaction following a previous dose of the vaccine or a known allergy against a vaccine constituent. For example, persons with an anaphylactoid reaction to eggs should not receive influenza vaccine grown in eggs. Patients with severe allergies to certain antibiotics also require careful consideration before receiving vaccinations that contain that antibiotic. Both available polio vaccines contain neomycin, streptomycin, and polymyxin, whereas the measles, mumps, rubella (MMR) and varicella vaccines contain trace amounts of neomycin. Anaphylactoid reactions to these antibiotics are considered a contraindication to vaccination, whereas milder reactions such as rash are not. No currently available vaccine contains penicillin or penicillin products, and allergy to this antibiotic is not a contraindication to vaccination. The CDC provides a vaccine information sheet (VIS) for each vaccine, containing information on individual vaccine constituents, and they should be reviewed before administration.

Vaccinations should be postponed in the setting of moderate or severe acute illness with or without fever. Although a common misconception, a vaccination does not need to be deferred in patients with a mild illness or low-grade fever. Concurrent treatment with antibiotics also does not represent a contraindication to vaccination with the single exception of the oral typhoid vaccine (which is a live attenuated construct), because certain antibiotics may interfere with the effectiveness of this live attenuated bacterial vaccine. Similarly, the live varicella vaccine should not be administered in conjunction with antiviral chemoprophylaxis.

Patients with immunoglobulin A (IgA) deficiency (estimated frequency in the community in the United States is ~1:223 to 1:1000) should not receive Ig preparations unless the risk of illness outweighs the risk of potential reaction to the residual IgA in the preparation, which is an anaphylaxis-like reaction.

### Adult Immunization Recommendations

The CDC's National Center for Immunization and Respiratory Diseases maintains annual updates of recommended

childhood, adolescent, and adult immunization. Table 4.2 demonstrates the most recent recommended adult immunization schedule that has been approved by the ACIP. For newer vaccines, future surveillance efforts of the durability of vaccine-associated immunity help to determine the optimal booster interval.

### Influenza

The influenza vaccine is administered annually in the fall or winter (influenza season in the United States). Several available formulations of the influenza vaccine are used as an inactivated influenza preparation administered intramuscularly (IM). A live attenuated influenza vaccine (LAIV) administered via a nasal spray was previously used, but controversy regarding efficacy has led to it not being recommended for use in the United States for the 2016–2017 influenza season. The vaccine is available as a trivalent or quadrivalent vaccine and usually contains two influenza A virus antigens (H3N2 and H1N1) and 1 or 2 B virus antigens. A high-dose inactivated influenza vaccine containing four times the amount of antigens present in a standard-dose vaccine (60 µg of hemagglutinin antigen [HA] per strain vs. 15 µg of HA per strain, respectively) is approved for use in adults 65 years of age or older. A cell-culture-based (not egg-based) and a recombinant vaccine (can be given in case of severe egg allergy) are also available. Seasonal influenza epidemics occur because of antigenic drift, prompting the need for annual reassessment of circulating strains and formulation of the vaccine. Antigenic shifts occur less frequently; however, they can result in novel influenza A subtypes and pandemics (such as the 2009 influenza A H1N1 strain of swine origin) because of lack of preexisting immunity. Although the vaccine does not provide complete protection against all influenza strains, both the LAIV and the inactivated vaccines are efficacious in preventing influenza corresponding to the strains they contain.

The inactivated influenza vaccine is recommended for persons 6 months of age and older, including pregnant women, and specifically for persons with chronic medical problems (e.g., diabetes, renal dysfunction, cardiac disease, hemoglobinopathy). Patients with compromised respiratory function or increased risk of aspiration (e.g., seizure disorder, spinal cord injury, cognitive impairment) should also receive the vaccine. In addition, persons living in chronic care facilities or who work or live with high-risk people should be vaccinated, including all health care personnel. Vaccination of close contacts of vulnerable individuals is an effective infection control measure, because it provides a ring of protection. The vaccine may also be considered for any adult interested in decreasing his or her risk of becoming ill with influenza or spreading it to others.

A high-dose trivalent (Fluzone High-Dose) containing 180 µg total of influenza virus hemagglutinin antigen (standard vaccine contains 45 µg total of influenza virus hemagglutinin antigen) elicited higher hemagglutination

TABLE  
4.2

Recommended Adult Immunization Schedule by Vaccine and Age Group: United States, 2016

	19–21 Years	22–26 Years	27–49 Years	50–59 Years	60–64 Years	≥65 Years
Influenza	1 dose annually					
Tetanus, diphtheria, pertussis (Td/Tdap)	Substitute Tdap for Td once; then boost with Td every 10 years					
Varicella	2 doses					
Human papillomavirus (HPV)	3 doses					
Zoster					1 dose	
Measles, mumps, rubella (MMR)	1 or 2 doses					
Pneumococcal polysaccharide (PPSV23)	1 or 2 doses depending on indication					1 dose
Pneumococcal conjugate (PCV13)	1 dose					1 dose
Meningococcal 4-valent conjugate (MenACWY) or polysaccharide (MPSV4)	1 or more doses depending on indication					
Meningococcal B (MenB)	2 or 3 doses depending on vaccine					
Hepatitis A	2 or 3 doses depending on vaccine					
Hepatitis B	3 doses					
<i>Haemophilus influenzae</i> type b (Hib)	1 or 3 doses depending on indication					

**Yellow**, Recommended for all persons who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection; zoster vaccine is recommended regardless of past episode of zoster.

**Purple**, Recommended for persons with a risk factor (medical, occupational, lifestyle, or other indication).

*No shading*, No recommendation.

From Kim DK, Bridges CB, Harriman KH, et al. Advisory Committee on Immunization Practices recommended immunization schedule for adults aged 19 years or older—United States, 2016. *MMWR Morb Mortal Wkly Rep.* 2016;65:88–90.

inhibition (HI) titers against all three influenza virus strains compared with standard dose influenza vaccine in adults aged 65 years and older. It also provided modestly better protection against laboratory-confirmed influenza illness compared with the standard-dose vaccine (1.4% vs. 1.9% respectively, relative efficacy 24.2%; 95% confidence interval [CI], 9.7–36.5). High-dose influenza vaccine is currently approved for use in this age group who historically had lower response rate to standard dose influenza vaccine. A new adjuvanted (MF59) trivalent influenza vaccine (Fluad) was also recently approved for use in adults aged 65 years and older. An intradermal inactivated influenza vaccine (Fluzone intradermal) is also available for use in adults aged 18 to 64 years of age.

Administration of any influenza vaccine is contraindicated in a person with a history of previous anaphylaxis to this vaccine or any of its components. A recombinant influenza vaccine (Flublok) could be administered to those with severe egg allergy. Vaccination may also be deferred

during moderate or severe acute illness and in any patient with a history of Guillain-Barré syndrome occurring within 6 weeks of prior influenza vaccination.

## Pneumococcus

*Streptococcus pneumoniae* is an encapsulated gram-positive bacterium that remains a leading cause of pneumonia, otitis media, bacterial meningitis, and bacteremia. It is also an important cause of other invasive bacterial infections including acute sinusitis, brain abscess, osteomyelitis, septic arthritis, peritonitis, endocarditis, and pericarditis. The pneumococcal polysaccharide vaccine (PPSV) contains 23 serotypes of pneumococcal capsular polysaccharide corresponding to 85%–90% of all pneumococcal disease. This vaccine is specifically recommended for all persons aged 65 years or older and adult persons aged 19 through 64 years at high risk of complication from pneumococcal infection, namely persons with chronic cardiac or pulmonary disease,

chronic liver disease, diabetes, alcoholism, or who smoke cigarettes. A conjugated polysaccharide vaccine (Prevnar) containing 13 serotypes of pneumococcal capsular polysaccharide (PCV13) is available and recommended as the pediatric vaccine series and for those >65 years of age. In addition, it should be considered for patients who are at highest risk for poor outcome associated with pneumococcal infection. This group includes patients with anatomic or functional asplenia or sickle cell disease; cerebrospinal fluid leaks; immunocompromised patients including persons with HIV infection, leukemia, lymphoma, multiple myeloma, other malignancy, chronic renal failure, or nephritic syndrome; persons receiving immunosuppressive therapy or who have received or are candidates for an organ or bone marrow transplant; and candidates for or recipients of cochlear implants. The ACIP recommends that adults aged  $\geq 19$  years in this high-risk group who are pneumococcal-vaccine naïve should receive a dose of PCV13 first, followed by a dose of PPSV23 at least 8 weeks later. A second PPSV23 dose is recommended 5 years after the first PPSV23 dose in this group. For adults aged  $\geq 19$  years in the high-risk group who previously have received one dose or more of PPSV23 should be given a PCV13 dose  $\geq 1$  year after the last PPSV23 dose was received. For those who require additional doses of PPSV23, the first such dose should be given no sooner than 8 weeks after PCV13 and at least 5 years after the most recent dose of PPSV23 (Kim et al., 2016).

A one-time booster of PPSV23 is administered at least 5 years after the initial dose in patients who are older than 65 years of age and who received the first dose of PPSV23 before age 65 years, and to those at highest risk of fatal pneumococcal infection. No further doses are currently recommended for persons vaccinated with PPSV23 at or after age 65 years.

## Meningococcus

*Neisseria meningitidis* is a leading cause of bacterial meningitis in the United States, particularly because of the successful vaccination campaigns and protection against *S. pneumoniae* and *Haemophilus influenzae* type B (administered in childhood). *N. meningitidis* is spread through direct contact with respiratory secretions from either infected patients or asymptomatic carriers, and disease is associated with a high fatality and morbidity rate. In the United States most cases are sporadic, although localized outbreaks have occurred. Postexposure antibiotic prophylaxis for close contacts, ideally within 24 hours after identification of the index patient, is effective in reducing nasopharyngeal carriage of *N. meningitidis*. Acceptable and recommended antimicrobial agents include rifampin, ciprofloxacin, and ceftriaxone; azithromycin also has activity against *N. meningitidis* and is approved for use among children. Meningococcal vaccination is also an important control measure in outbreak settings.

*N. meningitidis* is an encapsulated organism, and meningococcal vaccination is recommended for all adults with anatomic or functional asplenia or terminal complement

component deficiencies. Vaccination is also recommended for college freshmen living in a dormitory, microbiologists who are routinely exposed to isolates of *N. meningitidis*, military recruits, and travelers to endemic areas such as the “meningitis belt” of sub-Saharan Africa. The government of Saudi Arabia also requires vaccination for all travelers to Mecca during the annual Hajj.

The meningococcal vaccine is currently available in two formulations in the United States: a polysaccharide vaccine (MPSV4 or Menomune) and a polysaccharide conjugate vaccine (MCV4 or Menactra), and both contain purified meningococcal polysaccharides of groups A, C, Y, and W-135. Neither vaccine provides protection against all serogroups of *N. meningitidis*, most notably serogroup B. Recently a new meningococcal vaccine against serogroup B (Men B vaccine) has been approved in the United States and is indicated in persons aged  $\geq 10$  years who are at increased risk for meningococcal disease. These persons include those with persistent complement component deficiencies including patients who are taking eculizumab, persons with anatomic or functional asplenia, microbiologists routinely exposed to isolates of *N. meningitidis*, and persons identified as at increased risk because of a serogroup B meningococcal disease outbreak. Young adults aged 16 through 23 years may be vaccinated with a series of Men B vaccine to provide short-term protection against most strains of serogroup B meningococcal disease (Category B recommendation: individual clinical decision making; MacNeil et al., 2015).

The polysaccharide conjugate vaccine (MCV4) is the preferred vaccine among persons aged 11 to 55 years, although, if unavailable, MPSV4 is an acceptable alternative. The unconjugated vaccine, MPSV4, is currently recommended for persons aged >56 years. Both vaccines are usually administered as a single dose. However, for adults with functional asplenia, persistent complement component deficiencies or HIV infection, two doses of MCV4 at least 2 months apart are indicated.

Revaccination with MCV4 after 5 years is recommended for adults who previously received MCV4 or MPSV4 and who remain at increased risk for infection (functional asplenia or complement component deficiencies). There is no recommendation for Men B revaccination at this time. Men B vaccine may be administered concomitantly with any of the quadrivalent meningococcal vaccines (MCV4 and MPSV4) but at a different anatomic site.

## Haemophilus Influenzae B

*H. influenzae* type b (Hib) can cause severe bacterial infections primarily in infants and children under 5 years of age, and vaccination against this infectious agent is routinely administered to infants. A polysaccharide-protein conjugate vaccine is available and is indicated in persons who have anatomic or functional asplenia or sickle cell disease or are undergoing elective splenectomy. Hib vaccination is recommended 14 or more days before splenectomy if possible. Hib vaccine is not recommended for adults with HIV

infection because their risk for Hib infection is low. Stem cell transplant recipients should receive a three-dose regimen of Hib vaccine 6 to 12 months after transplantation.

## Tetanus, Diphtheria, Pertussis

Tetanus, although not a communicable disease, is preventable with vaccination. Adult disease is generally contracted via wound contamination with toxin-producing *Clostridium tetani*. Diphtheria is an acute infectious respiratory illness primarily caused by strains of *Corynebacterium diphtheriae* and is characterized by a grayish adherent membrane in the pharynx, palate or nasal mucosa, larynx, or trachea and can lead to airway obstruction. Diphtheria toxin can also cause systemic complications, most notably cardiac and neurologic. Immunization strategies in the United States have made both tetanus and respiratory diphtheria a rare occurrence; however, exposure to diphtheria is possible during travel to endemic areas. Because of waning immunity, adult booster immunizations with adult tetanus and diphtheria toxoids (Td) are recommended every 10 years.

Pertussis, an acute respiratory infection caused by *Bordetella pertussis*, remains endemic in the United States in large part due to waning immunity 5 to 10 years after childhood vaccination. Compared with older age groups, infants less than 12 months old are at the greatest risk for pertussis-related complications and hospitalizations, and adult close contacts have been implicated in pertussis transmission. Whereas adults are more likely to have asymptomatic infection, pertussis can cause pneumonia. In addition, prolonged paroxysmal cough is common and can lead to multiple physician visits and extensive medical evaluation when the etiology is unrecognized. Clinical complications of paroxysmal cough include rib fracture, cough syncope, urinary incontinence, as well as aspiration, pneumothorax, inguinal hernia, lumbar disc herniation, and subconjunctival hemorrhages.

In 2005 Tdap, consisting of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (marketed as Adacel and Boostrix), was licensed in the United States. To promote herd immunity, routine Tdap vaccination is recommended as a single replacement dose of a Td booster for all adults who have not previously received Tdap or for whom vaccine status is unknown. Tdap can be administered regardless of interval since the most recent tetanus or diphtheria-toxoid containing vaccine (Kim et al., 2016). In addition, Tdap is specifically recommended for pregnant women during each pregnancy (preferably between 27–36 weeks' gestation) to increase the likelihood of optimal protection for the pregnant woman and her infant during the first few months of the infant's life when the child is at the highest risk for severe illness and death from pertussis. Tdap can be administered regardless of interval since the most recent tetanus or diphtheria-containing vaccine.

Appropriate tetanus prophylaxis in the management of a contaminated wound depends on the patient's prior tetanus vaccination history. Injuries that are associated with a risk of tetanus include wounds contaminated with dirt, feces,

soil, or saliva. Puncture wounds, avulsions, or other injuries occurring because of frostbite, burns, crush, or missiles are also considered at increased risk for tetanus. Adults who completed the three-dose primary tetanus vaccination series and have received a tetanus-toxoid-containing vaccine (Td or Tdap) less than 10 years before the wound are considered protected and do not require further specific tetanus prophylaxis. Adults vaccinated  $\geq 10$  years earlier who have not received Tdap should receive Tdap rather than Td if possible. For adults vaccinated with Tdap in the past, Td should be used. Patients with unknown or uncertain previous tetanus vaccination histories may require both tetanus toxoid and passive immunization with tetanus immune globulin for full protection.

Clean, minor wounds do not require tetanus prophylaxis but provide an opportunity to complete the primary tetanus vaccination series. Adults with incomplete or unknown history of vaccination should receive the three-dose primary series. The preferred schedule is a single dose of Tdap, followed by Td at  $\geq 4$  weeks and another Td dose 6 to 12 months later. Tdap can substitute for any of the Td doses.

## Measles, Mumps, Rubella

The MMR vaccine contains three live attenuated viruses—measles, mumps, and rubella—and is generally administered to children around age 1 year and again at school entry (around 4–6 years of age). The second immunization is not a booster; rather, the objective of the second dose is to promote immunity in the small proportion of persons who do not respond to one dose. Any adult born after 1957 without serologic evidence of immunity should receive at least one dose of MMR. A second dose of MMR is recommended for (1) adults who have recently been exposed to measles or mumps or are in an outbreak setting, (2) adults previously immunized with an unknown type of measles vaccine between 1963 and 1967 or a killed measles vaccine, (3) students in postsecondary educational institutions, (4) health care workers, and (5) persons planning international travel. Women of childbearing age with unknown rubella vaccination history or who lack serologic evidence of immunity should also receive one dose of MMR. Women should be counseled to delay pregnancy at least 4 weeks after receiving MMR.

Serious adverse events with MMR vaccination include encephalitis, pneumonia, epididymo-orchitis, and arthropathy (rubella), particularly in postpartum women. These adverse events, however, are quite rare and are outweighed by the risks of naturally acquired measles, mumps, or rubella disease.

## Varicella Zoster Virus

The varicella zoster virus (VZV) can cause both primary infection (varicella, chickenpox) and recurrent, or reactivated, infection (herpes zoster, shingles). Infection with varicella carries the highest hospitalization rates among

adults older than 19 years of age and infants <1 year of age (in comparison to children aged 5–9 years). Complications leading to hospitalization include skin and soft tissue infection, particularly invasive group A streptococcal infection, pneumonia, dehydration, and encephalitis. In the prevaccine era, prenatal infection was uncommon because most women of childbearing age had acquired natural immunity to VZV through childhood infection; however, prenatal maternal infection can have adverse outcomes for the fetus and infant.

Three vaccines are currently available in the United States, each containing increasing concentrations of the live-attenuated (Oka strain) varicella virus. The varicella vaccine Varivax contains 1440 plaque-forming units (pfu) and is recommended for children older than 12 months of age and any adult who does not have evidence of immunity to VZV. Evidence of immunity to varicella in adults includes any of the following: (1) US-born before 1980 (although this does not suffice as evidence for health care personnel and pregnant women), (2) documentation of two doses of varicella vaccine administered at least 4 to 8 weeks apart, (3) history of varicella based on diagnosis or verification by a health care provider, (4) history of herpes zoster based on health care provider diagnosis, or (5) laboratory evidence of immunity or confirmation of disease.

Adolescents (aged 13 years and older) and adults without evidence of varicella immunity should receive two doses of Varivax spaced 4 to 8 weeks apart. Special consideration should be given to at-risk groups including school-aged children, members of households with children, college students, employees, residents and staff of institutional settings, and nonpregnant women of childbearing age. Breakthrough varicella disease postvaccination has been documented but is usually mild. The varicella vaccine Proquad has 9800 pfu of the live varicella vaccine (seven times Varivax) as well as MMR and is approved only for children ages 12 months through 12 years old. A third varicella vaccine, Zostavax, contains 19,400 pfu, about 14 times the amount of live attenuated (Oka strain) varicella vaccine as the varicella vaccine and is US Food and Drug Administration (FDA)–approved for adults older than 50 years of age, whether or not they report a prior episode of shingles; however, the ACIP continues to recommend that zoster vaccination begins at age 60 years. For persons aged 60 years and older who anticipate immunosuppressive therapy, zoster vaccine should be administered at least 14 days before the start of therapy. Persons taking antiviral medications active against herpes viruses (e.g., acyclovir, famciclovir, or valacyclovir) should discontinue these medications 24 hours before receiving the zoster vaccine and not resume therapy for at least 14 days after immunization. Zoster vaccine should not be administered to any person with a primary or acquired immunodeficiency including leukemia, lymphoma, and HIV infection complicated by AIDS (CD4 count <200). A new subunit adjuvanted zoster vaccine is currently in development. A phase 3 study of this vaccine involving 15,411 older adults (≥50 years of age) recently published showed

an overall vaccine efficacy of 97.2% against herpes zoster compared with placebo (95% CI, 93.7–99.0;  $p < .001$ ) (Lal, 2015). One of the potential advantages of this subunit adjuvanted vaccine is that it can be used in immunocompromised patients, if shown to be immunogenic in this population, because it does not contain a live-replicating virus. Studies on vaccine efficacy in immunocompromised patients are currently under way.

## Human Papillomavirus

Genital human papillomavirus (HPV) is the most common sexually transmitted infection in the United States. Most HPV infections are transient and asymptomatic; however, persistent infection can result in cervical cancer in women as well as anogenital cancers and warts in both men and women. There are over 100 types of HPV, and about 40 are mucosal types that can infect the anogenital area. “High-risk” types (types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 69, 73, and 82) have been linked with low-grade and high-grade cervix cell changes, precancers, and anogenital cancers. Nearly all cases of cervical cancer are related to HPV, and about 70% are caused by HPV type 16 or 18. Genital warts, or condyloma acuminata, are associated with “low-risk” types, with approximately 90% of cases due to types 6 and 11. Low-risk types can also cause cervical cellular changes that do not develop into cancer.

A quadrivalent HPV vaccine (HPV4, Gardasil) targeting types 6, 11, 16, and 18 and a nine-valent vaccine (HPV9, Gardasil-9) that includes five additional oncogenic types (31, 33, 45, 52, and 58) are licensed for use in the United States among women and men aged 11 through 26 years old. A second vaccine that targets HPV types 16 and 18 only (HPV2, Cervarix) is licensed for use in females only. Neither vaccine provides protection against persistent infection, development of genital warts, or precursor cancer lesions for an HPV type that a woman is infected with at the time of vaccination. HPV vaccination does protect, however, against disease caused by other not-yet acquired vaccine HPV types. Ideally, vaccination should occur before the onset of sexual activity and potential exposure to HPV, and the recommended age for vaccination is 11 to 12 years. Catch-up vaccination is recommended for women aged 13 to 26 years who have not yet been vaccinated. The recommended schedule is three doses administered at 0, 1 to 2 months, and 6 months, and it can be simultaneously administered with other vaccines. HPV4 and HPV9 are recommended for males 11 to 12 years of age with catch-up vaccination recommended for males 13 to 21 years of age. HPV4 and HPV9 vaccine are also recommended for previously unvaccinated males 22 to 26 years of age who are immunocompromised, HIV infected, or men who have sex with men (MSM). It is expected that HPV4 will be phased out in the near future because HPV9 is now available.

Side effects include local reactions, most commonly pain, as well as swelling and erythema at the injection site.

Vasovagal syncope has been observed after vaccination, especially among adolescents and young adults, and patients receiving this vaccine should be observed for 15 minutes after administration. The HPV vaccine is a recombinant vaccine produced with *Saccharomyces cerevisiae* (baker's yeast) and is contraindicated for any person with a history of immediate hypersensitivity to yeast (or any vaccine component). Owing to limited data, this vaccine is not recommended for use in pregnancy. Vaccination with the HPV vaccine does not replace routine cervical cancer screening.

## Hepatitis A Virus

Hepatitis A virus (HAV) can cause either asymptomatic or symptomatic infection. Infection is typically asymptomatic in children under the age of 6 years and symptomatic among older children and adults. The majority of clinical syndromes last less than 2 months (although approximately 10%–15% experience a prolonged or relapsing course lasting up to 6 months). Persons with chronic liver disease, especially due to HCV, are at increased risk for fulminant hepatitis A and death. In the United States, transmission is primarily via a fecal-oral route, and young asymptomatic children can act as sources of infection for others. Persons at increased risk of HAV infection include travelers to endemic areas, MSM, users of injection and noninjection drugs (suggesting infection via both percutaneous and fecal-oral routes), persons with clotting factor disorders, and persons working with nonhuman primates susceptible to HAV infection. Improvements in viral inactivation procedures, donor screening, and vaccination strategies have decreased the risk of transmission from clotting factors.

Hepatitis A vaccination is recommended routinely for children, for persons at increased risk of infection or at high risk of complications of infection (persons with chronic liver disease), and for anyone interested in obtaining immunity. During community-outbreak settings, hepatitis A vaccination should be considered. Routine vaccination of all food handlers is not recommended, primarily due to cost, but may be considered. Proper hygiene to reduce the risk of fecal contamination of food and awareness of the signs and symptoms of hepatitis A remain the mainstay of food preparation safety.

Hepatitis A vaccines currently licensed in the United States are made from inactivated HAV: two types of single-antigen vaccines (Havrix and Vaqta) and a combination vaccine containing both HAV and HBV antigens (Twinrix). Havrix and Vaqta are both available in two formulations that differ according to the patient's age (pediatric vs. adult). In adults, Havrix is administered in two doses scheduled at 0 and 6 to 12 months; Vaqta is administered in two doses scheduled at 0 and 6 to 18 months.

After hepatitis A exposure in nonvaccinated persons, either administration of the single-antigen hepatitis A vaccine or hepatitis A Ig is recommended for postexposure prophylaxis and should be administered as soon as possible (within 2 weeks). Hepatitis A Ig is 80% to 90% effective in

preventing hepatitis A when administered within 2 weeks postexposure. A single dose of 0.02 mL/kg of Ig provides effective protection for 3 months, and a dose of 0.06 mL/kg provides protection for 3 to 5 months (CDC, 2016). Hepatitis A vaccine administration in exposed persons younger than 40 years of age appears to be as efficacious as Ig in preventing disease. Owing to a paucity of data, hepatitis A Ig is preferred among exposed persons older than 40 years of age or those with underlying medical illnesses, including chronic liver disease. In these groups, although hepatitis A Ig is preferred, vaccine can be used if hepatitis A Ig is unavailable. Persons who receive hepatitis A Ig and who meet criteria for routine hepatitis A vaccination should initiate the vaccine series simultaneously with Ig (at separate sites). Household and sexual contacts of, as well as people who have shared illicit drugs with, a person with serologically confirmed hepatitis A should receive postexposure prophylaxis.

Hepatitis A vaccine can be administered as preexposure prophylaxis to travelers to endemic areas. Persons who are either allergic to a vaccine component or elect not to receive the vaccine should receive a single dose of hepatitis A Ig (CDC, 2016). Persons who are older than 40 years of age, immunocompromised, or have chronic liver disease should receive Ig in addition to the vaccine if they plan to travel to a high-risk area within the next 2 weeks (before the development of optimal protection from vaccination).

## Hepatitis B Virus

HBV can cause both acute and chronic hepatitis with viral transmission occurring via percutaneous or mucosal exposure to infectious blood or body fluids (e.g., saliva, semen). Before routine hepatitis B vaccination in the United States, 30% to 40% of chronic infections were attributable to perinatal or early childhood transmission. Chronic hepatitis B infection carries an increased risk of cirrhosis and hepatocellular carcinoma as well as liver failure and death, thus making the hepatitis B vaccine the first vaccine effective in preventing the development of a cancer. Routine screening of pregnant women for chronic infection and universal immunization of newborns and previously unvaccinated children have greatly reduced the incidence rate of acute hepatitis B in the United States. In addition, vaccination of health care workers and adherence to universal precautions have also significantly decreased the occupational hazard of HBV infection. Adult groups at increased risk for infection in the United States include injection drug users, household contacts of persons with chronic HBV infection, developmentally disabled persons in long-term care facilities, hemodialysis patients, and persons with chronic liver disease or HIV infection. Persons engaging in higher-risk sexual behaviors, such as MSM, are also more likely to contract HBV infection. Travelers to HBV-endemic areas may also be at risk if they are involved in disaster relief activities, receive medical care, or partake in drug use or sexual

activity. Vaccination for hepatitis B is recommended for long-term travelers. Pregnancy is not a contraindication to vaccination.

Available hepatitis B vaccine formulations in the United States contain recombinant hepatitis B surface antigen (HBsAg) and are available both as a single-antigen and combination formulations. The licensed single-antigen vaccines for adults are Recombivax HB and Engerix-B, both produced using recombinant HBsAg. The recommended dosing schedule is three injections at 0, 1, and 6 months, and the different formulations of the vaccine may be interchanged. Twinrix, a combination formulation of recombinant HBsAg and inactivated HAV, is also licensed for adult administration.

The response rate in adults younger than 40 years of age is greater than 90% after the complete three-dose series. The protective antibody response diminishes in the elderly (only 75% of persons 60 years of age or older develop protective antibody). Smoking, obesity, and immune suppression are also associated with lower response rates. Serologic testing for immunity is not necessary after routine vaccination of adults; however, it is recommended for health care workers and public safety workers, chronic hemodialysis patients, HIV-infected persons and other immune-compromised patients, and sex partners of HBsAg-positive persons. Testing should be performed 1 to 2 months after the completion of the series, and those with low anti-HBs concentrations (<10 mIU/mL) should be revaccinated with the three-dose series.

Hepatitis B immune globulin (HBIG) may be administered along with hepatitis B vaccine for postexposure prophylaxis or administered alone following exposure for nonresponders to prior hepatitis B vaccination. Postexposure prophylaxis with HBIG plus hepatitis B vaccine, hepatitis B vaccine alone, and HBIG alone have all been demonstrated to be effective in preventing HBV transmission. The effectiveness of HBIG postexposure decreases with delayed administration, and the recommended interval for administration is less than 7 days after a needle stick and less than 14 days for sexual exposures.

## Further Considerations

### Spacing of Multiple Immunizations

Inactivated vaccines may be effectively administered either simultaneously or at any time before or after another vaccine. Nonsimultaneous administration of live vaccines, however, may lead to interference in the immune response and impaired protective effect. If live vaccines are not administered on the same day, their administration should be separated in time by at least 4 weeks. Exceptions to this rule are the live oral typhoid and yellow fever vaccines.

Blood and other antibody-containing blood products (e.g., intravenous immune globulin) may inhibit the response to live vaccines with the inhibition potentially lasting for longer than 3 months. The measles and rubella vaccines are

particularly impaired in the setting of blood product administration; data regarding the mumps and varicella vaccines are more limited. No interference between blood products and Ty21a typhoid or yellow fever vaccine has been observed, and, except for these two vaccines, the administration of a live vaccine should be delayed for at least 3 months after receipt of an antibody-containing blood product to allow sufficient degradation of the passive antibody (Kroger and Strikas, 2015).

### Special Risk Groups

#### Timing of Vaccines for Persons With Immunosuppression

Immunosuppressed adults are at increased risk for severe infection with several vaccine-preventable infections. However, as discussed earlier, live vaccines should be deferred until immune function improves. Inactivated vaccines administered during periods of severe immunosuppression may have to be repeated after immune function has improved.

Although corticosteroid therapy alters immune competence, it is not a contraindication to vaccination with a live virus. Persons who may safely receive live virus vaccines include those receiving short-term oral corticosteroid therapy (<2 weeks) or low-dose to moderate-dose therapy (<20 mg of prednisone daily) or are on replacement therapy.

Adults with anatomic or functional asplenia are at increased risk of infection by encapsulated bacteria, namely *S. pneumococcus*, *N. meningitidis*, and Hib. If splenectomy is elective, vaccines against these agents should be administered at least 2 weeks before surgery. If not, they should be administered as soon as clinically possible. See Table 4.3 for additional immunization recommendations for special risk groups.

All hematopoietic cell transplant recipients should be routinely revaccinated after stem cell transplantation. Most inactivated vaccines can be administered as early as 6 months after transplantation. Live vaccine (MMR, VZV) can be administered 24 months after transplantation if patients are no longer on immunosuppression and are free of graft-versus-host disease.

#### Close Contacts of Immunocompromised Persons

Close contacts (including household members and care providers) of immunocompromised persons should receive all age-appropriate vaccines, including an annual influenza vaccine. Owing to the potential for shedding of live virus, household contacts of immunosuppressed persons should not receive the live oral polio virus; however, MMR and varicella virus vaccines are reasonably safe.

### Acknowledgment

The authors and editors gratefully acknowledge the contributions of the previous author Mary L. Pisculli to the development and writing of this review.

**TABLE 4.3 Vaccines Indicated for Adults With Specific Medical Conditions**

	Pregnancy	Immunocompromising Conditions (Excluding HIV)	HIV		MSM	Kidney Failure, ESRD, on Hemodialysis	Heart Disease, Chronic Lung Disease, Alcoholism	Asplenia, Splenectomy, Complement Deficiencies	Chronic Liver Disease	Diabetes	Health Care Personnel	
			CD4<200 Cells/μL	CD4≥200 Cells/μL								
Influenza	1 dose annually											
Tetanus, diphtheria, pertussis	1 dose Tdap each pregnancy	Substitute Tdap for Td once; then boost with Td every 10 years										
Varicella	Contraindicated		2 doses									
HPV		3 doses through age 26 years			3 doses through age 26 years (F), 21 years (M)							
Zoster	Contraindicated			1 dose								
MMR	Contraindicated		1 or 2 doses depending on indication									
PPSV23					1, 2 or 3 doses depending on indication							
PCV13				1 dose								
Meningococcal 4-valent conjugate (MenACWY) or polysaccharide (MPSV4)	1 or more doses depending on indication								1 or more doses			
Meningococcal B (Men B)		2 or 3 doses depending on vaccine										
Hepatitis A							2 or 3 doses depending on vaccine					
Hepatitis B		3 doses										
<i>Haemophilus influenzae</i> type b (Hib)		3 doses post-HSCT only	1 dose									

ESRD, End-stage renal disease; HIV, human immunodeficiency virus; HPV, human papillomavirus; HSCT, hematopoietic stem cell transplant; MMR, measles, mumps, rubella; MSM, men who have sex with men; PCV13, pneumococcal 13-valent conjugate vaccine; PPSV23, pneumococcal polysaccharide vaccine.

- Yellow, Recommended for all persons who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection; zoster vaccine is recommended regardless of past episode of zoster.
- Purple, Recommended for persons with a risk factor (medical, occupational, lifestyle, or other indication).
- No shading, No recommendation.
- Red, Contraindicated.

From Kim DK, Bridges CB, Harriman KH, et al. Advisory Committee on Immunization Practices recommended immunization schedule for adults aged 19 years or older—United States, 2016. *MMWR Morb Mortal Wkly Rep.* 2016;65:88–90.

## Chapter Review

### Questions

1. A 25-year-old male with sickle cell disease presents for regular follow up. He received pneumococcal polysaccharide vaccine, *Haemophilus influenzae* type b vaccine, and two doses of meningococcal conjugated vaccine more than 5 years ago. Which of the following vaccines are indicated at this time?
  - A. Pneumococcal conjugated vaccine (PCV13) followed by pneumococcal polysaccharide vaccine (PPSV23) at least 1 year after PCV13 and a second dose of PPSV23 (booster dose) at least 5 years after the last PPSV 23 dose
  - B. Pneumococcal conjugated vaccine (PCV13) followed by pneumococcal polysaccharide vaccine (PPSV23) at least 5 years after the last PPSV 23 dose
  - C. Pneumococcal conjugated vaccine (PCV13) and a second dose of *Haemophilus influenzae* type b vaccine
  - D. Pneumococcal conjugated vaccine (PCV13) and meningococcal polysaccharide vaccine (MPSV4)
2. Which of the following vaccines is contraindicated in household contacts of a patient with acute myeloid leukemia who underwent stem cell transplantation 3 months ago?
  - A. Measles, mumps, and rubella (MMR) vaccine
  - B. Varicella vaccine
  - C. Oral typhoid vaccine
  - D. None of the above
3. Meningococcal serogroup B vaccine is indicated in these persons, other than:
  - A. Persons with anatomic or functional asplenia
  - B. Persons with persistent complement component deficiencies
  - C. Persons with multiple myeloma
  - D. Persons receiving eculizumab for treatment of paroxysmal nocturnal hemoglobinuria

# 5

## Tropical Infections

JAMES H. MAGUIRE

Diseases endemic to the tropics and subtropics remain major causes of morbidity and mortality in resource-poor areas of the world and are a challenge for practitioners in industrialized countries who care for returning travelers and immigrants. As a rule, the infectious diseases of travelers differ from those of persons who have lived for long periods of time in endemic areas. For example, hepatitis A is rare among immigrants arriving from the tropics, who typically acquired infection and lasting immunity early in life, whereas travelers from industrialized countries lack immunity unless vaccinated and are at high risk of becoming infected during travel. This chapter discusses several of the most common clinical syndromes and the tropical infectious diseases that cause them.

### Fever

Fever following travel requires prompt attention because infections such as falciparum malaria, typhoid fever, and meningococemia can be rapidly fatal. Prompt recognition of other illnesses such as hepatitis A, measles, pulmonary tuberculosis, Ebola, and other viral hemorrhagic fevers is necessary for timely implementation of infection-control measures to prevent transmission to others. Leading causes of febrile illness in travelers who seek medical attention in travel clinics are listed in [Table 5.1](#).

### Malaria

*Anopheles* mosquitoes transmit malaria to several hundred million persons in the tropics and subtropics, of whom more than 400,000 die each year. At least 1500 cases of malaria are imported into the United States annually, and several persons die because of missed diagnosis, delay in diagnosis, and/or failure to administer appropriate treatment in a timely fashion. The risk of malaria to travelers is highest in sub-Saharan Africa, Papua New Guinea, and several islands in the south Pacific; lower in the Indian subcontinent; and lowest in Latin America and Southeast Asia. In the United States, more than half of the imported cases of malaria occur among persons who visit friends and relatives in their countries of origin and do not take proper chemoprophylaxis.

### Clinical Features

Fever, rigors, headache, nausea, vomiting, myalgia, anemia, and thrombocytopenia occur in infections caused by all species of *Plasmodium*. *Plasmodium falciparum* accounts for nearly all the deaths from malaria because of its ability to infect erythrocytes of all ages and attain high parasitemias. It also expresses antigens on the surface of infected red blood cells that cause the cells to adhere to the endothelium of small blood vessels and block flow of blood, and it elicits production of high levels of tumor necrosis factor and other cytokines. As a result, falciparum malaria progresses rapidly, and its various complications can mimic other infectious processes such as meningitis, encephalitis, pneumonia, hepatitis, and sepsis ([Box 5.1](#)). In contrast, *Plasmodium vivax*, *Plasmodium malariae*, and *Plasmodium ovale* are rarely fatal. Vivax and ovale malaria can relapse up to 4 years later or longer if treatment does not include primaquine, which eliminates persistent parasites in the liver. *Plasmodium knowlesi*, a parasite of rhesus monkeys, is responsible for a growing number of human infections, including fatal cases, in persons living in or traveling from forested areas of south-eastern Asia.

### Diagnosis, Treatment, and Prevention

Malaria should be considered in all persons who develop fever 1 week or longer after travel or residence in an endemic area, and thin and thick Giemsa-stained smears of peripheral blood should be examined by a skilled microscopist. Rapid tests that detect malaria antigens in the blood can be used to screen persons with fever, but microscopic examination of blood is necessary for confirmation of both negative and positive tests. Chloroquine is the drug of choice for infections caused by *P. malariae*, *P. ovale*, and chloroquine-sensitive strains of *P. vivax* and is an alternative for chloroquine-sensitive strains of *P. falciparum*. After glucose-6-phosphate dehydrogenase deficiency has been ruled out, primaquine should also be given to persons with vivax or ovale malaria to prevent relapses. *P. falciparum* should be considered chloroquine-resistant unless acquired in the Caribbean, Central America, parts of the Middle East, and North Africa. Drugs for treating falciparum malaria are listed in [Table 5.2](#). Two artemisinin derivatives have become

**TABLE 5.1 Common Causes of Fever in Persons Arriving From the Tropics**

Disease	Percentage of Febrile Travelers With Disease
Malaria	27%
Dengue	12%
Rickettsial disease	4%
Enteric fever	6%
Mononucleosis syndrome	8%
Diarrheal disease	15%
Respiratory illness	14%
Hepatitis	1%

Fever in returned travelers: results from the GeoSentinel Surveillance Network. *Clin Infect Dis.* 2007;44:1560-1568.

**• BOX 5.1 Complications of Falciparum Malaria**

Cerebral malaria (alterations of consciousness including coma)  
 Hypoglycemia  
 Noncardiac pulmonary edema, acute respiratory failure  
 Renal failure, including blackwater fever (hemoglobinuria)  
 Severe anemia  
 Lactic acidosis and shock  
 Jaundice, tender hepatomegaly  
 Diarrhea, dysentery, malabsorption  
 Placental dysfunction

**TABLE 5.2 Treatment of Falciparum Malaria****Mild to Moderate Cases**

Chloroquine-sensitive strains	Oral artemether-lumefantrine Alternative: oral chloroquine or hydroxychloroquine
Chloroquine-resistant strains	Oral artemether-lumefantrine Alternatives: oral atovaquone-proguanil or oral quinine and either doxycycline or clindamycin

**Severe Cases or Persons Unable to Take Oral Medications**

All strains	Intravenous artesunate (available through Centers for Disease Control and Prevention in the United States) followed by atovaquone-proguanil, doxycycline, or mefloquine Alternative: intravenous quinidine gluconate and either doxycycline or clindamycin
-------------	---

the drugs of choice: oral artemether (in combination with lumefantrine) and, for severe cases, intravenous artesunate. Artemether and artesunate are faster acting and better tolerated than other antimalarials. They are always given with a second agent, such as lumefantrine, mefloquine, or atovaquone-proguanil, to prevent recrudescences. Monotherapy with artemisinin derivatives has led to drug resistance in parts of Southeast Asia.

Chemoprophylaxis, as outlined in Table 5.3, should be given to all travelers to malarious areas. Travelers should avoid mosquito bites by using repellents, protective clothing, insecticide-impregnated nets, and screens on windows.

**Babesiosis**

Babesiosis, a tick-borne protozoan disease, is rarely reported from tropical areas, but it is a life-threatening problem for residents of, or travelers to, endemic areas in the north-eastern United States, Minnesota, Wisconsin, California, and Washington State. *Babesia microti* and other species of *Babesia* cause malaria-like illness with fever, splenomegaly, anemia, and thrombocytopenia. Asplenic persons, the elderly, and persons receiving immunosuppressive drugs are at risk for high parasitemias, respiratory failure, and death. Mild to moderate illness is treated with atovaquone and azithromycin; the combination of quinine and clindamycin is indicated for severe illnesses. Because the tick vector of *B. microti* may be coinfecting with other pathogens, Lyme disease and anaplasmosis (human granulocytic ehrlichiosis) should be considered in persons who remain ill after appropriate treatment of babesiosis.

**Dengue, Chikungunya, and Zika**

Increasing numbers of cases among tourists and other returning travelers have paralleled the global resurgence and rapid spread of three mosquito-borne viral infections: dengue, chikungunya, and Zika. The mosquito vectors

**TABLE 5.3 Chemoprophylaxis of Malaria**

Areas Without Chloroquine Resistance	Chloroquine or Hydroxychloroquine
Areas without chloroquine resistance and >90% of malaria is <i>Plasmodium vivax</i>	Primaquine
Areas with chloroquine resistance	Doxycycline or Atovaquone-proguanil or Mefloquine (not in certain border areas in southeast Asia)
Terminal prophylaxis for <i>Plasmodium vivax</i> , <i>Plasmodium ovale</i> malaria	Primaquine (check glucose-6-phosphate dehydrogenase screen)

*Aedes aegypti* and *Aedes albopictus* are widely distributed throughout the tropics and subtropics, as well as the southern United States, where cases of local transmission have occurred. Initial manifestations of all three infections are similar, making it difficult to distinguish them on clinical grounds. After an incubation period of usually 2 to 7 days and occasionally longer, fever, chills, headache, myalgia, arthralgia, and in varying percentage of cases, an erythematous macular rash occurs, although some cases may be subclinical. Life-threatening complications of dengue include hemorrhage and shock from capillary leak, typically among persons who experience a second infection but with a different serotype. Chikungunya virus infection may cause severe polyarthralgias or arthritis with synovitis that persists for months or longer in one-third or more of persons. Zika infection during pregnancy can cause microcephaly and fetal brain defects, and there has been an increased incidence of Guillain-Barré syndrome in persons following Zika infection.

A clinical diagnosis of dengue, chikungunya, or Zika is confirmed by polymerase chain reaction (PCR)-based assays to detect virus during the first 5 days of illness or later by serologic tests. Treatment is supportive because no antiviral therapy is available. There are no vaccines yet for chikungunya or Zika, and the available dengue vaccine is not recommended for travelers. Infection is avoided by prevention of mosquito bites. Women should avoid travel to Zika-endemic areas during pregnancy, and precautions should be taken to prevent sexual transmission of Zika, which can occur for weeks to months after infection.

## Rickettsial Infections

*Rickettsia africae*, the agent of African tick typhus, has become a common cause of fever among travelers returning from safaris or other outdoor activities in sub-Saharan Africa, especially in southern Africa. Patients present with fever, headache, myalgia, regional lymphadenopathy, leukopenia, thrombocytopenia, and an erythematous lesion with a black necrotic center at the site of the tick bite (Fig. 5.1).

• **Fig. 5.1** Ulcerative lesion with eschar in a traveler with African tick bite fever.

Rashes are usually absent. The diagnosis is confirmed by serologic tests, and the illness responds quickly to doxycycline. Travelers may encounter other tick-borne rickettsial infections in different parts of the world. The spotted fever group includes Rocky Mountain spotted fever caused by *Rickettsia rickettsii* in the Americas and Mediterranean spotted fever (boutonneuse fever) caused by *Rickettsia conorii* in southern Europe, northern Africa, and western Asia. Scrub typhus (tsutsugamushi fever) is caused by *Orientia tsutsugamushi*, which is transmitted by the bite of larval mites in the Far East, South Pacific, and Australia.

## Typhoid

*Salmonella enterica* serotype Typhi (*S. typhi*) and serotype Paratyphi (*S. paratyphi*) cause enteric fever in persons who ingest fecally contaminated food or water. The risk is highest for travelers to the Indian subcontinent, Southeast Asia, Africa, and Latin America.

### Clinical Features

Typhoid fever is characterized by the gradual onset of rising temperatures, rigors, and headache followed by sustained high fevers (often with a comparatively slow pulse), abdominal pain, and hepatosplenomegaly. Constipation is frequent, but up to 50% of patients have diarrhea. Complications include bowel perforation, intestinal bleeding, and shock.

### Diagnosis, Treatment, and Prevention

Diagnosis is made by culture of blood, stool, urine, or bone marrow. Ciprofloxacin, other fluoroquinolones, and ceftriaxone are active against most isolates, but increasing resistance to fluoroquinolones and cephalosporins has made azithromycin the drug of choice in some areas of India.

Prevention of typhoid fever includes avoidance of contaminated food and water and vaccination, either with a single dose of polysaccharide vaccine (Vi) or four doses of oral attenuated live Ty21a vaccine. Neither vaccine is 100% protective, and neither prevents infection with *S. paratyphi*.

## Meningococcal Infection

Meningococcal meningitis and meningococcemia occur throughout the world, but risk is high in the “meningitis belt” of sub-Saharan Africa, which extends from Senegal to Ethiopia during outbreaks in the dry months of November to June. Outbreaks also have occurred during the Hajj. Prompt diagnosis and treatment with ceftriaxone, cefotaxime, or chloramphenicol, which is still used in developing areas, are essential for preventing fatalities, neurologic deficits, and gangrene. Quadrivalent vaccine should be administered to travelers to high-risk destinations.

## Leptospirosis

Transmission of *Leptospira interrogans* occurs by contact of skin or mucous membranes with fresh water or moist soil contaminated with the urine of rodents and other mammals. Infection of animals occurs worldwide, and outbreaks have been associated with flooding, military operations, ecotourism, whitewater rafting, and other water sports.

Leptospirosis presents with fever, headache, myalgia, conjunctival suffusion, and often hepatosplenomegaly or rash. Complications include aseptic meningitis and Weil syndrome with hepatitis, intense jaundice, renal insufficiency, and hemorrhage. The diagnosis is usually made with serologic tests, although the organism can be identified by dark field microscopy or culture on special media. Doxycycline, penicillins, or ceftriaxone are equally effective for treatment, and weekly doxycycline can prevent infections in persons with unavoidable exposures.

## Diarrhea

Diarrhea is the most common health problem of travelers to the tropics and developing countries. Bacterial infections are the most frequent cause of travelers' diarrhea, and most cases present acutely and resolve within a week. The most common pathogens, enterotoxigenic *Escherichia coli*, *Salmonella*, *Campylobacter*, and *Shigella* respond to short courses of fluoroquinolones or azithromycin; the latter is active against fluoroquinolone-resistant *Campylobacter*, which is becoming more prevalent in parts of the world. Persistent diarrhea (i.e., lasting at least 2 to 3 weeks) is a common problem that prompts returning travelers to seek health care. [Box 5.2](#) lists the principal causes of persistent diarrhea.

## Intestinal Protozoa

Intestinal protozoan infections, including giardiasis, amebiasis, cryptosporidiosis, cyclosporiasis, and cystoisosporiasis, account for many cases of persistent diarrhea in returning travelers. All are transmitted by ingestion of fecally contaminated drink or water containing the cyst stage and, except for *Cyclospora cayentanensis* and *Cystoisospora belli*, can be transmitted by direct person-to-person contact. *Giardia*, *Cryptosporidium*, *Cyclospora*, and *Cystoisospora* infect the small bowel and cause voluminous watery stool, often with nausea, vomiting, or malabsorption. In cases of cryptosporidiosis, cyclosporiasis, or cystoisosporiasis, diarrhea lasting longer than 3 to 4 weeks or that reoccurs after treatment, should raise suspicion of HIV infection or other immune deficiency. *Entamoeba histolytica* infects the colon and causes dysentery with cramping and frequent, bloody, small-volume stools. Amebiasis may also cause episodes of nondysenteric diarrhea that may alternate with periods of constipation.

### • BOX 5.2 Causes of Persistent Diarrhea in Travelers Returning From the Tropics

#### Infections

Intestinal protozoan infections (giardiasis, amebiasis, cryptosporidiosis, cyclosporiasis, and cystoisosporiasis)  
Intestinal helminth infections (schistosomiasis, strongyloidiasis)  
Infection with enteroadherent *Escherichia coli*, *Plesiomonas*, *Aeromonas*

#### *Clostridium difficile* Colitis

Unusually prolonged episodes of common enteric bacterial infections (salmonellosis, shigellosis, *Campylobacter* infection)  
Tropical sprue (infectious agent not identified)

#### Underlying Gastrointestinal Unmasked by Enteric Infections

Inflammatory bowel disease  
Celiac sprue  
Colonic malignancies

#### Postinfectious Processes

Lactase deficiency  
Bacterial overgrowth with malabsorption  
Irritable bowel syndrome

Evaluation of persistent diarrhea should include three stool examinations for ova and parasites in a qualified laboratory. Antigen tests of stool are available for individual pathogens (*Giardia*, *Cryptosporidium*, *E. histolytica*), but these will miss less common protozoa that cause diarrhea, such as *C. cayentanensis*, *C. belli*, and *Dientamoeba fragilis*, and intestinal helminths. *E. histolytica* cannot be differentiated from the nonpathogenic *Entamoeba dispar* by microscopy, and specific diagnosis may require a special stool antigen test or PCR-based technique.

Treatment depends on the pathogen: metronidazole or tinidazole for giardiasis; metronidazole or tinidazole plus an agent effective in the lumen of the bowel such as paromomycin or iodoquinol for amebiasis; trimethoprim-sulfamethoxazole for cyclosporiasis and cystoisosporiasis; and nitazoxanide for cryptosporidiosis.

## Skin Diseases

Common dermatologic problems among persons returning from warm tropical areas include sunburn, insect bites, dermatophyte infections, superficial streptococcal and staphylococcal infections, scabies, and sexually transmitted diseases such as herpes simplex and syphilis. The most common cause of fever and maculopapular rash among travelers is dengue. Because some of the causes of fever and maculopapular rash can be life threatening, patients with these symptoms deserve immediate attention ([Box 5.3](#)). Persons with exposure to beaches and other sandy areas may present with cutaneous *larva migrans*, and travelers to nature parks and persons with exposure to rural and forested areas may return with myiasis or cutaneous leishmaniasis.

• **BOX 5.3** Differential Diagnosis: Fever and Diffuse Macular Rash in Travelers Returning From Tropics and Subtropics

Leptospirosis  
Drug reaction  
Others

• **Fig. 5.2** Cutaneous larva migrans.

### Cutaneous Larva Migrans (Creeping Eruption)

Cutaneous larva migrans occurs when larval forms of the dog or cat hookworm penetrate bare skin following contact with moist, sandy soil contaminated with animal feces in tropical and subtropical climates. Larvae migrate through the skin at a rate of 2 to 4 cm per day and produce a pruritic, elevated, erythematous, serpiginous rash, often with vesicles (Fig. 5.2). The diagnosis is made by inspection, and treatment is with either a 3-day course of albendazole or a single dose of ivermectin.

### Furuncular Myiasis

Larvae (maggots) of the human botfly *Dermatobia hominis*, in Latin America, and the tumbu fly, *Cordylobia anthropophaga*, in Africa, penetrate human skin and produce boil-like lesions in which they develop and grow until they emerge spontaneously several weeks later. Patients complain of pain and a sensation of movement within the lesions, and close examination reveals a central punctum through which the organism breathes. The maggots can be extracted by occluding the punctum with petroleum jelly and squeezing the boil or making a small incision in the skin.

• **Fig. 5.3** Cutaneous leishmaniasis.

### Cutaneous Leishmaniasis

Tiny phlebotomine sand flies transmit over 20 different species of the protozoan *Leishmania* in warm climates throughout the world except in Australia, Southeast Asia, and the South Pacific. Parasites replicate at the site of the insect bite and produce slow-healing or nonhealing painless nodules or, more commonly, ulcers with heaped-up edges (Fig. 5.3). The diagnosis is made by identifying parasites by culture, smears, or histopathology of specimens taken by biopsy, needle aspirate, or scrapings of the ulcer base. Treatment, which may be topical or systemic, is based on the site of the lesion, species of parasite, and geographic origin. Drugs of choice include antifungals such as fluconazole, ketoconazole, and amphotericin-containing compounds, antimonials such as sodium stibogluconate, oral miltefosine, topical agents such as paromomycin, and others. Adequate treatment of lesions caused by *Leishmania braziliensis* in Latin America is necessary to prevent mucosal leishmaniasis, which causes destructive and disfiguring lesions of the upper airways.

### Common Chronic Infections of Immigrants

Immigrants may harbor chronic infections that place them at risk for serious complications in the future. In addition to latent tuberculosis, HIV infection, and hepatitis B, clinicians should consider parasitic diseases such as strongyloidiasis, schistosomiasis, Chagas disease, cysticercosis, filariasis, echinococcosis, and others when evaluating immigrants, including those who left their native countries years or decades ago. Peripheral blood eosinophilia may be the first indication of chronic helminthic infections and, less commonly, other infections associated with travel.

### American Trypanosomiasis (Chagas Disease)

*Trypanosoma cruzi*, the agent of American trypanosomiasis, or Chagas disease, infects approximately 5 to 7 million persons in Mexico and Central and South America and perhaps

as many as 250,000 immigrants living in the United States. Most infected persons acquired their infection while living in poorly constructed houses in rural areas infested by the vector triatomine bug (kissing bug, reduviid bug). Infection also occurs via blood transfusion or organ transplantation from infected donors, from an infected mother to the fetus in utero, and occasionally by ingestion of soups or juices contaminated with triatomine bugs or their parasite-laden feces. Screening of blood donors since 2007 in over 75% of blood banks in the United States has identified more than 2000 infected donors, nearly all immigrants from endemic areas, but also a small number of persons who acquired infection from the insect vector in the southern United States. Several Latin American countries have eliminated both insect-borne and transfusion-associated transmission to human beings, and control programs in the other endemic countries are making progress toward interruption of transmission.

### Clinical Features

Infection is lifelong and, in most cases, asymptomatic. Acute infection may present with a mononucleosis-like illness or acute myocarditis or meningoencephalitis, but it is usually not recognized. Only 20% to 30% of persons with chronic infection develop symptoms, which appear after a latent period of two or more decades. Chronic Chagas heart disease is a progressive cardiomyopathy that causes congestive heart failure, sudden cardiac death, arrhythmias, and heart block; right bundle branch block is present in most persons who become ill. Denervation of the esophagus or colon leads to megaesophagus or megacolon and difficulty swallowing or defecating, respectively. Persons with advanced HIV infection or receiving immunosuppressing medications may experience reactivation of infection with fever, acute myocarditis, and focal lesions of the brain or skin.

### Diagnosis and Treatment

The diagnosis of acute or reactivated infection is made by visualizing parasites in the blood or tissues. The diagnosis of chronic infections requires identification of specific antibodies by at least two different types of serologic tests (e.g., immunofluorescent antibody and enzyme-linked immunosorbent assay). Treatment is with either nifurtimox or benzimidazole, oral medications available in the United States from the Centers for Disease Control and Prevention. Treatment is indicated for all acute or reactivated infections, chronic infections in all persons 18 years old or younger, and women of child-bearing age who are not pregnant. Supportive measures include cardiac medications, pacemakers, implanted defibrillators, or cardiac transplant for cardiomyopathy and dietary modification and surgery for megaesophagus or megacolon.

## Intestinal Roundworm Infections

### Clinical Features

The roundworms *Ascaris lumbricoides*, the whipworm *Trichuris trichiura*, and the hookworms *Necator*

*americanus* and *Ancylostoma duodenale* infect more than 1 billion persons in warm climates where sanitation is inadequate. Infection with adult worms lasts about 1 year for persons with ascariasis, 4 to 7 years for those with trichuriasis, and occasionally longer for persons with hookworm infection.

Most infected persons are infected with a small number of worms and have no symptoms. Peripheral blood eosinophilia is prominent during larval migration during the first several months of infection and then subsides to low levels or, in the case of *Ascaris*, subsides altogether. Moderately heavy infection with adult worms in children can impair growth and cognitive development. Heavy infection can lead to intestinal obstruction due to a bolus of adult *Ascaris* in the lumen of the small bowel, iron deficiency anemia from hookworms attaching to small bowel mucosa and feeding on blood, and dysentery or rectal prolapse from whipworms embedded in colonic mucosa. Obstruction of the biliary or pancreatic ducts by a single or few adult *Ascaris* can cause biliary colic, cholangitis, or pancreatitis.

### Diagnosis, Treatment, and Prevention

Diagnosis is made by microscopic identification of eggs in stool or occasionally by identification of adult worms passed in feces. Depending on the infection, treatment is with one to three doses of oral albendazole, mebendazole, pyrantel pamoate, or ivermectin. Infection is prevented by avoiding eating uncooked vegetables or other foods that may be contaminated, handwashing before meals, drinking clean water, and wearing shoes to prevent contact of bare skin with contaminated soil.

## Schistosomiasis (Bilharzia)

### Clinical Features

Approximately 230 million persons in South America, the Caribbean, Africa, the Middle East, the People's Republic of China, Southeast Asia, and the Philippines suffer from infection with schistosomes, flukes that live in the lumen of veins that drain the intestines or lower urinary tract. Infection is acquired when cercariae (larval parasites) penetrate skin during contact with fresh water containing the snail intermediate host. Acute schistosomiasis occurs 2 to 8 weeks after infection in previously uninfected persons and is an important cause of fever and eosinophilia, typically in returning travelers but not immigrants.

Chronic schistosomiasis is seen more commonly among immigrants from endemic areas than in short-term travelers. Adult worms live about 3 to 5 years but can persist for as long as 30 years. Schistosome eggs that are trapped in tissue elicit an immune response with granulomas and fibrosis, which are responsible for the disease. Chronic infections are usually light and asymptomatic, and eosinophilia is present in fewer than half of infected persons. Heavy infections can cause chronic diarrhea, hepatic fibrosis, and portal hypertension with splenomegaly and esophageal varices (*Schistosoma mansoni*, *japonicum*), or hematuria, bladder polyps, urinary

tract infections, obstructive uropathy, and bladder cancer (*Schistosoma haematobium*). Aberrant deposition of eggs in the brain or spinal cord can lead to cerebral mass lesions, seizures, focal neurologic signs, and transverse myelitis.

### Diagnosis, Treatment, and Prevention

All persons with a history of freshwater contact in an endemic area should be evaluated for schistosomiasis. Serologic tests are more sensitive than microscopic examination of urine or stool for eggs. Praziquantel is the drug of choice. Infection is prevented by avoiding snail-infested freshwater bodies in endemic countries.

### Strongyloidiasis

Infection with the intestinal roundworm *Strongyloides stercoralis* occurs worldwide, but it is most common in developing areas with poor sanitation, where infection results from contact of bare skin with larvae on fecally contaminated soil. Because *Strongyloides* can complete its life cycle within its host, infection can persist for life. Direct person-to-person transmission can occur because infective larvae are shed in the stool.

### Clinical Features

Asymptomatic infections are common, but 75% of persons have peripheral blood eosinophilia. When present, symptoms of chronic strongyloidiasis include abdominal pain and intermittent diarrhea and pruritic rashes, including urticaria and a migrating rash called *larva currens*. Persons with human T-lymphotropic virus-1 infection (but not HIV infection) and immunosuppressed persons, especially those receiving corticosteroids, may develop highly lethal hyperinfection with dissemination of larvae throughout the body.

### Diagnosis, Treatment, and Prevention

Strongyloidiasis should be ruled out in any person who may have been exposed to infection and is receiving or about to receive immunosuppressive therapy. Serology is more sensitive than microscopic examination of stool, which requires special techniques and multiple specimens because the number of larvae shed in the stool is small. The drug of choice is one or two doses of ivermectin for chronic infection; the alternative, albendazole, is less effective even when given for 10 days or longer. Treatment of hyperinfection or disseminated strongyloidiasis requires longer courses of ivermectin, and a successful outcome may require reversal of immunosuppression.

### Cysticercosis

Cysticercosis, infection with the larval stage of the pork tapeworm, *Taenia solium*, is acquired by ingestion of eggs shed in the stool of a person harboring an adult tapeworm in the intestinal tract. Infection with the adult tapeworm, which can live for several decades, develops when pork containing cysticerci is ingested without proper cooking. Pork tapeworms are transmitted in developing areas with poor sanitation and

• **Fig. 5.4** Cysticercosis: magnetic resonance image showing fluid-filled cyst with scolex.

inadequate inspection of meat. Mexico, Central America, northern South America, Haiti, Dominican Republic, Cape Verde, India, and the Philippines are areas with a high prevalence of infection. Transmission of cysticercosis can occur wherever there is an adult tapeworm carrier, including in the United States and other nonendemic countries.

### Clinical Features

Most persons harboring an adult tapeworm have no symptoms other than passing egg-laden tapeworm segments in the stool. Cysticerci, fluid-filled cysts containing the tapeworm scolex, typically cause no symptoms while they are alive and are able to evade the host immune response. Symptoms occur on average 2 to 5 years after infection, when degenerating cysts provoke an inflammatory response. Cysts in the central nervous system cause seizures, hydrocephalus, aseptic meningitis, increased intracranial pressure, and other complications.

### Diagnosis, Treatment, and Prevention

MR or CT scans identify cysticerci in the brain and spinal cord (Fig. 5.4). Serologic tests confirm the clinical suspicion of cysticercosis, but these may be negative in persons infected with one or a few cysts that have not begun to degenerate. Microscopic examination of stool identifies only about 30% of adult tapeworm carriers. Segments of tapeworms passed in the stool need to be distinguished from segments of the beef tapeworm, *Taenia saginata*. Treatment of cysticercosis is with oral albendazole or praziquantel. Corticosteroids and anticonvulsants may be needed to prevent seizures and other complications resulting from the inflammatory response to degenerating cysts. Adult tapeworm carriers respond to single doses of either niclosamide or praziquantel. Cysticercosis is prevented by identifying and treating persons harboring an adult tapeworm. In endemic areas, handwashing and avoiding food or water potentially contaminated with *T. solium* eggs are important as well. Prevention of infection with the adult tapeworm requires proper cooking of pork.

## Summary

- Potentially life-threatening infections such as falciparum malaria, typhoid fever, and meningococcal infection should always be considered in travelers returning from the tropics.
- Falciparum malaria can present with neurologic, pulmonary, gastrointestinal, and other complications and can be rapidly fatal if not treated promptly.
- Important viral causes of fever and macular rashes in travelers include dengue, chikungunya, Zika, enteroviral infection, measles, acute HIV infection, and others.
- Ulcerative lesions covered with an eschar in travelers with fever suggest rickettsial infection, painless ulcers in travelers without fever suggest cutaneous leishmaniasis, and boil-like lesions with a sensation of movement within suggest myiasis (infestation with a fly larva).
- Travelers with more than 2 weeks of diarrhea should be evaluated for protozoan, helminthic, and bacterial infections; underlying gastrointestinal diseases unmasked by diarrhea; and postinfectious conditions that may cause malabsorption.
- Asymptomatic immigrants from endemic areas should be evaluated for infections that put them at risk for severe complications in the future. Examples include latent tuberculosis, HIV infection, hepatitis B, American trypanosomiasis, strongyloidiasis and other intestinal roundworm infections, schistosomiasis, cysticercosis, and others.

## Chapter Review

### Questions

1. Which of the following is a complication of chronic Chagas disease (American trypanosomiasis)?
  - A. Hydrocephalus
  - B. Esophageal varices
  - C. Rectal prolapse
  - D. Sudden death
  - E. Megaloblastic anemia
2. A young woman returning from a trip to India presents with fever, chills, and headaches and is found to have *Plasmodium falciparum* on Giemsa-stained smears of the peripheral blood with 1% parasitemia. Which of the following is the most appropriate therapy?
  - A. Chloroquine and primaquine
  - B. Quinine and doxycycline
  - C. Atovaquone and proguanil
  - D. Artemether and lumefantrine
  - E. Mefloquine monotherapy
3. A 37-year-old man from Ecuador presents with fever, abdominal pain, and bloody diarrhea 6 weeks after receiving a kidney transplant. Blood cultures are positive for *Escherichia coli*. He immigrated to the United States 7 years earlier. Pretransplant evaluation was remarkable for mild epigastric pain and 7% eosinophilia in his peripheral blood. In addition to antibiotics and decreasing the dose of steroids, which of the following is most appropriate therapy?
  - A. Liposomal amphotericin
  - B. Ganciclovir
  - C. Ivermectin
  - D. Metronidazole
  - E. Trimethoprim-sulfamethoxazole

### Answers

1. D
2. D
3. C

## Sexually Transmitted Diseases

SIGAL YAWETZ

Sexually transmitted infections remain a major public health problem around the globe. The reemergence of certain pathogens such as the L2 serovar of *Chlamydia trachomatis* and the emergence of drug resistance in others, such as *Neisseria gonorrhoeae*, continue to pose new challenges. Many infectious agents can be transmitted sexually (Box 6.1), and their presentations are not always confined to the urogenital tract. Not all sexually transmitted infections are symptomatic. According to the most recent Centers for Disease Control and Prevention (CDC) surveillance data, the most common reportable sexually transmitted diseases (STDs) in the United States in 2015 were *Chlamydia*, gonorrhea, and early syphilis. Increasing incidence between 2014 and 2015 was seen for all three. Case reporting is not required for many other common STDs, such as genital herpes simplex virus (HSV), *Trichomonas*, and human papillomavirus (HPV) infections. In this chapter, several of the most common ulcerative and nonulcerative STDs are discussed. HPV, viral hepatitis viruses (A, B, and C), and HIV merit individual attention and are not addressed here. Vaginitis and HPV are also not discussed.

### The Ulcerative Sexually Transmitted Diseases

Most genital ulcers are caused by sexually transmitted infections. However, nonsexually transmitted infections and noninfectious etiologies should be considered when evaluating a patient with a genital ulcer. In the United States, the most common infectious agents causing genital ulcers are HSV and *Treponema pallidum* (the cause of syphilis). In recent years, lymphogranuloma venereum, which is caused by *C. trachomatis* serovars L1-3, reemerged in the United States and Europe, with outbreaks among men who have sex with men (MSM), primarily in large urban centers. Less common causes of ulcerative STDs include chancroid, which is caused by *Haemophilus ducreyi* and Granuloma inguinale, which is caused by *Klebsiella granulomatis*. Rarely primary HIV infection may present with a genital ulcer.

When evaluating a patient with a genital ulcer, a careful history and a physical examination (Table 6.1) are essential to guide the evaluation but can be misleading, and

diagnostic testing is essential. The medical history should include a sexual behavioral history and risk assessment with details about number and gender of sexual contacts, sites and mode of contact (oral, anal, genital, insertive, or receptive), and how often barrier protection is used. Information about area of residence and of sexual contact and travel history and prior STDs should also be obtained. Document the number and location of ulcerative lesions (single or multiple) and associated localized and systemic symptoms such as pain, discharge, urinary or rectal symptoms, sore throat, lymphadenopathy or mass, rash, fever, or other constitutional symptoms. All patients presenting with genital ulcers should undergo testing for herpes and syphilis, whereas testing for chancroid (*H. ducreyi* culture of the leading edge of the lesion) and lymphogranuloma venereum should be reserved for individuals at known risk. Given limitations of testing modalities, when pretest probability is high, providers should consider empirical treatment of the most likely diagnosis while awaiting laboratory test results; despite comprehensive evaluation, it is estimated that at least 25% of patients with genital ulcers never have a laboratory-confirmed diagnosis. Ulcerative STDs are also cofactors for HIV transmission. Routine HIV screening is now recommended for all adult and sexually active adolescent patients; regardless of prior testing, all patients with a

**TABLE 6.1** Features of Genital Ulcers by Etiology

	Herpes Simplex Virus	Syphilis	Chancroid	Lymphogranuloma Venereum	Donovanosis (Granuloma Inguinale)
Ulcer	Painful, often many, papules	Painless	Painful, purulent, irregular, deep	Small, painless, heals before lymph nodes	Large, irregular, bleeding
Lymph nodes	Rare in primary infection	Small	1–2 weeks later	Large draining nodes	None, hypertrophied tissue
Comments	Common	Must test for and treat	Unusual in the United States	At-risk populations	Rare in the United States

new STD should be tested for HIV. When the pretest probability of STD is low, additional testing for an alternative diagnosis could be initiated as well. Testing methods and treatment for individual infections will be discussed later.

## Genital Herpes Simplex Virus

### Epidemiology

It is estimated that 50 million adolescents and adults in the United States (approximately 16% of all US residents 14 to 49 years of age) are infected with HSV-2, the most common cause of genital herpes. These estimates are based on serologic testing for HSV-2 and do not include genital HSV-1 infections, although recent data suggest HSV-1 accounts for a growing number of genital HSV infections and may be as common as HSV-2 for new or incident infections. Large epidemiologic surveys suggest that as many as 70% to 90% of HSV-2–seropositive individuals are not aware of their infection. Risk factors for HSV-2 infections in the United States include female gender, duration of sexual experience, African-American ethnicity, and history of prior genital infections. Other risk factors may include number of sex partners and socioeconomic status. A previous HSV-1 infection in an individual does not affect the likelihood of HSV-2 acquisition, but it does decrease the likelihood of developing a symptomatic infection with HSV-2.

### Etiology and Pathogenesis

HSV is a double-stranded DNA virus. Two human HSV types cause genital HSV. They are distinguished based on their envelope glycoproteins: HSV-1 (glycoprotein G1) and HSV-2 (glycoprotein G2). In the past, most genital HSV infections were caused by HSV-2, but the proportion of HSV-1 as the cause for genital HSV among adolescents and young women is increasing over time, and in young American women, HSV-1 may now account for the majority of newly acquired genital HSV infections.

Initial genital HSV infection occurs through direct contact of the virus with the genital mucosa or nonintact skin in the genital area. Primary HSV infection occurs when an individual acquires HSV-1 or HSV-2 without previously having antibodies to either viral type. A nonprimary first episode occurs when an individual who has antibodies to one viral type (e.g., HSV-1) acquires the other viral type

(e.g., HSV-2) for the first time. During primary infection, HSV infects cells in the epidermis and dermis and then becomes latent in the sensory neuron. Reactivation of viral replication in the sensory ganglia may result in subclinical viral shedding or in symptomatic outbreaks. A recurrent infection occurs when an HSV-1 or HSV-2 lesion develops in an individual with preexisting antibodies to the same HSV type. Subclinical shedding occurs when HSV can be isolated from a patient without symptoms. Recurrence and subclinical shedding in the genital tract are more common with HSV-2 than HSV-1 genital infection and in immunocompromised hosts. In patients with HSV-2 infection, viral shedding occurs at roughly the same rate for those who are symptomatic as for those who are asymptomatic.

### Clinical Manifestations

The classic presentation of primary genital herpes, present in about 60% to 70% of patients, is painful, clustered vesicular lesions. However, symptoms may range from asymptomatic infection to a severe systemic illness. Severe illness presents with multiple, bilateral, vesicular, pustular, or ulcerated, painful, or pruritic genital lesions and inguinal lymphadenopathy. Common associated symptoms include fever, myalgias, malaise, headache, and dysuria that may lead to urinary retention. Nonprimary first episodes are more likely to have less severe symptoms or be asymptomatic.

Symptoms of recurrent HSV infections are less severe than primary or nonprimary first episodes, and the duration of symptoms and viral shedding are typically shorter. Lesions of recurrent HSV are usually unilateral, and systemic symptoms are infrequent. Approximately 50% of patients with recurrent episodes describe a typical prodrome of neuropathic symptoms in the nerve distribution of the skin lesions, such as pruritus, tingling, or shooting pains. Recurrent genital herpes episodes are more common with genital HSV-2 than HSV-1, although the frequency is variable for both. Recurrences are earlier and more frequent in patients with more severe primary infection and in immunocompromised hosts.

Atypical presentations of genital HSV include vulvovaginitis or proctitis, often with fissures, urethritis, and cervicitis. HSV-2, the major cause of genital HSV, may also cause extragenital syndromes or complications. These may

**TABLE 6.2** Treatment of Genital Herpes Simplex Virus Disease

Treatment of Primary Episode	Treatment of Recurrent Genital HSV-2 Episodes	Daily Suppressive Therapy
Acyclovir, 400 mg orally 3 times daily for 7–10 days; or 200 mg orally 5 times daily for 7–10 days; or	Acyclovir, 400 mg orally 3 times daily for 5 days, or 800 mg orally twice daily for 5 days, or 800 mg 3 times daily for 2 days; or	Acyclovir, 400 mg orally twice daily; or
Famciclovir, 250 mg orally 3 times daily for 7–10 days; or	Famciclovir, 125 mg orally twice daily for 5 days, or 1 g orally twice daily for 1 day; or	Famciclovir, 250 mg orally twice daily; or
Valacyclovir, 1 g orally twice daily for 7–10 days	Valacyclovir, 500 mg orally twice daily for 3 days, or 1 g orally once daily for 5 days	Valacyclovir, 500 mg orally once daily; or Valacyclovir, 1 g orally once daily

*HSV, Herpes simplex virus.*

include involvement of other skin or mucosal sites (e.g., erythema multiforme, herpes labialis, disseminated herpes), meningitis (often recurrent or Mollaret meningitis), transverse myelitis, hepatitis, and disseminated skin and visceral infections. Disseminated infection and visceral involvement are more common in immunocompromised hosts.

### Diagnosis

Viral culture of the lesion remains the preferred diagnostic method for genital HSV, but the sensitivity of culture varies by disease and ulcer stage. HSV isolation rates are higher for primary as compared with recurrent lesions and decline as lesions begin to heal and crust over. More rapid testing for viral antigen by direct fluorescent antibody (DFA) may be performed within several hours. Polymerase chain reaction (PCR) testing for HSV DNA is the preferred test for diagnosing HSV in the cerebrospinal fluid (CSF); it is currently not approved for testing of genital specimens.

Serologic tests include type-specific and type-common antibodies, which develop within several weeks of infection. HSV-IgG remains positive for life. Type-specific glycoprotein IgG antibodies (GP-G1 and GP-G2 for HSV-1 or HSV-2) have a sensitivity of 80% to 98% and specificity of >96% for prior infection with the type tested. Such serologic tests may be helpful in evaluating culture-negative ulcers, in identifying asymptomatic carriers, counseling partners of infected individuals, and STD screening. However, IgG tests are limited by a lag time to the development of antibodies after initial infection and the fact that a positive result only indicates a previous exposure and may not be diagnostic of concurrent lesions. IgM tests are often less useful because they are not type-specific and may become positive again during a recurrent herpes episode.

### Treatment

Treatment of genital HSV disease is usually aimed at control of symptoms, prevention of symptomatic outbreaks, and prevention of shedding and transmission.

Treatment does not eradicate or cure latent infection. Systemic antiviral agents are the treatment of choice; topical antiviral therapy has minimal effect on shedding and symptoms. Specific regimens, based on the clinical syndrome, are outlined in [Table 6.2](#). Treatment of a first episode decreases symptom duration and shedding. Episodic therapy for outbreaks will decrease symptoms if administered during the prodrome, at the onset of an outbreak, or within 1 day of the appearance of a lesion. Daily suppressive therapy may reduce the frequency of outbreaks by 70% to 80% for patients who experience frequent (e.g., more than six annually) anogenital HSV outbreaks. Abstinence during outbreaks and routine condom use should be discussed as measures to reduce transmission to others, although condoms provide incomplete protection against transmission of HSV, and transmission may occur during asymptomatic shedding as well. Suppressive therapy may also be given to HSV-2–infected individuals to reduce transmission to seronegative partners.

### Pregnancy

Genital HSV infection during pregnancy poses a risk to both the developing fetus and the newborn. Approximately 10% of HSV-2–seronegative pregnant women have partners who are HSV-2 seropositive, and the overall rate of HSV-1 or HSV-2 seroconversion during pregnancy in the United States is about 2%. Most new infections in pregnant women are asymptomatic, and most neonatal HSV disease is in infants born to asymptomatic mothers. The risk of mother-to-child transmission (MTCT) of genital HSV is highest during primary infection (30%–50%), followed by nonprimary first episode and then recurrent disease (<1%). Pregnant women should be treated with systemic antiviral medications for active outbreaks. A cesarean delivery to prevent vertical transmission of HSV should be offered to all mothers with symptoms of an active herpetic genital lesion or a

typical herpes prodromal symptom at the time of labor. The use of suppressive antiviral therapy at 36 weeks of gestation for mothers with at least one episode of symptomatic HSV during pregnancy reduces shedding and the rate of symptomatic HSV at labor and thus the need for cesarean delivery for prevention of MTCT. However, such treatment may not fully protect against vertical transmission. There are no data to support a benefit in mothers without at least one active episode during their pregnancy. Suppressive regimens to prevent vertical transmission include either acyclovir 400 mg orally three times daily, or valacyclovir 500 mg orally twice a day, and are begun at 36 weeks of gestation.

### Immunocompromised Hosts

Atypical clinical presentations including more severe and prolonged symptoms are more common in immunocompromised patients, and HSV viral shedding is more common in HIV-infected individuals. The treatment of HSV in immunocompromised patients is outlined in Table 6.3. For severe HSV disease in immunocompromised patients, acyclovir, 5 mg/kg intravenously every 8 hours, should be considered. HSV acyclovir resistance is rare. However, in immunocompromised hosts, HSV resistance to acyclovir may be seen, and foscarnet should be considered in the treatment of acyclovir-resistant HSV disease.

## Syphilis

### Background and Epidemiology

Syphilis is a sexually transmitted systemic disease caused by the spirochete bacteria *T. pallidum*. Syphilis has been present worldwide for centuries and has recently reemerged in many parts of the world. In the United States, syphilis is a notifiable disease. Despite hopes for eradication after observing declining early syphilis rates between 1990 and 2000, annual rates of early syphilis began increasing again in the United States in 2001. In 2010, in response to the high incidence of syphilis among MSM, the CDC instituted a recommendation for annual syphilis screening among sexually active MSM. Rates among women have also increased in recent years, and with it the rates of congenital syphilis increased as well.

### Transmission, Disease Stages, and Clinical Manifestations

Early syphilis includes all stages of syphilis within the first year after infection. This includes primary infection, secondary infection, and early latent infection. Late syphilis includes all stages of syphilis after the first year since acquisition. This includes late latent infection and tertiary syphilis. Latent syphilis includes any case of asymptomatic syphilis infection: early within the first year of acquisition and late thereafter. Patients with late latent syphilis (asymptomatic infection of >1-year duration) are not considered to be infectious to their sex partners.

Sexual transmission of *T. pallidum* occurs through direct exposure to an open lesion during primary and secondary infection. The incubation period before the development of primary syphilis is up to 90 days. Primary infection is characterized by a painless ulcer (chancre) at the site of inoculation. The painless nature of the lesion often helps distinguish it from the lesions of chancroid and genital herpes; however, the painless chancre often goes unnoticed. Chancres heal spontaneously within several weeks, even without antimicrobial therapy. Secondary infection results from systemic dissemination and occurs 2 to 8 weeks after the appearance of the chancre in about 25% of untreated patients. Rarely, the primary chancre is still present when secondary infection develops. The most common presentation is a generalized skin rash. Lesions are usually discrete pink or red macules or pustules, beginning on the trunk and bilateral proximal extremities. Any surface of the body may be involved and, although their involvement suggests the diagnosis, the palms and soles (Fig. 6.1) are not always involved. Systemic symptoms of fever, headache, myalgia, malaise, and lymphadenopathy are common. Other common skin manifestations include mucocutaneous lesions, condylomata lata, and alopecia. Other organ involvement may lead to hepatitis, ulcerative gastroenteritis, synovitis, immune-mediated glomerulonephritis, and nephrotic syndrome. Tertiary infection may involve any organ system, but the most common form in the United States is neurosyphilis followed by cardiac manifestations and gummatous lesions. Neurosyphilis can occur at any stage of infection. When symptomatic, symptoms may include cognitive, motor, or sensory deficits; ophthalmic disease

**TABLE 6.3 Treatment of HSV Infection in HIV-Infected Patients**

Regimens for Daily Suppressive Therapy for HSV in HIV-Infected Patients	Regimens for Episodic HSV Infection in HIV-Infected Patients
Acyclovir 400–800 mg orally twice or 3 times daily; or	Acyclovir 400 mg orally 3 times daily for 5–10 days; or
Famciclovir 500 mg orally twice daily; or	Famciclovir 500 mg orally twice daily for 5–10 days; or
Valacyclovir 500 mg orally twice daily	Valacyclovir 1 g orally twice daily for 5–10 days

*HIV*, Human immunodeficiency virus; *HSV*, herpes simplex virus.

(e.g., uveitis or optic neuritis); auditory symptoms; cranial nerve palsies; or symptoms of meningitis. Tabes dorsalis is the slow degeneration and demyelination of the dorsal column of the spinal cord associated with neurosyphilis, leading to a variety of deficits including weakness, diminished reflexes, gait disturbances, and paresthesias (e.g., formication).

### Diagnosis and Screening

Diagnostic tests for syphilis depend on indication and disease stage and include direct visualization and serologic tests. Newer rapid tests are under development. The definitive diagnostic test for primary syphilis is direct visualization of the spirochete by dark field microscopy or DFA testing of

• **Fig. 6.1** (A) Palmar lesions of secondary syphilis. (B) Plantar lesions of secondary syphilis.

exudate from a lesion. However, these require expertise and are often not attainable. The most commonly used diagnostic tool for syphilis is serology, with tests falling into two categories: the nontreponemal tests and the treponemal tests (Table 6.4). The nontreponemal tests are the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR). They are used primarily as screening tools, and their titers are used to follow response to therapy. The two tests are equally valid, but the results of both tests cannot be directly compared so only one should be followed over time in a single patient. Nontreponemal tests may be negative in 20% to 30% of patients with a primary chancre. The tests may also be negative in up to 2% of patients with secondary syphilis because of a prozone phenomenon, in which a high antigen burden in undiluted serum leads to a false-positive result. In this case, dilution of the sample will correct the results. Negative results are also seen in a proportion of patients with late untreated or previously treated syphilis. Traditional treponemal tests are qualitative assays using *T. pallidum* antigens; they include the fluorescent treponemal antibody-absorption test and the *T. pallidum* particle agglutination (TP-PA) test. These tests are more specific and are used to confirm infection. The treponemal tests may be negative in a proportion of patients with primary syphilis but remain positive for life, despite treatment, in >90% of patients. Several newer automated treponemal tests are available including the *T. pallidum* enzyme immunoassays, chemiluminescence immunoassays, and the *T. pallidum* Western blot. The *T. pallidum* enzyme immunoassays (EIA) tests have a high sensitivity and may be automated so are useful for high-volume screening. Rapid diagnostic tests for syphilis are under testing and development. All patients diagnosed with syphilis should also be tested for HIV. Initial screening for syphilis may be done with a nontreponemal test, which is confirmed by a treponemal test if positive, or a treponemal test such as TP-EIA, followed by confirmation by either a nontreponemal test if positive or a traditional treponemal test. The positive and negative predictive values of the screening tests depend on the prevalence of syphilis in the screened population. Therefore test interpretation should take syphilis risk into account.

Neurosyphilis diagnosis is challenging because nontreponemal serologic tests may be negative in as many as

**TABLE 6.4 Serologic Tests for Syphilis**

	Test Features	Clinical Utility	Comments
Nontreponemal tests: RPR VDRL	Quantitative tests, high sensitivity (lower in HIV patients), poor specificity	Often screening tests, titers important to guide treatment for every patient	RPR false negatives with prozone phenomenon; dilute the sample
Treponemal tests: FTA-abs TP-PA EIA	Qualitative tests, high sensitivity and specificity (some false positive with EIA)	Used for confirmation of nontreponemal tests (only EIA used in screening)	Remain positive for life in most patients despite treatment

EIA, Enzyme immunoassay; FTA-abs, fluorescent treponemal antibody-absorption; RPR, rapid plasma reagin; TP-PA, *T. pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory.

**TABLE 6.5** Treatment of Syphilis

Stage of Infection	Preferred Regimen	Alternative Regimen <sup>a</sup>
Primary, secondary, or early latent syphilis	Benzathine penicillin G, 2.4 million units as a single intramuscular injection	Doxycycline, 100 mg orally twice daily (or tetracycline, 500 mg orally 4 times daily) for 14 days
Late latent syphilis, latent syphilis of unknown duration, or tertiary syphilis	Benzathine penicillin G, 2.4 million units intramuscularly once weekly for 3 weeks	Doxycycline, 100 mg orally twice daily (or tetracycline 500 mg orally 4 times daily for 28 days)
Neurosyphilis and ocular syphilis	Aqueous crystalline penicillin G, 18–24 million units intravenously per day, as continuous infusion or divided doses every 4 hours, for 10–14 days	Procaine penicillin, 2.4 million units intramuscularly once daily; plus probenecid, 500 mg orally 4 times daily, both for 10–14 days

<sup>a</sup>Alternative regimens should not be used for pregnant patients. Pregnant women with penicillin allergies should be desensitized to receive penicillin-based treatment.

25% of patients with neurosyphilis. Therefore a definitive diagnosis of neurosyphilis can be made by CSF analysis. CSF analysis for syphilis is recommended for any patient with suspected neurosyphilis. Those include patients with known syphilis or syphilis risk and compatible neurologic, ophthalmic, or otic symptoms, patients with active tertiary disease, and patients with treatment failure. Many authorities recommend CSF examination for all HIV-infected patients with latent syphilis or syphilis of unknown duration. It remains controversial whether CSF analysis should be performed for all patients with latent syphilis and a nontreponemal titer of  $\geq 1:32$ . CSF analysis should include a cell count, protein level, and CSF-VDRL titer. The CSF protein and CSF white blood cell (WBC) count are usually elevated, but these findings are nonspecific. The CSF-VDRL is specific but not sensitive for diagnosing neurosyphilis. When positive, titers are used for follow-up. When neurosyphilis is suspected clinically, empirical treatment should be strongly considered even when the CSF-VRDL is negative.

### Treatment

Treatment regimens for syphilis depend on the stage of disease, the presence or absence of central nervous system disease, and the host (Table 6.5). The preferred treatment for syphilis at any stage of disease is parenterally administered penicillin G (benzathine, aqueous procaine, or aqueous crystalline but not combination benzathine-procaine). For nonpregnant patients without neurologic, ocular, or otic involvement, who are allergic to penicillin, alternative therapy may include doxycycline and tetracycline. Ceftriaxone may also be considered at a dose of 1 g intramuscularly or intravenously daily for 10 to 14 days for primary or secondary syphilis and 2 g daily intravenously for 10 to 14 days for patients with neurosyphilis, but the data to support its use are lacking. Therefore this should be done in consultation with an expert and with assessment of the risk for penicillin allergy cross-reactivity

with ceftriaxone in the individual patient. Pregnant women with syphilis should always be treated with penicillin-based regimens, even if this requires desensitization in the case of a penicillin allergy. Penicillin-based therapies are the only regimens that have clearly been shown to be effective during pregnancy, including prevention of transmission to the fetus.

### Follow-Up After Treatment

After treatment of syphilis, all patients should be followed clinically and by nontreponemal test titer (RPR or VDRL). There are no definitive criteria for cure or treatment failure, but the primary goals of treatment are resolution of symptoms and a sustained decrease in titer of  $\geq 4$ -fold (e.g., 1:32 decreases to 1:8). Such response is expected by 6 to 12 months in patients with early treatment and 12 to 24 months in patients with late treatment. Titers are checked at months 6 and 12 for all patients; in addition, they are checked at months 18 and 24 for patients with neurosyphilis and at month 24 for patients with late syphilis. RPR titers in HIV-infected patients are followed more closely with testing at 3, 6, 9, 12, and 24 months after treatment. Before treatment is considered a failure, patients with persistent signs or symptoms of active disease and those who fail to achieve a 4-fold decrease in RPR or VDRL (or have an increase in RPR or VDRL titer) should be evaluated for reinfection. If treatment failure is still suspected, CSF analysis should be performed. If the CSF analysis is normal, these patients receive an additional course of benzathine penicillin G 2.4 million units intramuscularly once weekly for 3 weeks, and follow-up testing is resumed. All patients with treatment failure should be screened for HIV. Patients with neurosyphilis and abnormal CSF analysis should have a repeat CSF analysis at 6 months to follow up the cell count, protein, and VDRL titers. Protein and VDRL decline more slowly than the cell count. If abnormalities persist for 2 years, retreatment should be considered.

### Management of Sex Partners

Individuals who report sexual contact with persons with any stage of syphilis should be evaluated and tested. A partner who had sexual contact within 90 days of an individual's diagnosis with early syphilis diagnosis should be treated presumptively. Contacts with positive serologic tests for syphilis after a reported exposure should be treated according to the stage of their disease. Contacts who are seronegative after exposure to a sex partner with syphilis should be empirically treated for primary syphilis if the exposure occurred within 90 days before the partner's diagnosis of primary, secondary, or early latent syphilis or if patient follow-up for repeat testing and treatment is uncertain.

### Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a relatively infrequent genital ulcerative disease in the United States caused by three serovars (L-1, L-2, and L-3) of *C. trachomatis*. However, infections with the L-2 serovar have recently reemerged among MSM in US and European urban centers. The primary lesion of LGV, a small papule or ulcer that is often painless, usually presents 3 to 30 days following exposure and often goes unnoticed by the patient. Patients more commonly present for medical attention after developing unilateral painful lymphadenopathy, characteristic of the secondary stage of infection, which occurs approximately 2 to 6 weeks after exposure.

Clinical manifestations at this stage may also include systemic symptoms, local cellulitis, buboes, and proctocolitis (purulent, mucoid, or bloody) in the case of anal exposure. Late manifestations are the result of fibrosis and scarring and may include chronic ulceration, anal fistulae and strictures, genital elephantiasis, and male and female infertility. Diagnostic testing is not well standardized, and providers must often rely on clinical suspicion to guide treatment. Culture of genital or lymph node specimens has a poor sensitivity for diagnosis of LGV. Nucleic acid amplification tests (NAATs) for *C. trachomatis* may be helpful for genital samples but further testing to distinguish LGV subtypes is not always available, and this testing is not widely available for rectal samples. Chlamydia serologies by complement fixation (CF; positive titer is  $\geq 1:64$ ) or microimmunofluorescence (MIF; positive titer is  $\geq 1:128$ ) may be useful to support a clinical diagnosis where testing is available, but the interpretation of results has not been well standardized. The preferred regimen for treatment of LGV is doxycycline, 100 mg orally twice daily for 21 days. Alternative regimens, with less supporting data, are erythromycin 500 mg orally four times per day for 21 days or azithromycin 1 g orally once weekly for 3 weeks. Treatment of local complications of LGV (e.g., drainage of buboes) may also be necessary. Asymptomatic sex partners of patients with LGV should be treated with doxycycline 100 mg orally twice daily for 7 days or azithromycin 1 g orally as a single dose. Erythromycin 500 mg orally four times daily for 21 days (7 days for partners) is

still recommended by the CDC but rarely used and has been largely replaced by azithromycin in clinical practice.

### Granuloma Inguinale

Granuloma inguinale or donovanosis is rare in the United States but endemic in some tropical areas and developing nations. This ulcerative disease is caused by *Klebsiella granulomatis*, formerly known as *Calymmatobacterium granulomatis*, which is an intracellular pathogen and therefore difficult to culture. Clinically this disease usually manifests as progressive, painless, highly vascular ulcerative lesions, which may bleed easily. Lymphadenopathy is usually not present. Diagnosis is usually by identification of dark-staining Donovan bodies within a tissue crush preparation or biopsy sample. There are no serologic or PCR-based assays available for this disease. The preferred treatment for granuloma inguinale is azithromycin 1 g orally once weekly for a total of 3 weeks. Alternative regimens for treatment are doxycycline 100 mg orally twice daily for at least 21 days, ciprofloxacin 750 mg orally twice daily, erythromycin 500 mg orally four times per day, or trimethoprim-sulfamethoxazole 160 mg/800 mg (one double-strength tablet) orally twice daily, each for at least 21 days. If lesions persist at the end of the 21-day treatment course, treatment should be continued until all lesions are completely healed. Parenteral aminoglycosides may be added in the event of treatment failure or for pregnant women because other recommended regimens may not be safe for the fetus.

### Chancroid

Chancroid is also rare in the United States, occurring primarily in discrete outbreaks in endemic areas most often among patients who are also infected with HIV or other ulcerative STDs. The disease is caused by *H. ducreyi* and usually manifests as a painful genital ulcer with tender suppurative inguinal lymphadenopathy. The painful and irregular nature of the ulcer distinguishes it from the syphilitic chancre. Definitive diagnostic testing by culture of *H. ducreyi* from the leading edge of the lesion carries a sensitivity of <80% and can be performed only at the limited number of sites with access to the required special culture media. Because diagnostic testing is limited, clinical diagnosis is often important for the purposes of treatment and surveillance. A probable clinical diagnosis of chancroid rests on four criteria: (1) presence of one or more painful genital ulcers; (2) absence of evidence of syphilis, either by dark field examination of the ulcer exudate or by serologic testing performed more than 7 days after the appearance of the ulcer; (3) clinical appearance of the ulcer and lymphadenopathy consistent with chancroid; and (4) negative tests for HSV of the ulcer exudate. The preferred treatment regimens for chancroid are azithromycin 1 g orally in a single dose or ceftriaxone 250 mg intramuscularly in a single dose. Ciprofloxacin 500 mg orally twice daily for 3 days or erythromycin 500 mg three times daily for 7 days may also be used, but resistance to these medications has been reported.

## The Nonulcerative Sexually Transmitted Diseases

### Genital *Chlamydia Trachomatis* Infections Epidemiology

Genital chlamydia is the most commonly reported infectious disease in the United States. There were nearly 1.53 million cases of chlamydia reported to the CDC in 2015, more than any cases of any other reportable condition and growing in incidence by 6% since the prior year. It is caused by serovars D–K of the intracellular bacterium *C. trachomatis*. The majority of chlamydia infections asymptomatic infection is common, accounting for 50% to 75% of cases in women and up to 50% of cases in men. The highest infection rate is among women age <25 years. Risk factors among women include younger age, unmarried status, multiple sex partners, a recent new sex partner, inconsistent use of condoms, mucopurulent cervicitis and cervical ectopy, prior STD, and lower socioeconomic status. Annual screening for chlamydia is recommended for all women age <25 years and for all MSM who are sexually active, including screening for urethral infection, rectal infection, and pharyngeal infection depending on the mode of sexual intercourse. Rescreening every few months is recommended for individuals with a chlamydia diagnosis and ongoing risk.

### Clinical Manifestations

When symptomatic, *C. trachomatis* may cause urethritis, prostatitis, epididymitis, and proctitis in men and cervicitis, urethritis, pelvic inflammatory disease, and perihepatitis (Fitz-Hugh-Curtis syndrome) in women. Patients may also develop reactive arthritis, formerly known as Reiter syndrome, more commonly in men but also in women. If left untreated, up to 40% of women with chlamydia will develop pelvic inflammatory disease (PID) and be at risk for further complications of PID such as ectopic pregnancy, chronic pelvic pain, and infertility. *C. trachomatis* may also be transmitted to the neonate from exposure to a mother's infected cervix during delivery. Neonatal chlamydial infections may have ophthalmic, pulmonary, or urogenital manifestations, often with sustained sequelae, so screening and treatment of pregnant women are particularly important.

### Diagnosis and Screening

Cell culture techniques for *C. trachomatis* have a very low sensitivity. Therefore NAATs, which are highly sensitive and specific, have replaced cell culture in the diagnosis of chlamydial infections. In women, endocervical and vaginal specimens have high sensitivity, and self-collected vaginal swabs are equivalent in sensitivity to those collected by a clinician. First-catch urine in women is acceptable. In men, first-catch urine or urethral swabs are acceptable. NAATs are also used, although not US Food and Drug Administration (FDA) cleared, for pharyngeal or anal chlamydia diagnosis.

Self-collected rectal specimens have been shown to be a reasonable alternative if a clinician is not available.

Screening programs for *C. trachomatis* infections in young women have been shown to reduce the rates of lower genital tract infections and their long-term complications, as well as associated medical costs. For this reason, some practice guidelines and state health departments strongly recommend routine screening for chlamydia for all pregnant women, women age <25 years of age, and women age ≥25 years with risk factors. There is no evidence to support routine screening for men at this time, except in high-risk populations such as MSM, adolescents, patients at STD clinics, and incarcerated patients in correctional facilities.

### Treatment and Follow-Up

Treatment of genital *C. trachomatis* infection is aimed not only at resolution of symptoms but also prevention of complications of infection such as PID and prevention of transmission to sexual partners and neonates. Treatment options for both pregnant and nonpregnant patients are described in Table 6.6. Single-dose azithromycin may be given as directly observed therapy on site and thus is particularly recommended for patients with poor treatment compliance or unreliable follow-up. Azithromycin has recently replaced erythromycin as the preferred therapy for pregnant patients. Patients diagnosed with gonococcal infections should also be empirically treated for *C. trachomatis* because coinfection is common. Patients undergoing treatment should be instructed to abstain from sexual intercourse for 7 days and until all sex partners have been treated; sex partners should be treated even if asymptomatic. Patient-delivered partner therapy may be considered if the sex partner is unlikely to seek evaluation and treatment; however, this is not recommended for MSM because of the high prevalence of other STDs that require more thorough evaluation.

Unless poor treatment adherence is suspected or symptoms persist, test of cure (repeat testing 3–4 weeks after treatment) of *C. trachomatis* infection is not recommended except for pregnant women. However, repeated infections are common and are usually caused by reacquisition after treatment rather than to antibiotic resistance. Women with a diagnosis of chlamydia should therefore be rescreened for *C. trachomatis* infection 3 to 4 months after treatment or when they next present for care. To ensure prevention of transmission to the neonate, all pregnant women should have a test of cure approximately 3 weeks after completing therapy.

### Gonorrhea Background

Gonorrhea is the second most commonly reported STD in the United States; there were nearly 400,000 cases of gonorrhea reported in the United States in 2015, with an increase of 13% since 2014. It is caused by *N. gonorrhoeae*, a gram-negative diplococcus. Coinfection with *C. trachomatis* is common. Annual screening for gonorrhea is recommended for all women age <25 years and for all MSM who

**TABLE 6.6** Treatment of Genital *Chlamydia Trachomatis* Infections

	Preferred Regimen	Alternative Regimen
Nonpregnant patients	Azithromycin, 1 g orally as a single dose; or doxycycline, 100 mg orally twice daily for 7 days	Erythromycin base, 500 mg orally 4 times daily for 7 days, or erythromycin ethylsuccinate, 800 mg orally 4 times daily for 7 days; or ofloxacin, 300 mg orally twice daily for 7 days; or levofloxacin, 500 mg orally once daily for 7 days
Pregnant patients	Azithromycin, 1 g orally as a single dose	Erythromycin base, 500 mg orally 4 times daily for 7 days, or 250 mg orally 4 times daily for 14 days; or erythromycin ethylsuccinate, 800 mg orally 4 times daily for 7 days, or 400 mg orally 4 times daily for 14 days; or amoxicillin, 500 mg orally three times daily for 7 days

• **Fig. 6.2** (A) Pustule in a patient with disseminated gonorrhea infection. Note the red base. (From Anna R. Thorner, MD. Published on the Partners Infectious Disease Images website, [www.idimages.org](http://www.idimages.org).) (B) Petechial lesion in a patient with disseminated gonorrhea infection. Note the red base. (From Arnold N. Weinberg, MD. Published on the Partners Infectious Disease Images website, [www.idimages.org](http://www.idimages.org). Reprinted with permission.)

are sexually active. In MSM, screening for urethral, rectal, and pharyngeal infection is recommended depending on the site of sexual exposure.

### Clinical Manifestations

Asymptomatic infection may occur in both men and women but is much less common in men. An asymptomatic lower-tract infection in a woman may still lead to upper-tract infection (PID) with complications such as infertility, chronic pelvic pain, and ectopic pregnancy. When symptomatic, genital manifestations include urethritis, epididymitis, prostatitis, cervicitis, and PID. Extragenital manifestations may include pharyngitis, proctitis, conjunctivitis, or disseminated gonococcal infection (DGI) from gonococcal bacteremia. DGI commonly causes acral skin lesions (petechiae or raised pustules on a red base; Fig. 6.2), unilateral tenosynovitis, and polyarticular septic arthritis. Less commonly, DGI may cause hepatitis, meningitis, or

endocarditis. Neonates may acquire *N. gonorrhoeae* infection from cervical exudates during delivery. Manifestations of neonatal disease may include ophthalmic complications, arthritis, meningitis, or frank sepsis.

### Diagnosis

Available diagnostic tests for gonorrhea include Gram stain, culture, DNA probes, and nucleic acid amplification techniques. A Gram stain of urethral smear exudates from symptomatic men, looking for intracellular gram-negative diplococci, and has a high sensitivity and specificity; however, this test performs poorly in asymptomatic men and women. When a specimen is collected for culture, viability of the fastidious organism on a cotton swab is limited; therefore the exudate must be quickly transferred to an appropriate culture medium, such as a modified Thayer-Martin medium. Culture remains the gold standard for diagnosis and the test of choice for diagnosis of *N. gonorrhoeae*

**TABLE 6.7** Treatment of Gonorrhea

	Preferred Regimen	Alternative Regimen <sup>a</sup>
Uncomplicated infections of the cervix, urethra, or rectum	Ceftriaxone 250 mg intramuscularly in a single dose; plus azithromycin 1 g orally once	Cefixime 400 mg orally in a single dose; plus azithromycin 1 g orally once
Uncomplicated pharyngeal infections	Ceftriaxone 250 mg intramuscularly in a single dose; plus azithromycin 1 g orally	
Disseminated infection	Ceftriaxone 1 g intramuscularly or intravenously every 24 hours; plus azithromycin 1 g orally	Cefotaxime 1 g intravenously every 8 hours; or ceftizoxime 1 g intravenously every 8 hours; plus azithromycin 1 g orally

<sup>a</sup>If severe cephalosporin allergy precluding the safe use of cephalosporins, oral gemifloxacin 320 mg once plus oral azithromycin 2 g orally once or intramuscular gentamicin 240 mg once plus oral azithromycin 2 g once. Because of concerns over emerging resistance, cephalosporin following desensitization is favored especially in complicated cases.

infection of nongenital sites (e.g., pharynx, rectum). Culture is also useful for antimicrobial susceptibility testing in cases of suspected treatment failure. For genital disease, testing by nonculture assays is rapid and reliable. NAATs have a high sensitivity and specificity for cervical, urethral (in men), vaginal, and first-catch urine samples. NAATs are not currently FDA approved for rectal or pharyngeal sites, but there are data to support the use of these assays for nongenital sites, and this use is implemented in some clinical settings with proper laboratory performance specifications. All patients diagnosed with gonorrhea should also have screening testing for chlamydia; testing for other STDs, including HIV and syphilis, should be strongly considered.

### Treatment

The emergence of antibiotic resistance among *N. gonorrhoeae* isolates has shifted antimicrobial treatment recommendations for gonorrhea over the years with new CDC treatment guidelines published in 2015 (Table 6.7). Because of emerging antibiotic resistance, the CDC now recommends dual therapy for gonorrhea, with a cephalosporin plus either azithromycin, even if NAAT for *C. trachomatis* was negative. Although isolates remain sensitive to third-generation cephalosporins, minimum inhibitory concentrations for these agents are shifting up, and oral cefixime is no longer a preferred treatment option. Oral cefixime does not provide as sustained bactericidal blood level as ceftriaxone, and its efficacy in treating pharyngeal gonorrhea is lower. At present, all US isolates remain susceptible to ceftriaxone. If alternative therapy with cefixime rather than ceftriaxone is used for pharyngeal gonorrhea, then patients should have a test of cure. Test of cure is ideally performed by culture or by NAAT with follow-up culture and susceptibility testing in cases with positive results. Empiric use of fluoroquinolones is no longer recommended because of increasing rates of quinolone-resistant *N. gonorrhoeae*. All sex partners of patients diagnosed with gonorrhea should be referred for evaluation and treatment. Patient-delivered partner therapy

may be considered if the sex partner is unlikely to seek evaluation and treatment; however, this is not recommended for MSM because of the high prevalence of other STDs requiring more thorough evaluation. Patients undergoing treatment should be instructed to abstain from sexual intercourse until both they and their partners have completed treatment and are no longer symptomatic. Because spectinomycin is not available in the United States, infectious diseases consultation is recommended for pregnant women who cannot tolerate a cephalosporin.

### Nongonococcal Urethritis and Epididymitis

#### Etiologies and Clinical Manifestations

Nongonococcal urethritis (NGU) may result from a variety of pathogens, and the etiology is often unknown. The most common cause of NGU is *C. trachomatis* infection, but *Ureaplasma urealyticum*, *Mycoplasma genitalium*, *Trichomonas vaginalis*, enteric bacteria, HSV, and adenovirus may also cause NGU. By definition, urethritis must be present to support the diagnosis of NGU. Urethritis may present with symptoms of dysuria, urethral discharge, or pelvic pain.

#### Diagnosis

All patients with urethritis or suspected urethritis should be tested for chlamydia and gonorrhea. NGU is defined as urethritis with negative testing for gonorrhea. Urethritis is diagnosed by the presence of a mucopurulent urethral discharge or smear of urethral discharge showing at least 5 WBC per high-power field or a positive leukocyte esterase test or >10 WBC per high-power field in a first-void urine specimen. Detection of other pathogens causing NGU may be difficult, so empirical treatment is often recommended.

#### Treatment

When a causative pathogen is identified, organism-specific therapy should be prescribed. If the cause is unknown, the preferred empiric treatment regimens for NGU are azithromycin 1 g orally as a single dose or doxycycline

100 mg orally twice daily for 7 days. Azithromycin may be advantageous for treatment of *U. urealyticum*, *Mycoplasma hominis*, and *M. genitalium*, and a single dose may be given on site as directly observed therapy. Erythromycin, ofloxacin, levofloxacin, and moxifloxacin are alternative treatment options. Sex partners should be referred for evaluation and treatment, and patients should abstain from sexual intercourse until they and their partners have been treated and symptoms have resolved. Patients with acute epididymitis, who are sexually active, should be treated with a single 250-mg intramuscular dose of ceftriaxone plus a 10-day course of either doxycycline 100 mg twice daily, levofloxacin 500 mg once daily, or ofloxacin 300 mg twice daily. The fluoroquinolones should be selected over doxycycline, when enteric pathogens are possible (MSM who practice anal sex).

### Follow-Up

Patients with persistent symptoms after treatment should be tested for *T. vaginalis* by NAAT or a culture of urethral swab or a first-void urine specimen. Repeat testing for *C. trachomatis* and *N. gonorrhoeae* should be considered when reinfection may have occurred. Empiric retreatment with azithromycin should also be considered if initial treatment with doxycycline failed, given the difference in efficacy for some causative agents. Additional empiric treatment with a single 2-g oral dose of metronidazole or tinidazole should be administered to patients with persistent urethral inflammation without an identified pathogen.

## Pelvic Inflammatory Disease

### Etiology

PID is a general term for inflammation of the female upper genital tract involving any combination of the reproductive pelvic organs (uterus, ovaries, fallopian tubes) and surrounding pelvic peritoneum. Infections are often polymicrobial. The sexually transmitted pathogens *N. gonorrhoeae* and *C. trachomatis* are frequently involved. Other associated pathogens include *Gardnerella vaginalis*, enteric gram-negative rods, anaerobes, *H. influenzae*, *M. hominis*, *U. urealyticum*, *M. genitalium*, and cytomegalovirus (CMV). In women with a retained intrauterine device (IUD), *Actinomyces israelii* may be involved. PID caused by *Mycobacterium tuberculosis* infections is seen in endemic areas. Fitz-Hugh Curtis syndrome, or perihepatitis, is the extension of gonococcal or chlamydial PID to the liver capsule without significant parenchymal involvement.

### Complications

Symptoms of PID may range from subtle to severe, and early diagnosis and initiation of therapy are essential because the long-term sequelae can be devastating and costly. Complications of PID include infertility, ectopic pregnancy, and chronic pelvic pain. Sex partners of patients with PID should be tested for STDs and treated appropriately to reduce the risk of reinfection. There is an increased risk of PID during the first few weeks after IUD insertion.

## Diagnosis

PID is a clinical diagnosis that may be challenging because of the broad spectrum of manifestations of the disease. PID is often associated with only mild symptoms, resulting in a delay in diagnosis. A diagnosis of PID is presumed in sexually active young women experiencing pelvic or lower-abdominal pain, without another identified cause, who have cervical motion, uterine, or adnexal tenderness. Additional features to support the diagnosis of PID include fever  $>38.3^{\circ}\text{C}$ , mucopurulent cervical or vaginal discharge, abundant WBC on wet preparation of vaginal secretions, elevated erythrocyte sedimentation rate and/or C-reactive protein, and diagnosis of *C. trachomatis* or *N. gonorrhoeae* genital infection. Diagnosis may be confirmed by endometrial biopsy, transvaginal ultrasound, MRI, or laparoscopic examination, but these tests are not frequently used. All patients with PID should have a pregnancy test. A differential diagnosis includes conditions that are surgical emergencies. Some conditions on the differential diagnosis include ectopic pregnancy, ovarian torsion or ruptured cyst, gastroenteritis, diverticulitis, appendicitis, urinary tract infection, renal calculi, and other gynecologic and abdominal conditions.

### Treatment

Even when endocervical testing is negative, treatment of PID must include therapy for both *C. trachomatis* and *N. gonorrhoeae* (Table 6.8). It remains unclear whether the addition of treatment for anaerobic pathogens is of added clinical benefit. PID is often treated with outpatient oral therapy, but hospitalization is appropriate for severe disease. Indications for hospitalization are clinical and may include pregnancy, poor response to outpatient therapy, poor tolerance of or adherence to outpatient regimens, severe symptoms such as severe pain, nausea or vomiting, the need to exclude a surgical emergency, the presence of a tubo-ovarian abscess, or other complications that may require an invasive intervention. The patient's age by itself is not a criterion for hospitalization.

## Bacterial Vaginosis

Bacterial vaginosis (BV) is the most common cause of vaginal discharge or malodor. Sexual activity is a risk factor because the cause of BV is believed to be replacement of normal vaginal flora (*Lactobacillus* species) with other bacteria (*G. vaginalis*, *M. hominis*, *Prevotella* spp., and *Mobiluncus* spp.) in sexually active women. Although the development of BV seems to be related to sexual activity, the pathogenesis is poorly understood, and it is unclear whether the pathogens are actually sexually transmitted. BV is most frequently diagnosed by clinical criteria including a thin white vaginal discharge with a fishy odor (whiff test), the presence of clue cells (vaginal epithelial cells with a stippled appearance) on wet-prep

**TABLE 6.8 Treatment Regimens for Pelvic Inflammatory Disease**

	Preferred Regimen	Alternative Regimen
Intramuscular/oral therapy (for outpatients)	Ceftriaxone 250 mg intramuscularly in a single dose; plus doxycycline 100 mg orally twice daily for 14 days; with or without metronidazole 500 mg orally twice daily for 14 days; or cefoxitin 2 g intramuscularly in a single dose and probenecid, 1 g orally in a single dose; plus doxycycline 100 mg orally twice daily for 14 days; with or without metronidazole 500 mg orally twice daily for 14 days; or other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime); plus doxycycline 100 mg orally twice daily for 14 days; with or without metronidazole 500 mg orally twice daily for 14 days	
Parenteral therapy (for patients requiring hospitalization)	Cefotetan 2 g intravenously every 12 hours or cefoxitin 2 g intravenously every 6 hours; plus doxycycline 100 mg orally or intravenously every 12 hours; or clindamycin 900 mg intravenously every 8 hours; plus gentamicin intravenously	Ampicillin/sulbactam 3 g intravenously every 6 hours; plus doxycycline 100 mg orally or intravenously every 12 hours

examination, and a vaginal fluid pH >4.5. Gram stain used to identify the relative concentrations of vaginal bacteria may be useful, but culture of *G. vaginalis* is not recommended because of low specificity. One rapid antigen detection test (BD diagnostics AFFIRM VPIII test) is currently approved for diagnosis of *G. vaginalis* infection. All symptomatic women should be treated with metronidazole 500 mg orally twice daily for 7 days, or metronidazole gel (0.75%) 5 g intravaginally once daily for 5 days, or clindamycin cream (2%) 5 g intravaginally once daily for 7 days. Oral tinidazole, oral clindamycin, or clindamycin ovules may be used as alternative treatment regimens. Oral single-dose 2 g metronidazole has lower efficacy. All symptomatic pregnant women and those asymptomatic pregnant women who are already at increased risk for preterm labor should be evaluated and treated. Pregnant women should be treated with systemic (oral) regimens. Routine treatment of sex partners has not been shown to decrease incidence of recurrence and is not recommended. BV may be associated with PID and endometritis, particularly in patients who have recently had invasive genital procedures such as abortions.

### Trichomoniasis

Trichomoniasis is caused by the protozoan *T. vaginalis*. Infected men and women are often asymptomatic. When symptomatic, men may develop urethritis and women may develop a malodorous yellow-green vaginal discharge or vulvar irritation. *T. vaginalis* NAAT of vaginal or endocervical secretions has a sensitivity of 95% to 100% and can detect three to five times more *T. vaginalis* infections than microscopic inspection by wet-mount, for which the sensitivity is about 60%. Rapid point-of-care antigen detection tests have a sensitivity of approximately 83% and specificity of approximately 97%. The sensitivity of culture, which was the gold standard for diagnosis until NAAT was approved, is 75% to 96% and is higher for vaginal secretions than for urine. The preferred treatment for trichomoniasis is oral single-dose metronidazole (2 g) or oral single-dose tinidazole (2 g). An alternative is metronidazole 500 mg orally twice daily for 7 days. Sex partners should also be treated to reduce the risk of recurrence, which in one study was shown to be 17% within 3 months. Treatment failure is rare, and follow-up examination or testing is not necessary unless symptoms persist after treatment.

## Chapter Review

### Questions

- Which of the following statements about genital herpes is not correct?
  - HSV-1 does not cause genital herpes.
  - Most infected individuals have no or only minimal signs or symptoms from HSV-1 or HSV-2 infection.
  - Genital HSV-2 infection is more common in women than in men.
  - Congenital HSV can lead to potentially fatal infections in neonates.
- A 22-year-old male presents to the STD clinic complaining of a sore on his penis for 1 week. His last sexual exposure was approximately 3 weeks previously and was without a condom. He indicates that he has predominantly female partners although he has occasionally had sexual relations with a male partner. His HIV test 6 months ago was negative. Physical examination was unremarkable except for a genital examination that showed an uncircumcised penis with a red, indurated, clean-based, and nontender lesion on the ventral side near the frenulum. He also had two enlarged tender right inguinal nodes.  
The most likely diagnosis is:
  - Primary syphilis
  - HSV
  - Chancroid
  - LGV
- Risk factors for PID include all of the following except:
  - Douching
  - Presence of an IUD
  - More than one sexual partner
  - Past history of a sexually transmitted infection
  - Over the age of 40 years and being sexually active
- A 28-year-old pregnant woman is screened for syphilis during her first prenatal visit. Her RPR titer is reactive at 1:8, and her TP-PA test is reactive. A repeat RPR is again positive at a titer of 1:8. She has had three life-time sex partners. She reports no medical history of, or current, genital ulcer or other manifestations of early or late syphilis. She has never been tested for or treated for syphilis. She has a childhood allergy to penicillin, listed as a rash. She has no recollection of the allergy. Her examination is normal. Which of the statements regarding her management is correct?
  - No treatment recommended. This is a false-positive test, which is common during pregnancy.
  - Doxycycline 100 mg twice daily for 28 days is the alternative regimen for penicillin-allergic pregnant patients.
  - Azithromycin is an adequate alternative to penicillin-allergic pregnant patients with syphilis because it crosses the placenta well.
  - Penicillin G is the only recommended treatment for syphilis in pregnancy. Skin testing is recommended to determine if desensitization is needed.
  - Delaying treatment until after delivery is the best course of action.
- Which of the following groups has the highest rate of *C. trachomatis* infection?
  - Males age 20 to 24 years
  - Females age 20 to 24 years
  - Females age 25 to 29 years
  - Males age 25 to 29 years

## Dermatologic Manifestations of Infectious Disease

SHINJITA DAS AND PETER C. SCHALOCK

Infections are a leading cause of death globally. Skin can serve as either a primary site for infection or manifest as an outward sign of systemic infection. This chapter aims to review the common fungal, bacterial, and viral skin infections; skin manifestations of sexually transmitted diseases (STDs); and bugs and bites of medical importance.

### Cutaneous Fungal Infections

#### Superficial Fungal Infections

Fungal infections are the most common infections worldwide, affecting up to 25% of the population. Skin infections are characterized as either superficial (affecting keratin of stratum corneum, hair, or nails) or deep (typically disseminated disease arising from inhalation). The most frequent causes of superficial mycoses are dermatophytes and yeasts. Common dermatophytes include members of *Trichophyton* (most common), *Epidermophyton*, or *Microsporum* genera. Risk factors for widespread tinea infections include immunosuppression (either locally using topical corticosteroids or calcineurin inhibitors, or systemically through disease states, such as HIV/AIDS, cancer therapy, or autoimmune connective tissue disease). Typical skin lesions are pruritic, erythematous annular plaques with leading scale, although vesicular or bullous variants can be seen, especially on the feet. Dermatophyte infections are named by body site of involvement: tinea capitis (scalp), tinea faciei (face), tinea corporis (body), tinea cruris (groin), tinea pedis (feet; Fig. 7.1). Tinea capitis is caused by *Trichophyton tonsurans* and seen most commonly among children 3 to 7 years old. Severe cases of tinea capitis may result in a deep boggy inflammatory plaque studded with pustules (kerion) and can be associated with fever, pain, and lymphadenopathy. Majocchi granuloma is dermatophyte infection of the hair follicle that presents with perifollicular pustules and nodules (frequently on the legs of women). It can occur in the setting of topical steroid application to unsuspected tinea corporis.

Up to 30% of superficial dermatophytoses manifest as onychomycosis (tinea unguium), infection of the nails that is often associated with tinea pedis. Onychomycosis accounts for nearly 50% of nail abnormalities and affects around 4% of the North American population (Rosen et al., 2015). The three most common subtypes are identified based on pattern of nail invasion: distal lateral subungual onychomycosis (DLSO, which begins at the hyponychium, noted in Fig. 7.1), proximal subungual onychomycosis (PSO, from invasion at the proximal nail fold), and superficial white onychomycosis (SWO, invasion of the superficial dorsal nail plate). DLSO and PSO are typically caused by *Trichophyton rubrum*, and SWO is caused by *Trichophyton mentagrophytes* (in immunocompetent individuals) or *Trichophyton rubrum* (in immunocompromised individuals). SWO and PSO can be signs of HIV infection, and recognition of these forms of onychomycosis should prompt further investigation. A fourth form of onychomycosis is candidal onychomycosis.

Superficial fungal infections can also be caused by yeasts, such as in tinea versicolor (*Malassezia* spp.). Patients can present with asymptomatic hypopigmented, hyperpigmented, or reddish tan patches with subtle powdery scale on the upper trunk and neck. Hypopigmentation (which is more prominent when a patient is tan) is caused by inhibition of tyrosinase enzyme by azelaic acid produced by *Malassezia*, and it can take months to normalize. Treatment with topical preparations (selenium sulfide lotions/shampoos and azole antifungals) is frequently successful, although recurrence is common, especially during warm/humid months.

Definitive diagnosis of a fungal or yeast infection is made by performing a potassium hydroxide (KOH) wet mount from the scale and seeing characteristic hyphae or pseudo-hyphae. Alternatively, a fungal culture can be sent but can take 3 to 4 weeks for definitive results. Diagnosis of onychomycosis can also be done performing periodic acid–Schiff stain on nail clippings. Treatment for limited cutaneous infection is topical (terbinafine, azole derivatives [e.g., ketoconazole], and ciclopirox). Of note, topical steroid application will worsen infection, although it can sometimes

• **Fig. 7.1** Erythematous plaque with leading scale of tinea pedis. Also note distal lateral subungual onychomycosis on the great toe.

mitigate the associated pruritus. A systemic agent should be considered for extensive surface involvement, tinea capitis, or onychomycosis. The most common oral treatment is terbinafine, which prevents fungal production of ergosterol by inhibiting squalene epoxidase. Fluconazole also can successfully treat dermatophyte infections of both the nail and skin but is not US Food and Drug Administration–approved for these indications and should thus be reserved for candidal infections.

### Systemic Fungal Infections

Multiple invasive fungi can infect the skin, with inoculation through local trauma, intravenous (IV) catheters, or inhalation. In the United States, coccidioidomycosis, histoplasmosis, and blastomycosis are the most common systemic fungal infections, with skin manifestations occurring rarely as a result of dissemination (and evenly more rarely from direct inoculation). Immunosuppressed individuals may develop cryptococcal infections of the skin. Diagnosis of cutaneous involvement of systemic fungal infections requires histologic and tissue culture evaluation.

Coccidioidomycosis is caused by the dimorphic fungi *Coccidioides immitis* (limited geographically to the San Joaquin Valley in California) and *Coccidioides posadasii* (in the desert southwest of the United States, Mexico, and Central/South America). Infection is acquired through the respiratory route and up to 60% of infected individuals are asymptomatic. Systemic manifestations may range from low-grade fever to more fulminant symptoms, including fevers, chills, malaise, night sweats, and severe headaches (rare). Skin manifestations are rare, occurring more commonly as hypersensitivity reactions (erythema multiforme or erythema nodosum, which occur in up to 30% of woman and 15% of men) rather than primary (painless, firm nodules) or disseminated (papules, pustules, plaques) manifestations. Skin lesions develop in 20% to 25% of cases of disseminated disease, which accounts for less than 1% of infections.

*Histoplasma capsulatum* is another dimorphic fungus endemic to the central United States (Ohio, Missouri, and Mississippi River valleys) that causes respiratory infections

and rare skin infections. North American blastomycosis is caused by *Blastomyces dermatitidis* and is found in similar areas as *Histoplasma*. They rarely cause skin disease in immunocompetent individuals, but cutaneous infection can occur in immunocompromised patients. Cutaneous histoplasmosis may present as erythematous papules, ulcerations, or acneiform or molluscum-like lesions. Hypersensitivity to histoplasmosis can manifest as erythema multiforme or erythema nodosum (about 4% of patients). Although a rare occurrence, disseminated blastomycosis most commonly affects the skin (80% of cases of disseminated disease) and can present as ulcers, abscesses, and verrucous plaques. Cutaneous cryptococcosis (*Cryptococcus neoformans*) also may occur in HIV-infected individuals with multiple presentations, including cellulitis, papules/plaques/ulcerations, or lesions similar to molluscum contagiosum (head and neck are the most common sites).

### Cutaneous Deep Fungal Infections

Chronic fungal infection caused by direct infection of the skin can occur due to a variety of organisms. *Sporothrix schenckii* lives on decaying organic material and is implanted most often in the skin of an extremity (characteristically by prick from a rosebush thorn). Fungal infection develops and spreads along lymphatic channels, causing erythematous nodules in a linear lymphatic distribution (75% of cases vs. 20% of cases remaining as fixed cutaneous plaques). Mycetoma is caused by a wide variety of fungal species including *Nocardia* spp., *Pseudallescheria boydii* (the most common cause worldwide), *Acremonium* spp., and *Madurella* spp. Men are more affected than women and present with nodules with draining sinus tracts from traumatic inoculation. This is rarely seen in the United States. Diagnosis is by KOH, fungal culture, and/or biopsy as well as examination of the type of “grains” produced by the infection. Black grains suggest a common fungal infection such as *Madurella*; small white grains suggest *Nocardia*. Grains with red coloration are caused by *Actinomyces pelletieri*. Larger yellow-white to white grains are either fungal or actinomycotic. Other fungal infections to consider include zygomycetes (such as *Mucor*) or chromoblastomycosis caused by multiple organisms, including *Phialophora verrucosa*, *Cladosporium carrionii*, *Rhinocladiella aquaspersa*, and *Fonsecaea* spp.

### Cutaneous Bacterial Infections

Bacterial infection of the skin can present in a variety of ways. Impetigo is superficial infection of the epidermis by gram-positive organisms (50%–70% of cases from *Staphylococcus aureus*, the rest from *Streptococcus pyogenes*) and presents as superficial pustules that rapidly rupture to form honey-colored crust (Fig. 7.2). When this crust is removed, the base is glistening and moist. A bullous variant also exists, most often caused by staphylococci. Ecthyma is a deeper infection, usually ulcerative on the lower extremities,

• **Fig. 7.2** Impetigo: honey-colored crusted erosion on the posterior neck.

• **Fig. 7.3** Cellulitis on the lower abdomen caused by *Staphylococcus aureus*.

and is caused by beta-hemolytic streptococci (with secondary staphylococcal infection). Treatments for impetigo and ecthyma include gentle debridement and cleansing, topical antibiotics (e.g., mupirocin), or appropriate oral antibiotics for more widespread disease.

Erysipelas and cellulitis are bacterial infections with deeper cutaneous involvement than impetigo and ecthyma. Erysipelas occurs from infection by group A beta-hemolytic streptococci (*S. pyogenes*) of superficial dermal lymphatics. It presents as tender, sharply demarcated, indurated erythematous plaques most commonly on the lower extremities and face. Cellulitis is infection of the dermis and subcutaneous tissues, and it presents as tender, swollen, erythematous, warm patches and plaques (Fig. 7.3), most commonly of the lower extremities. Most common causes include *S. aureus* and *S. pyogenes*; cellulitis with a violaceous color and bullae suggests infection by *Streptococcus pneumoniae*.

Staphylococcal scalded skin syndrome (SSSS) is characterized by skin tenderness, flaccid bullae formation, and denudation of the skin surface. It is caused by phage group 2 *S. aureus* toxin production (A and B toxin), which leads to cleavage of desmoglein 1 in epidermal desmosomes of the

granular cell layer, thus leading to the fragile bullae. SSSS is common in infants and children (98% of cases are <6 years old) and has a lower mortality (1%–5%) in this age group. It is uncommon in adults (who are generally immunocompromised) and is associated with higher mortality in this population (up to 50%). SSSS must be rapidly distinguished from Stevens-Johnson syndrome or toxic epidermal necrolysis, which are severe drug reactions. Distinction is made by skin biopsy and rapid histologic evaluation of frozen sections. Treatment of SSSS is penicillinase-resistant antistaphylococcal antibiotics, supportive skin care, and IV hydration.

## Cutaneous Viral Infections

Viral diseases of childhood, and occasionally adulthood, with skin manifestations are summarized in Table 7.1. Human herpes viruses, frequent causes of human disease, are summarized in Table 7.2. Nonspecific morbilliform exanthems are associated with many viral infections, although the most common cause is enterovirus. Many of these are considered diseases of childhood; however, it is important to consider the cause of a morbilliform eruption because many of these also affect adults.

### Human Papillomavirus: Warts/Condyloma

Human papillomavirus (HPV) infection causes warts and is a common cause of skin infection. (HPV can affect up to 25% of individuals during teenage/young adult years, which are the peak years for infection.) The main types that are commonly seen are verruca vulgaris (VV) on the hands/feet, condyloma acuminatum in the genital area (>50% of sexually active individuals), and flat warts on the face/arms. There are multiple subtypes of HPV that are responsible for the different types and morphologies seen. The typical VV is a discrete, well-demarcated, exophytic hyperkeratotic/rough papule, often found on the digits. VV on the feet can be exophytic (Fig. 7.4) or endophytic. A characteristic finding on examination is small red/black flecks on the surface, which are thrombosed capillary loops. Genital warts (condyloma acuminatum) range from subtle thin papules and plaques to large, exophytic plaques. Ninety percent of all genital warts are caused by HPV 6 and HPV 11. Some subtypes of HPV are carcinogenic and are associated with cervical cancer and dysplasia. The most common oncogenic types are HPV 16, 18, 31, and 33, which can also cause genital warts. Diseases and HPV types are reviewed in Table 7.3. Treatments are destructive in nature. The most common and successful therapy is superficial application of liquid nitrogen (LN<sub>2</sub>). Multiple visits are often necessary to achieve complete removal. There is a myriad of other options, including topical creams (salicylic acid, imiquimod), intralesional therapies (purified candida antigen, bleomycin), and surgical modalities (electrocautery, carbon dioxide laser, or surgical removal).

**TABLE 7.1** Common Viral Causes of Skin Rash

Disease	Cause	Notes
Hand-foot-mouth	Coxsackie virus A16 and Enterovirus 71	Usually children
Gianotti-Crosti syndrome	United States and Europe: EBV, otherwise hepatitis B	Syn.: papulovesicular acrodermatitis of childhood
Measles (rubeola)	Paramyxovirus of genus <i>Morbilli</i>	Rare in the United States
German measles (rubella)	Togavirus of genus <i>Rubella</i>	Infection in pregnancy can cause fetal infection and congenital rubella syndrome
Chickenpox	Varicella virus	Reactivation causes shingles (herpes zoster)
Erythema infectiosum	Parvovirus B19	Fifth disease; three phases: begins with slapped-cheek appearance, followed by morbilliform eruption, and finally a lacy reticular dermatitis
Papular-purpuric gloves and socks syndrome	Parvovirus B19	Reaction to viral infection: symmetric erythema/edema of hands and feet, progress to petechial and purpuric macules, papules, and patches, followed by fine desquamation. Sharp demarcation at the wrists and ankles.
Roseola (erythema subitum)	Human herpes virus 6	Sixth disease
Nonspecific exanthems	Echovirus, adenovirus, many others	
Infectious mononucleosis	EBV	Amoxicillin or ampicillin causes rash during infection with EBV
Transient generalized morbilliform dermatitis	Human immunodeficiency virus	Associated with primary infection

EBV, Epstein-Barr virus.

**TABLE 7.2** Human Herpes Viruses

Type	Disease/Condition	Transmission	Notes
HSV-1	Oral herpes simplex	Close contact	~10% of cases of genital HSV are caused by type 1
HSV-2	Genital herpes simplex	Close contact, usually sexual	Can occur on oral mucosa or away from the genitals
VZV	Shingles/herpes zoster/chickenpox	Contact or respiratory	Primary infection is chickenpox. Reactivation causes shingles (herpes zoster).
EBV	Infectious mononucleosis, oral hairy leukoplakia, Burkitt lymphoma, nasopharyngeal carcinoma	Saliva	No good therapy, EBV lacks thymidine kinase
CMV	Maternal-fetal transmission → congenital CMV, retinitis, and pneumonia problematic in AIDS	Contact, blood transfusions, transplantation, congenital, transplacental	Infection rate rises with age → 50% by age 35
Human herpes virus 6/7	Exanthem subitum/roseola infantum	Contact or respiratory	Infection >90% after age 2
Human herpes virus 8 (Kaposi sarcoma-associated herpes virus)	Kaposi sarcoma: 4 subtypes—classic, immunocompromised, endemic African, and AIDS-related	Unknown	Other HIV-associated disease: primary effusion lymphoma and multicentric Castlemans disease
Herpes B	Humans can have localized disease or fatal encephalomyelitis	Bites/trauma from infected monkeys	Infects primarily monkeys; no human-to-human transmission

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; HSV-1, herpes simplex virus type 1; HSV-2, herpes simplex virus type 2; VZV, varicella zoster virus.

From Hunt R. Microbiology and immunology online. Virology chapter 11: herpes viruses. <http://pathmicro.med.sc.edu/virol/herpes.htm>.

• **Fig. 7.4** Molluscum contagiosum: smooth pink umbilicated papules.

• **Fig. 7.5** Verruca plantaris.

**TABLE 7.3** Verruca and Condyloma

Verruca Type	Human Papillomavirus Type
Anogenital warts	<b>6, 11</b> , 42, 43, 44, 55, and others
Bowenoid papulosis	<b>16, 18, 34, 39, 42, 45</b>
Butcher warts (meat, poultry, and fish handlers)	<b>2, 7</b>
Common warts (verruca vulgaris)	<b>1, 2, 4, 26, 27, 29, 41, 57, 65</b>
Epidermodysplasia verruciformis (EV)	2, 3, <b>5, 8</b> , though >15 subtypes (5 and 8 are more common for SCC developing in EV)
Flat cutaneous warts (verruca plana)	<b>3, 10, 27, 28, 38, 41, 49</b>
Focal oral epithelial hyperplasia (Heck disease)	<b>13, 32</b>
Genital cancers	<b>16, 18, 31, 33, 35, 39, 45, 51</b>
Oral papillomas	6, 7, 11, <b>16, 32</b>
Plantar warts (verruca plantaris)	<b>1, 2, 4, 63</b>

Bold denotes the most common subtypes.  
SCC, Squamous cell carcinoma.

## Molluscum Contagiosum

Molluscum contagiosum is caused by poxvirus infection and presents as discrete white, pink, or skin-colored papules with a central umbilication (Fig. 7.5). They are most common in children, transferred via fomites and seen at higher rates in those using public swimming pools. Inoculation in adults is through intimate skin contact; consider concomitant STDs in adults with molluscum. Molluscum papules may spontaneously resolve at times, although lesions are communicable while present. Treatment is removal by destruction (LN<sub>2</sub>), topical imiquimod, cantharidin solution, or curettage.

## HIV Infection–Related Skin Findings

Individuals infected with HIV show a variety of skin manifestations (in up to 90% of HIV patients). With initial infection, a transient morbilliform eruption may occur. Kaposi sarcoma, a vascular neoplasm related to infection with human herpesvirus 8, can present with violaceous patches and papules/nodules at any point during HIV infection. Later manifestations, usually related to immunosuppression (CD4 <200, AIDS), include VV, condyloma acuminatum, mucocutaneous candidal infection, recurrent herpes zoster and herpes simplex virus (HSV) infections, recalcitrant seborrheic dermatitis, psoriasis, and oral hairy leukoplakia (caused by Epstein-Barr virus). Patients with CD4 counts <50 may present with unusual and refractory manifestations of opportunistic infections, such as chronic HSV or varicella zoster virus, giant/multicentric molluscum, atypical mycobacterial infections, and crusted scabies.

## Bugs and Bites: Tick-Borne

Bacteria of the genera *Rickettsia* and *Borrelia* are responsible for most tick-borne illnesses. The typical presentation of the rickettsioses consists of a triad of fever, headache, and rash. The Weil-Felix reaction tests for agglutinating antibody to antigens of *Proteus* O<sub>x</sub>-2, O<sub>x</sub>-19, and O<sub>x</sub>-K. The reaction is not specific, but it is positive in many rickettsioses. Complement fixation and immunofluorescence tests are more specific. These conditions are summarized in Table 7.4.

## Pediculosis

*Pediculus humanus* lice infect the scalp (*capitis*) and body (*corporis*), whereas pubic lice (*Phthirus pubis*) are common parasites on the hairs in the genital region. Head lice are passed by close contact or fomites. Pubic lice are passed by sexual contact in most cases and should prompt evaluation for other STDs, including HIV. Treatments are generally

**TABLE 7.4** Infections Caused by Arthropod or Insect Bites

Disease	Agent/Weil-Felix Test	Vector	Host/Notes
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i> (+)	<i>Dermacentor andersoni</i> (wood tick) <i>Dermacentor variabilis</i> (brown dog tick) Lone star tick	Dogs, small animals
Boutonneuse fever	<i>R. conorii</i> (+)	Ixodes tick <i>Rhipicephalus sanguineus</i> tick	Wild rodents and dogs
Rickettsialpox	<i>R. akari</i> (-)	<i>Allodermamyssus sanguineus</i> (house mouse mite)	House mouse
Epidemic typhus	<i>R. prowazekii</i> (+)	<i>Pediculus corporis</i> var. <i>humanus</i>	Flying squirrel and humans
Endemic typhus	<i>R. typhi</i> (+)	<i>Xenopsylla cheopis</i> (rat flea)	Rats
Scrub typhus	<i>R. tsutsugamushi</i> (+)	Trombiculid mite (chigger) ( <i>Leptotrombidium</i> spp.)	Rodents
Lyme disease	<i>Borrelia burgdorferi</i>	Ixodes tick	Deer
Cat scratch fever	<i>Bartonella henselae</i>	Cat bite/scratch, fleas	Cats
Bacillary angiomatosis	<i>B. henselae</i> , <i>Bartonella quintana</i> (gram-negative rod)	Cat flea/ <i>Pediculus corporis</i> var. <i>humanus</i>	Cats
Trench fever	<i>B. quintana</i>	<i>Pediculus corporis</i> var. <i>humanus</i>	Humans
Carrion disease (Oroya fever) (Bartonellosis), verruca peruana	<i>Bartonella bacilliformis</i>	Sandfly ( <i>Lutzomyia verrucarum</i> )	Frequent coinfection with <i>Salmonella</i>
Ehrlichiosis	<i>Ehrlichia chaffeensis</i> , <i>Ehrlichia sennetsu</i>	<i>Amblyomma americanum</i> (lone star tick)	Dogs
Q fever	<i>Coxiella burnetii</i>	Various tick species, though transmission respiratory route not bite	Cattle, sheep, goats, cats
Leishmaniasis	<i>Leishmania</i> spp.	Sandfly (various species)	Humans, rodents, hyrax, dogs

topical with permethrin or lindane. Neither of these external parasite infections is known to be a vector of internal disease, in contrast to the body louse. *P. humanus* var. *corporis* mites live on clothing and not on the human body. Often those with infections live in close contact with others and have poor hygiene. Trench fever, caused by *Bartonella quintana*, and epidemic typhus, caused by *Rickettsia prowazekii*, are both spread by the body louse vector.

### Flies, Fleas, and Mosquitoes

Bites of various flying and jumping insects cause skin disease. Bites of the blackfly *Simulium* transmit *Onchocerca volvulus*, the cause of various types of onchocerciasis. Filariasis (tropical elephantiasis) is transmitted by mosquitoes of the genera *Anopheles*, *Culex*, *Aedes*, and *Mansonia*. African sleeping sickness is caused by the tsetse fly of genus *Glossina*. Tungiasis is caused by sand flea (or chigger) *Tunga penetrans* larvae living in the skin of the human host. It is rarely seen in North America, but it is seen in travelers returning from endemic areas. The rat flea, *Xenopsylla cheopis*, transmits infection with *Rickettsia typhi* causing endemic typhus as well as *Yersinia pestis* causing bubonic plague.

### Scabies

*Sarcoptes scabiei* var. *hominis* mites are human parasites that live in the stratum corneum. Infection is passed by close contact and rarely by fomites. Skin findings are superficial linear burrows, excoriations, and in some cases nonspecific dermatitis on the finger webspaces, arms, waistline, and genitalia. Severe pruritus is often a characteristic feature, and it is often worst in the evening or bedtime. The skin reactions and pruritus are not caused by the mite itself but are allergic reactions to the scabies feces. Crusted, thickened plaques with hundreds of scabies mites called *crusted scabies* may present in immunosuppressed/immunocompromised or institutionalized individuals. In common cases of scabies infections only a few mites will be present on the body.

First-line therapy is topical permethrin cream applied from the neck down and left on overnight, then repeated in 10 to 14 days. Other topical agents include crotamiton, lindane, and malathion. A 10% sulfur ointment can also be used safely for infants under 2 months of age (who may also have face/scalp involvement) or pregnant women. Alternatively, oral therapy with ivermectin is effective in most cases. For everyone, cleaning of all bedding, clothing, and other

**TABLE 7.5** Sexually Transmitted Diseases

Disease	Cause	Skin Findings	Ulcer	Lymphadenopathy
Chlamydia	<i>Chlamydia trachomatis</i>	None	n/a	n/a
Gonorrhea	Gram-negative diplococci: <i>Neisseria gonorrhoeae</i>	See text	n/a	n/a
Chancroid	<i>Haemophilus ducreyi</i> “school of fish” on pathologic examination	Tender papule initially, then ulceration	Painful ulcer (3 mm–5 cm)	Painful
Granuloma inguinale	<i>Klebsiella granulomatis</i>	Nontender papules, subsequently ulcerate	Painless	None
Lymphogranuloma venereum	<i>Chlamydia trachomatis</i> types L1–L3	Genital papules/ulcers, also rectal ulcers	Painless	Painful
Syphilis	<i>Treponema pallidum</i>	See text	Painless	Painless

areas of frequent contact is essential. Close contacts must also be treated to prevent reinfection.

### Bites

Arthropod bite reactions are type IV delayed-type hypersensitivity reactions. Findings are typically linear or grouped papules/wheals, sometimes with a small central punctum. Pruritus is nearly universal. In general, these reactions are self-limited, although a persistent bite reaction, most often to mosquito bites, can be seen in those with chronic lymphocytic leukemia. Leukemia patients can also have persistent bite-like reactions that are not clearly temporally linked to bites. The most common biting insects are mosquitoes (various genera and species), bedbugs (*Cimex lectularius*), fleas (various genera and species; *Pulex irritans* is the human flea), ticks, and various species of flies. Treatment is symptomatic including topical steroids or, in extensive cases, oral corticosteroids.

### Sexually Transmitted Diseases

STDs are commonly presenting problems in the outpatient setting. The most common STDs, such as chlamydia and gonorrhea, rarely have skin findings.

Chlamydia, caused by *Chlamydia trachomatis*, is the most common bacterial sexually transmitted infection (1.4 million cases reported to the Centers for Disease Control and Prevention [CDC] in 2014, although 2.86 million cases are estimated; approximately two-thirds of new cases occur in those 15 to 24 years old). It does not present with skin ulceration or lymphadenopathy (other than in lymphogranuloma venereum [LGV]). There can be a thin urethral discharge in males, but the symptoms are generally non-dermatologic. Gonorrhea is caused by the gram-negative diplococcus *Neisseria gonorrhoeae*, and estimates suggest 820,000 new cases annually (mostly among those 15 to 24 years of age). Gonorrhea has dermatologic findings in

25% of cases, including morbilliform, pustular, necrotic, or vesicular eruptions that commonly present below the neck. A characteristic finding is pustules over a joint. Other less-common findings include erythema nodosum, urticaria, hemorrhagic lesions, or erythema multiforme. Skin lesions often present in different stages of development. Syphilis is again increasing in prevalence in the United States (2.1 cases of primary/secondary syphilis per 100,000 in 2000/2001, compared with 6.3 cases per 100,000 in 2014). Syphilis has both common and rare skin findings that will be discussed later. Other less common STDs include chancroid, granuloma inguinale, and LGV. These conditions are discussed subsequently and summarized in [Table 7.5](#).

Chancroid (*Haemophilus ducreyi*) is found more frequently in developing countries in commercial sex workers and their contacts. Although worldwide the prevalence has decreased from 69% to 15% (2000), underdeveloped nations (such as in Asia, Africa, and the Caribbean) still have a disproportionately high incidence of disease. Chancroid is characterized by an incubation period of 3 to 7 days and development of a tender papule that rapidly becomes a painful ulcer with shaggy borders and associated lymphadenopathy. Although this combination is suggestive of chancroid, syphilis and herpes simplex must first be ruled out. Patients with chancroid should be screened for HIV. Recommended treatment is azithromycin 1 g orally as a single dose, ceftriaxone 250 mg intramuscularly (IM) as a single dose, ciprofloxacin 500 mg twice a day (BID) for 3 days, or erythromycin 500 mg three times a day for 7 days.

Granuloma inguinale (donovanosis, *Klebsiella granulomatis*) is rarely diagnosed in the United States but is a common STD in developing countries (with <100 cases per year reported annually in the United States). Patients present with nontender papules or nodules after 10 to 40 days of incubation, typically at the base of the penis, labia, or perianal region; rarely, vaginal or cervical disease can occur. After some time, the nodules ulcerate and ooze. Tissue destruction

and spread will not cease until the disease is treated. CDC-recommended treatment is azithromycin 1 g orally weekly (or 500 mg daily) for at least 3 weeks, or until all lesions have healed. Alternative regimens include doxycycline, ciprofloxacin, erythromycin, and trimethoprim-sulfamethoxazole.

LGV is caused by three serotypes of *Chlamydia trachomatis*, L1–L3. LGV presents in three stages: (1) painless genital papule or pustule, which ulcerates and then heals without scarring within a week; (2) several weeks after healing of primary lesions, lymphatic spread leads to development of painful inguinal buboes that rupture; and (3) penile and scrotal elephantiasis caused by fibrosis of lymphatic channels. Patients who practice receptive anal intercourse may present with anorectal disease characterized by rectal ulcers, bleeding, pain, and discharge. Treatment is doxycycline 100 mg BID for 21 days or erythromycin 500 mg four times a day for 21 days.

## Syphilis

Syphilis (*Treponema pallidum*) can have cutaneous manifestations at every stage (primary, secondary, tertiary) and in congenital syphilis infections. Primary syphilis occurs about 3 weeks after direct inoculation and presents as a painless asymptomatic papule that ulcerates (chancre). Syphilitic chancres spontaneously resolve within several weeks, but patients will progress to secondary syphilis if untreated. Secondary syphilis results from hematogenous and lymphatic spread and has myriad cutaneous manifestations, lending to the moniker of “the great imitator.” These cutaneous manifestations include macular eruptions, livedo reticularis, papular eruptions, papulosquamous eruptions, patchy alopecia with “moth-eaten” appearance, and follicular lichenoid eruptions. Presentation of copper-colored nonpruritic scaly plaques on the palms and soles (“copper pennies”) should alert the clinician to possible secondary syphilis. Tertiary syphilis can develop months to years after secondary syphilis and is characterized by multiorgan involvement, including cardiovascular, central nervous system, bone, and skin. Cutaneous manifestations include nodules on the face, trunk, and extremities, as well as gummas (irregularly shaped plaques with central ulceration, caused by granulomas with central coagulative necrosis) on the scalp, face, oral cavity (palate, tongue—superficial glossitis, atrophy of

papillae, and scarring), trunk, and legs. Osseous syphilitis are gummatous osteoarthritis and Charcot joint. Signs of neurosyphilis include Argyll Robertson pupils, tabes dorsalis, and a positive Romberg sign. Cardiovascular manifestations include development of aortic aneurysms. Latent syphilis is characterized by serologic evidence of syphilis without symptomatic disease.

Congenital syphilis is contracted either in utero or during vaginal delivery and is subdivided into early and late stages. Early congenital syphilis develops before 2 years of age and presents with features such as rhinitis (“snuffles”—blood-stained nasal drainage), mucous patches, hepatosplenomegaly, lymphadenopathy, intrauterine growth retardation, hemolytic anemia, thrombocytopenia, and periostitis. Late congenital syphilis (after 2 years of age) manifests with symptoms comparable with tertiary syphilis, leading to malformation of the nervous system, bones, and teeth. Hutchinson triad (interstitial keratitis, Hutchinson incisors, and cranial nerve VIII deafness) are pathognomonic for late congenital syphilis. Other manifestations include rhagades (fissures at angles of mouth and nose), frontal bossing of the forehead, saddle nose deformity, high palatal arch, and short maxillary teeth.

Syphilis is diagnosed by skin biopsy, darkfield or immunofluorescent examination of spirochetes from skin lesions, or serologic testing. Nontreponemal screening tests (sensitive but not specific) include Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR), which become positive within 6 weeks after infection and negative with therapy and in late syphilis. Many systemic conditions (e.g., viral infections, Lyme disease, borreliosis, lymphoma, pregnancy, HIV, and autoimmune connective disease) can give false-positive results. On the other hand, the prozone phenomenon can occur with secondary syphilis, when very high undiluted antibody titers produce a false-negative result. Microhemagglutination assay for *T. pallidum* (MTA-TP) and fluorescent antibody absorption test (FTA-ABS) are specific treponemal tests used to confirm positive VDRL or RPR tests; MTA-TP and FTA-ABS become positive early and remain positive for life, even after treatment. Primary, secondary, and early latent syphilis are treated with benzathine penicillin G 2.4 million units IM in a single dose. Tertiary, late latent, or latent syphilis of unknown duration is treated with benzathine penicillin G 2.4 million units IM weekly for three doses (7.2 million units total).

## Chapter Review

### Questions

1. A 30-year-old woman presents with an itchy rash on the right leg that has been getting worse despite diligent application of clobetasol cream for 3 weeks. Examination reveals an erythematous scaly plaque studded with perifollicular pustules. What should you do next?
  - A. Switch from topical to oral corticosteroid treatment.
  - B. Perform bacterial wound culture and treat with an oral antibiotic.
  - C. Perform Tzanck smear and treat with acyclovir.
  - D. Perform potassium hydroxide and treat with systemic antifungal.
  - E. Perform a mineral prep and treat with permethrin.
2. A 32-year-old patient presents with an itchy rash involving the umbilicus, genitals, and interweb spaces of the digits. His pregnant wife and toddler also have similar itchy rashes. Which of the following statements is true?
  - A. First-line therapy includes permethrin cream.
  - B. One-time treatment is sufficient.

- C. First-line therapy includes econazole cream.
  - D. Pruritus will resolve immediately after appropriate treatment.
  - E. Pregnant women should not be treated.
3. A 28-year-old woman presents with a rash that has not responded to topical steroids. On examination, she has nonpruritic copper-colored round scaly plaques on the palms and soles but no other rash. You send a diagnostic blood test that returns negative. What is the most appropriate next step in management?
- A. Switch to a topical antifungal cream.
  - B. Call the laboratory to repeat the test on a diluted blood sample.

- C. Perform a skin biopsy.
- D. Perform a scabies prep.
- E. Perform a bacterial wound culture.

### Answers

- 1. D
- 2. A
- 3. B

# Board Simulation: Infectious Disease

JENNIFER A. JOHNSON AND SARAH P. HAMMOND

## Questions

1. A 62-year-old man with history of hypertension and diabetes mellitus presents with acute appendicitis. On laparotomy, he is found to have a perforated appendix that is removed. He is treated with ceftriaxone. Two hours after surgery the patient develops fever and hypotension. Electrocardiogram demonstrates a 4-mm ST depression in V4–V6 and troponin I returns positive. A multilumen catheter is inserted in the right internal jugular vein. Blood cultures are collected and grow gram-negative anaerobes, eventually identified as *Bacteroides fragilis*. Metronidazole is added to the antimicrobial regimen. He is transferred to the cardiac care unit for further care. His hospital course is complicated by a non-Q-wave acute myocardial infarction, acute kidney injury (serum creatinine peaked at 3.2 mg/dL), and hypotension from acute gastrointestinal bleeding (peptic ulcer). The patient requires two therapeutic endoscopies to stop the bleeding and is transfused 4 units of packed red blood cells. The patient is placed on high-dose proton pump inhibitor and fluconazole prophylaxis. Eight days after admission he is transferred to the step-down unit. Two days later his temperature spikes to 102°F. You notice the central line insertion site is erythematous so you draw two sets of blood cultures, remove the line, and start vancomycin. The next day his temperature is down to 100.5°F, and the microbiology laboratory reports yeast cells growing on one of four blood culture bottles. What is the best management of this result?
  - A. Dismiss culture, likely a contaminant.
  - B. Culture is real, but central line has been removed; nothing to do.
  - C. Culture is real, patient already on fluconazole; nothing to do.
  - D. Start amphotericin B, discontinue fluconazole.
  - E. Start caspofungin, discontinue fluconazole.
2. A 35-year-old male truck driver is admitted with a week-long history of cough, fever and chills, and right-sided chest pain. He reports a 30-lb weight loss over the previous 3 months as well as fatigue and

occasional headaches that he treats with over-the-counter ibuprofen. He appears emaciated. His blood pressure is 80/40 mm Hg, heart rate is 140 beats per minute, and temperature is 101°F. Examination reveals oral hairy leukoplakia, and chest radiographs confirm the diagnosis of right lower-lobe pneumonia with a small effusion. His blood pressure normalizes with intravenous (IV) fluids after placing a central line, and treatment is started with IV ceftriaxone and oral azithromycin after sputum and blood cultures are obtained. The sputum culture grows *Streptococcus pneumoniae*, which is pansusceptible. Blood cultures are negative. He is leukopenic and lymphopenic. He is anemic with a hemoglobin of 10 g/dL, with a normochromic normocytic pattern. The patient admits to having multiple female sexual partners and former IV drug use. He agrees to be tested for HIV. Three days later the patient remains febrile and continues to experience daily headaches. Blood cultures are redrawn. HIV-1/2 antigen/antibody testing returns positive. CD4 count is 30 cells/mm<sup>3</sup>. Two days later the microbiology laboratory reports yeast cells growing in one of four bottles from the most recent blood cultures. What is the best management for this new blood culture result?

- A. Dismiss culture, likely a contaminant.
  - B. Remove the central line
  - C. Start fluconazole 400 mg/day.
  - D. Start amphotericin B 0.7 mg/kg.
  - E. Start caspofungin 70 mg/day, followed by 50 mg/day.
3. A 70-year-old woman with hypertension, chronic kidney disease (baseline serum creatinine of 1.8 mg/dL), and osteoarthritis presents with a 1-day history of cough, rigors, and progressive dyspnea. On examination in the emergency room, her blood pressure is 75/40 mm Hg, heart rate is 135 beats per minute, respiratory rate is 34 breaths per minute, and SpO<sub>2</sub> 81%. She appears cyanotic, and there are signs of consolidation in her right lower chest, which are confirmed on a chest x-ray. Blood cultures are drawn, and she is started on levofloxacin together with a 2-liter normal saline bolus

and supplemental oxygen. Initial laboratory values reveal a white blood cell count of  $2K/\mu\text{L}$ , 25% bands, serum creatinine of 2.7 mg/dL, and serum  $\text{HCO}_3^-$  of 12 mEq/L, and an arterial blood gas reveals a pH of 7.25. She remains hypotensive, so vasopressors and mechanical ventilation are initiated. Blood cultures grow gram-positive diplococci in pairs. What do you do next?

- A. Add vancomycin.
  - B. Add gentamicin.
  - C. Add ceftriaxone.
  - D. Add low-molecular-weight heparin.
  - E. Add nitric oxide.
4. A 76-year-old man is admitted with a new cough, malaise, dyspnea, and fever of 102°F. A chest x-ray reveals right middle and lower lobe consolidative opacities, and a urine legionella antigen is positive. His medical history is notable for coronary artery disease status-post coronary artery bypass grafting 5 years ago and paroxysmal atrial fibrillation diagnosed four months ago. His medications include low-dose aspirin, rosuvastatin, lisinopril, apixaban, and dofetilide. He is breathing 22 times per minute and has an oxygen saturation of 91% on room air that increases to 97% on 2 L of oxygen by nasal canula. He is treated with 500 mg of azithromycin and admitted to the medical service. His fever curve begins to improve, and his oxygen saturation improves to 95% on room air over the next 36 hours. He continues on azithromycin. In the evening on the second day of his hospitalization he is found unresponsive. What is the most likely explanation of his sudden decompensation?
    - A. Cardiorespiratory failure caused by untreated *Legionella* pneumonia
    - B. Intracranial hemorrhage related to a drug-drug interaction between azithromycin and apixaban
    - C. Ventricular tachycardia related to drug-drug interaction between azithromycin and dofetilide
    - D. Cardiorespiratory failure caused by pulmonary embolism associated with *Legionella* pneumonia
  5. Three days after sustaining hand and arm lacerations when his motorcycle spun off the road into the dirt, a 17-year-old man presents with fever, severe arm pain, and malaise. Examination reveals a temperature of 101.8°F, blood pressure 90/50 mm Hg, and dusky blue fingers with erythema extending to the elbow. Radiograph of the arm reveals subcutaneous gas in the hand, below an area of healing laceration. The antimicrobial regimen that has the best activity against the most likely pathogen is:
    - A. Ceftriaxone
    - B. Vancomycin and gentamicin
    - C. Trimethoprim-sulfamethoxazole
    - D. Cefazolin and metronidazole
    - E. Clindamycin and penicillin
  6. An elderly man with long-standing aortic stenosis is admitted to the hospital with fever and malaise for 1 week. He reports that he had an infection around his fingernail a few weeks ago that was treated with a 7-day course of cephalexin and seemed to be better until the fever started a few days later. Admission blood cultures grow *Staphylococcus aureus* in 4/4 bottles. Transthoracic echocardiogram shows new aortic insufficiency and a 4-mm vegetation. The organism is susceptible to methicillin/oxacillin, cefazolin, vancomycin, and clindamycin but is resistant to penicillin by in vitro susceptibility testing. The patient reports that he is allergic to penicillins; he developed hives after taking dicloxacillin for a dental infection 2 years ago. Which is the most appropriate antimicrobial regimen to treat his newly diagnosed native-valve endocarditis?
    - A. Nafcillin
    - B. Vancomycin
    - C. Cefazolin
    - D. Clindamycin
    - E. Nafcillin and gentamicin
  7. A 32-year-old man is admitted for induction chemotherapy after he is newly diagnosed with acute myelogenous leukemia. He is treated with 7 days of cytarabine by continuous infusion and 3 days of daunorubicin infusion ("7 + 3"). He becomes neutropenic a few days after chemotherapy starts and develops a fever to 101.2°F on day 5. Cefepime is started, and he defervesces. Blood cultures grow no bacteria. On day 12 after the start of chemotherapy he redevelops fever to 102.7°F and complains of right-sided pleuritic chest pain. His absolute neutrophil count is 20. A chest CT scan performed that day demonstrates a nodular infiltrate 3 cm in diameter with surrounding ground glass in the right lower lobe abutting the pleura. Galactomannan EIA index is 1.2 (normal < 0.5). What additional treatment is the most appropriate?
    - A. Liposomal amphotericin B
    - B. Micafungin
    - C. Fluconazole
    - D. Voriconazole
    - E. Hold off on therapy and request a bronchoscopy.
  8. Which of the following patients needs prophylaxis to prevent endocarditis?
    - A. A 58-year-old woman with a prosthetic aortic valve and breast cancer undergoing routine Foley catheter placement before elective breast reconstruction surgery
    - B. A 35-year-old woman with mitral valve prolapse with regurgitation who is undergoing dental extraction
    - C. A 50-year-old man with a history of prior endocarditis, undergoing suturing of a finger laceration from razor injury
    - D. A 28-year-old woman who uses intravenous drugs with a history of tricuspid valve endocarditis undergoing incision and drainage of an abscess

9. An elderly diabetic patient presents with a 3-week history of earache. On examination there is purulent drainage and granulation tissue in the right external auditory canal, and a facial nerve palsy is present on the ipsilateral side. There is no fever, and the peripheral white blood cell count is normal. Appropriate initial therapy includes which of the following agents?
- Topical ciprofloxacin
  - Amphotericin B
  - Ceftazidime
  - Isoniazid and rifampin
  - Vancomycin
10. A group of four college-aged friends all present to the university health center within 12 hours of each other with nausea, vomiting, and watery nonbloody diarrhea without abdominal pain or fever. Two days before they became ill, they returned from a 3-day camping trip where they slept in tents, drank stream water, and ate fish that they caught in a stream. When they returned, they ate a meal together in a local fast-food restaurant and then returned to their separate residences. The most likely cause of their illness is:
- Giardia* acquired from stream water
  - Norovirus acquired from the food they consumed upon their return
  - Scombroid acquired from undercooked fresh fish
  - Campylobacter* acquired from grilled chicken consumed on their camping trip
11. A 76-year-old woman with a history of breast cancer 15 years ago and rheumatoid arthritis presents with new right arm soreness and throbbing pain that developed overnight. She abruptly developed a fever to 102.1°F this morning, and she now notes that her right upper arm has become swollen and red in the last few hours. All of these symptoms are similar to three previous episodes of right arm cellulitis. Her medical history is notable for undergoing lumpectomy and right axillary lymph node dissection followed by radiation 15 years ago. More recently she developed right arm lymphedema for which she wraps her arm at night. Rheumatoid arthritis was diagnosed 23 years ago and is currently treated with weekly methotrexate and prednisone 7.5 mg daily. On examination, the right upper arm is edematous, red, warm, and tender. The erythema extends to the right chest and the upper outer quadrant of her right breast. There is no fluctuance, crepitus, or purulence over the affected areas. She is admitted to observation for intravenous antibiotics. The best antibiotic to treat this infection is:
- Cefazolin
  - Trimethoprim-sulfamethoxazole
  - Vancomycin
  - Aztreonam
  - Linezolid
12. A 12-year-old girl with asthma develops a heavy paroxysmal cough with posttussive emesis about 1 week after she had a cold with a runny nose and low-grade fever. She lives with her mother, father, and 19-year-old brother, all of whom are healthy. She attends a local junior high school where three children in a different class were recently diagnosed with suspected whooping cough. Her pediatrician begins empiric azithromycin and obtains a nasopharyngeal swab for pertussis testing that later confirms the diagnosis. Appropriate management of her adult household contacts includes:
- Identification of carriers
  - Treatment only in the presence of symptoms
  - Antibiotic prophylaxis
  - Booster vaccination
  - Do nothing
13. A 49-year-old woman with recent daily headaches presents with fever to 103.5°F, stiff neck, and photophobia. Her medical history is notable for undergoing endoscopic sinus surgery for chronic sinusitis last year. Her only medication is nasal fluticasone. Shortly after she arrives in the emergency department, she undergoes lumbar puncture that reveals a cerebrospinal fluid pleocytosis. Cerebrospinal fluid Gram stain demonstrates gram-positive diplococci, and culture later grows *S. pneumoniae*. Review of her records shows that this is her third admission in the last 10 months for pneumococcal meningitis. Which of the following underlying conditions is most likely?
- Deficiency of terminal components of complement
  - Neutrophil dysfunction
  - Dural epidermoid cyst
  - Cerebrospinal fluid leak
  - Mollaret meningitis
14. A 76-year-old female with a history of chronic obstructive pulmonary disease and dementia is seen in clinic in December with 1 day of fever, malaise, cough, and myalgias. Another patient on her floor at the skilled nursing facility where she lives has similar symptoms and was admitted to the hospital for treatment of influenza. On examination, her temperature is 101.2°F and heart rate is 96 beats per minute. The rest of the examination is unremarkable. Her chest x-ray is normal. A nasopharyngeal swab for influenza polymerase chain reaction returns positive for influenza A. Treatment with oseltamivir is started. How should her contacts at the nursing facility be managed?
- Treat her exposed roommate and nurses at the skilled nursing facility with oseltamivir prophylaxis.
  - Revaccinate all residents of the facility with influenza vaccine.
  - Treat all unvaccinated residents at the facility with rimantadine prophylaxis.
  - Treat all residents with oseltamivir prophylaxis.
  - Treat all unvaccinated residents at the facility with oseltamivir.

15. A 35-year-old Brazilian man is admitted to the hospital following a generalized seizure. A CT scan of the head shows a ring-enhancing lesion in the right parietal lobe. The least likely pathogen to cause this type of presentation and imaging is:
- Mycobacterium tuberculosis*
  - Taenia solium*
  - Borrelia burgdorferi*
  - Toxoplasma gondii*
16. A 40-year-old man with recently diagnosed multiple myeloma has pain in the right flank and upper abdomen. He has just completed his third cycle of lenalidomide, bortezomib, and dexamethasone chemotherapy. Physical examination shows several coalescent vesicles, which begin under the right costal margin and extend from the flank to the midline anteriorly in two distinct (non-contiguous) dermatomes. The most appropriate therapy would be:
- Analgesics for pain
  - Prednisone
  - Intravenous acyclovir
  - Zoster immune globulin
  - Oral valganciclovir
17. A 38-year-old man from Oregon had diarrhea consisting of four to five loose stools per day, abdominal cramps, bloating, and nausea while on a business trip in South America. The symptoms began on the fifth day of the trip, lasted for 3 days, and were partially relieved by an antimotility agent. The most likely cause of his illness was:
- Enteroinvasive *Escherichia coli*
  - Enterotoxigenic *E. coli*
  - Salmonella* species
  - Campylobacter jejuni*
  - Shigella* species
18. A 39-year-old Albanian woman presents with ulcerative colitis that is poorly controlled with mesalamine and has required several courses of corticosteroids in the last year. She also has a history of chronic hepatitis B infection with normal liver function tests (chronic carrier) and has taken tenofovir for the prevention of hepatitis B reactivation for about a year because of her frequent steroid pulses. Initiation of infliximab for better control of her ulcerative colitis is planned, so testing for tuberculosis (TB) is undertaken. An interferon gamma release assay (IGRA) for TB returns positive. She reports that she was vaccinated with the bacille Calmette-Guérin (BCG) vaccine when she was a child. She denies cough, shortness of breath, hemoptysis, or fever. She has gained 12 pounds in the last 3 months during her most recent prolonged steroid pulse. A chest x-ray is clear of any pulmonary opacities. The best management plan for her IGRA result is:
- Daily rifampin and pyrazinamide for a 4-month course
  - Retest for TB exposure with a purified protein derivative (PPD) because IGRA tests cross-react with the BCG vaccine
  - Weekly rifapentine and isoniazid for a 12-week course
  - It is not safe to treat for latent TB or treat with infliximab because of the chronic hepatitis B infection; choose a different medication for better inflammatory bowel disease control.
19. A 35-year-old man who is the captain of a fishing boat has fever, chills, and several hemorrhagic bullae on the left wrist and dorsal surface of the hand. Lymphangitis and left epitrochlear and axillary lymphadenopathy are present. The captain harvested shrimp 4 days ago. The most likely causative organism is:
- S. aureus*
  - Haemophilus influenzae*
  - Clostridium perfringens*
  - Vibrio vulnificus*
  - Pseudomonas aeruginosa*
20. An elderly man has bacteremia with *Salmonella typhimurium* that has relapsed three times after 28-day courses of ciprofloxacin, to which the organism is susceptible. The most likely site of infection is the:
- Gallbladder
  - Colon
  - Aorta
  - Spine
21. A 21-year-old man with chronic sinusitis presents to an urgent-care center with fever and headache. He is diagnosed with a viral upper respiratory infection and told to drink fluids. Over the next 24 hours, he continues to have fever and also develops confusion and a mildly stiff neck. He presents to the emergency department where he has neurologic deficits that rapidly progress to hemiparesis, hemisensory defects, and hemianopsia. He has several focal seizures, and signs of increased intracranial pressure appear. He undergoes emergent brain imaging, and antibiotics are started. The most likely diagnosis is:
- Bacterial meningitis
  - Cavernous sinus thrombosis
  - Brain abscess
  - Subdural empyema
22. A 28-year-old man who underwent splenectomy 4 years ago following trauma in a motor vehicle accident experiences the sudden onset of high fever, rigors, and hypotension. He was vaccinated for *S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis* shortly after his splenectomy and has not been hospitalized since that time. By the time he reaches the emergency room, he has multiple petechiae and purpura over his face, arms, and legs. His initial laboratory results demonstrate acute kidney injury and disseminated intravascular coagulation. He reports that he has a new pet dog that has recently scratched and bitten him a few times. He is monogamous with his wife and denies any other recent exposures. A gram-negative bacillus is isolated from blood cultures. The most likely pathogen is:
- Pasteurella multocida*
  - Fusobacterium necrophorum*

- C. *Capnocytophaga canimorsus*  
 D. *Ehrlichia canis*  
 E. *Neisseria gonorrhoeae*
23. A 27-year-old man who works the door at a bar is bitten on the right arm when breaking up a bar brawl. The bite broke the skin and bled a little after he washed it off. He presents to his primary care physician's office 3 days later for assessment. The bite area has become red and tender. He denies fever or other systemic symptoms. He has no significant past medical history and takes no medications. He is not allergic to any medications. On examination, there is a 3-cm area of erythema and warmth surrounding the bite mark, which is on the ulnar aspect of the midforearm. There is no purulence, and he has no pain with passive or active movement of the right wrist or elbow. The most appropriate therapy is:
- A. Clindamycin  
 B. Azithromycin  
 C. Refer to the emergency room for IV vancomycin and surgical debridement  
 D. Amoxicillin-clavulanate  
 E. Cephalexin
24. A 37-year-old woman presents to an urgent care center with 2 days of dysuria and frequency similar to a previous episode of urinary tract infection 3 years ago. Her medical history is notable for two previous cesarean sections at the birth of her children, now 7 and 2 years of age. She denies fever, nausea, vomiting, or flank pain. She takes a daily multivitamin and occasional ibuprofen for menstrual cramps. She is allergic to sulfa drugs, which cause hives. On examination, she has suprapubic tenderness and no flank tenderness. Urinalysis reveals many white blood cells, and urine pregnancy test is negative. The best treatment plan is:
- A. Treat with a single dose of fosfomycin  
 B. Culture the urine and wait for identification and susceptibilities before treating  
 C. Treat with ciprofloxacin for 3 days  
 D. Treat with amoxicillin-clavulanate for 5 days
25. A previously healthy 42-year-old man presents for assessment of urethral discharge a week after he returned from a bachelor party in Las Vegas. He denies other symptoms including fever, rash, arthritis, or arthralgias. He reports that he has never had a sexually transmitted infection and is monogamous with his wife, but on questioning reports that he had unprotected vaginal intercourse with two women during the trip. Physical examination is notable for no genital ulcers or enlarged lymph nodes. A small amount of white discharge is present at the urethral meatus. In addition to performing HIV-1/2 antigen/antibody testing and urine nucleic acid testing for gonorrhea and chlamydia, what is the best management now?
- A. Intramuscular ceftriaxone 250 mg × 1 and oral levofloxacin 750 mg × 1  
 B. Oral cefixime 400 mg × 1 and oral azithromycin 1 g × 1  
 C. Intramuscular ceftriaxone 250 mg × 1 and oral doxycycline 100 mg twice a day for 7 days  
 D. Intramuscular ceftriaxone 250 mg × 1 and oral azithromycin 1 g × 1
26. A 46-year-old woman presents with erythema, mild pain, and cloudy discharge from her lower abdomen for 10 days. She reports undergoing a "tummy tuck" a month prior during a visit to a Caribbean island. She has had no fever or sweats. She is prescribed a course of clindamycin, but she notes no improvement after 7 days so her treatment is changed to trimethoprim-sulfamethoxazole. The wound remains red, but the drainage improves a little during this therapy. The most likely organism causing this infection is:
- A. *S. aureus*  
 B. *Mycobacterium abscessus*  
 C. *Aeromonas* sp.  
 D. *Ancylostoma braziliense*  
 E. *Leishmania major*
27. A 56-year-old male Logan airport employee in Boston, Massachusetts, presents with fever to 103.1°F, malaise, fatigue, and myalgias for 1 week in September. Initial blood work demonstrates new onset of anemia (hemoglobin 11.3 g/dL), mild leukopenia, and thrombocytopenia. Reticulocyte count is 6%, lactate dehydrogenase is elevated, and Coombs tests are negative. Blood smear results are shown in Fig. 8.1. This infection was most likely transmitted by:
- A. *Anopheles quadrimaculatus*  
 B. *Aedes aegypti*  
 C. *Culex pipiens*  
 D. *Ixodes scapularis*  
 E. None of the above
28. A 27-year-old landscaper who lives in Maryland presents in July with 2 days of malaise, chills, and a large red patch over the midabdomen. He reports that his symptoms are identical to an episode of Lyme disease

• Fig. 8.1 Giemsa-stained blood smear demonstrating intraerythrocytic parasites.

that he had in April last year (15 months ago). At that time, he was treated with a 14-day course of oral doxycycline and felt better afterward. The best course of action is:

- A. Admit to initiate intravenous ceftriaxone to treat chronic Lyme disease.
- B. Hold off on therapy while waiting for results of Lyme serologies.
- C. Collect blood cultures and start cephalexin for cellulitis because a single episode of Lyme disease results in long-lasting immunity.
- D. Treat with doxycycline for 14 days.

### Answers

1. E. The patient developed candidemia in the setting of gastrointestinal perforation and prolonged intensive care unit stay. *Candida* blood isolates cannot be dismissed as contaminants, and in current practice all patients with candidemia should be treated. Blood cultures should be repeated until persistently negative, and treatment should continue for at least 2 weeks following the last positive blood isolate. Given the risk factors of the patient, his doctors elected to use fluconazole prophylaxis. This practice is not routinely recommended and in this case increased the risk of fluconazole-resistant *Candida* infection. For a patient who develops candidemia during fluconazole administration, azole resistance is likely and other treatments should be used while the isolate is identified and susceptibility testing is performed. Antifungal treatment options for this patient include any of the echinocandins (casposungin, micafungin, or anidulafungin) or amphotericin B or one of its lipid formulations. An echinocandin is currently recommended as the first-line initial antifungal agent to treat patients with candidemia by the Infectious Diseases Society of America (IDSA) (Pappas PG et al. *Clin Infect Dis*. 2016;62(4):e1-50). In addition, the patient already has acute renal dysfunction, which could be worsened by the use of an amphotericin-based treatment; thus the best option for the patient is an echinocandin. Echinocandins are fungicidal against *Candida* spp. by disrupting fungal cell wall synthesis by inhibiting 1,3- $\beta$ -d-glucan synthase. They are as effective as amphotericin B with a better safety profile (Mora-Duarte J et al. *N Engl J Med*. 2002;347:2020–2029). An ophthalmologic examination is recommended to exclude endophthalmitis. We favor routine identification of *Candida* species and susceptibility testing of all invasive infections. Patients with fluconazole or voriconazole susceptible isolates can be safely switched to oral azole treatment after susceptibility testing results become available. *Candida* treatment guidelines (Pappas PG et al. *Clin Infect Dis*. 2016;62(4):e1-50) are available at [www.idsociety.org](http://www.idsociety.org).
  2. D. Not all yeasts isolated from blood culture are *Candida* species. This patient is at increased risk for cryptococcosis given his new diagnosis of AIDS and history of headaches. AIDS patients often present with more than one synchronous problem. This patient is also at risk for candidemia given the central venous access placed under urgent conditions. For this reason, consideration of removing his central access is reasonable, but the most important intervention is initiation of antifungal therapy directed at these two potential pathogens. Although fluconazole is often active against *Candida* and *Cryptococcus* spp., it is not currently considered first-line initial therapy for bloodstream infections with either of these yeasts (Perfect JR et al. *Clin Infect Dis*. 2010;50:291–322; Pappas PG et al. *Clin Infect Dis*. 2016;62(4):e1-50). In this case, there is concern for disseminated or central nervous system involvement by *Cryptococcus* spp.; fluconazole in this setting is associated with treatment failures and emergence of resistance. Caspofungin and other echinocandins are not active against *Cryptococcus neoformans*, so they are not good treatment options if cryptococcosis is in the differential.
- The best empirical treatment in this case is amphotericin B. If cryptococemia is confirmed by identification of the yeast or by determination of a serum cryptococcal antigen, the patient should undergo examination of his cerebrospinal fluid to exclude or confirm presence of cryptococcal meningitis. If cryptococcal meningitis is confirmed, flucytosine at 100 mg/kg/day divided four times per day can be added to the initial regimen for induction treatment for cryptococcal meningitis (Day JN et al. *N Engl J Med*. 2013;368:1291-1302). For further details on the management of cryptococcosis, please see Perfect JR et al. *Clin Infect Dis*. 2010;50:291–322; available at [www.idsociety.org](http://www.idsociety.org).
3. C. This patient has severe community-acquired pneumonia with septic shock and respiratory failure requiring mechanical ventilation. The combination of third-generation cephalosporins, such as ceftriaxone, and quinolones or a macrolide provides excellent empirical treatment for community-acquired pneumonia for severely ill patients (Mandell LA et al. *Clin Infect Dis*. 2007;44:S27-72). *S. pneumoniae* is the most likely cause of pneumonia and sepsis in this case and is also the most common microbiologically identified cause of community-acquired pneumonia. Although vancomycin should be used empirically for the treatment of pneumococcal meningitis until antimicrobial susceptibilities are available, vancomycin is not usually indicated for treatment of pneumococcal pneumonia or bacteremia. Gentamicin adds little to the regimen chosen in the emergency room given the clinical impression, has poor lung penetration, and may worsen the patient's acute kidney injury.
  4. C. This patient with underlying structural heart disease and paroxysmal atrial fibrillation has *Legionella* pneumonia. Appropriate therapy for legionellosis includes macrolides such as azithromycin and quinolones such

as levofloxacin. Azithromycin causes QT prolongation and is considered to have a major drug-drug interaction with dofetilide and other medications that also cause QT prolongation. Ventricular arrhythmias such as torsades des pointes can result more frequently with coadministration. A few recent postmarketing studies have assessed the risk of cardiovascular death in patients taking azithromycin. Although the risk for cardiovascular death remains low overall in a relatively healthy cohort, in those with cardiovascular disease (such as this patient) the risk of cardiovascular death while taking azithromycin was higher (Ray WA et al. *N Engl J Med.* 2012;366:1881-1890; Svanström H, 2013;366:1881-1890; Svanström H et al. *N Engl J Med.* 2013;368:1704-1712). Based on the history given that he had begun to improve from his pneumonia, respiratory failure caused by legionellosis is an unlikely cause of his unresponsiveness. Unlike clarithromycin, which is a strong inhibitor of the hepatic enzyme CYP 3A4, azithromycin has a very mild inhibitory effect on this hepatic enzyme and does not have a major drug interaction with apixaban. Legionellosis is not specifically associated with pulmonary embolism, and this would be an unexpected problem in a patient on apixaban.

5. E. This patient has a classic presentation of clostridial myonecrosis (gas gangrene) caused by traumatic exposure to *Clostridium* sp. (most commonly *C. perfringens*). Features include soft tissue trauma followed in 1 to 4 days by the sudden onset of unrelenting pain at the wound site with evidence of gas in the underlying tissue. Optimal management includes prompt surgical debridement and antibacterial administration with empiric broad-spectrum antibiotics typically with a combination of agents such as vancomycin with piperacillin-tazobactam or a carbapenem (Stevens DL et al. *Clin Infect Dis.* 2014;59:e10-52). Once the causative pathogen is identified, therapy can be targeted. Penicillin G in combination with clindamycin is considered the treatment of choice for clostridial gangrene. Other agents with activity are considered second-line agents, including chloramphenicol, metronidazole, imipenem, and combination beta-lactam/beta-lactamase inhibitors. Although hyperbaric oxygen therapy was a consideration in the past, it is no longer recommended because no randomized study has demonstrated its efficacy and pursuing hyperbaric therapy can lead to significant delay in surgical intervention (Stevens DL et al. *Clin Infect Dis.* 2014;59:e10-52).
6. C. The treatment of choice for native valve methicillin-sensitive *S. aureus* (MSSA) endocarditis is an antistaphylococcal-penicillin such as nafcillin or oxacillin. However, this patient has a recent documented allergy to penicillins which is why answers A and E are incorrect. Based on his history, it is clear that he tolerates cephalosporins. Therefore the next best choice for treatment is cefazolin. The typical treatment course for left-sided native valve endocarditis caused by MSSA is 6 weeks of therapy in the absence of complications such as perivalvular abscess or other related visceral abscesses. See the American Heart Association guidelines for management of endocarditis (Baddour LM et al. *Circulation.* 2015;132:1-53).
- Vancomycin and clindamycin are both active against MSSA but are not recommended as first-line agents to treat endocarditis in patients who can be treated with a beta-lactam because of poorer efficacy for treating MSSA infections in general and risk of relapsed endocarditis respectively. Although the combination of gentamicin and nafcillin used to be a consideration for treatment of MSSA endocarditis, a multicenter study showed that the combination in comparison to nafcillin alone did not result in improved mortality or reduction in complications of endocarditis (Murray HW et al. *Arch Intern Med.* 1976;136:480-483).
7. D. The chest CT image describes a lung nodule with a "halo sign." The presence of a halo sign is consistent with invasive aspergillosis in a patient with prolonged neutropenia after induction chemotherapy for acute leukemia or hematopoietic stem cell transplantation. Other angioinvasive molds, such as *Mucor* or *Rhizopus*, and hematogenous seeding of the lung from septic emboli can have the same radiographic appearance. The presence of elevated circulating serum levels of galactomannan, a carbohydrate present specifically in the cell wall of *Aspergillus* and *Penicillium* species increases the certainty that the infection is indeed invasive aspergillosis. Although a definitive diagnosis of invasive aspergillosis requires biopsy of the affected site and growth in culture of the mold, the clinical scenario, the presence of the halo sign, and an elevated galactomannan make a diagnosis of invasive aspergillosis probable. Bronchoscopy is sometimes helpful in establishing a microbiologic cause of pulmonary infection in neutropenic patients, but in this case additional information that would result from a bronchoscopy is unlikely to change the diagnostic certainty and should not interfere with the initiation of antifungal therapy in this neutropenic patient with recurrent fever.
- Voriconazole outperformed amphotericin B in terms of treatment success and survival in clinical trials of patients with invasive aspergillosis and is the current recommended first-line treatment for probable or proven invasive aspergillosis (Patterson TF et al. *Clin Infect Dis.* 2016;63(4):e1-e60). A newer agent, isavuconazole, is also US Food and Drug Administration (FDA)-approved for the treatment of invasive aspergillosis and performed comparably to voriconazole in a clinical trial of invasive mold infections (Maertens JA et al. *Lancet.* 2016;387:760-769) but is recommended as an alternative therapy to voriconazole by the IDSA based on limited clinical trial data and clinical experience. Micafungin is approved for salvage but not for initial treatment of invasive aspergillosis in patients

intolerant or refractory to standard treatment. Liposomal amphotericin B is also recommended as second-line therapy for invasive aspergillosis. Fluconazole is not active against mold species including *Aspergillus*. (Patterson TF et al. *Clin Infect Dis*. 2016;63(4):e1-e60; available at [www.idsociety.org](http://www.idsociety.org)).

8. D. Prophylaxis for endocarditis is recommended for individuals with high-risk underlying conditions undergoing certain high-risk procedures (Wilson W et al. *Circulation*. 2007;116:1736-1754). Conditions that raise the risk of developing endocarditis and are associated with poor outcomes warrant routine prophylaxis including prosthetic valves, previous bacterial endocarditis, complex congenital heart diseases, and valvulopathy in a heart transplant recipient. Although mitral valve prolapse with regurgitation increases the lifetime risk of endocarditis, the absolute increase in risk does not warrant routine antibacterial prophylaxis with dental or other procedures, and it is no longer recommended according to the American Heart Association (Wilson W et al. *Circulation*. 2007;116:1736-1754). Procedures requiring prophylaxis for those at highest risk include dental extractions and periodontal work, teeth cleaning if bleeding is anticipated, surgery on respiratory mucosa, gastrointestinal surgery, Foley catheter placement with infected urine, and drainage of an abscess. Prophylaxis is not recommended for suturing clean lacerations or for procedures performed under sterile conditions, such as central venous catheter placement or routine preoperative placement of a Foley catheter.
9. C. The clinical syndrome of otalgia, otorrhea and granulation tissue visible in the external auditory canal is typical of malignant otitis externa, a severe necrotizing infection that involves soft tissue, cartilage, and bone. The disease occurs almost exclusively in diabetic patients and is nearly always caused by *Pseudomonas aeruginosa*. Involvement of cranial nerves, especially the facial nerve, is common as infection spreads. Although treatment with systemic ciprofloxacin has been reported to be highly successful, initiating treatment with ceftazidime is preferable given its good tissue penetration and lower risk of baseline resistance to this antibiotic among *Pseudomonas* isolates. Uncomplicated otitis externa or swimmer's ear is a benign and self-limiting process that responds to topical antibiotics and corticosteroids; *P. aeruginosa* is often the predominant organism in this clinical illness also. Fungi such as *Aspergillus* may also be isolated in cases of benign otitis externa; topical therapy is sufficient in such cases. Tuberculous otitis media can lead to a chronically draining ear.
10. B. Norovirus is one of the most common causes of food-borne gastroenteritis (Belliot G et al. *Clin Microbiol Infect*. 2014;20:724-730). These students have symptoms most consistent with norovirus infection, likely related to a shared food source 1 to 2 days before the illness occurred (possibly the fast food restaurant). Although they were at risk for exposure to giardia and campylobacter during the camping trip, these illnesses are characterized predominantly by diarrhea with bloating and diarrhea with abdominal pain, respectively. Nausea and vomiting are not prominent or common symptoms of either of these illnesses. Vomiting, diarrhea, and hives are common symptoms of scombroid fish poisoning which typically occurs during or immediately after fish consumption, so the timing of the illness relative to fish consumption suggests this is not the cause. The symptoms of scombroid are related to high levels of histamines present in the fish, which has typically been inadequately refrigerated for some time before it is consumed (Bedry R et al. *N Engl J Med*. 2000; 342:520-521).
11. A. This patient with underlying rheumatoid arthritis on low-dose steroids is presenting with recurrent nonpurulent cellulitis in an arm with lymphedema. Not only does lymphedema predispose to cellulitis, but chronic low-dose steroids lead to skin weakening, which also increases her risk. The most common cause of cellulitis in this clinical scenario is *Streptococcus* and less commonly *S. aureus*. The IDSA recommends the following antibiotics for the first-line treatment of moderate nonpurulent cellulitis: penicillin, cefazolin, clindamycin, or ceftriaxone (Stevens DL et al. *Clin Infect Dis*. 2014;59:e10-52). Vancomycin, linezolid, and trimethoprim-sulfamethoxazole would all be active against staphylococci, including methicillin-resistant *S. aureus* (MRSA), but MRSA in particular is a rare cause of nonpurulent cellulitis. Furthermore, although vancomycin and linezolid have activity against streptococci, by far the most likely pathogen, trimethoprim-sulfamethoxazole has poor activity against this pathogen and would not be a good choice. Aztreonam is a beta-lactam whose spectrum of activity does not include gram-positive organisms including staphylococci or streptococci. (Stevens DL et al. *Clin Infect Dis*. 2014;59:e10-52).
12. C. The efficacy of the pertussis vaccine wanes with time. As a result, many adolescents and adults are susceptible to infection. Outbreaks have been reported in some states linked to waning immunity in school-aged children and adolescents (CDC. Pertussis Epidemic—Washington, 2012. *MMWR*. 2012;61(28):517-522; Misegades LK et al. *JAMA*. 2012;308:2126-2132). Erythromycin has been shown to decrease the risk of infection following exposure to *Bordetella pertussis*, and prophylaxis of all directly exposed individuals without prior testing for infection with a macrolide (azithromycin, clarithromycin, or erythromycin) is recommended (Tiwari T et al. *MMWR*. 2005;54:1-16). A booster vaccination with acellular pertussis vaccine is now recommended for all adults regardless of exposure, and for pregnant women during each pregnancy

- (preferably between 27 and 36 weeks of pregnancy) (Kim DK et al. *Ann Intern Med.* 2016;164:184-194).
13. D. Chronic leakage of cerebrospinal fluid can lead to recurrent meningitis, most commonly caused by *S. pneumoniae*. Trauma, arising from either an accident or iatrogenesis (such as during functional endoscopic sinus surgery), is typically the most common cause of chronic cerebrospinal fluid leakage. Recurrent meningococcal meningitis is more often reported in patients with congenital terminal complement deficiencies and in those treated with eculizumab, a monoclonal antibody to C5 complement (approved for management of atypical hemolytic uremic syndrome or paroxysmal nocturnal hemoglobinuria). Chronic neutrophil dysfunction causes increased vulnerability to infection with staphylococci, among other pathogens. Dural epidermoid cysts can be the source of recurrent episodes of aseptic meningitis and is in the differential diagnosis of recurrent aseptic meningitis, also called Mollaret meningitis. The most common cause of Mollaret meningitis is recurrent herpes simplex 2 infection.
  14. E. The patient has influenza A infection and is the second person at her nursing home to have an influenza diagnosis in the last 48 hours, which constitutes an emerging outbreak at that facility. Prophylaxis with an active antiviral medication, oseltamivir or zanamivir (based on recent circulating influenza strains), is indicated for all residents of this type of facility in this setting based on the generally high risk for complications of influenza among residents (Harper SA et al. *Clin Infect Dis.* 2009;48:1003-1032). The prophylaxis should continue for 2 weeks or longer if more cases occur during the prophylaxis period (at least 10 days after the last case is diagnosed) (Fiore AE et al. *MMWR.* 2011;60:1-24). Influenza vaccination is helpful for patients who have not been vaccinated in an outbreak setting but cannot be relied on in this patient population to adequately control an outbreak. Rimantadine and amantadine bind to the M2 nucleocapsid protein of influenza A but are not active against B; more importantly, resistance to these drugs is common in the influenza strains circulating in the last decade and so these drugs are no longer recommended for prophylaxis (Fiore AE et al. *MMWR.* 2011;60:1-24). Both zanamivir and oseltamivir are active against both influenza A and B, as well as against avian strains such as H5N1. Zanamivir is available only in inhaled form and can cause bronchospasm.
  15. C. *M. tuberculosis* may cause focal lesions in the brain (tuberculomas) as well as subacute meningitis. Cysticercosis, caused by the larval form of the pig tapeworm, *T. solium*, is a common cause of seizures in persons in many developing countries. *T. gondii* produces necrotizing lesions of the brain in patients with acquired immunodeficiency syndrome. Localized central nervous system lesions of this type are not seen with *B. burgdorferi*, the cause of Lyme disease. Neurologic manifestations of Lyme disease include aseptic meningitis, cranial nerve palsies, motor and sensory radiculoneuropathy, and meningoencephalitis. (For more information about nervous system Lyme disease, refer to Halperin JJ et al. *Neurology.* 2007;69:91-102).
  16. C. The clinical presentation of radicular pain and vesicular rash with a dermatomal distribution is highly suggestive of herpes zoster infection. The diagnosis can be confirmed by the finding of multinucleated giant cells on a Tzanck (Giemsa) smear or by direct fluorescent antigen staining of a sample obtained from an unroofed vesicle. Herpes zoster is associated with prolonged lesions in immunosuppressed patients including stem cell transplant recipients and those with multiple myeloma. This patient's lesions will probably continue to progress during the next 3 to 4 days. Prednisone has been shown to prolong the course of herpes zoster in immunosuppressed patients and is not recommended in this setting. Systemic antiviral treatment (acyclovir, valacyclovir, famciclovir) decreases the frequency of dissemination and the morbidity in patients with malignancies. The presence of varicella zoster virus in two noncontiguous dermatomes suggests dissemination, and treatment should be initiated promptly. IV acyclovir has been used initially in this situation, but it may not be necessary in most cases with the availability of valacyclovir and famciclovir, which have good bioavailability. Valganciclovir is an antiviral medication active against varicella, but its primary indication is for the prevention and treatment of cytomegalovirus infection in vulnerable patients and it typically causes medication-related leukopenia and therefore would not be a good treatment choice for this patient. Because herpes zoster is caused by reactivation of a latent varicella-zoster infection, circulating antibodies to varicella-zoster antigens are already present. Zoster immune globulin has not been shown to affect herpes lesions or to reduce complications. Patients with multiple myeloma treated with bortezomib, a proteasome inhibitor, are at significantly increased risk for developing zoster relative to patients treated with nonbortezomib containing regimens (Chanan-Khan A et al. *J Clin Oncol.* 2008;26:4784-4790). For this reason, prophylaxis for zoster with acyclovir or valacyclovir is indicated for patients with myeloma being treated with bortezomib and was missing from the case patient's regimen.
  17. B. This patient had traveler's diarrhea, which occurs in approximately one-third of travelers from industrialized countries traveling to developing countries in Latin America, Africa, the Middle East, and Asia. Although the spectrum of clinical illness varies considerably, four to five loose or watery stools per day is characteristic.

Various infectious agents that are acquired through ingestion of fecal-contaminated food and water may cause traveler's diarrhea. In all countries, enterotoxigenic *E. coli* is the most common cause. Other organisms that cause traveler's diarrhea less commonly include viruses, enteroinvasive *E. coli*, *Salmonella* species, *Shigella* species, *C. jejuni*, *Giardia lamblia*, *Cryptosporidium*, and *Entamoeba histolytica*.

Antimotility drugs such as loperamide or diphenoxylate, or absorbents such as bismuth subsalicylate, are usually effective treatment for milder forms of traveler's diarrhea. Antimicrobial agents such as quinolones, trimethoprim-sulfamethoxazole, doxycycline, or rifaximin have been shown to shorten the duration of illness.

18. C. Steroids and tumor necrosis factor (TNF)- $\alpha$  inhibitors such as infliximab can increase the risk for reactivation of both latent TB and also hepatitis B in a patient with chronic inactive infection ("inactive carrier"). Although this patient was appropriately screened for hepatitis B infection and treated with prophylactic antiviral therapy when she started steroids (Reddy KR et al. *Gastroenterol.* 2015;148:215-219), she was not screened for TB until TNF- $\alpha$  therapy was planned. Either a PPD or an IGRA are appropriate screening tests (even in patients previously vaccinated with BCG). A PPD >5 mm is considered reactive for a patient in whom TNF- $\alpha$  therapy is planned. Although the results of the PPD can be falsely positive because of previous BCG vaccine, the IGRA test is not affected (thus B is wrong). Based on her IGRA result, review of symptoms, and clear chest x-ray, this patient has latent TB. Recommended regimens for the treatment of latent TB include isoniazid daily or twice weekly for 9 months (or 6 months if 9 months cannot be completed), rifampin daily for 4 months, and weekly rifapentine and isoniazid for 12 weeks ([www.cdc.gov/tb/topic/treatment/tbti.htm](http://www.cdc.gov/tb/topic/treatment/tbti.htm), accessed 9/1/16). Regimens that are not daily should be given by directly observed therapy. Rifampin and pyrazinamide together are no longer recommended for the treatment of latent TB because of reports of serious hepatotoxicity and death. Chronic hepatitis B infection is not a contraindication to treatment of latent TB nor is it a contraindication for treatment with a TNF- $\alpha$  inhibitor because she is already on prophylaxis to prevent hepatitis B reactivation.
19. D. The epidemiologic and clinical features of this patient strongly suggest wound infection caused by *V. vulnificus*, an organism that lives in coastal waters. Infection is usually associated with exposure to brackish or saltwater or to shellfish harvested from these waters. Cellulitis, bullae, necrosis, lymphangitis, and lymphadenopathy are characteristic. Myositis occasionally may develop. Therapy should consist of vigorous surgical debridement and antibiotics. Although *S. aureus* and *H. influenzae* may cause wound infection similar to that occurring in this patient, neither pathogen is associated with handling of shellfish. *C. perfringens* causes gas gangrene or cellulitis, usually occurring after trauma or vascular compromise. Ecthyma gangrenosum (characteristic ulcerative skin lesion surrounded by an erythematous halo) typically occurs in neutropenic patients with cancer and *P. aeruginosa* bacteremia. Another cause of cellulitis that may follow handling of raw seafood is *Erysipelothrix rhusiopathiae*.
20. C. Although the gallbladder is a common site of *Salmonella* carriage, it is rarely the source of bacteremia. Persons who chronically carry *Salmonella* in the gallbladder shed the organism in the stool. Prolonged colonic carriage also occurs following *Salmonella* gastroenteritis, especially after treatment with antibiotics. *Salmonella* may cause chronic osteomyelitis of the spine and other bones, but the associated bacteremia is usually transient. Persistent bacteremia is characteristic of endovascular infections with *Salmonella*. Infected aneurysms and large atherosclerotic plaques give rise to high-grade bacteremias that recur following antibiotic therapy unless the vascular lesion is excised. Other conditions associated with prolonged *Salmonella* bacteremia include HIV infection, other immunodeficiency states, and chronic hepatosplenic schistosomiasis (Crum Cianflone NF et al. *N Engl J Med.* 2013;368:1291-1302).
21. D. Catastrophic neurologic complications such as those described in this case can occur with bacterial meningitis, cavernous sinus thrombosis, and brain abscesses, all of which may be sequelae of chronic sinusitis. However, the rapid development of defects involving one entire hemisphere, and progression to increased intracranial pressure are characteristic of subdural empyema, a condition that occurs most commonly in persons with frontal sinusitis. Subdural empyema is a neurosurgical emergency and requires surgical drainage and antibiotics together. (Osborn MK, Steinberg MP. *Lancet Infect Dis.* 2007;7:62-67; Dolan RW, Chowdhury K. *Oral Maxillofac Surg.* 1995;53:1080-1087).
22. C. Splenectomized persons are at risk for overwhelming infection with a variety of organisms, including encapsulated bacteria (especially *Pneumococcus*) and *Babesia* (Rubin LG, Schaffner W. *N Engl J Med.* 2014;371:349-356). There have been a number of cases of overwhelming sepsis following dog bites or licks caused by *C. canimorsus* (formerly known as DF-2), an organism found in the oral cavity of healthy dogs. *P. multocida*, a gram-negative bacillus, is part of the normal oral flora of cats (and, to a lesser extent, dogs); it is responsible for cellulitis, tenosynovitis, septic arthritis, osteomyelitis, sepsis, and a variety of other syndromes, but infections are not more severe in persons without spleens. *E. canis*, a rickettsia transmitted by ticks, causes pancytopenia in dogs; ehrlichiosis in human beings is also tick-borne; the organism cannot

be cultivated in routine blood cultures. *F. necrophorum* is a gram-negative anaerobic bacillus that is part of the normal flora of the human oral cavity. It is associated with aggressive infections such as necrotizing pneumonia and septic thrombophlebitis of the internal jugular vein caused by parapharyngeal space infection, also known as Lemierre disease. *N. gonorrhoeae* is a gram-negative coccus (not bacillus) and is not commonly cited as a cause of overwhelming postsplenectomy sepsis.

23. C. Infections that develop after human bites are often polymicrobial because of oral flora including streptococci, multiple types of oral anaerobes, *Eikenella corrodens*, and occasionally *S. aureus* (Stevens DL et al. *Clin Infect Dis*. 2014;59:e10-52). *E. corrodens* is a small gram-negative bacillus that is characteristically resistant to clindamycin, macrolides, and first-generation cephalosporins; thus clindamycin, azithromycin, and cephalexin are all poor choices to treat a human bite-associated infection. Amoxicillin-clavulanate and ampicillin-sulbactam typically have activity against *E. corrodens* and are also typically active against streptococci, MSSA, and anaerobic organisms, so they are a good choice in this case. *E. corrodens* may cause necrotizing soft tissue infections, and it is one of the HACEK (*Haemophilus*, *Aggregatibacter*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella*) group of fastidious bacteria that cause subacute bacterial endocarditis, but the case patient does not have clinical evidence of a systemic or necrotizing infection nor does he have apparent joint involvement, all of which might require surgical debridement. Although vancomycin would treat streptococci and staphylococci, it would not be active against anaerobes and *E. corrodens*, which may be contributing to this infection.
24. A. This patient is a premenopausal nonpregnant woman with uncomplicated cystitis. The majority of these infections are caused by *E. coli*. Recommended treatment regimens for this infection include nitrofurantoin for 5 days, trimethoprim-sulfamethoxazole for 3 days, or fosfomycin 3 g once (Gupta K et al. *Clin Infect Dis*. 2011;52:e103-e120). Fosfomycin is an organophosphonate antibiotic that achieves high concentrations in the urinary tract and is currently FDA approved for the treatment of lower urinary tract infection caused by *E. coli* and *Enterococcus*. Quinolones are quite effective at treating cystitis but have been linked to alteration of gastrointestinal flora that can lead to colonization and infection with resistant organisms and risk for *Clostridium difficile* infection. For this reason, and based on recent toxicities of quinolones reported by the FDA, quinolones are not recommended for this indication if alternative therapies are available (FDA safety announcement, <http://www.fda.gov/Drugs/DrugSafety/ucm500143.htm>, accessed 8/23/16). Fosfomycin and nitrofurantoin, in particular, appear to have limited impact on gastrointestinal flora but remain effective at treating *E. coli* in the urine. Amoxicillin alone is not recommended because of rates of resistance among *E. coli* isolates, and other beta-lactams including amoxicillin-clavulanate are also not recommended as first-line therapy because of the potential for impact on gastrointestinal flora. Waiting for urine culture results before treating is typically not necessary for uncomplicated cystitis episodes, and delay in treating could theoretically increase risk for development of pyelonephritis.
25. D. This patient has urethritis, which is most often caused by *N. gonorrhoeae* or *Chlamydia trachomatis*. Other less common causes of nongonococcal urethritis include *Mycoplasma genitalium*, *Trichomonas vaginalis*, and viral infections including adenovirus and herpes simplex. Empiric treatment for chlamydia and gonorrhea is indicated for a presentation similar to this. Increasing fluoroquinolone and cefixime resistance among gonorrhea isolates has been noted in the United States over the last decade, leading to the elimination of fluoroquinolones as recommended therapy for gonorrhea infections, and led to the move to make ceftriaxone and azithromycin the single preferred regimen to treat gonorrhea urethritis (Workowski KA and Bolan GA. *MMWR*. 2015;64:1-135). The inclusion of azithromycin in this regimen also treats chlamydia and susceptible *M. genitalium*. Cefixime and azithromycin is currently an alternative regimen to treat gonococcal urethritis, and doxycycline remains an alternative agent to treat chlamydia or *M. genitalium*.
26. B. Multiple outbreaks of subcutaneous and other surgical-site infections caused by rapidly growing nontuberculous mycobacteria have been described and reported (Schnabel D et al. *MMWR*. 2014;63:201-202; Furuya EY et al. *Clin Infect Dis*. 2008;46:1181-1188). The infections are subacute and have been associated with contaminated surgical solutions and suboptimal equipment sterilization techniques. These bacteria can grow on usual culture systems or on special mycobacterial media. Sometimes tissue biopsy is required for definitive diagnosis. *Mycobacterium chelonae*, *M. fortuitum*, and *M. abscessus* are the most common isolates. Treatment requires prolonged antimicrobial therapy, often with more than one agent.
  - S. *aureus* is a very common cause of surgical-site infections, although subacute, indolent presentations are less common and it should have responded better to her antibiotic courses. *Aeromonas* cellulitis can occur in patients who are exposed to water sources. Cutaneous larva migrans occurs because of skin contact with soil/sand infested with animal hookworm larvae (*Ancylostoma braziliense*, which can infect cats and dogs), but it is usually a nonsuppurative process. Cutaneous leishmaniasis can present with single or multiple ulcerative lesions, papules, or nodules but is usually not a suppurative process.

27. D. The smear demonstrates intraerythrocytic merozoites of *Babesia microti*, a zoonosis endemic in the north-eastern United States and areas of the Midwest. It is transmitted by the deer tick, *I. scapularis*. The patient is at some risk of malaria given his work at the airport, where cases have been described from infected *Anopheles* sp. mosquitoes that travel inside airplanes and then go on to infect people in the surrounding areas (“airport malaria”), but the intraerythrocytic forms do not resemble ring forms or merozoites of *Plasmodium* species (CDC. *MMWR*. 2002;51:921-923). *C. pipiens* is the main vector of West Nile virus, and *A. aegypti* is the main vector of dengue fever and Zika virus, but neither of them is known to transmit babesiosis.
28. D. This patient has early Lyme disease. Lyme disease is an infection caused by *B. burgdorferi* transmitted by *Ixodes* tick bites. Many people who present with Lyme disease in the early stages present with erythema migrans (“early Lyme disease”), a red targetlike rash that can occupy a large area (like the case patient). If serologies are checked when a patient presents with erythema migrans, they are often negative as it is too early in the course of the illness to detect seroconversion. If

a patient presents with erythema migrans and a history consistent with early Lyme disease, they should be treated with any of the recommended antibiotic regimens: doxycycline, cefuroxime, or amoxicillin for 10 to 21 days (Wormser GP et al. *Clin Infect Dis*. 2006;43:1089-1134).

For those patients previously infected with *B. burgdorferi*, such as the case patient, immunoglobulin G can remain positive from previous infection, but previous infection does not confer immunity to prevent reinfection. According to the IDSA, there is no clear evidence that chronic Lyme disease exists in those who have been previously treated with an appropriate course of antibiotics (Wormser GP et al. *Clin Infect Dis*. 2006; 43:1089-1134). A recent study of patients with two or more episodes of erythema migrans in their lifetime demonstrated that the genotype of *B. burgdorferi* detected with subsequent episodes of erythema migrans episodes differed, providing evidence that most patients presenting with erythema migrans after a previous episode for which they were appropriately treated for Lyme disease likely have a new infection (Nadelman RB et al. *N Engl J Med*. 2012;367:1883-1890).

# 9

## Infectious Disease Summary

MICHAEL KLOMPAS AND PAUL E. SAX

### **Staphylococcus aureus Infection**

*Staphylococcus aureus* is the most frequent cause of severe infections in the inpatient setting. After decades of increasing rates of *S. aureus* bacteremia, incidence rates now appear to be decreasing. Likewise, the fraction of *S. aureus* infections attributable to methicillin-resistant *S. aureus* (MRSA) has also been decreasing over the past decade. Some of the factors that may be driving the drop in *S. aureus* rates include more frequent handwashing; the increasing availability and use of alcohol-based hand rubs; central line insertion and maintenance bundles; daily review of the necessity of central lines and other indwelling devices; increased appropriate use of perioperative prophylactic antibiotics; screening and isolation of MRSA carriers; decolonization of *S. aureus* carriers before surgery; and routine bathing of intensive care unit patients and other high risk populations with chlorhexidine.

### **Clinical Presentation**

Common clinical manifestations of *S. aureus* include skin and soft tissue infections, necrotizing pneumonia, endocarditis, and bacteremia. Skin and soft tissue infections can run the gamut from postsurgical infections to necrotizing fasciitis and the staphylococcal toxic shock syndrome. Necrotizing *S. aureus* pneumonia can be a complication of influenza. These patients present with a biphasic illness that begins with a classic influenza-like syndrome that transiently improves and then dramatically worsens with severe respiratory compromise. *S. aureus* pneumonia is often caused by methicillin-resistant strains.

### **Evaluation**

Evaluation of patients with *S. aureus* endocarditis and bacteremia should focus on locating the source of infection (most frequently indwelling lines or devices) and identifying all distant sites that might have been seeded with infection (typical destinations include heart valves, vertebrae, brain, and joints). Patients with 3 or more days of *S. aureus* bacteremia and patients with two or more simultaneous sites of infection merit an echocardiogram to assess for endocarditis (see next section).

### **Treatment**

Treatment success critically depends on removal of indwelling devices, particularly venous catheters, and drainage of abscesses. Antimicrobial therapy should be promptly instituted and continued for at least 4 to 6 weeks even in patients without identified metastatic foci of infection because these can often be subclinical. Patients with methicillin-susceptible strains should preferentially be treated with cefazolin, nafcillin, or oxacillin rather than vancomycin because beta-lactams are more potent agents than vancomycin. Cefazolin, nafcillin, and oxacillin appear to be equally potent, but cefazolin has a better safety profile and is thus preferred, particularly for the maintenance phase of therapy. Up to 20% of *S. aureus* isolates are now sensitive to penicillin; this is a reasonable treatment option for susceptible isolates.

There is an increasing number of novel antibiotics to treat methicillin-resistant infections including linezolid, tedizolid, daptomycin, tigecycline, ceftaroline, and the long-acting glycopeptides dalbavancin and oritavancin. These agents tend to be reserved for severe infections. Clinicians have also come to recognize the value of older oral agents to treat minor MRSA skin infections. These include trimethoprim-sulfamethoxazole, doxycycline, and clindamycin. Importantly, community-acquired MRSA isolates that are resistant to erythromycin can have inducible resistance to clindamycin; hence clindamycin should not be used to treat community-acquired MRSA if erythromycin resistance is present.

### **Infective Endocarditis**

#### **Epidemiology and Microbiology**

Patients with abnormal heart valves are at greatest risk for endocarditis. In the developing world, the most frequent underlying lesion is rheumatic heart disease. In the developed world, the majority of patients have prosthetic valves or mitral valve prolapse associated with valve thickening and mitral regurgitation.

The microbiology of endocarditis is usefully considered in two categories: native valve infections and prosthetic valve infections (Table 9.1). Native valves tend to get

**TABLE 9.1** Microbiology of Endocarditis

Native Valve (Community Acquired)	Native Valve (Hospital Acquired)	Prosthetic Valve (<30 Days Postimplantation) <sup>a</sup>
<i>Streptococcus viridans</i>	<i>Staphylococcus aureus</i>	Coagulase-negative staphylococci
<i>Streptococcus pneumoniae</i>	<i>Enterococcus</i> spp.	<i>Propionibacterium acnes</i>
	Gram-negative aerobes	<i>Staphylococcus aureus</i>
	<i>Candida</i> spp.	<i>Enterococcus</i> spp.

<sup>a</sup>After 30 days' postimplantation, the microbiology of prosthetic valve endocarditis increasingly resembles community-acquired native valve endocarditis.

infected with *Streptococcus* species, *S. aureus*, and enterococcus. The microbiology of prosthetic valve infections varies with proximity to surgery: patients with recently implanted valves tend to get infected with skin organisms such as coagulase-negative staphylococci or *Propionibacterium acnes* and nosocomial pathogens such as MRSA or vancomycin-resistant enterococci. Patients with valves in place for more than a year tend to be infected with the same pathogens as patients with native valves. The mitral valve and aortic valve are the most common sites of infection. Tricuspid valve disease is usually only seen in intravenous drug users and patients with long-term indwelling venous catheters.

## Diagnosis

The typical symptoms of endocarditis are prolonged fever, fatigue, weight loss, and back pain. Patients with this constellation of symptoms should be closely evaluated for cardiac murmurs. Additional findings on physical examination can include Roth spots, Osler nodes, Janeway lesions, splinter hemorrhages, and conjunctival petechiae. These findings are typically only present, however, in patients with subacute disease who have been infected for weeks to months. Patients should be carefully examined for metastatic sites of infection; typical destinations include the brain, vertebrae, joints, liver, spleen, and eye. Draw at least two sets of blood cultures before beginning empirical antibiotics.

Echocardiography is the test of choice for patients with suspected endocarditis. A transthoracic echocardiogram is a reasonable place to start because it is noninvasive, but endocarditis cannot be excluded until the patient gets a transesophageal echocardiogram. Transthoracic studies are only about 50% to 60% sensitive compared with transesophageal imaging.

## Treatment

Consultation with an infectious disease specialist is recommended for all patients with proven endocarditis to help

guide management. In general terms, however, treatment is tailored to the antimicrobial susceptibility of the specific pathogen isolated from the patient's blood or resected valve. Typical agents include penicillin or ceftriaxone for streptococci, with the addition of gentamicin for isolates with partial resistance to penicillin; ceftazolin or nafcillin or oxacillin for methicillin-susceptible *S. aureus*; vancomycin for methicillin-resistant organisms; and a combination of penicillin or vancomycin and gentamicin for enterococcal infections (the combination of ampicillin plus ceftriaxone appears to be as effective as ampicillin plus gentamicin to treat enterococcal infections and has been associated with fewer adverse effects). Patients should have blood cultures drawn daily until bacteremia has cleared. The length of treatment varies between 4 and 6 weeks depending on the specific pathogen. The duration of therapy is counted from the first day of negative blood cultures rather than from the first day antibiotics were administered. Some patients require surgical therapy in addition to antibiotics. Indications for surgery include hemodynamic compromise, significant valvular dysfunction, myocardial abscess, and persistently positive blood cultures despite appropriate therapy. In the case of hemodynamic compromise or congestive heart failure, surgery should not be delayed even when signs and symptoms suggest ongoing active infection. Early surgery may also decrease the risk of embolic events, including strokes.

## Prophylaxis

Only patients with cardiac conditions associated with a high risk of adverse outcomes from endocarditis are targeted for antibiotic prophylaxis. These include patients with prosthetic valves or prosthetic cardiac repair materials, previous endocarditis, unrepaired or incompletely repaired congenital cyanotic heart disease, and cardiac transplant patients with valve disease. These patients should receive 2 g of amoxicillin 30 to 60 minutes before dental work, respiratory tract procedures that include incision or biopsy, and surgery on infected skin, muscle, or bones. Antibiotic prophylaxis is not recommended for patients with other cardiac conditions (such as mitral valve prolapse) or for any patient undergoing gastrointestinal or genitourinary procedures.

## *Clostridium difficile*

### Epidemiology and Risk Factors

*Clostridium difficile* is the most frequent pathogen associated with nosocomial diarrhea and one of the most frequent causes of health care-associated infections in general. The disease has taken on new importance in the past decade because of the emergence of a hypervirulent strain associated with a substantially increased risk of colectomy and death. Evaluation of every hospitalized patient with unexplained diarrhea should include testing for *C. difficile*. The major risk factors for *C. difficile* are antibiotic exposure and

• **Fig. 9.1** Severe *Clostridium difficile* colitis (toxic megacolon).

hospitalization. Chemotherapy and proton-pump inhibitors also increase risk. Any antibiotic can precipitate *C. difficile*, including quinolones, cephalosporins, and penicillins as well as clindamycin. Antibiotic stewardship is a cornerstone of the prevention and control of *C. difficile* infections.

### Nosocomial Transmission

Nosocomial transmission of *C. difficile* is distressingly common because the organism forms spores that are resistant to conventional hospital cleaning agents. Bleach is the only common cleaning agent that kills *C. difficile* spores. Alcohol-based hand washes are ineffective against *C. difficile* spores. Clinicians need to wash their hands with soap and water for at least 2 minutes to mechanically rid their hands of *C. difficile* after touching a contaminated patient or environment. Patients suspected of having *C. difficile* should be isolated from the moment of suspicion to prevent the spread of infection to uninfected patients. Patients diagnosed with *C. difficile* should remain on precautions until hospital discharge even if they have been treated and their diarrhea has resolved because *C. difficile* carriers can also spread spores.

Indeed, there is increasing appreciation that asymptomatic carriers of *C. difficile* may be an important reservoir promoting the spread of *C. difficile* between patients. Asymptomatic carriers are also at increased risk of developing symptomatic *C. difficile* disease compared with noncarriers. Avoiding or limiting antibiotic exposures is the best way to prevent disease in these patients. There may also be a role for prophylactic probiotics or oral vancomycin if these patients need to be treated with antibiotics.

### Clinical Presentation

The clinical manifestations of *C. difficile* infection include fever, abdominal cramping or bloating, severe diarrhea, and leukocytosis. CT findings can include colonic dilatation and colonic wall thickening (Fig. 9.1). The organism is difficult to culture; hence diagnosis is accomplished by assaying

stool for *C. difficile* toxins using an enzyme immunoassay or polymerase chain reaction (PCR) for the toxin-producing gene. The immunoassay has variable sensitivity; thus a negative test in a patient with a high clinical probability of disease should prompt repeat enzyme immunoassay testing or PCR. Some hospitals begin testing with PCR. About 10% to 20% of hospitalized patients carry *C. difficile* in their intestines. Hence PCR testing should be reserved for patients who have symptoms of invasive disease (i.e., diarrhea) to avoid false-positive results. Likewise, “test of cure” is not recommended in patients responding to treatment because the organism often persists after treatment.

### Treatment

The treatment strategy for *C. difficile* depends on the severity of the infection. Patients with relatively mild disease (diarrhea but minimal abdominal pain, fever, or leukocytosis) can be treated with oral vancomycin or oral metronidazole. Patients with moderate severity disease should be treated with oral vancomycin. Patients with refractory or severe disease (septic physiology, high fever, severe abdominal pain, marked leukocytosis) should be treated with oral vancomycin along with intravenous metronidazole. A surgeon should be consulted in all patients with severe infection because early colectomy is sometimes the only way to save the life of someone infected with a hypervirulent strain. Consultation with an infectious disease specialist is also advised to guide the management of severe infections.

Up to one-third of patients infected with *C. difficile* will develop one or more recurrent infections. Initial therapy of recurrent infection is typically the same as an initial infection, but preventing further recurrences infections can be very challenging. Potential strategies include prescribing an extended course of vancomycin with gradually increasing intervals between doses, vancomycin pulse therapy, alternative agents such as fidaxomicin, and fecal microbiota transplantation. Consultation with an infectious disease specialist is recommended for patients with recurrent disease.

### Travel Medicine

#### Prevention

Pretrip counseling and vaccination are the keystones of travel medicine. Advice and immunizations ought to be tailored to the traveler’s destination, duration of time abroad, and planned activities. First ensure that the patient is up-to-date in routine immunizations such as measles, mumps, rubella; tetanus, diphtheria, acellular pertussis; *Haemophilus influenzae*; *Streptococcus pneumoniae*; and influenza. Depending on destination and activities, the patient might also merit vaccines against hepatitis A and B, *Neisseria meningitidis*, polio, typhoid fever, yellow fever, rabies, and Japanese encephalitis. Travelers to malaria-endemic regions should be offered malaria prophylaxis tailored to the resistance profile of parasites in the traveler’s destination. Clinicians are advised to

check the website of the Centers for Disease Control and Prevention (CDC; [www.cdc.gov/travel](http://www.cdc.gov/travel)) for specific recommendations on vaccines and malaria prophylaxis for different destinations.

### Traveler's Diarrhea

Diarrhea is the most common illness afflicting travelers to developing countries. Half or more of persons traveling to developing countries for 2 to 3 weeks develop diarrhea. The management of diarrhea begins with prevention. Advise travelers to avoid drinking untreated water and eating uncooked produce or vegetables that have come into contact with untreated water. The catch phrase is “peel it, boil it, or don't eat it.”

Should diarrhea develop, travelers should focus on aggressive self-hydration followed by empiric therapy with a quinolone (e.g., ciprofloxacin, 250 to 500 mg twice daily for 1–3 days) or single dose of azithromycin (1000 mg orally). Patients can also take loperamide for symptom relief so long as they are not experiencing fever or hematochezia.

Persistent diarrhea in a returning traveler can be divided into bloody and nonbloody categories. Bloody diarrhea is usually caused by enteroinvasive strains of *E. coli*, *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, and *Entamoeba histolytica*. The stool of patients with acute bloody diarrhea should be cultured for these pathogens to confirm diagnosis and determine antibiotic susceptibility. Empiric treatment with a quinolone or azithromycin is reasonable after a specimen has been taken. Patients with subacute, nonbloody diarrhea more typically have parasitic infections with organisms such as *Giardia lamblia* or *Cryptosporidium* species. These can be diagnosed with stool antigen detection assays or microscopic examination for ova and parasites. In the case of *Cryptosporidium* species, laboratories will need to use special stains to visualize the organism, and the clinician should alert the laboratory that this diagnosis is being considered. Some travelers with persistent symptoms despite negative stool studies have developed a postinfectious irritable bowel syndrome rather than active, ongoing infection.

### Fever in the Returning Traveler

The priority in a returning traveler with fever is evaluation for malaria. A delay in the diagnosis or treatment of malaria can lead to substantial morbidity and death. Returning travelers with fever should have thin and thick blood smears sent to assess for malaria. Antigen detection assays can supplement visual examination. A diagnosis of malaria should prompt rapid consultation with an infectious disease expert or a malaria clinician at the CDC (Malaria Hotline in the United States: 770-488-7788 or 770-488-7100 after working hours, weekends, or holidays).

Other causes of fever in returning travelers include enteric fever caused by *Salmonella typhi* or *paratyphi*, dengue, viral hepatitis, acute HIV, leptospirosis, schistosomiasis, tick-bite fever, and tuberculosis (Table 9.2). Dengue is

**TABLE 9.2** Sources of Fever in the Returning Traveler

Malaria	35%
Viral hepatitis	5%
Respiratory tract infections	5%
Dysentery	5%
Dengue fever	5%
Urinary tract infections	3%
Typhoid fever	2%
Tuberculosis	1%
Rickettsial infection	1%
Acute HIV infection	1%
Amebic liver abscess	0.5%

becoming increasingly prevalent. Large outbreaks of Chikungunya and Zika virus infections are currently active in Africa, South America, the Caribbean, and elsewhere. Clinicians are advised to check the CDC website for recent information on disease activity in specific destinations.

## Lyme Disease

### Epidemiology

Lyme disease is the most common tick-borne illness in the United States and Europe. The causative pathogen is the spirochete *Borrelia burgdorferi*. *Borrelia* is transmitted to humans by the deer tick *Ixodes scapularis* or *Ixodes pacificus*. Lyme disease is found throughout the United States, but it is most commonly reported in the northeastern part of the country and in northwest California. Most cases occur during the summer months, but cases can present year-round. People with dogs and those living in or visiting wooded areas are at greatest risk.

### Clinical Presentation

The clinical presentation of Lyme occurs in three stages (Table 9.3). The disease begins at the site of a tick bite with an erythema migrans rash (Fig. 9.2). For disease transmission to occur, an infected tick must feed on its human host for at least 36 hours. Nonetheless, many patients do not recall the precipitating tick bite. The appearance of an erythema migrans rash is diagnostic of Lyme disease. Patients with an erythema migrans rash ought to be treated without further investigation because up to 60% of patients with primary disease will have negative Lyme enzyme-linked immunosorbent assays (ELISA). Ticks often bite in areas that are not easily visualized (such as in the gluteal folds or back of the neck); thus patients may not be aware that they have erythema migrans and therefore do not present for medical care.

**TABLE 9.3** Lyme Disease: Stages, Presentation, Treatments

Stage	Clinical Presentation	Treatment	Duration
Stage 1	Erythema migrans	Doxycycline <sup>a</sup>	14 days
Stage 2 (early)	Fever, headache, fatigue, adenopathy, disseminated erythema migrans lesions	Doxycycline <sup>a</sup>	14 days
Stage 2 (late)	Cardiac: first-degree atrioventricular block	Doxycycline <sup>a</sup>	14 days
	Cardiac: complete heart block	Ceftriaxone	14–21 days
	Musculoskeletal: migratory joint pains, transient arthritis	Doxycycline <sup>a</sup>	28 days
	Neurologic: facial palsy	Doxycycline	14–28 days
	Neurologic: meningitis, encephalitis, radiculitis, mononeuritis multiplex	Ceftriaxone	14–28 days
Stage 3	Chronic encephalomyelitis Chronic arthritis Chronic axonal radiculopathy	Ceftriaxone	28 days

<sup>a</sup>Alternatives: amoxicillin 500 mg orally three times daily or cefuroxime 500 mg orally twice daily.

• **Fig. 9.2** Erythema migrans rash of early Lyme disease.

Within days to weeks of inoculation, the *Borrelia* spirochetes disseminate through the body. Patients at this second stage of infection can present with multiple erythema migrans rashes spread over the body and with systemic symptoms such as fever, chills, headache, myalgias, and fatigue (Fig. 9.3). A small subset of patients go on to develop transient focal disease in just about any organ of the body including meningitis, facial palsy, neuritis, conjunctivitis, atrioventricular heart block, myocarditis, migratory joint pains, and mild hepatitis. Patients at this stage of infection typically have positive Lyme ELISA tests.

Months to years later, a further subset of patients manifest with symptoms and signs of tertiary persistent infection. These patients can have intermittent pain and swelling of large joints (especially the knees) or neurologic complaints

• **Fig. 9.3** Disseminated Lyme disease.

such as encephalomyelitis or multiple axonal radiculopathies. These patients also have persistently positive Lyme ELISAs.

### Laboratory Diagnosis

The Lyme ELISA test is sensitive in the second and third stages of infection. By 1 month after inoculation, almost all patients have positive Lyme ELISA tests. The ELISA is prone, however, to false-positive results and hence the CDC recommends follow-up testing of all positive ELISA tests with a Western blot assay to increase specificity. The CDC has established criteria for interpretation of Western blots by designating certain bands as potentially significant. A Western blot is considered positive for immunoglobulin (Ig)M if a patient has at least two out of three designated bands present, whereas the IgG is considered positive if a patient has at least five out of 10 designated bands present. ELISA and Western blots can remain positive for many years, even with treatment; hence the diagnosis of repeat infections must be

made on clinical rather than laboratory grounds. Typically, only patients with early infections aborted by rapid therapy are susceptible to reinfection.

Some clinicians and patients maintain that negative Lyme testing in the face of symptoms such as fatigue and myalgia do not exclude the diagnosis of Lyme. Although it is well described that patients with early Lyme disease can have negative antibody tests, there is a substantial body of scientific evidence supporting the high sensitivity of Lyme antibody testing for patients with manifestations of late disease. Consequently, clinical guidelines published by the Infectious Diseases Society of America do not recommend antibiotic treatment for patients with nonspecific symptoms and negative Lyme antibody tests.

Patients suspected of Lyme disease should also be tested for ehrlichiosis and babesiosis because these diseases often cooccur with Lyme.

## Treatment

Patients who meet clinical diagnostic criteria (an erythema migrans rash) or laboratory diagnostic criteria (a positive ELISA followed by a positive Western blot) ought to be treated (see Table 9.3). Stage 1 and stage 2 disease including first-degree atrioventricular block can be treated with doxycycline 100 mg orally twice daily for 14 to 21 days, respectively. An alternative agent is amoxicillin 500 mg orally three times daily. Patients with arthritis should be treated with an oral agent for 28 days. Facial palsies can also be treated with an oral regimen, but patients with other neurologic manifestations or high-degree atrioventricular block merit intravenous penicillin or ceftriaxone for 14 to 28 days.

## Post-Lyme Disease Syndrome

A small percentage of patients have persistent myalgias, arthralgias, impaired cognition, and fatigue despite appropriate treatment. This appears to be a postinfectious syndrome. Randomized trials of prolonged intravenous and oral antibiotics versus placebo do not show any benefit of antimicrobial therapy for this population.

## HIV Infection and AIDS

### Epidemiology

The incidence of HIV in the United States has been steady over the past few years at approximately 55,000 new infections per year. Among men, approximately 75% acquire HIV through contact with other men; among women, a similar proportion contract it from a man infected with HIV. The major risk factor for HIV transmission in the United States is unprotected sexual intercourse with an infected partner or, to a lesser extent, intravenous drug use. A large driver for the persistently high number of new infections is thought to be a large reservoir of people unaware of their serostatus; in response, the CDC is encouraging more widespread testing;

every adult patient seen in any kind of health care facility ought to be tested at least once for HIV. Patients at high risk for HIV infection should be tested annually, and pregnant patients should be tested as part of their routine prenatal evaluation. The CDC advocates replacing opt-in testing (where providers seek written consent before testing) with opt-out testing (where patients are tested without written consent unless they explicitly refuse). Legislation varies by state; however, an increasing number of jurisdictions now permit testing for HIV with verbal consent alone.

## Natural History

Acute infection with HIV is often symptomatic. Days to weeks after virus acquisition, patients experience an acute mononucleosis-like syndrome characterized by fever, headache, sore throat, rash, myalgias, and fatigue. The syndrome typically resolves after a few days or weeks, and infected patients become asymptomatic. The seroconversion syndrome may be highly symptomatic at one extreme (requiring hospitalization) and completely asymptomatic at the other. People with HIV can subsequently remain asymptomatic for anywhere from a few years to 20 years or more. During this period, the HIV virus is actively replicating within the body, but new virions are destroyed by the immune system at the same rate as they are produced. HIV tends to harness the immune system's CD4 cells for viral replication, killing the cells in the process. Eventually, the number of CD4 cells in the body declines, viral replication exceeds immune destruction, and the viral load begins to rise. Decreasing CD4 cell counts lead to progressively more immune dysfunction and increasing susceptibility to opportunistic infections. Untreated patients typically succumb to opportunistic infections or neoplasms rather than directly to HIV itself.

## Opportunistic Infections

Patients become susceptible to different opportunistic infections at characteristic levels of CD4 counts (Table 9.4). HIV patients with relatively preserved CD4 counts ( $>350$  cells/mm<sup>3</sup>) are at increased risk of invasive pneumococcal infections, tuberculosis, and herpes zoster. When the CD4 count drops below 200 cells/mm<sup>3</sup>, patients become susceptible to oral thrush, esophageal candidiasis, and *Pneumocystis jirovecii* pneumonia. Below 50 to 100 CD4 cells/mm<sup>3</sup>, *Mycobacterium avium* complex, cryptococcal meningitis, and invasive cytomegalovirus (CMV) infections are possible. Importantly, these CD4 cell count thresholds are generalizations, and some individuals with HIV have opportunistic infections at higher levels, whereas others with severely depleted counts remain without infection for months or even years.

## Treatment

The decision to initiate treatment is a shared decision between patient and provider. Parties need to balance the

inconvenience and potential toxicity of antiretroviral therapy on the one hand against the risk of opportunistic infections and irreversible damage to the immune system on the other hand. Over the past few years, the trend has been toward offering patients treatment at earlier stages of infection considering the dramatic advances in HIV therapeutics, including the availability of potent agents with low pill burdens and few adverse effects. It is now possible to treat patients with a highly efficacious regimen requiring only a single pill (containing three or four different medications) once a day. There is also increasing evidence that a delayed introduction of therapy increases the risk for impaired immune reconstitution. Furthermore, early treatment has a public health benefit because it can abate the spread of infection. Current guidelines therefore advise treating all patients infected with HIV regardless of CD4 count.

Initial therapy should be with a combination of three active agents from two or more antiretroviral classes. The particular choice of agents should be guided by viral-resistance testing, prior antiretroviral exposure, comorbidities, and pregnancy status. Currently available antiretroviral classes include nucleoside reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors, protease inhibitors, fusion inhibitors, CCR5 antagonists, and integrase inhibitors. Typical first-line therapies include the nonnucleoside reverse transcriptase inhibitor dolutegravir and two nucleoside reverse transcriptase inhibitors such as tenofovir and emtricitabine or abacavir and lamivudine. The combination pill elvitegravir/cobicistat/tenofovir alafenamide/emtricitabine is another first-line alternative. The ritonavir-boosted protease inhibitor darunavir can be substituted for dolutegravir. Viral resistance genotype assays are critical to guide initial and subsequent therapies.

Before prescribing abacavir, clinicians should test patients for the presence of the multihistocompatibility complex class I allele human leukocyte antigen (HLA)-B\*5701. The

presence of this allele is highly correlated with hypersensitivity to abacavir, causing a multiorgan syndrome with fatigue, myalgias and fever, rash, diarrhea, or dyspnea. The absence of HLA-B\*5701 appears to reliably exclude the possibility of a severe hypersensitivity reaction to abacavir.

## Monitoring

HIV-infected patients should see a physician and have serial evaluation of their CD4 count and viral load every 3 to 6 months. Patients recently started on therapy or switched to a novel therapy should be seen more often and have viral-load testing within 2 to 8 weeks of the new prescription. Conversely, patients with persistently suppressed viral loads and few or no drug adverse effects can be seen and tested less often.

## Preexposure Prophylaxis

There is mounting evidence that preexposure prophylaxis (PrEP) with one pill of tenofovir-emtricitabine once daily offers substantial protection against acquiring HIV infection. Consider prescribing this regimen for patients at high risk for HIV acquisition as part of a comprehensive HIV-prevention plan. Eligible individuals could include HIV-negative individuals with HIV-positive sex partners, men who have sex with men, people with multiple sex partners, and people who exchange sex for drugs or money. The effectiveness of PrEP is highly dependent on adherence; only prescribe PrEP to patients who believe they can take the medication faithfully. Patients on PrEP need to be monitored quarterly for HIV acquisition, medication adherence, and medication adverse effects. PrEP does not provide any protection against sexually transmitted infections other than HIV, so patients need to be counseled about this ongoing risk and strategies to protect themselves.

**TABLE 9.4** Opportunistic Infections in HIV-Infected Patients

CD4 Count (Cells/mm <sup>3</sup> )	Disease	First-Line Treatment
>350	<i>Mycobacterium tuberculosis</i>	Isoniazid + rifampin + ethambutol + pyrazinamide
	<i>Streptococcus pneumoniae</i> pneumonia	Ceftriaxone
	<i>Herpes zoster</i> shingles	Valacyclovir, famciclovir, or acyclovir
<200	<i>Pneumocystis jirovecii</i> (PCP) pneumonia	Trimethoprim-sulfamethoxazole
	<i>Candida</i> spp. pharyngitis or esophagitis	Fluconazole
<100	<i>Toxoplasma gondii</i> encephalitis	Pyrimethamine + sulfadiazine + leucovorin
	<i>Cryptococcus neoformans</i> meningitis	Amphotericin B lipid formulation
<50	<i>Mycobacterium avium</i> complex	Clarithromycin + ethambutol ± rifabutin
	Cytomegalovirus retinitis, myelitis, or esophagitis	Valganciclovir orally or ganciclovir intravenously
	JC virus progressive multifocal leukoencephalopathy	HIV antiretrovirals to reconstitute the immune system

## Sexually Transmitted Infections

### Chlamydia

*Chlamydia trachomatis* is the most common sexually transmitted bacterial infection. The disease can present with symptoms of cervicitis or urethritis but frequently is asymptomatic in both men and women. Untreated infection can lead to pelvic inflammatory disease, ectopic pregnancy, infertility, and chronic pelvic pain. Chlamydia infection during pregnancy is also associated with poor outcomes, including miscarriage and premature birth. Consequently, the US Preventive Services Task Force (USPSTF) recommends screening all sexually active women 15 to 24 years of age for occult infection, as well as all older women with risk factors (history of sexually transmitted infections, new or multiple sex partners, inconsistent condom use, and exchanging sex for money or drugs). The most sensitive diagnostic test is a nucleic acid amplification test. Infected patients can be treated with azithromycin 1 g orally dosed once or doxycycline 100 mg orally twice daily for 7 days. Test of cure is recommended only for pregnant women; however, all patients with positive Chlamydia tests should be retested for reinfection about 3 months after their initial diagnosis. This is because reinfection from an untreated partner is very common. An increasing number of states now encourage “expedited partner therapy” where patients with chlamydia are provided with a prescription to give to their partner in addition to the one for themselves.

### Gonorrhea

Gonorrhea is the second most common sexually transmitted bacterial infection. *Neisseria gonorrhoeae* infection presents with cervicitis and urethritis. Depending on patients’ sexual practices, however, gonorrhea can also manifest as pharyngitis and proctitis. A small proportion of untreated local infections can disseminate to cause a syndrome of fever and arthritis accompanied by a small number of scattered pustules. Some patients, however, especially women, suffer no symptoms at all. The USPSTF therefore recommends

routine gonorrhea screening for all sexually active women until 24 years of age and all high-risk women over 24 years of age (same risk factors as described earlier for chlamydia). Diagnosis is based on nucleic acid amplification testing of urine or swabs from the urethra, cervix, pharynx, and/or anus. Localized infection should be treated with one dose of ceftriaxone 250 mg intramuscularly, and one dose of azithromycin 1 g orally. Quinolones are no longer recommended to treat this disease because of increasing resistance. Patients with gonorrhea should be empirically treated for concurrent chlamydia unless formal testing rules out coinfection. Patients with gonorrhea should also be screened for syphilis, HIV, and viral hepatitis. Patients treated with anything other than ceftriaxone require a test of cure 1 week following treatment. Ceftriaxone-resistant gonorrhea has been reported; hence patients with persistent symptoms despite treatment merit referral to a sexually transmitted disease clinic for formal culture and sensitivity testing.

### Syphilis

Syphilis infection proceeds in three stages (Table 9.5). About 3 weeks after inoculation, patients develop primary infection characterized by a painless ulcer called a *chancre* at the site of inoculation. The chancre spontaneously clears after 2 to 8 weeks. About 6 weeks after inoculation, a dramatic secondary stage develops characterized by fever, malaise, pharyngitis, diffuse lymphadenopathy, generalized rash involving the palms and soles, and mucous patches on the tongue. This phase can also spontaneously resolve, leading the patient to a period of asymptomatic latent infection. A small subset of patients go on to develop tertiary syphilis characterized principally by aortic disease (dilatation, aneurysm, aortic regurgitation) and neurologic disease (tabes dorsalis, ocular lesions, deafness, dementia).

Syphilis can be diagnosed by direct visualization of spirochetes under dark field microscopy. Suitable specimens for microscopy include swabs of chancres from patients with primary infection and swabs of oral mucous patches from patients with secondary infection. More commonly, serologic

**TABLE 9.5** Syphilis: Stages, Presentation, Treatments

Stage	Clinical Presentation	Tests	Treatment	Duration
Primary	Chancre (painless)	RPR+ FTA-Abs± TP-PA±	Penicillin G, 2.4 million units intramuscularly	1 dose
Secondary	Fever, generalized rash involving palms and soles, mucous patches, diffuse lymphadenopathy	RPR+ FTA-Abs+ TP-PA+	Penicillin G, 2.4 million units intramuscularly	1 dose
Latent	Asymptomatic	RPR+ FTA-Abs+ TP-PA+	Penicillin G, 2.4 million units intramuscularly	1 dose per week × 3 weeks
Tertiary	Aortitis (aneurysms, aortic regurgitation) Encephalitis (dementia, tabes dorsalis) Ophthalmic disease, deafness	RPR±, FTA-Abs+ TP-PA+	Penicillin G, 18–24 million units intravenously per day	10–14 days

FTA-Abs, Fluorescent treponemal antibody absorption test; RPR, rapid plasmin reagin test; TP-PA, *Treponema pallidum* agglutination test.

tests are used. There are two kinds of serologic tests available: (1) nonspecific, nontreponemal tests such as the rapid plasma reagin (RPR) and Venereal Diseases Research Laboratory (VDRL) tests; and (2) specific treponemal antibody tests directed against different treponemal antigens, such as the fluorescent treponemal antibody absorption test, the *Treponema pallidum* particle agglutination test, or the microhemagglutination-*T. pallidum* test. The nonspecific nontreponemal tests are useful as rapid, inexpensive screening tests and to monitor patients' response to therapy. The specific treponemal tests are useful to confirm diagnosis in patients with positive nontreponemal tests or compatible clinical syndromes. Another approach is to begin by screening patients for antitreponemal antibodies and limiting further testing to patients with antibody evidence of treponemal exposure.

Primary, secondary, and early latent (<1 year since infection) syphilis can be treated with a single intramuscular dose of benzathine penicillin, 2.4 million units. Late latent or syphilis of unknown duration should be treated with benzathine penicillin 2.4 million units intramuscularly once weekly for 3 weeks. Neurosyphilis is treated with intravenous dose of aqueous penicillin, 18 to 24 million units daily for 10 to 14 days administered as continuous infusion or divided into six doses per day.

## Bacterial Meningitis

### Epidemiology and Risk Factors

Despite widespread immunization against pneumococcus and meningococcus, acute bacterial meningitis continues to claim the lives of young, otherwise healthy people. Young people living in close quarters such as college dormitories or military barracks are at particular risk for meningococcal meningitis. Many cases begin with a prodrome of upper respiratory tract infection, otitis media, or sinusitis that

subsequently spreads to the central nervous system. Meningococcal vaccine is indicated for all teens, freshmen entering college, military recruits, people without spleens, and travelers to endemic areas. Vaccine protection lasts about 5 years; hence a booster shot is required for patients at continued or renewed risk of exposure.

### Clinical Presentation

The classic presentation of bacterial meningitis is fever, headache, and neck stiffness. Ongoing illness can lead to impaired consciousness and progressive neurologic deficits. Kernig sign (patient resists passive extension of the knee when hip is flexed), Brudzinski sign (passive flexion of the neck precipitates flexion of the hip and knees), and nuchal rigidity may be found on physical examination.

### Diagnosis

Patients with suspected meningitis should be evaluated and treated as expeditiously as possible. Treatment should not be delayed awaiting the execution or results of diagnostic tests. If possible, draw blood cultures before administering antibiotics. Patients with papilledema or focal neurologic deficits should get immediate empirical dexamethasone and antibiotics and then proceed to head CT to assess for space-occupying lesions before lumbar puncture. Patients without papilledema or focal neurologic deficits can proceed directly to lumbar puncture followed by empiric therapy with dexamethasone and antibiotics.

Cerebrospinal fluid from patients with bacterial meningitis typically has >1000 white blood cells/mm<sup>3</sup> with a neutrophil predominance, elevated protein, and low glucose. Less marked pleocytosis suggests viral meningitis or other non-bacterial etiology. The most common pathogens responsible for community-acquired meningitis are listed in [Table 9.6](#).

**TABLE 9.6** Common Causes of Meningitis and Their Treatment

<i>Streptococcus pneumoniae</i>	
Penicillin MIC <0.1 µg/mL	Penicillin G, 18–24 million units per day or ampicillin 2 g intravenously dosed every 4 hours
Penicillin MIC 0.1–1.0 µg/mL	Ceftriaxone, 2 g intravenously every 12 hours
Penicillin MIC >1.0 µg/mL	Vancomycin 15–20 mg/kg intravenously every 8–12 hours (goal trough 20 µg/mL) plus ceftriaxone 2 g intravenously every 12 hours
<i>Haemophilus influenzae</i>	
Beta-lactamase negative	Ampicillin 2 g intravenously every 4 hours
Beta-lactamase positive	Ceftriaxone 2 g intravenously every 12 hours
<i>Neisseria meningococcus</i>	
Penicillin MIC <0.1 µg/mL	Penicillin G 18–24 million units per day or ampicillin 2 g intravenously every 4 hours
Penicillin MIC 0.1–1.0 µg/mL	Ceftriaxone 2 g intravenously every 12 hours
<i>Listeria monocytogenes</i>	Ampicillin 2 g intravenously every 4 hours or penicillin G 18–24 million units per day

MIC, Minimum inhibitory concentration.

## Treatment

Empiric therapy should include vancomycin (one time loading dose of 25 to 30 mg/kg intravenously followed by 15 to 20 mg/kg intravenously dosed every 8 to 12 hours, goal trough 20 µg/mL), ceftriaxone 2 g intravenously dosed every 12 hours, and dexamethasone 10 mg intravenously dosed every 6 hours. The purpose of the vancomycin is to provide coverage for pneumococcal infections that are highly resistant to beta-lactam antibiotics. Early administration of dexamethasone has been shown to decrease mortality and morbidity, particularly in cases caused by *S. pneumoniae*. Add ampicillin 2 g intravenously dosed every 4 hours when treating elderly, alcoholic, and immunocompromised patients to cover *Listeria monocytogenes*. Add acyclovir 10 mg/kg intravenously dosed every 8 hours if there is a clinical suspicion of herpes simplex virus encephalitis. Once an etiologic pathogen has been identified, tailor antibiotic therapy accordingly (see Table 9.6).

## Prophylaxis

Close contacts of patients with proven *N. meningitidis* meningitis should receive antibiotic prophylaxis to eradicate possible colonization with invasive *N. meningitidis*. Close contacts are defined as household members (including roommates), day-care center contacts, and people directly exposed to the patient's oral secretions (e.g., kissing, mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management) but not school or office contacts. Acceptable agents to eradicate *N. meningitidis* include rifampin 600 mg orally dosed twice daily for 2 days, ceftriaxone 250 mg dosed intramuscularly once, and azithromycin 500 mg dosed orally once. Ciprofloxacin should be used with caution because of reports of quinolone-resistant *N. meningitidis* in Minnesota and North Dakota.

## Chapter Review

### Questions

- A 63-year-old man with a central venous catheter for chemotherapy develops a fever and hypotension. Blood cultures are drawn, and empiric treatment with vancomycin and ceftazidime is initiated. Blood cultures rapidly turn positive for *Staphylococcus aureus*. The susceptibility profile is as follows:  
Resistant: penicillin, levofloxacin, clindamycin  
Sensitive: oxacillin, vancomycin, linezolid  
Management of this patient should include:

  - Keep central line, continue vancomycin, continue ceftazidime.
  - Remove central line, continue vancomycin, continue ceftazidime.
  - Remove central line, continue vancomycin, stop ceftazidime.
  - Remove central line, stop vancomycin, stop ceftazidime, start cefazolin.
  - Keep central line, stop vancomycin, stop ceftazidime, start cefazolin.
- A 36-year-old woman from rural Maine is diagnosed with Lyme disease after presenting to her primary care physician with fever, fatigue, myalgias, and multiple annular patches of erythema scattered over her body. Lyme ELISA and confirmatory Western blot are both positive. She is treated with doxycycline for 21 days. Two months later she returns to her physician complaining of persistent severe fatigue and diffuse body aches. Appropriate management should include:

  - Repeat ELISA and Western blot; if positive, retreat with doxycycline for 28 days.
  - Repeat ELISA and Western blot; if positive, retreat with ceftriaxone for 28 days.
  - Re-treat immediately with doxycycline for 28 days.
  - Re-treat immediately with ceftriaxone for 28 days.
  - Symptomatic management alone with nonsteroidal antiinflammatory drugs and reassurance
- A 58-year-old woman with severe *Clostridium difficile* diarrhea is admitted to your inpatient internal medicine service. The following measures are proposed to prevent transmission of *C. difficile* from your patient to the other patients on the ward:  
Isolation of the patient in a single room  
Mandate all staff to wear gloves and gowns whenever caring for the patient  
Strict instructions to all staff to wash their hands with alcohol-based solution before and after every patient contact  
Fastidious daily cleaning of the patient's room and toilet with soap and hot water  
Which of the above measures have been shown to prevent transmission of *C. difficile* from patient to patient?

  - Single room, gloves and gowns, daily cleaning with soap and hot water
  - Single room, gloves and gowns, hand washing with alcohol-based solution
  - Single room, gloves and gowns
  - Gloves and gowns, hand washing with alcohol-based solution
  - Single room, gloves and gowns, hand washing with alcohol-based solution, daily cleaning with soap and hot water
- A 46-year-old woman with mitral valve prolapse and mild mitral regurgitation has been asked to see you by her new dentist before a planned root canal. She is

otherwise healthy, has no allergies, and takes no medications. Which of the following regimens should be prescribed to protect her from infective endocarditis?

- A. Nothing
  - B. Amoxicillin 2 g orally dosed once to be taken 30 to 60 minutes before the procedure
  - C. Amoxicillin 2 g orally dosed once to be taken 30 to 60 minutes after the procedure
  - D. Amoxicillin 2 g orally dosed once to be taken 30 to 60 minutes before the procedure and again 30 to 60 minutes after the procedure
5. A 32-year-old woman frantically phones you because she has just heard that a student in her son's grade 12 mathematics class has meningococcal meningitis. She requests antibiotics to protect herself and her

family from catching the infection. You recommend the following:

- A. Treat her and her family.
- B. Treat only her son.
- C. Treat only her son and his brother, with whom he shares a bedroom.
- D. Reassure her that treatment is not indicated for anyone.

### Answers

- 1. D
- 2. E
- 3. C
- 4. A
- 5. D

## SECTION 2

# Hematology and Oncology

# 10

## Breast Cancer

CHRISTINA I. HEROLD AND WENDY Y. CHEN

Among women in the United States, breast cancer is the most common cancer (excluding basal and squamous cell skin cancer) and the second most common cause of cancer mortality. In 2016 there were approximately 246,660 new breast cancer cases (29% of all new cancers among women) and 40,450 deaths (14% of cancer deaths in women). The incidence and mortality of breast cancer peaked around 1998 at 145 cases and 32 deaths per 100,000 women. Since then, improvements in screening, prevention, and risk factor modification have led to a modest reduction in breast cancer incidence to approximately 123 cases per 100,000 women. Earlier diagnosis combined with improvements in treatment has led to a reduction in breast cancer mortality to 22 cases per 100,000 women. Whereas breast cancer is more common among Caucasian women (128 cases/100,000 women) compared with African-American women (124 cases/100,000 women), breast cancer deaths are more common among African-American women (31 deaths/100,000 women) compared with Caucasian women (22 deaths/100,000 women).

### Risk Factors

Risk factors for breast cancer include female gender, age, benign breast disease, exposure to ionizing radiation, family history of breast cancer, mutations in inherited cancer susceptibility genes, race/ethnicity, diet, alcohol, and estrogen exposure (Table 10.1). Older age and gender are the strongest risk factors for breast cancer. The lifetime risk of breast cancer is about 12%, and half of all breast cancers are diagnosed after age 61. Although breast cancer can develop in men, it is rare, comprising only 1% of breast cancers in the United States. Exposure to therapeutic chest radiation at a young age, such as that administered for the treatment of lymphoma, is associated with an increased risk of breast cancer and has become an indication for early and more intensive screening.

Family history is a heterogeneous risk factor. A woman's risk of developing breast cancer is 1.8-fold greater if she has one affected first-degree relative. However, the magnitude of this risk increases with younger age at diagnosis of the affected relative and a greater number of affected first-degree relatives. Despite this, only 15% to 20% of all women who

develop breast cancer report a family history of breast cancer. Approximately 5% to 10% of all breast cancer cases are attributable to an inherited breast cancer susceptibility gene, such as *BRCA1*, *BRCA2*, *TP53* (Li-Fraumeni), *PTEN*, *CDH1*, *STK11*, *NF1*, *PALB2*, *ATM* (ataxia-telangiectasia), *CHEK2*, and *NBN*. *BRCA1/2* carriers have a lifetime breast cancer risk that varies from family to family but can approach 80%; they are also at increased risk for ovarian and other cancers. Criteria for referral to genetic counseling to consider testing for an inherited breast cancer susceptibility gene include a personal history of early onset breast cancer at age 50 years or younger, triple-negative breast cancer at age 60 years or younger, a personal history of two primary breast cancers, being part of an ethnic group with a documented high prevalence for an inherited genetic risk (e.g., Ashkenazi Jews for select *BRCA* mutations), and a family history of individuals diagnosed with breast cancer at a young age, two primary breast cancers, breast and ovarian cancer, male breast cancer, or multiple family members with breast and ovarian cancer.

Epidemiologic studies have established that being overweight or obese is a risk factor for postmenopausal breast cancer. In postmenopausal women, a body mass index (BMI)  $\geq 28$  kg/m<sup>2</sup> is associated with approximately 25% increase in risk compared with those with lower BMI. Although the mechanism is debated, the risk may be related to the conversion of androgens to estrogens in the peripheral fat with higher adiposity yielding higher levels of circulating estrogen. Conversely, in premenopausal women, most studies have demonstrated an inverse relationship between weight and breast cancer risk. Longer exposure to and higher concentrations of endogenous estrogen (as manifested by early menarche, nulliparity, older age at first birth, older age at menopause, and lack of breastfeeding) is associated with a higher risk of breast cancer.

Although oral contraceptives do not greatly increase breast cancer risk, prolonged use of menopausal hormone therapy (MHT) formulations containing estrogen and progesterone does. The Women's Health Initiative comprised two randomized controlled trials that evaluated the effects of MHT on chronic disease risk. Over 16,000 women with an intact uterus were randomized to either placebo or oral estrogen and progesterone, and over 10,000 women with

**TABLE 10.1** Risk Factors for Development of Breast Cancer

Increase in Risk	Decrease in Risk	Uncertain Effect on Risk

*BMI*, Body mass index; *NSAID*, nonsteroidal antiinflammatory drug.

prior hysterectomy were randomized to oral estrogen alone or placebo. The trials were stopped early because of an overall greater chance of harm than benefit. At the time the active intervention was stopped, median duration was 5.2 years in the estrogen and progesterone group and 7.1 years in the estrogen-only group. After 13 years of follow-up, the risk of breast cancer with combined estrogen and progesterone was highest during intervention, decreased upon discontinuation, but persisted after exposure with a 1.37-fold relative increase in risk. For estrogen only, there was an observed reduction in breast cancer risk during intervention that was not sustained during later follow-up.

Finally, alcohol is an established risk factor for breast cancer with 10% increase in breast cancer per 10 g of daily alcohol intake (a 4-oz glass of wine has 11 g of alcohol).

## Prevention

Factors that may reduce the risk of developing breast cancer include minimizing the duration of MHT, avoiding weight gain as an adult, engaging in regular physical activity, limiting alcohol consumption, having a first child at an earlier age, and breastfeeding for at least 6 months. Among *BRCA1/2* mutation carriers, prophylactic mastectomy and prophylactic oophorectomy reduce the risk of developing breast cancer. Selective estrogen receptor modulators (SERMs), such as tamoxifen (20 mg/day × 5 years) and raloxifene (60 mg/day × 5 years), reduce the risk of developing

invasive breast cancer by 50%. When given for primary breast cancer prevention in healthy women, neither medication has been shown to improve overall survival. Tamoxifen is associated with a modest increase in the risk of uterine cancer and thromboembolic events that increases with age. Tamoxifen has been evaluated in both premenopausal and postmenopausal women, whereas raloxifene has been evaluated only in postmenopausal women. Aromatase inhibitors (AIs), such as exemestane (25 mg/day × 5 years) and anastrozole (1 mg/day × 5 years), are also effective for primary prevention in postmenopausal women; they are associated with an increased risk of osteoporosis, among other side effects. In selecting the most appropriate preventive strategy for a postmenopausal woman, it is worth noting that SERMs improve bone density whereas AIs accelerate bone loss. Finally, although large randomized clinical trials have established that AIs are as effective as SERMs, only the SERMs are currently US Food and Drug Administration (FDA)-approved for primary prevention of breast cancer.

## Screening

Mammography screening either yearly or every 2 years can detect asymptomatic early-stage breast cancers. A systematic review conducted for the US Preventive Services Task Force (USPSTF) found that mammography reduced the relative risk of breast cancer mortality to 0.92 among women 39 to 49 years of age (a statistically nonsignificant result), to

0.78 among women 50 to 69 years of age (significant), and to 0.80 among women 70 to 74 years of age (nonsignificant). Most facilities routinely use digital mammography. Tomosynthesis (or three-dimensional mammography) is a modified digital mammogram with additional views that is available at some facilities, although it is unclear if patient outcomes differ between standard digital mammogram and tomosynthesis. Potential harms of screening include discomfort, false-positive results, radiation exposure, and overdiagnosis/overtreatment of ductal carcinoma in situ (DCIS) and small invasive breast cancers.

Most expert groups recommend discussion of mammography screening beginning at age 40 years with individualized risk assessment and routine screening beginning at age 45 years (American Cancer Society) or 50 years of age (USPSTF). For women in their 40s, the overall benefits of screening mammography are lower than that of women in their 50s because of the lower risk of developing breast cancer and higher risk of false positives among women in their 40s. The decision to stop screening should also be individualized. Few studies of screening mammography included women older than 74 years of age, so some groups recommend screening as long as a woman's life expectancy is >10 years (American Cancer Society). Remember that mammography is unremarkable in approximately 10% of breast cancers, so a suspicious lump should be evaluated further with ultrasound, MRI, and/or biopsy, even if the mammogram is negative.

In countries with access to mammography, breast self-examination does not increase the rate of breast cancer diagnosis, change the stage at diagnosis, or reduce the risk of death from breast cancer. Therefore routine breast self-examinations are no longer recommended. Instead, a woman is encouraged to be aware of any changes in her breast and to discuss these with her provider. Ultrasound is inferior to mammography for screening but can be used to follow-up on an abnormal clinical examination or screening mammogram. MRI has been evaluated as a screening test and is more sensitive than mammography at detecting invasive cancers, but it has more false positives. MRI has never been shown to improve breast cancer mortality compared with screening mammography, so it should not be routinely used for screening. However, MRI can be considered for younger women at higher risk of breast cancer where mammography may be less sensitive, such as for *BRCA1/2* mutation carriers or women who underwent therapeutic chest radiation as a child or young adult.

## Pathology and Staging

Normal breast tissue contains epithelial elements (branching ducts that connect lobules to the nipple) and stromal elements (adipose and fibrous connective tissue). The vast majority (>95%) of breast cancers arise from epithelial cells and are therefore classified as carcinomas. Breast carcinomas can be in situ (where cancer cells are confined inside ducts or lobules and do not invade into the surrounding

stroma) or invasive (where cancer cells invade into the breast stroma and consequently have the potential to metastasize). In situ carcinomas have two major histologic types: DCIS and lobular carcinoma in situ (LCIS). There are several different histologic types of invasive breast cancer, including invasive ductal carcinoma (IDC), invasive lobular carcinoma, mixed ductal/lobular carcinoma, mucinous (colloid) carcinoma, tubular carcinoma, medullary carcinoma, and papillary carcinoma. IDC is the most common histologic subtype, accounting for approximately 75% of all invasive breast cancers. Although most histology types are thought to behave similarly, tubular and colloid cancers have a lower risk of systemic recurrence and are generally considered favorable histology types.

Several factors affect the prognosis and influence the treatment of breast cancer, including grade, stage, hormone-receptor status, and human epidermal growth factor receptor (HER)2 status. Histologic grade, a description of the microscopic architectural and cytologic features of a cancer, is usually classified as well differentiated (grade 1), moderately differentiated (grade 2), or poorly differentiated (grade 3). Stage, a description of the anatomic extent of cancer, is based on the size of the tumor (T), the extent of axillary lymph node involvement (N), and the presence or absence of distant metastases (M). Noninvasive disease (i.e., DCIS or LCIS) is considered stage 0 (TisN0M0). Invasive cancer that is confined to the breast and/or regional lymph nodes is classified as stage I, II, or III. Invasive cancer that has spread to distant sites is classified as stage IV. As with grade, a higher stage is associated with a higher risk of recurrence and shorter survival. An initial core needle biopsy has replaced a surgical excisional biopsy to make the diagnosis of cancer and plan treatment. Hormone-receptor and HER2 status can be reliably assessed on core needle biopsy as long as there is enough tumor tissue.

Inflammatory breast cancer (IBC) is a less common clinical presentation of breast cancer in which the skin overlying the breast is warm, thickened, and has a *peau d'orange* ("orange peel") appearance. It can have variable estrogen, progesterone, and HER2 status. A palpable breast mass may not be found. IBC is a particularly aggressive form of breast cancer with a relatively high risk of recurrence. Multidisciplinary treatment modalities are crucial, including chemotherapy as initial treatment (neoadjuvant chemotherapy), mastectomy (rather than breast-conserving surgery), and the routine use of postmastectomy adjuvant radiation therapy.

## Stage 0 Breast Cancer (Carcinoma in Situ)

DCIS is a noninvasive form of breast cancer that is confined within the duct system of the breast. Before routine mammography, DCIS was uncommon, representing <2% of breast cancers diagnosed in 1980. With the increased use of screening mammography, DCIS is the most rapidly growing subgroup of breast cancer, accounting for approximately 25% of all new cases diagnosed each year in the United States. DCIS encompasses a heterogeneous group of lesions

with a variable likelihood to develop into invasive cancer. Because it is impossible to precisely characterize the malignant potential of a specific DCIS lesion, the treatment for all types of DCIS is generally the same. Surgical management involves complete removal of the tumor by either lumpectomy (breast-conserving therapy) or mastectomy. Radiation therapy to the breast after lumpectomy reduces the risk of local recurrence by 50% and is typically recommended, although studies are trying to identify whether some women can omit radiation. Axillary lymph node biopsy is not indicated for cases of pure DCIS without invasive cancer. The overall prognosis associated with DCIS is excellent: Both mastectomy and lumpectomy followed by radiation therapy confer a high likelihood of survival (>98%). Compared with mastectomy, lumpectomy followed by radiation therapy is associated with a higher risk of in-breast recurrence. When in-breast recurrence does occur, about half of these tumors are invasive and half are in situ. Tamoxifen and AIs after surgery for DCIS have been shown to reduce the risk of developing DCIS or invasive breast cancer in the future. Distant metastases are rare for DCIS without an associated invasive breast cancer.

LCIS is a noninvasive form of breast cancer that arises from the lobules. It is not usually associated with physical examination or radiographic findings. Instead, it is most frequently identified incidentally on microscopic pathologic examination when a biopsy is performed to evaluate an unrelated abnormality. The presence of LCIS serves as a marker for an increased risk of developing invasive breast cancer in either breast; the risk of developing a subsequent invasive breast cancer in either breast is approximately 1% per year and persists indefinitely. Complete surgical excision to negative margins and radiation therapy are not indicated. Management options include continued surveillance or primary prevention with a SERM or AI. Prophylactic bilateral mastectomy has not been shown to improve overall survival and is not routinely recommended.

## Stage I, II, and III Breast Cancer (Nonmetastatic)

### Local Therapy

Cure is the goal of therapy for invasive breast cancer confined to the breast and/or axillary lymph nodes. Surgery, either mastectomy or lumpectomy, is recommended to remove the primary cancer. A lumpectomy allows a woman to retain normal breast tissue but is contraindicated if there is cancer in more than one quadrant (multicentric), the woman has received breast radiation therapy, the resection margins are persistently positive after reasonable attempts at excision, or for IBC. Breast reconstruction, either with implant or construction of an autologous tissue flap, is an option following mastectomy.

To reduce the risk of local cancer recurrence and to improve overall survival, radiation therapy to the breast following lumpectomy is generally recommended. Radiation

therapy to the chest wall following mastectomy is recommended for certain cases (e.g., large tumors, involvement of multiple axillary lymph nodes, IBC). Radiation therapy sometimes also encompasses the regional lymph nodes, such as the axillary and supraclavicular areas. Radiation treatments are usually given 5 days per week over 5 to 6 weeks, although a shorter course (called *hypofractionation*) may be an option for some women with small, node-negative, low-risk cancers. Overall survival after mastectomy compared with lumpectomy followed by radiation therapy is the same. The risk of local recurrence after lumpectomy and radiation therapy is low—5% or less at 5 years.

Axillary lymph node biopsy is indicated in most patients to determine prognosis, define optimal treatment, and reduce the likelihood of an axillary recurrence. For a clinically negative axilla, a sentinel node biopsy is the preferred sampling method. Using blue dye and/or radioactive tracer injected into the breast at the time of surgery, it is usually possible to identify one or more lymph nodes to which the cancer is most likely to spread. If the sentinel lymph nodes are clear, then it is unlikely that any other lymph nodes will be involved with cancer, and a completion axillary lymph node dissection and its associated risks can be avoided. If multiple sentinel lymph nodes are involved with cancer, a completion dissection and removal of the level 1 and 2 axillary lymph nodes may be recommended. However, some women treated with lumpectomy who have limited involvement of the sentinel lymph nodes (one or two involved nodes) and are going to receive postlumpectomy radiation therapy may be able to forgo completion axillary dissection without any impact on survival. Serious complications following complete dissection are uncommon, but approximately 10% to 20% of women experience chronic lymphedema.

### Systemic Therapy

Some patients with cancer confined to the breast and/or axilla may be cured by local therapy alone (surgery ± radiation), but many are still at risk for developing metastatic disease. The risk of developing a recurrence depends on the stage (tumor size and nodal involvement) and biologic characteristics of the cancer (grade and hormone-receptor and HER2 status). Blood tests and radiologic scans do not help to predict which patients will eventually develop recurrence. Hormone receptor–negative breast cancers tend to recur within 5 years of diagnosis, whereas for hormone receptor–positive disease, only about half of the recurrences occur within the first 5 years. The goal of adjuvant therapy is to reduce the risk of cancer recurrence and involves the use of systemic medications to kill microscopic foci of cancer that were not removed by surgery or killed by radiation. The decision of whether to administer adjuvant therapy, and if so, what type, depends on the risk of recurrence and the type of cancer. The higher the risk of recurrence, the greater the potential absolute benefit of adjuvant therapy. Risk factors for

the development of metastatic breast cancer include larger tumor size, higher tumor grade, presence of lymphovascular invasion in the breast, hormone receptor–negative disease, and axillary node involvement. For women with newly diagnosed breast cancer, multiparameter gene expression analyses (e.g., OncotypeDX recurrence score) may also help estimate the risk of cancer recurrence. For early-stage hormone positive, HER2-negative breast cancer, the OncotypeDX recurrence score provides estimates regarding both the likelihood of distant recurrence and the relative benefit of the addition of adjuvant chemotherapy to adjuvant endocrine therapy.

Determining what type of adjuvant therapy to administer also depends on the biologic characteristics of the cancer, because some therapies are effective only at treating certain types of breast cancer. The key factors that help determine treatment are the hormone-receptor and HER2 status (Table 10.2). Women with hormone receptor–positive breast cancer (either estrogen receptor–positive or progesterone receptor–positive) can benefit from hormonal therapy. Hormonal therapy is given for 5 to 10 years starting after the completion of surgery and, if given, chemotherapy. The minimum duration is 5 years, but several studies have suggested a modest benefit associated with 10 years of therapy. However, this would need to be weighed against the risks of extended therapies and the risk of recurrence. For premenopausal women, the usual adjuvant hormonal therapy is tamoxifen ± ovarian suppression depending upon the risk of recurrence. For postmenopausal women, the standard treatment is either an AI or sequential therapy with a combination of tamoxifen and an AI. Adjuvant hormonal therapy reduces the risk of death by approximately one-third. The side effect profiles of the hormonal therapies differ somewhat. Tamoxifen increase the risk of thromboembolic disease, uterine cancer, hot flashes, and irregular menses. AIs increase the

risk of musculoskeletal symptoms, vaginal dryness, and osteoporosis.

Approximately 25% of breast cancers overexpress the HER2 protein. Patients with untreated HER2-positive breast cancer experience a higher risk of recurrence compared with patients with HER2-negative breast cancer. Trastuzumab is a humanized monoclonal antibody designed to target HER2-positive cancer cells. When given in conjunction with adjuvant chemotherapy, trastuzumab reduces the relative risk of recurrence and death by 50% and 33%, respectively. Adjuvant trastuzumab and chemotherapy is now routinely recommended for patients with HER2-positive node-positive cancer or node-negative cancer measuring >1 cm. Approximately 2% to 3% of patients who receive trastuzumab develop symptomatic congestive heart failure. Consequently, this medication is contraindicated in patients with preexisting heart failure. For patients who receive trastuzumab, monitoring of left ventricular ejection fraction periodically throughout treatment is recommended. In the neoadjuvant setting for higher risk, node-positive, HER2-positive breast cancer, the antibody pertuzumab is also used in combination with trastuzumab and chemotherapy. Pertuzumab is a monoclonal antibody that blocks dimerization of the HER2 protein which is required for its activation.

Regardless of the hormone-receptor and/or HER2 status, adjuvant chemotherapy is sometimes indicated for higher-risk tumors and can reduce the risk of recurrence for all types of breast cancer. In the Oxford overview meta-analysis, adjuvant chemotherapy reduced the relative risk of relapse and death by 37% and 30% for women <50 years of age and by 19% and 12% for women 50 to 69 years of age. The benefits of chemotherapy for women >70 years of age have not been clearly established but should still be considered for someone in generally good health with an estimated life expectancy >5 years. Adjuvant chemotherapy usually involves the administration of two or three medications with nonoverlapping toxicity profiles. Commonly used medications include cyclophosphamide, methotrexate, 5-fluorouracil, doxorubicin, carboplatin, paclitaxel, and docetaxel. Regimens that include three chemotherapy medications appear to confer greater benefit than two-drug regimens but are also associated with increased toxicity and so are reserved for patients with higher-risk tumors. Potential side effects/risks from chemotherapy include fatigue, hair loss, nausea, diarrhea, constipation, fever, infection, neuropathy, infusion reaction, amenorrhea, premature menopause, heart failure, and leukemia (Table 10.3). Chemotherapy is a standard recommendation for women with hormone receptor–negative cancer measuring >1 cm, hormone receptor–positive cancer involving the axillary lymph nodes, and HER2-positive cancers who will be receiving HER2-based therapy. Chemotherapy for node-negative hormone receptor–positive, HER2-negative cancer is not routinely used but is considered for higher-risk cancer, based upon either standard pathologic characteristics or a gene expression profiling test, such as OncotypeDx.

**TABLE 10.2** Benefits and Harms of Mammogram Screening

Benefits and Harms	Age (Years)	
	40–49	50–59
10-year chance of dying from breast cancer		
• No screening	3.5/1000	5.3/1000
• Screening	3.0/1000	4.6/1000
• Deaths avoided because of screening	0.3/1000	0.8/1000
False-positive screening tests requiring a biopsy	121/1000	93/1000
Overdiagnosis and treatment (of cancers that would not have caused symptoms or led to premature death)	1–5/1000	1–7/1000

## Stage IV Breast Cancer (Metastatic)

Approximately 10% to 15% of women diagnosed with breast cancer have stage IV (metastatic) disease at initial presentation, and approximately 20% of all women diagnosed with nonmetastatic breast cancer eventually develop recurrent metastatic disease. Common sites of metastatic breast cancer include bone, lymph nodes, lungs, liver, and brain. At the time of metastatic recurrence, a biopsy can be useful to update the estrogen, progesterone, and HER2 status of the metastases. These markers can change from the original breast cancer to metastasis, and knowledge of the metastatic marker status is critical for selecting optimal systemic therapy. Metastatic breast cancer is not curable. Overall median survival with metastatic breast cancer is approximately 2.5 years, but there is considerable variability by subtype with hormone receptor–positive and HER2–positive disease generally having a more favorable prognosis and longer median survival. Other factors associated with a longer survival include a good performance status, fewer sites of metastatic disease, less visceral organ involvement, treatment responsive disease, and a long disease-free interval between the original cancer diagnosis and recurrence. The primary goal of therapy for patients with metastatic breast cancer is to maximize quality of life by reducing cancer-related symptoms without causing excessive therapy-related side effects.

The initial management of hormone receptor–positive metastatic breast cancer most commonly involves the administration of an antiestrogen medication. Approximately 75% of cancers respond to initial hormonal therapy. Hormonal treatment options include tamoxifen with or without a gonadotropin-releasing hormone agonist for premenopausal women and an AI (e.g., anastrozole, letrozole, or exemestane) for postmenopausal women. The initial management of hormone receptor–negative metastatic breast cancer typically involves the administration of systemic chemotherapy. Chemotherapy is also a reasonable treatment option for any woman with extensive visceral involvement or symptomatic metastatic disease, regardless

of the cancer's hormone-receptor status. Approximately 50% to 75% of cancers experience clinical benefit from initial treatment (i.e., the cancer shrinks or remains stable). Once started, a systemic treatment such as hormonal therapy or chemotherapy is usually continued until the cancer progresses or the patient develops intolerable side effects related to treatment.

## Targeted Therapies for Breast Cancer

Hormonal therapy for breast cancer was one of the first targeted cancer therapies and there have been recent advances in developing new targeted therapies for hormone receptor–positive breast cancer. In 2012 and 2015 the FDA approved two different oral targeted therapies for treatment of advanced disease along with hormonal therapy. Everolimus, an inhibitor of the mammalian target of rapamycin pathway, in combination with the AI exemestane improves median progression-free survival by approximately 4 months compared with exemestane alone. Palbociclib, a cyclin-dependent kinase 4/6 inhibitor, significantly improves progression-free survival in combination with the AI letrozole or the estrogen-receptor antagonist fulvestrant, compared with hormonal therapy alone. For example, in the first-line setting, the combination of palbociclib and letrozole improved median progression-free survival by approximately 10 months compared with letrozole alone.

Besides the hormonal pathway, the HER2 pathway has led to tremendous advances in targeted therapies. A key example is trastuzumab, a monoclonal antibody that targets the HER2 receptor. Trastuzumab is used for the treatment of both early stage and metastatic disease. In the adjuvant setting, the addition of trastuzumab to chemotherapy is associated with relative reductions of approximately 33% in breast cancer–related mortality and 50% in breast cancer recurrence compared with chemotherapy alone. Meanwhile, when used in combination with chemotherapy in the metastatic setting, trastuzumab improves overall survival by approximately 5 months. In addition, there are several

**TABLE 10.3**

**Common Hormonal Medications Used to Treat Breast Cancer Across the Spectrum of Disease**

Drug Class	Medication Name	Possible Adverse Effects	Notes
Antiestrogen: selective estrogen receptor modulator (SERM)	Tamoxifen	Hot flashes/sweats Vaginal spotting Vaginal discharge Irregular menses Endometrial cancer Leg cramps Blood clots	Tamoxifen used for prevention and treatment for both premenopausal and postmenopausal women
Antiestrogen: aromatase inhibitor (AI)	Anastrozole Letrozole Exemestane	Hot flashes/sweats Vaginal dryness Headache Joint/muscle aches Fatigue Osteoporosis	Only effective among postmenopausal women

newer therapies that also target the HER2 receptor. Pertuzumab, a monoclonal antibody that blocks HER2 dimerization, which is necessary for activation, is now indicated for first-line treatment of HER2-positive metastatic breast cancer based upon a pivotal study that showed an almost 16-month improvement in median overall survival when pertuzumab was given with trastuzumab and docetaxel chemotherapy. Similar to trastuzumab, pertuzumab has also been shown to improve the rate of pathologic complete response when given with chemotherapy and is now FDA approved in the neoadjuvant setting. Trastuzumab emtansine (T-DM1), a novel antibody drug conjugate of the chemotherapy DM-1 attached to trastuzumab, is another important HER2-directed therapy with a 3-month improvement in progression-free survival compared with the combination of lapatinib and capecitabine for metastatic disease. The role for T-DM1 in early-stage disease is an active area of current breast cancer research. Finally, the combination of capecitabine (chemotherapy) and lapatinib, an oral tyrosine kinase inhibitor of HER2, improves progression-free survival compared with capecitabine alone for metastatic breast cancer.

### Palliation of Metastatic Breast Cancer

Local therapies such as surgical excision, radiation therapy, or radiofrequency ablation are sometimes indicated to palliate symptomatic metastases but have not been shown to improve overall survival. Treating pain, anxiety, depression, and other symptoms commonly experienced by women with metastatic breast cancer is an integral aspect of cancer care as well. For women with bone metastases, the regular administration of an intravenous bisphosphonate (e.g., pamidronate or zoledronic acid) or the subcutaneous medication denosumab (a RANK [receptor activator of nuclear factor kappa-B] ligand inhibitor) helps prevent the development

of skeletal complications and palliates bone pain. Finally, providing optimal palliative care often requires the collaboration of multiple specialists including the oncologist, psychiatrist, social worker, and the hospice service.

### Summary of Breast Cancer Treatment

With nonmetastatic breast cancer (stages 0–III), the goal of therapy is cure, and surgery is essential to achieve this goal. However, even with optimal surgery, there is still a risk that breast cancer can recur. Radiation therapy (to the breast, chest wall, and/or surrounding lymph nodes) is sometimes used to reduce the risk of local recurrence. Systemic medications (antiestrogen, HER2-directed and/or cytotoxic chemotherapy) are sometimes used to reduce the risk of local (breast and ipsilateral axillary lymph nodes) and distant (beyond the breast and local lymph nodes) recurrence. Reducing the risk of recurrence helps increase the chance of cure. The major factors that providers consider when deciding which treatments to recommend and their sequence include stage, biologic subtype (hormone-receptor status, HER2 status, and grade), age, menopausal status, comorbid medical conditions/general health, and patient preference. After completing definitive therapy for nonmetastatic breast cancer, the only surveillance study recommended routinely is mammography to the remaining breast tissue; other radiologic scans and laboratory studies to screen for distant recurrence in asymptomatic women are not recommended. Metastatic (stage IV) breast cancer is not curable but can be responsive to treatment. The goals of therapy for metastatic breast cancer are to alleviate cancer-related symptoms and hopefully prolong survival. The primary treatment for metastatic breast cancer usually involves systemic medications depending upon the subtype. Surgery and radiation are used only in a palliative context to help control symptoms but do not improve survival with metastatic breast cancer.

## Chapter Review

### Questions

1. A 63-year-old woman is 8 years' status postlumpectomy and radiation therapy for a 1.5 cm, estrogen receptor–positive, node-negative breast cancer. She completed 5 years of an AI 3 years ago. She presents to your office with severe, localized midback pain. Physical examination is normal, including the neurologic examination. The alkaline phosphatase is 330 U/L (elevated). A bone scan is positive in several areas of the thoracic and lumbar spine, as well as in several ribs. The first course of action at this point should be:
  - A. Combination chemotherapy
  - B. AI
  - C. MRI scan of the spine
  - D. Radiation therapy to areas of localized disease
  - E. Stem cell transplantation
2. A 46-year-old woman presents to your office for routine health care. She is concerned about the possibility of developing breast cancer and asks you about her risk factors. Which statement is most correct?
  - A. A previous breast biopsy that showed LCIS does not substantially increase her risk of developing breast cancer.
  - B. Presence of a *BRCA1* germline mutation will substantially increase her risk of developing breast cancer.
  - C. A maternal aunt with postmenopausal breast cancer will substantially increase her risk of developing breast cancer.
  - D. The majority of women with breast cancer have identifiable risk factors for the development of breast cancer.
  - E. The duration of estrogen (endogenous and exogenous) exposure is not associated with increased risk of developing breast cancer.

3. Regarding potential effects of tamoxifen and raloxifene, which statement is most correct?
  - A. Raloxifene is a bone-strengthening agent, but tamoxifen is not.
  - B. Both increase the risk of endometrial cancer.
  - C. Both decrease the risk of developing a future breast cancer.
  - D. Tamoxifen increases risk of hot flashes, but raloxifene does not.
  - E. Both can be used in premenopausal women.
4. A 42-year-old premenopausal woman is diagnosed with a 3-cm poorly differentiated breast cancer with five involved axillary lymph nodes. The cancer is estrogen receptor–negative and HER2–positive. What would you counsel the patient?
  - A. The patient can omit adjuvant chemotherapy if she agrees to take tamoxifen for 10 years.
  - B. Adjuvant chemotherapy is not effective in reducing the risk of metastatic breast cancer.
  - C. Trastuzumab, when added to chemotherapy, substantially reduces the risk of developing metastatic disease.
  - D. An AI would further improve the cure rate for this patient.
  - E. The addition of trastuzumab to chemotherapy is not associated with any additional short-term or long-term complications.

## Lung Cancer

JODY C. CHUANG AND JOEL WILLIAM NEAL

### Overview

Cancer of the lung is a group of heterogeneous malignant disorders composed of small cell lung cancer (SCLC) (13%), nonsmall cell lung cancer (NSCLC) (86%), and rare thoracic malignancies such as mesothelioma and lower grade neuroendocrine tumors. In 2016 the American Cancer Society estimated that 224,390 people in the United States would develop lung cancer, and 158,080 people would die of their disease. In men, the age-adjusted cancer death rate for lung cancer peaked in 1990 at approximately 90 deaths per 100,000 and has since decreased to 60 per 100,000. In women, the incidence reached a plateau in 1998 at 53 per 100,000. These changes are in part caused by alterations in smoking patterns. Despite the trend of decreased smoking rates in industrialized countries, lung cancer remains the leading cause of cancer death in both men and women in the United States ([American Cancer Society, 2016](#)). Lung cancer is also the leading cause of cancer death worldwide.

### Risk Factors

A number of environmental factors are causally related to the development of lung cancer. In contrast, no simple genetic association has been identified. The single most important risk factor, smoking, accounts for approximately 85% of all lung cancers. Other associated factors include exposure to radon, asbestos, and heavy metals.

### Smoking

Before 1900, lung cancer was considered a relatively unusual malignancy. As tobacco smoking became more popular throughout the 20th century, the incidence of lung cancer increased. Worldwide, over 1 billion people smoke, which makes lung cancer an epidemic of global proportions.

The epidemiologic relationship between tobacco smoke and lung cancer was demonstrated in the 1950s. Both amount and duration of smoking appear to increase the risk of developing lung cancer ([Bartecchi et al., 1994](#); [MacKenzie et al., 1994](#); [Hecht, 1999](#)). People who smoke one to nine cigarettes daily, or have smoked for more than 15 years, have a 4-fold increase in the risk of lung cancer. Smoking

>20 cigarettes daily or for >40 years further raises the risk by between 15-fold and 20-fold over nonsmokers. This results in a cumulative lifetime risk for smokers of up to 30% ([Samet, 1991](#)). Second-hand household smoke, which is associated with a reduced intensity but earlier and chronic exposure to tobacco smoke, appears to double the risk of developing lung cancer. The effect of workplace and other second-hand smoke is also beginning to be appreciated ([U.S. Department of Health and Human Services, 2006](#)).

Smoking cessation is the single most effective way to reduce mortality from lung cancer. After quitting, the risk of developing lung cancer appears to transiently rise in epidemiologic studies, possibly from the subsequent diagnosis in people who quit due to preexisting symptoms of cancer. However, the risk of lung cancer starts to fall 5 years after quitting. After 10 years, it is only 4-fold above never-smokers, and at 25 years it is less than 2-fold above never-smokers ([Samet, 1991](#)). Therefore physicians who assist their patients with smoking cessation can make a tremendous impact in reducing morbidity and mortality from lung cancer as well as other tobacco-related diseases.

### Radon, Asbestos, and Other Exposures

Radon is a colorless, odorless, radioactive gas resulting from the decay of radioactive metals in the soil. It can accumulate in poorly ventilated homes in certain geographic areas. Radon exposure appears to result in significant risk of developing lung cancer in miners and a small but linear risk of lung cancer in others. An analysis of multiple case-control studies suggests that 10% or more of lung cancers in both smokers and nonsmokers may be attributable to radon exposure in the home ([Darby et al., 2005](#)).

Asbestos is the term for a group of naturally occurring silicate fibers whose heat-resisting properties made them historically useful in construction and industrial applications. Asbestos fiber exposure has been strongly correlated with mesothelioma risk. However, exposed workers have a higher overall chance of developing adenocarcinoma of the lung than mesothelioma. Unlike the relationship between smoking and lung cancer, the risk of mesothelioma following asbestos exposure increases with time even after exposure has stopped, peaking at around 20 to 40 years ([Berry and Gibbs, 2008](#)).

Lung cancer has also been associated with exposure to wood smoke, previous chest radiotherapy, and a number of metals including arsenic, chromium, nickel, beryllium, and cadmium. However, the total fraction of lung cancers attributable to these factors is likely small.

### Never-Smokers

It is estimated that there are approximately 25,000 deaths each year in the United States from lung cancer in never-smokers, which as a separate entity would be the seventh leading cause of cancer mortality (Samet et al., 2009). Indeed, 10% to 20% of all lung cancers are not attributable to tobacco or other environmental exposures. It is unclear whether the incidence of lung cancer in never-smokers is increasing or has remained at a previously undetected baseline level. In the first half of the 1900s before smoking became widespread, it is likely that lung cancer diagnoses were overlooked or even misattributed to tuberculosis. Also, it appears that some populations are more susceptible to develop lung cancer in the absence of smoking, such as women more than men, and African Americans and Asians more than Caucasians, and potential susceptibility loci have been identified (Lan et al., 2012). While risk factors for developing lung cancer in never-smokers include second-hand smoke, radon, air pollution, occupational exposures, and genetic susceptibility, the majority of patients have no directly attributable causative factor. The biology of lung cancer in never-smokers is distinct from smoking-associated lung cancer. NSCLC adenocarcinoma is the most common histology, and in comparison to lung cancer in smokers appears less complex with a higher likelihood to have targetable driver mutations (see Molecular Changes in Non-small Cell Lung Cancer).

## Clinical Detection of Lung Cancer

### Symptoms

In a patient population that smokes heavily, the respiratory symptoms of lung cancer often mimic the effects of chronic tobacco use. Many patients present with cough, worsening dyspnea, or hemoptysis, which can also be symptoms of bronchitis or pneumonia. Symptoms such as weight loss, chest pain, bone pain, hoarseness, or neurologic symptoms should prompt a more extensive workup but often correspond to invasive or metastatic disease.

### Paraneoplastic Syndromes

Paraneoplastic syndromes more commonly manifest in patients with SCLC, but they can be seen in either type of lung cancer.

### Hematologic Abnormalities

Leukocytosis has been observed in up to 15% of patients with NSCLC and may be caused by tumor secretion of granulocyte colony-stimulating factor. This can result in

white blood cell counts over three times the upper limit of normal with a marked left shift, known as a *leukemoid reaction*.

Anemia may be observed in up to 40% of patients presenting with NSCLC, and thrombocytosis in up to 15%.

### Syndrome of Inappropriate Antidiuretic Hormone Secretion

Up to 10% of SCLC may secrete antidiuretic hormone, resulting in profound hyponatremia in the setting of euvolemia. This syndrome responds to treatment of underlying malignancy within a few weeks, but patients can be managed in the interim with free water restriction, drugs that promote free water excretion such as demeclocycline, and vasopressor receptor antagonists such as tolvaptan or conivaptan. Rapid correction must be avoided because it can lead to central pontine myelinolysis.

### Hypercalcemia

Hypercalcemia in malignancy may result from direct bone invasion or secretion of osteoclast-activating factors. In particular, high levels of parathyroid hormone-related peptide may cause hypercalcemia and are more often associated with NSCLC of squamous histology. Clinical manifestations can include polydipsia, nephrolithiasis, renal failure, nausea, and constipation, and in severe cases, confusion or even coma. Treatment should include intravenous (IV) hydration, bisphosphonates, and/or calcitonin.

### Cushing Syndrome

Excess production of adrenocorticotropic hormone by tumor tissue can lead to Cushing syndrome: truncal obesity, hypertension, hyperglycemia, hypokalemic alkalosis, and osteoporosis. Most often seen in patients with SCLC, cortisol excess correlates with a poor prognosis.

### Pancoast Syndrome

Lung tumors that arise in the superior sulcus of either lung can cause damage to the brachial plexus and the sympathetic ganglia. This results in a syndrome of shoulder/arm pain, ipsilateral Horner syndrome, bone destruction, and atrophy of the hand muscles. Typically, superior sulcus tumors arise from NSCLC of squamous histology.

### Thrombosis

All patients with cancer are predisposed to develop disorders of hypercoagulability, including deep vein thrombosis and pulmonary embolism. Patients who develop spontaneous clots without a clear predisposing factor should undergo screening for malignancy and be treated with low-molecular-weight heparin instead of warfarin (Lee et al., 2003).

### Hypertrophic Pulmonary Osteoarthropathy

Hypertrophic pulmonary osteoarthropathy is most often associated with NSCLC. Clinical manifestations include clubbing of the fingers, periostitis of long bones, and

arthritis. Skin thickening can also be observed. In addition to treatment of the underlying malignancy, symptomatic treatment can include nonsteroidal antiinflammatory drugs and bisphosphonates.

### Lambert-Eaton Syndrome

Lambert-Eaton syndrome (LES) is an unusual paraneoplastic syndrome more likely associated with SCLC but can also be seen in NSCLC. It is manifested as proximal muscle weakness, reduced tendon reflexes, and autonomic changes. The presentation is similar to myasthenia gravis, but a key distinguishing feature for LES is that the muscle strength improves with repeated activity.

### Diagnosis

A nodule on a chest x-ray (CXR) or CT scan often leads to the diagnosis of lung cancer. A CT scan of the chest with IV contrast gives an overview of the extent parenchymal disease and regional nodal involvement and can also demonstrate metastatic disease to the bones, liver, or adrenal glands. Positron emission tomography (PET) scans and combined PET/CT scans are used to further evaluate the extent of regional or metastatic disease. With the exception of small NSCLC <1 cm in diameter, most patients with lung cancer should have brain imaging at the time of staging with a brain MRI, but a head CT scan with contrast can be done if an MRI is contraindicated.

Establishing the diagnosis of NSCLC involves obtaining tissue for histopathologic analysis. In general, the initial diagnosis should be made via the least invasive means to obtain the highest pathologic stage. Therefore patients with a potential metastasis should have that site biopsied for staging. Patients with possible mediastinal lymph node involvement can undergo diagnostic mediastinoscopy. CT-guided fine-needle biopsy of the lung is often used to establish the diagnosis but does carry a risk of pneumothorax and severe pulmonary hemorrhage. Bronchoscopy, increasingly in combination with endobronchial ultrasound, is most useful for proximal tumors and can yield information about a primary tumor and lymph node staging. Although the diagnosis can be made from fine-needle aspiration alone, advanced molecular testing requires more tissue in the form of a nondecalified core biopsy or surgical sample.

### Screening

Owing to the high mortality associated with advanced lung cancer, as well as the strong association with smoking, there are a number of trials that have attempted to screen for lung cancer. Although radiologic imaging can detect malignant lung nodules, these tumors tend to be less aggressive than lung cancers detected by clinical criteria.

Four large early randomized trials, together including >30,000 patients, have been conducted using various combinations of CXR and sputum cytology. However, none of these compares screening with a completely unscreened

group of patients. Instead, they have tested the effect of adding sputum cytology to CXR screening, or testing annually versus more-frequent CXR screening. These studies generally demonstrate an increased detection of early-stage lung cancer but no difference in survival. The Mayo Lung Project, which randomized almost 11,000 male smokers to sputum cytology plus CXR every 4 months versus usual care with an annual CXR, demonstrated significantly more lung cancer-related deaths in the screened group at 20-year follow-up (Marcus et al., 2000). The Prostate, Lung, Colorectal, and Ovarian (PLCO) clinical trial randomized over 150,000 patients, of any smoking status, to screening with a CXR at baseline and annually up to 3 years versus no screening. There was no significant difference in lung cancer incidence rates or mortality rates (Oken et al., 2011).

The lack of positive results using CXR screening led to an increased interest in screening with modern CT scanning techniques. Observational cohort studies demonstrate that CT scanning can identify more early-stage lung cancers than CXR, but CT scans also lead to more false-positive scans resulting in biopsy. These also tend to identify very early-stage tumors that may have a more favorable natural history than tumors identified clinically. In the National Lung Screening Trial, over 50,000 smokers (who smoked 1 pack per day for 30 years or more and continue to smoke or quit within the last 15 years), aged 55 to 74 years, without symptoms, were randomized to undergo either annual CXR or low-dose CT screening exams for 3 years (Aberle et al., 2011). There was a 20% relative reduction in lung cancer specific mortality and a 6.7% relative reduction in all-cause mortality with CT screening as compared with CXR. Based on these results, centers are beginning to offer low-dose CT screenings for lung cancer. The US Preventive Services Task Force updated guidelines in December 2013 based on grade B evidence to recommend “annual screening for lung cancer with low-dose computed tomography in adults aged 55 to 80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years; screening should be discontinued once a person has not smoked for 15 years or develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery” (<http://www.uspreventiveservicestaskforce.org/>).

## Nonsmall Cell Lung Cancer

### Pathology

#### Histology

NSCLC accounts for approximately 86% of primary lung tumors. The diagnosis includes a variety of morphologic subtypes that fall primarily into the categories of adenocarcinoma and squamous cell carcinoma (Box 11.1). Historically, the histologic subtype has not influenced treatment decisions. However, there is increasing recognition that many therapies are particularly active in specific histologic subtypes.

### • BOX 11.1 Selected Nonsmall Cell Lung Cancer Histologic Subtypes

- I. Squamous cell carcinoma  
Variants: papillary, clear cell, small cell, basaloid
- II. Adenocarcinoma
  - Preinvasive lesions
    - Atypical adenomatous hyperplasia
    - Adenocarcinoma in situ ( $\leq 3$  cm) (formerly BAC)
      - Nonmucinous
      - Mucinous
      - Mixed mucinous/nonmucinous
  - Minimally invasive adenocarcinoma ( $\leq 3$  cm lepidic predominant tumor with  $\leq 5$  mm invasion)
    - Nonmucinous
    - Mucinous
    - Mixed mucinous/nonmucinous
  - Invasive adenocarcinoma
    - Lepidic predominant (formerly nonmucinous BAC pattern, with  $>5$  mm invasion)
      - Acinar predominant
      - Papillary predominant
      - Micropapillary predominant
      - Solid predominant with mucin production
  - Variants of invasive adenocarcinoma
    - Invasive mucinous adenocarcinoma (formerly mucinous BAC)
      - Colloid
      - Fetal (low and high grade)
      - Enteric
- III. Large cell carcinoma  
Variants: large cell neuroendocrine carcinoma, combined large cell neuroendocrine carcinoma, basaloid carcinoma, lymphoepithelioma-like carcinoma, clear cell carcinoma, large cell carcinoma with rhabdoid phenotype
- IV. Adenosquamous carcinoma
- V. Carcinomas with pleomorphic, sarcomatoid, or sarcomatous elements
- VI. Unclassified carcinoma (i.e., poorly differentiated)

BAC, Bronchioloalveolar carcinoma.

### Molecular Changes in Nonsmall Cell Lung Cancer

Clinically, evident lung cancers have many thousands of individual genomic abnormalities and are among the most highly mutated of many cancer types with 10 or more somatic mutations per megabase of DNA (Alexandrov et al., 2013). Among these are dominant driver oncogenes that are fundamentally

required for tumor growth, including *EGFR*, *KRAS*, *ALK*, *ROS1*, *RET*, *HER2*, *BRAF*, and *MET*. Some of these are gain-of-function mutations, and others are chromosomal rearrangements leading to activation of the resulting protein. In addition, there are alterations in many more tumor suppressors and passenger mutations that are of varying clinical significance.

Mutations in the tyrosine kinase domain of *EGFR* are seen in 10% to 15% of NSCLC in the United States and in 40% to 50% of lung cancers in Asian countries. They are more prevalent in never-smokers, women, and people of Asian descent, and they are virtually always associated with adenocarcinoma histology. These mutations cause constitutive activation of the *EGFR* signaling pathway, which drives tumor proliferation and prevents apoptosis. The small-molecule tyrosine kinase inhibitors (TKIs) gefitinib, erlotinib, and afatinib potently inhibit many mutant forms of *EGFR*, resulting in profound responses in patients with exon 19 deletions or the L858R point mutation (Sequist and Lynch, 2008).

### Staging of Nonsmall Cell Lung Cancer

Lung cancer is currently staged using the American Joint Committee on Cancer, seventh edition, staging system (Table 11.1). In the workup of patients with suspected lung cancer, the extent of the workup is determined by the patient's presentation, performance status, and treatment preferences. The goal of the staging is to determine the extent of disease. If metastatic disease is confirmed, curative treatment is generally not possible.

Owing to the high frequency of metastatic disease (25%–30% of patients with lung cancer), even those with small tumors, most patients with suspected lung cancer should have the following workup: chest CT with IV contrast (often used during diagnosis); PET with CT localization; head MRI with contrast (or head CT with contrast if MRI is contraindicated); pulmonary function testing (for possible operative candidates); and laboratory workup to rule out hematologic, electrolyte, renal, or hepatic abnormalities.

Many patients who are considered surgical candidates have historically undergone mediastinoscopy to rule out the possibility of mediastinal nodal involvement. PET scanning and coregistered PET/CT scanning helps to identify the extent of lymph node involvement or can identify metastatic disease, which helps patients avoid unnecessary surgery. A combined PET/CT scan that demonstrates neither enlarged mediastinal lymph nodes nor PET activity in the mediastinum has only a 5% false-negative rate (Pieterman et al., 2000).

### Treatment

#### Stage I–II Nonsmall Cell Lung Cancer

Even early-stage NSCLC has only a 50% to 70% 5-year survival (see Box 11.1). Therefore an aggressive and often combined-modality approach to treatment is essential to maximize the chance of cure.

Initial treatment for stage I (small tumor without lymph node involvement) and stage II (larger and more invasive

**TABLE 11.1** Seventh Edition Nonsmall Cell Lung Cancer Staging

Stage	Tumor	Nodes	Met	Median Survival Time (Months)*	5-Year Survival <sup>a</sup>
Stage IA	T1a,b	N0	M0	60–119	50%–73%
Stage IB	T2a	N0	M0	43–81	43%–58%
Stage IIA	T1a,b	N1	M0	34–49	36%–46%
	T2a	N1	M0		
	T2b	N0	M0		
Stage IIB	T2b	N1	M0	18–31	25%–36%
	T3	N0	M0		
Stage IIIA	T1, T2	N2	M0	14–22	19%–24%
	T3	N1, N2	M0		
	T4	N0, N1	M0		
Stage IIIB	T4	N2	M0	10–13	7%–9%
	Any T	N3	M0		
Stage IV	Any T	Any N	M1a,b	8–12	<2%

**Definition of TNM****Primary Tumor (T)**

- TX: Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ
- T1: Tumor ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus). The uncommon superficial spreading tumor of any size is classified as T1 even when extending to the main bronchus, as long as the invasive component is limited to the bronchial wall.
  - T1a: Tumor ≤2 cm in greatest dimension
  - T1b: Tumor >2 cm but ≤3 cm in greatest dimension
  - T2: Tumor >3 cm but ≤7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if ≤5 cm)
    - Involves the main bronchus, ≥2 cm or more distal to the carina
    - Invades the visceral pleura
    - Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
      - T2a: Tumor >3 cm but ≤5 cm in greatest dimension
      - T2b: Tumor >5 cm but ≤7 cm in greatest dimension
    - T3: >7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe
    - A tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
    - T4: Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe

**Regional Lymph Nodes (N)**

- NX: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes including involvement by direct extension of the primary tumor
- N2: Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)
- N3: Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

**Distant Metastasis (M)**

- MX: Distant metastasis cannot be assessed
- M0: No distant metastasis
- M1a: Separate tumor nodule(s) in a contralateral lobe, tumor with pleural nodules or malignant pleural or pericardial effusion
- M1b: Distant metastasis

\*First number in range denotes survival by clinical stage, second number by pathologic stage.

Modified from Goldstraw P, Crowley J, Chansky K, et al. The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the *TNM Classification of Malignant Tumours*. *J Thorac Oncol*. 2007;2(8):706-714.

tumors or hilar lymph node involvement) consists of surgical resection, which can be achieved through several different procedures. The choice of the optimal surgical procedure depends on the extent of primary tumor, nodal involvement, and underlying pulmonary function of the patient. Lobectomy (removal of the entire lobe including hilar nodes) is the procedure of choice for early-stage NSCLC because it has a lower recurrence risk than wedge resection or segmentectomy. Performing lobectomy via video-assisted thoracoscopic surgery (VATS) is gaining acceptance. Pneumonectomy (resection of an entire lung with associated nodes) may be necessary for many large tumors or tumors with proximal airway invasion, but the procedure may result in a higher rate of postoperative complications. For proximal tumors, sleeve resection allows sparing of distal lung tissue via construction of an airway anastomosis.

For patients with impaired pulmonary function, this may be a reasonable option to preserve lung function. Wedge resection (removal of a section of lung without respect to anatomic borders) can result in a higher local failure rate. Segmentectomy (removal of a defined anatomic segment) is likely better than wedge resection when feasible. High-dose radiosurgery (stereotactic body radiotherapy or stereotactic ablative body radiotherapy) involving a few daily fractions of radiation is increasingly being offered to patients with isolated lung tumors who are poor surgical candidates (Chang et al., 2015). Radiotherapy has a high rate of local control (>90%), but because it is often done without surgical lymph node staging and dissection it may have a higher chance of eventual nodal failure.

For large stage IB tumors, and for all stage II tumors, it is estimated that patients have approximately a 5% overall survival benefit in receiving cisplatin-based doublet adjuvant chemotherapy (Pignon et al., 2008). For small stage I tumors, there is no evidence of benefit from adjuvant chemotherapy, so current practice guidelines recommend close monitoring of these patients after resection. There is no established role for routine adjuvant radiation therapy in completely resected NSCLC in the absence of positive margins.

### Stage III Nonsmall Cell Lung Cancer

Stage III NSCLC encompasses a heterogeneous spectrum of disease, ranging from large superior sulcus tumors without lymphadenopathy and a 5-year survival rate of 40% to tumors with extensive mediastinal nodal involvement and a 5-year survival <5% (see Box 11.1).

The treatment strategy for stage III NSCLC involves a combination of chemotherapy, radiation, and sometimes surgical resection. Stage IIIB disease is generally considered surgically unresectable and is treated with concurrent chemotherapy and high-dose radiation with curative intent (definitive treatment). Sometimes additional cycles of chemotherapy are given, either before or after chemoradiation.

The treatment of stage IIIA disease is less standardized and often includes surgery. One treatment strategy uses neoadjuvant concurrent chemotherapy with limited doses

of radiation, followed by surgical resection, then chemotherapy. Patients may also have initial surgical resection followed by chemotherapy, or preoperative chemotherapy followed by surgery, with radiation depending on the operative results.

### Stage IV Nonsmall Cell Lung Cancer

Stage IV NSCLC has a median survival of 8 to 12 months (see Box 11.1), and these patients are generally not considered curable. However, rare patients with oligometastatic disease, consisting of a single resectable lung primary and a solitary brain or adrenal metastasis, may have up to a 10% 5-year survival following definitive treatment of both sites of disease. For stage IV NSCLC, the goals of treatment are to prolong survival while minimizing side effects and morbidity. Radiation is often used for control of symptomatic lesions, and palliative care is a paramount part of the treatment of metastatic NSCLC.

Systemic chemotherapy is the cornerstone of the treatment of stage IV NSCLC of patients with good performance status—that is, those who are minimally symptomatic from their disease and out of bed most of the time. Standard first-line chemotherapy consists of platinum-based doublet chemotherapy. Most platinum-based doublets (carboplatin or cisplatin, in combination with paclitaxel, docetaxel, gemcitabine, vinorelbine, or pemetrexed) have roughly equivalent impacts on survival. In a large trial comparing four different platinum-based chemotherapy doublets, all regimens appeared equivalent regarding response and survival (Schiller et al., 2002).

Treatment with platinum-based doublets continues for four to six total cycles of therapy. Following treatment, patients who respond are monitored with periodic CT scans and symptom screening for signs of disease recurrence, but mounting evidence may suggest a role for early second-line or maintenance therapy with nonplatinum-based chemotherapy.

A number of novel agents have been combined with chemotherapy for advanced disease, but most have failed to improve outcome. Bevacizumab, an antiangiogenic monoclonal antibody against vascular endothelial growth factor, was the first targeted agent to improve median survival in NSCLC to over 1 year when administered in combination with chemotherapy in a large clinical trial (Sandler et al., 2006); however, patients with squamous cell histology, untreated brain metastasis, recent surgical procedures, and necrotic tumors are at higher risk for bleeding complications from this agent. Ramucirumab, an anti-VEGFR2 antibody, improves outcomes when combined with second-line docetaxel. Necitumumab, a monoclonal antibody to EGFR, also appears to provide modest benefit in squamous NSCLC when combined with first-line chemotherapy.

Testing for driver mutations is now recommended in select patients with NSCLC because of the availability and effectiveness of targeted therapies in reducing tumor burden, reducing symptoms, and improving survival (Kris et al., 2014).

The presence of EGFR mutations in the tumor predicts response to small molecule EGFR TKIs. Gefitinib, erlotinib,

and afatinib are all now US Food and Drug Administration (FDA)-approved first-line treatments for EGFR mutant NSCLC based on randomized trials showing superior outcome compared with chemotherapy (Mok et al., 2009; Rosell et al., 2012; Sequist et al., 2013). Unfortunately, most patients eventually develop resistance to these TKIs. The most common mechanism of acquired resistance is a secondary T790M point mutation, which alters EGFR TKI binding. The small molecule EGFR TKI, osimertinib, was FDA-approved based on its activity in EGFR mutant NSCLC with a T790M mutation (Jänne et al., 2015).

The *EML4-ALK* genetic rearrangement has also been identified as a driver oncogene in about 4% of NSCLC adenocarcinomas. The small molecules crizotinib, ceritinib, alectinib, and brigatinib have all been recently FDA-approved for activity in the treatment of ALK-positive NSCLC (Shaw et al., 2013; Solomon et al., 2014; Kim et al., 2017). While initially approved for refractory patients, ceritinib, alectinib, and brigatinib have an emerging role in first-line treatments.

The *ROS1* gene rearrangement is present in about 1% to 2% of NSCLC. NSCLC tumors harboring this genomic alteration also respond to crizotinib, which was recently approved for this small subgroup of patients. There is emerging evidence of targeted therapy efficacy in patients with NSCLC harboring other driver alterations including *BRAF* V600E, *HER2* exon 20 insertion mutations, *MET* gene amplification, *MET* exon 14 skipping mutations, and *RET* gene rearrangements. *KRAS* mutations, although the most common driver mutation, have also presented the most challenges to target directly; however, approaches including targeting downstream pathways such as *MEK* are being pursued.

In addition to chemotherapy and targeted therapy, immunotherapy with checkpoint inhibitors has remarkable efficacy in lung cancer treatments. Programmed cell death protein 1 (PD-1) is a checkpoint protein T cell that prevents T-cell activation by attaching to ligand PD-L1, a protein that can be found on some normal and cancer cells. Certain cancer cells overexpress PD-L1, thus facilitating immune evasion. Monoclonal antibodies that target either PD-1 or PD-L1 can potentially boost the immune response against cancer cells. Two such PD-1 inhibitors have been FDA-approved for NSCLC. Currently, these drugs are approved in the second-line treatment of NSCLC, following platinum failure, but are being studied in the first-line setting both alone and in combination with other treatments. Nivolumab was approved based on two randomized trials versus docetaxel, which showed overall survival benefit in both squamous and nonsquamous NSCLC (Brahmer et al., 2015; Borghaei et al., 2015). Pembrolizumab was initially approved on the expansion cohort of a phase 1 trial in multiple cancer types, and activity was confirmed in a randomized trial against docetaxel (Herbst et al., 2016). Notably, pembrolizumab has been approved for patients with metastatic NSCLC whose disease has progressed after platinum-based chemotherapy if their tumors are positive for PD-L1 expression by an FDA-approved

immunohistochemical assay. Nivolumab is approved for use regardless of PD-L1 expression, but response rates are higher for positive tumors. The indications for these PD-1 inhibitors are expanding. Moreover, the PD-L1 inhibitor atezolizumab has also been recently approved.

At the time of disease progression, subsequent treatment can consist of single-agent nonplatinum chemotherapy, clinical trials, or supportive care. The expected clinical benefit from chemotherapy is lower with each successive round of chemotherapy.

## Small Cell Lung Cancer

### Pathology of Small Cell Lung Cancer

SCLC is a high-grade neuroendocrine tumor arising from the lungs. Development of SCLC is strongly associated with smoking and can be distinguished from NSCLC due to the small cell size as well as expression of the neuroendocrine immunohistochemical markers chromogranin A and synaptophysin. Low and intermediate grade neuroendocrine tumors can also arise from the lung (also known as *carcinoid tumors*), but the management of these is unique because of their slower growth rates and relative resistance to chemotherapy and radiotherapy.

### Diagnosis and Staging of Small Cell Lung Cancer

Staging of SCLC uses CT scans of the chest, abdomen, and pelvis; cranial imaging; and bone scan or PET scan. Staging is broken into two categories: limited stage and extensive stage. Limited-stage disease fits within a single radiation field (one side of the chest including associated lymph nodes), whereas extensive-stage disease is more widespread and often involves metastases to the lungs, liver, adrenal glands, bones, or brain. SCLC is frequently associated with paraneoplastic syndromes such as syndrome of inappropriate antidiuretic hormone secretion and Cushing syndrome (see earlier discussion).

### Treatment

#### Limited-Stage Small Cell Lung Cancer

The standard of care for treatment of limited-stage SCLC involves concurrent radiotherapy and concurrent full-dose chemotherapy with cisplatin and etoposide, followed by chemotherapy alone. This treatment can result in a response rate of over 80% and median survival of 14 to 20 months. At 5 years, 15% to 20% of patients may still be alive without disease. Surgery has not been shown to improve survival in patients with SCLC, and even small localized tumors have a high likelihood of recurrence after surgical resection.

Following chemotherapy and radiation, patients with controlled disease should undergo prophylactic cranial irradiation, which has been shown to improve overall survival.

### Extensive-Stage Small Cell Lung Cancer

Extensive-stage SCLC is incurable, with a median survival between 9 and 11 months. Similar to stage IV NSCLC, it is initially treated with platinum-based doublet chemotherapy, but the expected response rate is much higher at 70% to 80%. Patients who respond to initial therapy also have a survival benefit from prophylactic cranial irradiation. Second-line therapy is more successful in patients

with a disease-free interval longer than 3 months after initial therapy (relapsed disease) than patients with a disease-free interval of <3 months (refractory disease) and generally consists of single-agent chemotherapy. Targeted therapies have not been shown to be effective in SCLC, although anti-PD1 immunotherapies may have some efficacy. Supportive care also plays an essential role in the management of SCLC.

## Chapter Review

### Questions

1. A 60-year-old man with a 50-pack-year history of smoking, who still smokes 1 pack per day, presents to the clinic. He is currently asymptomatic. What is your recommendation for his care?
  - A. Provide smoking cessation management only.
  - B. Provide smoking cessation management and discuss that there is insufficient evidence to recommend chest CT, CXR, sputum cytology, or a combination of these tests.
  - C. Provide smoking cessation management and initiate a discussion regarding recent data suggesting a survival benefit using low-dose screening chest CT for lung cancer.
  - D. Provide smoking cessation management and recommend screening CXR plus sputum cytology.
2. A 45-year-old woman who has never smoked develops a cough. Three weeks after antibiotic treatment, the cough persists. CXR demonstrates a 4-cm mass in the left lung. Chest CT scan confirms a mass in the left upper lobe and demonstrates a 2-cm left adrenal mass and numerous hypodense 1- to 2-cm lesions in the liver. Brain MRI shows no abnormalities. What is the best way to establish a diagnosis?
  - A. Bronchoscopy to evaluate for endobronchial lesions
  - B. VATS and mediastinoscopy to evaluate extent of disease
  - C. Biopsy of the primary lung mass via CT-guided needle biopsy
  - D. Biopsy of the adrenal gland or the liver nodules via CT-guided or ultrasound-guided needle biopsy
3. Biopsy of the patient in question 2 reveals that she has metastatic adenocarcinoma consistent with NSCLC. Molecular testing of her initial core biopsy demonstrates an exon 19 deletion mutation in the *EGFR* gene. Her functional status is excellent. Which first-line treatment option offers the highest likelihood of a response and the longest duration of response?
  - A. Anti-EGFR small molecule targeted therapy (gefitinib, erlotinib, or afatinib)
  - B. Platinum-based doublet chemotherapy
  - C. Single-agent chemotherapy with pemetrexed or docetaxel
  - D. Best supportive care
4. A 65-year-old male with heavy smoking history and metastatic squamous cell lung cancer has recently progressed after first-line doublet chemotherapy with carboplatin and gemcitabine. He continues to have excellent performance status and is interested in more cancer-directed therapy. Which one of the following has the highest overall survival benefit as second-line treatment?
  - A. Anti-EGFR small molecule targeted therapy (i.e., erlotinib, afatinib)
  - B. Anti-PD1 immunotherapy (nivolumab, pembrolizumab)
  - C. Single-agent chemotherapy (docetaxel)
  - D. Best supportive care

### Answers

1. C
2. D
3. A
4. B

# 12

## Gastrointestinal Cancers

ANUJ K. PATEL AND JEFFREY A. MEYERHARDT

**G**astrointestinal cancers are the most common group of cancers in the United States. Nationwide, an estimated 300,000 new cases of gastrointestinal cancers are diagnosed annually, and over 150,000 deaths are attributable to gastrointestinal malignancies (Table 12.1). Globally, gastrointestinal cancers will account for an estimated 6 million new cases and 2.5 million deaths per year. The most common gastrointestinal cancers in the United States are esophageal, gastric, pancreatic, liver, and colorectal, and these are the focus of this review.

### Esophageal Cancer

Esophageal cancer is diagnosed in approximately 17,000 individuals in the United States annually, leading to nearly 16,000 deaths. There are two major histology types, squamous cell carcinoma and adenocarcinoma—although, rarely, melanomas, carcinoids, lymphomas, and sarcomas can arise from the esophagus. Squamous cell carcinomas develop in the upper third and middle third of the esophagus; adenocarcinomas primarily develop in the lower third of the esophagus. Squamous cell carcinomas have relatively decreased in incidence over time. Adenocarcinomas, particularly those at the gastroesophageal junction, have increased in the past several decades. This shift in incidence of each histology reflects changes in the likelihood of exposure to associated risk factors.

### Risk Factors for Esophageal Cancer

The primary risk factors for squamous cell carcinomas are tobacco and alcohol use (Table 12.2). Risk is correlated with duration of smoking and number of cigarettes. Cessation of smoking will decrease one's risk of esophageal squamous cell carcinoma, particularly after 10 years. There is a synergistic effect of tobacco and alcohol exposure leading to chronic irritation and inflammation of the esophageal mucosa. Because these factors are also strongly associated with risk of head and neck cancers, a prior history of these cancers is associated with increased risk of squamous cell carcinoma of the esophagus; about 2% of patients with newly diagnosed head and neck cancer will have a synchronous esophageal cancer.

Other conditions that lead to irritation of the esophageal mucosa and increase the risk of squamous cell carcinoma are achalasia, caustic injury to the esophagus, and esophageal diverticula. Rare conditions that carry a very high risk of squamous cell carcinoma are nonepidermolytic palmoplantar keratoderma (tylosis), a rare autosomal dominant disorder characterized by hyperkeratosis of the palms and soles and thickening of the oral mucosa, and Plummer-Vinson syndrome, a nutritional deficiency characterized by dysphagia, iron-deficiency anemia, and esophageal webs.

Adenocarcinomas of the esophagus principally develop in the setting of Barrett esophagitis (see Table 12.2). Risk factors associated with Barrett esophagitis, including gastroesophageal reflux disease (GERD) and obesity, are thus associated with lower-esophageal cancers. Approximately one in seven Americans has GERD. Reflux can cause the normal squamous epithelium of the esophagus to develop metaplasia. Approximately 5% to 8% of those with GERD will develop metaplasia (Barrett esophagitis) of the esophagus. Of those with metaplasia, 4% per year will evolve into low-grade dysplasia, and 1% per year will evolve into high-grade dysplasia. Once patients have high-grade dysplasia, the rate of development of adenocarcinoma is 5% per year. Overall, the risk of esophageal adenocarcinoma is 0.5% per year for patients with metaplasia and 0.05% for those with GERD. Most guidelines recommend endoscopic screening for certain patients with GERD and surveillance for certain patients with Barrett esophagitis, although this remains controversial. The optimal management for both low-grade and high-grade dysplasia is also uncertain. Additional risk factors for adenocarcinoma of the esophagus are tobacco smoking (although smokers have a relatively higher risk of squamous cell histology) and prior radiation exposure to the esophagus, principally related to treatment of breast cancer. As opposed to squamous cell carcinoma, smokers who quit do not lower their associated risk of adenocarcinoma even decades after cessation.

### Clinical Presentation and Management of Esophageal Cancer

Patients with esophageal cancer most commonly present with symptoms of difficulty swallowing (dysphagia) and, less commonly, pain with swallowing (odynophagia).

**TABLE 12.1** Estimated Incidence and Mortality Associated With Gastrointestinal Malignancies in the United States in 2016

Disease	New Cases	Deaths
Esophageal	16,910	15,690
Stomach	26,370	10,730
Small bowel	10,090	1,330
Colorectal	134,490	49,190
Anal	8,080	10,80
Liver and intrahepatic bile duct	39,230	27,170
Gallbladder and other biliary	11,420	3,710
Pancreatic	53,070	41,780
Other digestive organs	5,270	2,350

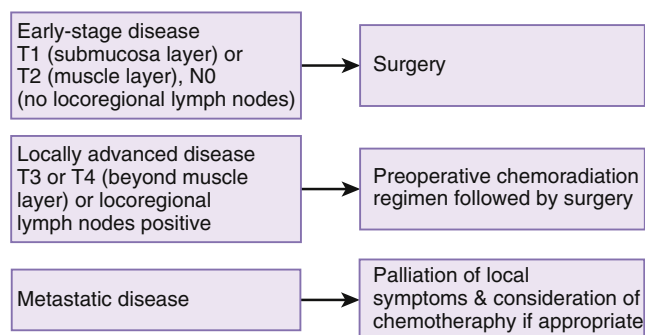

From Siegel RL, Miller KD, Jemal A. Cancer statistics, 2016. *CA Cancer J Clin*. 2016;66:7-30.

**TABLE 12.2** Risk Factors for Esophageal Cancer

Squamous Cell Histology	Adenocarcinoma Histology
Tobacco usage	Barrett esophagitis
Alcohol usage	Gastroesophageal reflux
Prior history of head and neck cancer	Obesity
Caustic injury to esophagus	Tobacco usage
Achalasia	Prior radiation for breast cancer
Tylosis (diffuse nonepidermolytic palmoplantar keratoderma or Howell-Evans syndrome)	
Plummer-Vinson syndrome	
Prior radiation for breast cancer	

Initially, patients will have dysphagia to certain solids, then most solids, and eventually liquids if undiagnosed. They may also present with hematemesis, unexpected weight loss, cough, hoarseness, or symptoms related to areas of metastases.

Treatment and prognosis of esophageal cancer are strongly associated with the stage of disease at diagnosis. For the most part, squamous cell carcinomas and adenocarcinomas have a similar workup and treatment strategy (Fig. 12.1). Patients who are diagnosed with esophageal cancer by upper endoscopy should undergo staging workup. CT of the chest, abdomen, and pelvis is standard to assess for metastases. The most common sites of metastases are liver, lung, lymph nodes, and bone. Brain imaging is warranted only if the patient has neurologic symptoms. Up to 50% of patients will have metastatic disease at presentation, and initial scanning will diagnose most such cases. For patients without evidence of metastatic disease, further workup for resectability is warranted. Patients should undergo an endoscopic ultrasound to determine the extent of invasion of the tumor through the wall of the esophagus and whether or not any localized lymph nodes are involved. In addition, positron emission tomography (PET) scans have been shown to be beneficial when evaluating for resectability, because they are better able to detect distant metastatic disease and to evaluate suspicious

• **Fig. 12.1** Treatment algorithm for esophageal cancer.

regional or distant lymph nodes that may have been detected on CT scans or endoscopic ultrasound. For patients with tumors in the upper third of the esophagus, bronchoscopy is recommended to rule out a fistula between the esophagus and trachea.

For patients with disease that does not extend beyond the muscle layer of the esophageal wall and that is without evidence of lymph node involvement, immediate surgery is recommended. For those with disease that extends beyond the muscle layer or with locoregional lymph nodes, neoadjuvant therapy with chemotherapy and radiation should be considered before surgery. Chemoradiation

therapy is given over 5 to 6 weeks with daily radiation and various acceptable combinations of chemotherapy agents. The data for neoadjuvant therapy are mixed, with multiple trials demonstrating a survival benefit but a few trials not. Multiple metaanalyses also suggest a benefit to chemoradiotherapy before surgery. Most thoracic surgeons, medical oncologists, and radiation oncologists favor such an approach for locally advanced disease before surgery. Following the completion of neoadjuvant therapy, restaging is recommended, followed by surgery approximately 6 weeks after the last dose of radiation. In contrast, studies for adjuvant chemotherapy or radiation after surgery have not shown a benefit (except for patients with tumors at the gastroesophageal junction, who can be treated similarly to those with gastric cancer).

For patients with localized disease who are not surgical candidates because of concurrent medical conditions, or who refuse surgery, a randomized trial of chemoradiation versus radiation alone demonstrated a survival advantage for combined modality therapy. Furthermore there seems to be a definitive long-term recurrence-free rate (up to 25%) in patients treated with chemoradiation alone.

Patients with metastatic disease should be considered for palliative therapy. Chemotherapy can palliate symptoms related to swallowing and can prolong overall survival. There is no single optimal first-line chemotherapy regimen, although in general, patients are offered combination regimens that include a platinum agent. As in gastric cancer, trastuzumab should be added to first-line chemotherapy regimens for patients with human epidermal growth factor-2 (HER2)-positive metastatic esophageal adenocarcinoma. Other options for relief of dysphagia in patients with metastatic disease include radiation (either alone or with chemotherapy) or endoscopically placed esophageal stenting.

The prognosis of patients with esophageal cancer is stage dependent. Patients diagnosed with disease limited to the submucosal layer of the esophageal wall and no lymph node involvement experience a 50% to 80% 5-year survival. If the disease is more extensive within the wall but not involving lymph nodes, 5-year survival is 30% to 40%. Patients with nonmetastatic disease but positive locoregional lymph nodes have a 10% to 30% 5-year survival. Patients with involvement beyond locoregional lymph nodes or with distant metastases have a 5-year survival of <5%. The median survival with metastatic esophageal cancer treated with palliative chemotherapy is 8 to 10 months.

## Gastric Cancer

An estimated 26,000 new cases of gastric cancer and 11,000 related deaths occur in the United States annually. The incidence of gastric cancer in the United States has markedly decreased over decades, likely related to near elimination of certain risk factors for the disease. In 1930 there were 33 new cases of gastric cancer per 100,000 men and 30 new cases per 100,000 women; in 1990 incidence rates dropped to 10 and 5 per 100,000 men and women, respectively. Despite

E-cadherin mutation families

this decline, however, gastric cancer remains the fourth most commonly diagnosed cancer (estimated 934,000 new cases annually) and the second leading cause of cancer-related death (700,000 deaths annually) worldwide.

## Histology Types of Gastric Cancers

The vast majority of tumors in the stomach are adenocarcinomas. Other, markedly less frequent, histologies are lymphomas, carcinoids, leiomyosarcomas, and gastrointestinal stromal tumors. There are two subtypes of gastric adenocarcinomas: an intestinal type, with cohesive neoplastic cells forming gland-like tubular structures, and a diffuse type, in which individual cells infiltrate and thicken the stomach wall. Intestinal-type lesions occur in the distal stomach more often than the diffuse type and are often preceded by a prolonged precancerous phase. Diffuse carcinomas are detected more often in young patients, develop throughout the stomach (particularly the cardia), and are associated with a worse prognosis.

## Risk Factors for Gastric Cancer

Multiple factors have been associated with the risk of developing gastric cancer (Box 12.1). Chronic atrophic gastritis and its associated condition, intestinal metaplasia, can result in reduced gastric acid production and progression to metaplasia, dysplasia, and eventually adenocarcinoma. Infection with *Helicobacter pylori* has been associated with gastric cancer. Prospective studies have demonstrated between a 3-fold and 6-fold increased risk of gastric cancer in patients serologically positive for *H. pylori*. Nonetheless, most patients who are *H. pylori* positive will not develop gastric cancer.

The marked decline in gastric cancer in the United States is presumed to be related to dietary and environmental exposure. The introduction of refrigeration has led to reduced use of salting, smoking, and pickling of food and to improved food preservation—factors that have been associated with atrophic gastritis. Before refrigeration, nitrates and nitrites were used to preserve meat, fish, and vegetables. Foods rich in nitrates, nitrites, and secondary amines can form *N*-nitroso compounds that have been associated with gastric tumors in animal models. Further, anaerobic bacteria, which colonize in areas with atrophic gastritis or intestinal metaplasia, can convert nitrates and nitrites to carcinogenic nitroso compounds.

### Clinical Presentation and Management of Gastric Cancer

Early detection of gastric cancer is difficult because most early-stage lesions do not cause symptoms. In the United States, most patients are diagnosed with locally advanced or metastatic disease. In contrast, screening endoscopy programs are more prevalent in Asia because of higher incidence rates of gastric cancer, leading to more frequent detection of localized disease. The most common symptoms leading to medical attention are unexplained weight loss, abdominal pain, fatigue, nausea, anorexia, dysphagia, early satiety, and melena. Initial evaluation of symptoms suspicious for gastric cancer includes barium swallow and/or upper endoscopy. Once a diagnostic biopsy demonstrates adenocarcinoma, staging with CT is recommended. However, imaging is limited in detecting peritoneal metastases, which can be present in up to 30% of patients who appear to have localized disease on CT. At the time of surgery, an initial exploratory laparotomy is necessary, and detection of peritoneal disease or distant metastases should lead to either a palliative resection or bypass gastrojejunostomy.

The clinical or pathologic stage is the most important determinant of prognosis and establishes treatment strategy. Patients with metastatic disease should be considered for palliative chemotherapy. Multiple randomized trials have shown that chemotherapy prolongs survival in patients with metastases and maintains or improves quality of life compared with best supportive care only. No single regimen is considered standard. For patients with a good performance status, combination regimens that include a platinum agent are reasonable first-line choices.

Targeting HER2 has demonstrated a survival benefit in some patients with metastatic gastric cancer. HER2 expression within tumors can be evaluated by immunohistochemistry, whereas gene amplification can be evaluated through fluorescence in situ hybridization. HER2 overexpression or amplification can be found in 15% to 25% of gastric cancer patients. In a landmark study, patients with advanced gastric or gastroesophageal junction tumors that were HER2-positive who received chemotherapy plus the HER-2 targeting antibody trastuzumab had increased survival compared with those who received chemotherapy alone.

For the patient with nonmetastatic disease, surgery can be curative. Cancers in the proximal and distal stomach are approached differently surgically, but both have the principle of wide margins and adequate lymph node dissection. The extensiveness of lymph node dissection remains controversial. In general, patients in Asia undergo considerably more extensive removal of lymph nodes (sometimes including splenectomy) than those in the United States and Europe. Randomized trials in Western populations have not demonstrated a survival benefit to removing lymph nodes beyond 3 cm from the tumor. More problematic is increasing evidence that many surgeries in the United States have an inadequate nodal resection, which likely affects outcomes.

Following surgical resection, nonmetastatic patients whose disease extended beyond the muscle layer of the gastric wall or with positive lymph nodes should be considered for adjuvant chemoradiotherapy. A large randomized North American trial demonstrated a survival advantage to a program of chemotherapy and combined chemotherapy and radiation lasting approximately 5 months after surgery. Most trials for adjuvant chemotherapy alone have not demonstrated a statistically significant advantage, although metaanalyses of these trials suggest some modest benefit. Although combined modality adjuvant therapy is considered preferable after surgery, for patients who have a contraindication to radiation (most commonly caused by prior radiation for a different cancer that included some of the stomach field) or who refuse radiation, adjuvant chemotherapy alone may be considered an option.

An alternative approach for nonmetastatic gastric cancer has been validated in Europe. Patients deemed surgically resectable are treated with 3 months of combination preoperative chemotherapy, followed by surgery, followed by further chemotherapy. This schema showed a statistically significant survival advantage over surgery alone. The survival rates from these two approaches (surgery followed by adjuvant chemoradiotherapy vs. perioperative chemotherapy) are not comparable, given differences in timing when defining survival as well as the bias inherent in selecting out patients with peritoneal or other undetected metastases when evaluating for upfront surgery.

Survival is dependent on stage. Five-year survival is 65% to 80% for patients with either T1 N0-1 disease (limited to the submucosa and either no positive lymph nodes or fewer than seven positive nodes) or T2 N0 disease (extension into the muscularis propria but node-negative). Patients with more advanced but nonmetastatic disease have considerably worse outcomes, with 5-year survival ranging from 10% to 40%. Metastatic disease is not considered curable, and median survival with chemotherapy is 8 to 10 months.

### Pancreas Cancer

Pancreas cancer is one of the most fatal cancers because it is rarely detected at an early stage. Although it is the tenth most common cancer in incidence in the United States, it

is the third most common cause of cancer-related deaths (behind lung and colorectal cancers, recently surpassing breast cancer). An estimated 53,000 new cases and 42,000 deaths occur annually in the United States. Despite much research in pancreatic cancer, outcomes have not dramatically changed in the last several decades.

### Risk Factors for Pancreatic Cancer

Pancreatic adenocarcinoma has been associated with various hereditary syndromes (Box 12.2). Hereditary nonpolyposis colorectal cancer (HNPCC) results from mutations of mismatch repair genes and, although most commonly associated with colorectal and gynecologic cancers, is also associated with an increased risk of pancreatic cancer. Inherited mutations of p16 result in familial atypical multiple-mole melanoma syndrome associated with melanomas and pancreatic cancer. Other syndromes in which the risk of pancreatic cancer is increased are BRCA2 hereditary breast–ovarian cancer syndrome, ataxia-telangiectasia, Peutz-Jeghers syndrome, and hereditary pancreatitis.

Diabetics appear to have an increased risk of pancreatic cancer. Initially, the association was primarily reported for recently diagnosed diabetics, which is likely more a reflection of a symptom of pancreatic cancer rather than a cause. However, more recent observational studies have shown that long-time diabetics have a modestly increased risk of pancreatic cancer compared with nondiabetics. Tobacco is the one modifiable risk factor most consistently associated with the development of pancreatic cancer; however, obesity and certain dietary factors may increase the risk as well.

### Clinical Presentation and Management of Pancreatic Cancer

Nearly three-quarters of pancreatic cancers derive from the exocrine pancreas ductal system and are adenocarcinomas. The other histologies are neuroendocrine tumors that arise in the islets of Langerhans, lymphomas, or metastatic disease. Adenocarcinomas most commonly arise in the head of the pancreas (65%) and less commonly are restricted to the body or tail (15%), or they appear diffusely throughout the

#### • BOX 12.2 Risk Factors for Pancreatic Cancer

##### Likely Risk

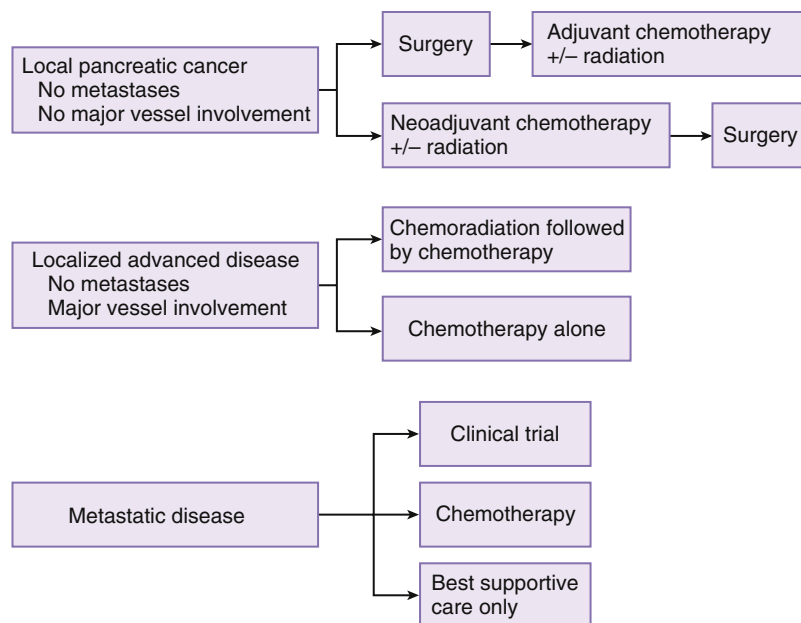

Chronic pancreatitis  
Cystic fibrosis  
Pernicious anemia  
Obesity

pancreas (20%). Whereas treatment strategies are similar regardless of origin (although surgical approach is different), the likelihood of curing patients with body or tail lesions is nearly 0%.

Although painless jaundice is a classic presentation of pancreatic cancer, patients more commonly present with unexpected weight loss, back pain wrapping to the right upper quadrant, anorexia, and nausea. Laboratory tests may show elevated levels of total bilirubin and other liver-function tests (alkaline phosphatase more frequently than transaminases). Patients with suspicious symptoms are usually evaluated by CT, leading to detection of a pancreatic mass. For patients with metastatic disease at presentation, the liver is the most common site of metastasis, although distant lymph nodes, peritoneum, and lungs are other frequent areas of spread. Biopsy of the primary pancreatic mass or metastases can be done percutaneously, with the assistance of ultrasound or CT, or endoscopically via endoscopic ultrasound. Patients who present with jaundice should have an endoscopic retrograde cholangiopancreatography with stent placement, cytology by brushings, and/or biopsy.

Although the tumor, node, metastases (TNM) system used for solid organ tumors exists for pancreatic cancer, the more practical classification of pancreatic cancers divides them into three stages: local, locally advanced, and metastatic disease (Fig. 12.2). Local disease implies surgical resectability and is the only potentially curable stage of pancreatic cancer. Unfortunately, only 15% of patients have local disease at diagnosis. For surgery to be considered, preservation of fat planes around the major blood vessels in the area is required, including the celiac axis vessels, superior mesenteric artery, superior mesenteric vein, and portal vein. Typically, either pancreatic protocol CT or MRI can determine the status of these vessels. Ultimately, however, the determination of resectability is based on a surgeon's judgment at the time of laparotomy. For lesions at the head of the pancreas, a pancreaticoduodenectomy (Whipple) operation is performed, with resection of part of the pancreas and duodenum, common bile duct, gallbladder, and distal stomach (Fig. 12.3). For lesions of the body or tail of the pancreas, a distal pancreatectomy with or without splenectomy is performed. Resection of body or tail lesions is considerably less common because most such cancers are metastatic at the time of diagnosis. Following resection, adjuvant therapy is considered with either chemotherapy alone or the combination of chemotherapy and radiation. Only 15% to 20% of patients who undergo surgical resection will not have recurrences; most recurrences will be detected within the first 2 years after surgery. Given the high risk of recurrence and challenges in delivering adjuvant therapy after a pancreatic surgery, there are ongoing efforts to define the safety and efficacy of neoadjuvant therapy approaches before surgery.

Patients who are not surgically curable because of invasion of at least one major blood vessel, but do not have evidence of distant metastases, are staged as locally advanced.

• **Fig. 12.2** Treatment algorithm for pancreatic cancer.

• **Fig. 12.3** Classical pancreaticoduodenectomy and pylorus-sparing pancreaticoduodenectomy.

Randomized clinical trials have demonstrated a survival benefit to combined-modality chemotherapy and radiation compared with radiation alone. Alternatively, patients with locally advanced pancreatic cancer can be treated with chemotherapy alone. Nonrandomized comparisons and several metaanalyses of chemotherapy versus chemoradiation suggest similar survival outcomes. Ultimately, patients with locally advanced disease will develop metastatic disease. An intermediate group of borderline-resectable disease has been recently defined, and efforts are under way to define

neoadjuvant strategies to potentially convert patients to resectable disease.

Chemotherapy has provided limited benefit to patients with metastatic disease. Median survival without therapy ranges from 3 to 6 months and with palliative chemotherapy from 6 to 11 months, depending on the aggressiveness of the chemotherapy used. The first step in approaching patients with metastatic pancreatic cancer is palliation of symptoms (either with surgery or nonoperative interventions) and determination of overall performance status to

assess their suitability for palliative chemotherapy. Gemcitabine, a deoxycytidine analogue that inhibits DNA replication and repair, has long been considered a first-line agent for metastatic pancreatic cancer. Two randomized clinical trials have demonstrated appreciable, statistically significant improvements in survival for alternative chemotherapy regimens when compared with gemcitabine alone: one is a four-drug regimen of 5-fluorouracil (5-FU), irinotecan, oxaliplatin, and leucovorin; the other is a combination of gemcitabine with nab-paclitaxel. Although these regimens may offer a survival advantage, both are associated with an increased risk of toxicities. As such, both regimens may be considered as first-line options in patients with good performance status. Most treatment guidelines suggest that clinical trials should be considered for patients with metastatic pancreatic cancer, even in the first-line setting.

## Liver Cancer

The most common cancers found in the liver are metastases from other sites. Primary liver cancer, nonetheless, represents a significant source of mortality worldwide. Although it is the sixth most common cancer in the world, it is the second leading cause of cancer-related deaths with approximately 782,000 new cases diagnosed and 745,000 attributable deaths annually. In the United States, an estimated 39,000 new cases will be diagnosed and 21,000 people will die of liver cancer per year. Although the worldwide incidence of primary liver cancer is thought to be declining, the incidence and mortality rate in the United States has been on the rise for several decades.

### Risk Factors for Liver Cancer

Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer, representing approximately 75% of all primary liver cancers. Other histologies include adenocarcinomas (or intrahepatic cholangiocarcinomas), various sarcomas, and hepatoblastoma (the most common primary liver cancer in children). Mixed hepatocellular cholangiocarcinomas are also rarely seen.

Hepatitis B virus (HBV) and hepatitis C virus (HCV) infections are the most important risk factors for HCC. Globally, chronic HBV infection is the primary cause of HCC, and HCC is most prevalent in regions where HBV is endemic, including sub-Saharan Africa and East Asia. A decline in the worldwide incidence of HCC has been seen with the introduction of broad HBV vaccination programs. Another apparent risk factor for HCC in these same regions is dietary exposure to aflatoxin B<sub>1</sub>, a mycotoxin produced by *Aspergillus flavus* and *Aspergillus parasiticus*. Aflatoxin exposure alone can increase the risk of developing HCC up to 4-fold; however, that increase in risk in HBV carriers can be up to 60-fold.

The majority of HCC cases in the United States and Europe are secondary to HCV infection. The rising incidence of HCC in the United States is thought to be

secondary to the prevalence of HCV infection as well as, possibly, a rise in modifiable risk factors such as alcohol abuse, nonalcoholic steatohepatitis, and metabolic syndrome. HCV exposure in the United States peaked during the 1960s to 1980s, before the virus was discovered and blood-related transmission was understood. Because of this, the US Preventive Services Task Force recommends one-time HCV screening for all adults born between 1945 and 1965.

HBV has direct oncogenic activity, and HCC can arise in HBV-infected patients in the absence of chronic liver disease and inflammation. For all other etiologies of HCC, however, hepatocarcinogenesis arises in the setting of cirrhosis. Other possible risk factors for HCC therefore are those diseases that cause chronic liver inflammation and cirrhosis, including autoimmune hepatitis, primary sclerosing cholangitis, primary biliary cirrhosis, and the inherited disorders hereditary hemochromatosis and alpha-1-antitrypsin deficiency.

### Clinical Presentation and Management of Liver Cancer

Patients with HCC often only present with symptoms related to their underlying liver disease and cirrhosis. In some cases, patients might develop weight loss, early satiety, or abdominal pain. Commonly, HCC is first identified through elevated alpha fetoprotein levels or a mass on imaging identified through screening studies for patients with cirrhosis.

In many cases, the diagnosis of HCC can be made through noninvasive means. For patients with cirrhosis and a mass larger than 1 cm in diameter, multiphase contrast-enhanced CT or MRI demonstrating enhancement during the early arterial phase and rapid washout in the portal venous phase can be considered diagnostic for HCC. If the lesion does not show both characteristic findings, a second study (in the other modality) or image-guided biopsy should be considered.

Multiple staging systems exist for HCC, incorporating characteristics of both the cancer and the underlying liver disease. The Barcelona-Clinic Liver Cancer staging system integrates tumor size and extent, Child-Pugh score, and patient performance status. It also links stage with treatment strategies. In patients with solitary lesions, preserved liver function, and no evidence of portal hypertension, surgical resection can be a potentially curative therapy. After resection, however, recurrence is common, although it is often not clear whether these are true recurrences or second primaries.

Liver transplantation can be considered in select patients; in the United States, the United Network for Organ Sharing uses the Milan criteria, with appropriate patients having either a single lesion less than or equal to 5 cm or no more than three separate lesions (none larger than 3 cm), no evidence of vascular invasion, and no extrahepatic disease (nodal or distant metastases). Although few patients meet

these strict criteria, those who do and undergo transplantation can experience long-term survival rates over 75%.

In patients who are not candidates for liver transplantation or resection, a number of local liver-directed therapies have been developed for HCC. In smaller tumors, radiofrequency ablation (RFA) is frequently performed. Transarterial chemoembolization (TACE) or radioembolization can also be used, even with multifocal tumors. Other modalities for local control include radiation therapy and percutaneous ethanol injection. Both RFA and TACE have been shown to improve survival in patients with localized disease, and both have been studied as methods to downstage tumors to meet criteria for liver transplantation. These local therapies are limited by tumor size, location, underlying liver function, and portal venous involvement; they should not be used in patients with extrahepatic disease.

For patients with extrahepatic disease, or who are not candidates for liver-directed treatments, systemic therapy might be appropriate. The antiangiogenic tyrosine kinase agent sorafenib is the only agent that has a proven survival benefit with advanced HCC. In two parallel multinational randomized trials, sorafenib demonstrated a survival benefit over placebo. Sorafenib has primarily been studied in patients with Child-Pugh A liver function, although studies have suggested that toxicities may be manageable in Child-Pugh B patients. Overall benefits from systemic therapies in HCC are limited, and clinical trials or best supportive care should always be considered as management options.

## Colorectal Cancer

Colorectal cancer is the third most common cancer diagnosed in men and women in the United States and the fourth most common cancer overall. Approximately 134,000 people in the United States are diagnosed annually with colorectal cancer. It is the second most common cause of cancer-related death in the United States, with an estimated 49,000 deaths each year. Worldwide, over 1 million people are diagnosed annually and 500,000 die from colorectal cancer. Colorectal cancer is likely the cancer with the most consistent research implicating modifiable risk factors associated with its development (Table 12.3) as well as the most effective screening techniques for precursor lesions, albeit underused.

## Risk Factors for Colorectal Cancer

Up to 25% of patients with colorectal cancer have a family history of the disease. Multiple hereditary syndromes carry a markedly increased risk of colorectal cancer. Familial adenomatous polyposis (FAP) results from truncating mutations of the adenomatous polyposis coli (*APC*) gene. Afflicted individuals develop hundreds to thousands of polyps by their second decade of life and, if untreated, will inevitably develop colorectal cancer by age 40 years. Patients should have a total colectomy by age 20 years. Variants of FAP include Gardner syndrome (in which prominent extraintestinal lesions such as desmoid tumors and sebaceous or epidermoid cysts are seen in addition to extensive polyposis) and Turcot syndrome (brain tumors, particularly medulloblastomas, are seen in addition to colonic tumors).

HNPCC, or Lynch syndrome, is characterized by the early onset of colorectal cancer, often involving the right side of the colon, and typically occurring in the absence of numerous colonic polyps. Several germline defects responsible for HNPCC have been identified; the most common of these are mutations in *hMLH1* and *hMSH2*. These genes are essential components of a nucleotide mismatch repair system. HNPCC is also associated with the development of extracolonic tumors including malignancies of the endometrium, ovary, stomach, and small bowel. Genetic screening for individuals at risk for HNPCC is available.

In addition to familial syndromes, a family or personal history of colorectal cancer increases one's risk of developing colorectal cancer. This risk is modified by the number of family members affected and the age of diagnosis of family members, particularly first-degree relatives. Importantly, this risk is similar for individuals with a family history of adenomatous polyps, likely because such polyps may have evolved to cancer if untreated.

Patients with inflammatory bowel disease (IBD) have an increased risk of colorectal cancer that can be 3-fold to 5-fold higher than that of the general population. This risk is associated with both ulcerative colitis and Crohn disease, particularly for patients with Crohn disease affecting the large bowel. Extent of disease involvement in the colon and rectum and duration of disease are the main determinants of the increased risk. In general, patients with ulcerative colitis

**TABLE 12.3 Risk Factors Associated With Colorectal Cancer Development**

Decrease Risk	Increase Risk	Uncertain Impact
Screening	Family history	Folic acid
Exercise	Familial syndrome	Fiber
Vitamin D/calcium	Obesity	Fruits/vegetables
Postmenopausal estrogen	Diabetes	Cholesterol-lowering agents
Aspirin/NSAIDs	Inflammatory bowel disease	Glycemic index
	Red meat	
	Alcohol	
	Smoking	
	Acromegaly	

NSAIDs, Nonsteroidal antiinflammatory drugs.

do not have an appreciable increase in risk until about 8 to 10 years from time of diagnosis.

Two other medical conditions associated with a higher risk of colorectal cancer are diabetes mellitus and acromegaly. Case-control and cohort studies have suggested that diabetic patients have a 1.3-fold to 1.5-fold increased risk of colorectal cancer, compared with nondiabetics. Given the prevalence of diabetes, such a relative risk is clinically significant. Individuals with acromegaly have a 2.5-fold increased risk of colorectal cancer.

Obesity and physical activity have consistently been shown to influence the risk of colorectal cancer. Greater body mass index and lower levels of physical activity increase the risk of developing colorectal cancer, with relative risks ranging from 1.4 to 2 in most studies. Recent hypotheses have linked physical activity, obesity, and adipose distribution to circulating insulin and free insulin-like growth factor 1.

Studies of diet and colorectal cancer have led to mixed results. The most consistent results show an increased risk of colorectal cancer with higher intakes of red meat. Fiber, fruit, and vegetables have been studied extensively as risk factors, although most studies show little or no association except with very low intake of these dietary factors.

There is emerging evidence consistently demonstrating that individuals with lower serum levels of vitamin D have an increased risk of colorectal cancer. Because the minority of vitamin D is obtained from diet, supplementation and/or sunlight exposure may be protective. Folic acid was considered to have consistent evidence of a protective effect against colorectal cancer, although a recent intervention trial of folic acid supplementation in patients with prior history of adenomatous polyps has challenged prior evidence; further studies are required to determine if there is an association between folic acid and colorectal cancer.

An association between alcohol consumption and an increased risk of colorectal cancer has been observed in several studies. A pooled analysis of eight cohort studies estimated a 40% increased risk of colorectal cancer in those whose alcohol consumption exceeded 45 g per day. Cigarette smoking has been associated both with increased incidence and mortality from colorectal cancer.

Preclinical, epidemiologic, and intervention studies support a protective effect of aspirin, nonsteroidal antiinflammatory medications, and selective cyclooxygenase-2 inhibitors on the risk of colorectal cancer and adenomas. However, the risks of bleeding and renal dysfunction associated with these agents may outweigh the benefit if universally adopted in normal-risk individuals.

The most protective factor against colorectal cancer is screening. The most recent revision of guidelines from the American Cancer Society recommended flexible sigmoidoscopy every 5 years, colonoscopy every 10 years, double contrast barium enema every 5 years, or CT colonography (virtual colonoscopy) every 5 years, as screening options to

detect polyps or cancer. Furthermore, annual guaiac-based fecal occult blood testing (FOBT), annual fecal immunochemical testing, or intermittent stool DNA testing are options to screen for cancer. The method with the strongest evidence of protection from colorectal cancer mortality is FOBT; four randomized trials have demonstrated statistically significant benefits to FOBT screening. However, colonoscopies are the most sensitive and specific screening test and have the advantage of intervening on precursor lesions as well as biopsying malignant lesions at the time of screening. Patients without a family history of colorectal cancer or personal risk factors should initiate screening at age 50. Those with a family history should initiate screening at least 10 years before their family member's diagnosis or at age 40, whichever is earlier. Patients with a known familial syndrome or with IBD might need to start screening tests much earlier in life and continue them more frequently.

### Pathologic Features and Presentation of Colorectal Cancer

Over 98% of large intestine cancers are adenocarcinomas. The remaining 2% of colorectal cancers consist of lymphomas, leiomyosarcomas, and miscellaneous tumors. Most colorectal carcinomas originate from adenomatous polyps. Progression from early adenomatous proliferations through adenomatous polyp, high-grade dysplasia, and, ultimately, invasive carcinoma occurs as a continuum. This progression coincides with the accumulation of genetic alterations within the neoplasm, including mutations of tumor suppressor genes—for example, *p53* and *APC*, as well as activation and/or overexpression of oncogenes—for example, *C-MYC* and *KRAS*. Although the order of occurrence of these genetic changes may vary, the quantitative accumulation of defects correlates with biological and histologic parameters of neoplastic progression, suggesting a multistep model of tumorigenesis.

Patients with cancer of the cecum and ascending colon usually present with anemia caused by intermittent gastrointestinal bleeding. Obstruction is rare because the bowel wall is more distensible and has a greater circumference than the descending colon. These cancers are often large and may be fungating or friable. Carcinomas of the transverse colon and either the hepatic or the splenic flexure, which account for about 10% of total cases, are somewhat less common than cecal neoplasms and much less common than rectosigmoid tumors. They frequently cause cramping pain and bleeding, and sometimes obstruction or perforation. Large bowel obstruction is the most common complication of colon carcinoma and may lead to proximal ulceration or perforation. Other complications include iron deficiency anemia, hypokalemia (particularly associated with large villous rectal lesions), and intussusception in adults. Tumors of the sigmoid colon and rectum cancers usually cause changes in normal bowel habits with tenesmus, decrease in stool caliber, secretion of mucus, and hematochezia.

## Management of Colorectal Cancer

Colorectal cancers are generally staged at the time of surgery. CT scans of the abdomen and pelvis and chest radiographs or CTs are usually performed to evaluate for metastatic disease. Bone scans are not routinely carried out in the absence of bone pain because of the low incidence of bone metastases. Similarly, brain metastases are extremely rare, and brain imaging is necessary only if presenting with neurologic symptoms. Extension of primary rectal cancers into adjacent soft tissues can often be assessed by endorectal coil MRI or endoscopic ultrasound. The commonly used staging system is the TNM staging classification (Fig. 12.4). In stage I and II cancers, disease is localized to the bowel wall without involvement of regional lymph nodes or presence of distant metastases. Patients with stage III disease have involvement of regional lymph nodes but no distant metastases, whereas those with stage IV disease have distant metastases (most commonly liver, lung, distant lymph nodes, and peritoneum).

Colorectal cancers spread by direct invasion, through lymphatic channels, along hematogenous routes, and by implantation. Spread of colon cancers through the portal venous circulation leads to liver metastases. Cancers that

originate below the peritoneal reflection (12–15 cm from the anal verge) are considered rectal cancers. The location of these lesions and the lymphatic drainage of this area necessitate special management decisions. Rectal cancers situated below the peritoneal reflection have a high rate of local recurrence. Cancers of the lower rectum may metastasize via the paravertebral plexus to supraclavicular nodes, lungs, bone, and brain, without liver involvement.

Initial staging remains the most predictive prognostic factor for overall survival. Patients with stage I disease have >90% 5-year survival with surgery. Patients with stage II disease have 70% to 85% 5-year survival (dependent on extent of disease through bowel wall and existence of other prognostic features: clinical bowel obstruction, bowel perforation, and poor differentiation lead to higher risk for recurrence). Patients with stage III disease have a 5-year survival ranging from 35% to 70% (depending on number of positive lymph nodes and presence of other high-risk features). Finally, patients with stage IV disease (metastatic) have 5% to 8% long-term survival.

Treatment for colorectal cancer also depends on stage of disease (Table 12.4). The bases of the treatment algorithm are both the potential curability of the disease

• Fig. 12.4 TNM staging of colorectal cancer. (From American Joint Commission on Cancer Version 6.)

and likelihood of recurrence. The principal treatment modalities used are surgery, chemotherapy, and radiation therapy.

Surgery is considered the only curative therapy for colorectal cancers. Although other modalities, including chemotherapy and radiation, are critical components of many patients' treatment, a critical step in approaching patients is determining the suitability and timing of surgery. Eighty percent of patients will present without detectable metastases. For such patients with colon cancer, surgery is usually the first step in treatment. For patients with rectal cancer, preoperative staging with either pelvic MRI or endorectal ultrasound is required to determine whether the patient clinically has stage II or III disease; in most patients with stage II or III disease, neoadjuvant combined chemotherapy and radiation should be offered.

For patients with metastatic disease, removal of the primary tumor remains an important consideration to palliate and prevent symptoms caused by the colorectal lesion (including bleeding and obstruction). Increasingly, a select subset of patients with metastatic disease may be considered for curative-intent surgery through both resection of the primary tumor and metastatectomies. These patients may be treated with chemotherapy before one or all components of surgery. Disease recurrence rates following resection of metastases remains high.

Multiple clinical trials have demonstrated a survival benefit for adjuvant chemotherapy in stage III (lymph node–positive) colon cancer patients following surgery. In 1990 a National Cancer Institute consensus conference recommended fluorouracil-based adjuvant therapy as standard of care for patients with resected stage III colon cancer. No single randomized clinical trial has demonstrated a survival benefit for adjuvant therapy in patients with stage II colon cancer. In addition, subset analyses of trials that included patients with stage II and III disease have repeatedly failed to demonstrate a statistically significant survival benefit for stage II patients. An expert panel convened by the American Society of Clinical Oncology

(ASCO) concluded that direct evidence from clinical trials does not support the routine use of adjuvant therapy in patients with stage II colon cancer and that the absolute survival benefit in these patients is unlikely to exceed 5%. Although prospective data are lacking, a benefit for adjuvant therapy has been suggested in patients with stage II colon cancer with high-risk features, such as inadequate lymph node sampling, lymphovascular or perineural invasion, T4 tumor stage, clinical colonic perforation or obstruction, and poorly differentiated histology. Although these features may indicate an increased risk of recurrence, they do not necessarily predict for efficacy of chemotherapy. Nonetheless, patients with high-risk stage II colon cancer should be considered for adjuvant therapy.

Clinical trials of combined chemotherapy and radiation for patients with stage II and III rectal cancer have also demonstrated a survival benefit. Although there is some controversy on the benefit of radiation in good-risk, T3 N0 rectal cancers, such patients should be considered for therapy in addition to surgery. In the past several years, neoadjuvant chemoradiotherapy followed by surgery, followed by further adjuvant chemotherapy, has become the standard approach in the United States for patients whose tumor extends at least through the muscle layer or who are lymph node–positive by endoscopic ultrasound or endorectal coil MRI. Radiation is used with rectal cancer and not colon cancer because the bony constraints of the pelvis limit surgical access to the rectum, leading to a lower likelihood of achieving widely negative margins and a higher risk of local recurrence.

Chemotherapy is an important component of the treatment of patients with metastatic disease as well as many patients with surgically resected tumors. The backbone of colorectal cancer treatment for the past four decades is the fluorinated pyrimidine 5-FU. Over the years, multiple new agents have been added to the treatment armamentarium for colorectal cancer. In addition to intravenous fluorouracil, oral fluoropyrimidines include capecitabine, uracil plus tegafur, and trifluridine and tipiracil. Two other traditional cytotoxic therapies that have definitive activity against colorectal cancer

**TABLE 12.4 Treatment Algorithm for Colorectal Cancer**

Stage	Colon	Rectal
I	Surgery only	Surgery only
II	Surgery ± adjuvant chemotherapy	Surgery, radiation, chemotherapy (either neoadjuvant chemoradiation followed by surgery followed by chemotherapy or surgery followed by adjuvant chemotherapy and radiation)
III	Surgery and adjuvant chemotherapy	Surgery, radiation, chemotherapy (either neoadjuvant chemoradiation followed by surgery followed by chemotherapy or surgery followed by adjuvant chemotherapy and radiation)
IV	Chemotherapy (consider surgery for primary tumor and if metastases are resectable)	

include irinotecan and oxaliplatin. Finally, more specific targeted therapies against the vascular endothelial growth factor (bevacizumab, ziv-aflibercept, ramucirumab, and regorafenib) and epidermal growth factor receptor (cetuximab and panitumumab) are having an expanding role against colorectal cancer. For patients with metastatic colorectal cancer, the expansion of agents has led to multiple viable combinations and lines of therapy to palliate symptoms and prolong survival. Whereas in the era of only 5-FU, the median survival of patients with metastatic colorectal cancer was 12 months, patients able to receive all the available agents in some sequence experience a median survival of over 2 years.

Multiple studies have highlighted the role of certain mutations in colorectal cancer. Microsatellite instability (MSI) is caused by a failure of the DNA mismatch repair mechanism. Inactivation of at least one DNA mismatch repair gene can lead to an accumulation of defects in DNA and consequent genetic instability, presenting as a hypermutability phenotype. MSI is found in 15% of colorectal cancers. Approximately 2% to 3% result from germline mismatch repair mutations associated with Lynch syndrome; the remainder are sporadic mutations within the tumor. MSI-high tumors are associated with a slightly better prognosis than microsatellite stable (MSS) tumors. Patients with MSI-high tumors, however, do not appear to derive a survival benefit from adjuvant therapy with 5-FU alone.

Mutations in *RAS* and *BRAF* also appear to have some prognostic and predictive value. Approximately 40% of colorectal cancer tumors harbor an activating mutation in *KRAS* exon 2. An additional 10% to 15% have mutations in *KRAS* exons 3 or 4 or in *NRAS*, and 5% to 10% carry mutations in *BRAF*; mutations in *KRAS*, *NRAS*, and *BRAF* are, essentially, mutually exclusive. *BRAF* mutations have been associated with significantly poorer prognosis, independent of stage, particularly in patients with MSS tumors. *RAS* mutations may also be associated with poorer outcomes, although this association is less clear. Patients with *RAS* mutations derive no benefit from anti-EGFR therapy with cetuximab or panitumumab, either alone or in combination with chemotherapy. Current guidelines recommend testing for MSI, either by immunohistochemistry for mismatch repair proteins or polymerase chain reaction for MSI, in all patients diagnosed with colorectal cancer at or below the age of 70 years, patients diagnosed after 70 years of age meeting the Bethesda Guidelines, and all patients with metastatic disease. *RAS* and *BRAF* testing should be performed for all patients with metastatic colorectal cancer.

Following surgical resection, with or without adjuvant therapy, patients with nonmetastatic colorectal cancer should have regular follow-ups with their treating physicians. Despite multiple attempts at addressing the question of optimal follow-up strategies, no single trial has adequately determined which tests and what frequency of tests should be applied for all patients. Most recurrences will occur in the first 2 to 3 years after surgery, and nearly all recurrences happen within 5 years. Consequently, follow-up should be more frequent in the first few years and continue until at least 5 years post resection. The most common surveillance tools that are recommended and are being used include physician visits, carcinoembryonic antigen (CEA) monitoring, colonoscopic surveillance, and additional sigmoidoscopies for rectal cancer patients. Conversely, there is general agreement that liver function tests and complete blood counts are not useful in detecting cancer recurrences. The main controversy has been on the utility and frequency of imaging, including chest x-rays, CT scans, and liver ultrasound. Three metaanalyses have concluded that more-intensive surveillance (which has generally included radiology imaging) provides a modest but statistically significant survival advantage to less-intensive surveillance. As a result, most oncology societies have endorsed the use of imaging in surveillance of colorectal cancer survivors. ASCO recently endorsed recommendations that colorectal cancer survivors should undergo history, physical examination, and CEA testing every 3 to 6 months for 5 years. The greatest importance was placed on the first 2 to 4 years, and patients with a higher risk of recurrence should be considered for more frequent testing within this range. An annual CT of the chest and abdomen was recommended for 3 years in most patients; CT every 6 months to 12 months could be considered for higher-risk patients. Pelvic CT was also recommended for patients with rectal cancer. In addition, the group recommended surveillance colonoscopy 1 year after the initial resection and, if normal, every 5 years thereafter. For patients with rectal cancer who underwent a low anterior resection and did not undergo radiation, more frequent rectosigmoidoscopies (every 6 months for 2–5 years) should be considered. It should be noted that an initial colonoscopy is often recommended by other organizations sooner than 3 years because there is a definitive, albeit low, risk of an adenoma or second colorectal cancer missed at the time of diagnosis before surgery. Finally, the ASCO recommendations noted that surveillance testing should not be performed if the patient is not thought to be a candidate for further surgery or systemic therapy.

## Chapter Review

### Questions

1. A 70-year-old smoker presents for evaluation of difficulty swallowing. He has had recent problems swallowing solid foods only (no difficulties with liquids). He does describe a long-standing history of gastroesophageal reflux symptoms, for which he has never sought evaluation. He does not have any other complaints.

Esophagogastroduodenoscopy reveals a partially obstructing mass in his distal esophagus. Biopsies reveal adenocarcinoma. CT shows distal esophageal thickening with no evidence of distal metastases. The next step in his care would be:

- A. MRI of the brain
- B. Endoscopic ultrasound

- C. Combination chemotherapy and radiation  
D. Minimally invasive esophagectomy
- A 52-year-old pianist presents to the emergency department with severe epigastric abdominal pain, radiating to her back. Before this presentation, the patient had excellent performance status. She has no chronic medical conditions. CT reveals a 3-cm mass in the head of the pancreas with complete encasement of the superior mesenteric artery and vein. Dilation of the main pancreatic duct is also seen. She undergoes esophagogastroduodenoscopy with endoscopic ultrasound, which shows the pancreatic head mass; no enlarged lymph nodes are seen. Cytology from fine-needle aspiration of the pancreatic mass confirms adenocarcinoma. Given the clinical presentation, which option would not be indicated as a treatment for this patient's pancreatic cancer?
    - Pancreaticoduodenectomy (Whipple resection)
    - Systemic chemotherapy with a multidrug regimen
    - Concurrent chemoradiation
    - Enrollment in a clinical trial
  - A 59-year-old woman with hepatitis C–associated cirrhosis has an elevated AFP level found on surveillance testing. Multiphasic CT shows six hepatic lesions, involving both lobes, with arterial phase hyperenhancement and portal venous phase washout. The largest of these measures 2 cm in diameter. Imaging of the chest shows no evidence of metastases. Her case is presented for multidisciplinary evaluation. The following is a contraindication to orthotopic liver transplantation:
    - HCV infection
    - Six liver lesions
    - Largest lesion 2 cm in diameter
    - Bilobar liver involvement
  - A 48-year-old school bus driver presents to a gastroenterologist after evaluation for microcytic anemia revealed positive FOBT. Colonoscopy demonstrates a small polypoid mass in the ascending colon, and biopsy confirms adenocarcinoma. He is referred to a surgeon and undergoes a laparoscopic hemicolectomy. Surgical pathology reveals a 1-cm moderately differentiated adenocarcinoma arising in a tubulovillous adenoma. Tumor invasion is confined to the submucosa. None of the 19 lymph nodes resected contains metastatic carcinoma. The next step in his management would be:
    - Observation with repeat colonoscopy in 1 year
    - Adjuvant chemotherapy with 5-FU, leucovorin, and oxaliplatin
    - Adjuvant radiotherapy
    - Adjuvant chemoradiotherapy with 5-FU
  - A 66-year-old computer technician presents to his primary care physician with right upper quadrant abdominal pain and worsening fatigue. CT reveals a large mass in the right colon, multiple enlarged abdominal lymph nodes, and innumerable liver masses. He undergoes a percutaneous liver biopsy, which shows a metastatic adenocarcinoma consistent with a colorectal primary. Mutational analysis reveals a mutation in codon 12 of exon 2 of the *KRAS* gene. The patient is not thought to be a surgical candidate because of the extent of liver involvement, and he is referred to an oncologist for evaluation. Which agent is contraindicated for current or future treatment regimens?
    - 5-FU
    - Bevacizumab
    - Cetuximab
    - Oxaliplatin

## Genitourinary Cancers

MARK M. POMERANTZ

### Prostate Cancer

#### Epidemiology and Risk Factors

Since the introduction of widespread prostate cancer screening in the United States in the late 1980s and early 1990s, the incidence of prostate cancer has increased substantially. In the prostate cancer-screening era, the majority of newly diagnosed cases are localized; the tumor is confined to the prostate gland. Therefore most patients have the opportunity for curative therapy. Yet the benefits of population-wide screening and optimal treatment remain controversial. This chapter will review the epidemiology, risk factors, and screening of prostate cancer, as well as treatment options at different stages of the disease.

In the United States, over 180,000 cases are diagnosed, and approximately 20,000 deaths occur annually. After skin cancers, prostate cancer is the most commonly diagnosed cancer in American men. The lifetime risk of prostate cancer for an American man is approximately 1 in 6 over the course of his lifetime. It is the second leading cause of cancer death in American men. The correlation between age and prostate cancer is remarkably strong. Prostate cancer is exceedingly rare in young men, but autopsy series suggest that the prevalence of the disease is >50% in men age >60 years. Prostate cancer has a strong heritable component. It is estimated that about 60% of risk is inherited and 40% is environmental. Certain ancestral groups are at higher risk than others. African Americans have the highest known incidence of prostate cancer in the world.

#### Screening and Diagnosis

Most prostate cancer diagnoses in the United States are made via prostate specific antigen (PSA) screening. Although prostate cancer incidence in the United States increased dramatically in the PSA era, prostate cancer-specific mortality decreased. Screening may be partly or largely responsible for the decline; however, this remains controversial. Randomized screening trials to date had flaws and have been unable to resolve this controversy. Currently, most guidelines recommend that men age  $\geq 50$  years discuss the pros and cons of PSA screening with their primary care physicians (Table 13.1).

Many have focused on improving the precision of the PSA test. The digital rectal examination, for example, adds significantly to the positive predictive value of PSA. Digital rectal examination has not been shown to serve adequately as a screening method by itself but should be part of routine PSA screening. Other attempts at improving PSA screening, such as PSA density and free PSA, have not consistently outperformed PSA alone when compared in retrospective series. PSA velocity and doubling time have also been studied. PSA velocity has proven the most useful in determining prognosis once a prostate cancer diagnosis has been established. A rise in PSA  $>2$  ng/mL in the year before diagnosis is associated with an increased risk of death because of prostate cancer.

When prostate cancer is suspected by PSA or examination, the prostate biopsy is performed using a transrectal 18-gauge core needle under ultrasound guidance. Twelve to 14 core needle biopsies are the current standard of care. A substantial proportion of patients report pain and discomfort with the procedure and, in one series, >50% developed hematospermia, and 22.6% developed hematuria following the biopsy. Bacteremia is also a concern, occurring in 1% to 4% of cases across several retrospective series.

When invasive cancer is identified in one or more core biopsies, the pathologist assigns a Gleason score. The Gleason score is a measure of the glandular architecture. Tumor cells with a lower score are more capable of forming glandular-appearing tissue than cells with a higher score. The pathologist grades the most prevalent cells in a tumor on a scale of 1 to 5, with 1 generally being the most and 5 being the least differentiated. The second most prevalent type of cell is similarly graded, and the two scores are added together to give an overall Gleason score. A score of  $\leq 6$  (Gleason 3+3) is considered low grade, 7 (Gleason 3+4 or 4+3) is considered intermediate grade, and  $\geq 8$  (Gleason 4+4) or above is considered high-grade disease.

When the Gleason score, PSA level, and clinical stage are used in combination, they are powerful predictors of outcome. A PSA  $<10$  and Gleason score  $<6$  and T2a (tumor confined to less than one-half of one lobe of the gland) or T1c (no palpable tumor) are considered low risk. PSA between 10 and 20 or Gleason 7 or T2b disease (tumor comprising more than one-half of one lobe) is considered

PSA, Prostate specific antigen.

intermediate risk. PSA  $>20$  or Gleason 8 to 10 or T2c disease (tumor in both lobes) is considered high risk. In one large series, 10-year disease-free survival after surgery in the three risk groups was 83%, 46%, and 29%, respectively.

Further staging via bone scan and/or CT scan is not necessary in all newly diagnosed patients. Although bone is the most common site of distant prostate metastases, only 1% of patients with Gleason score  $<7$ , a PSA  $<50$  ng/mL, and tumor confined to 1 lobe of the prostate will have an abnormal bone scan. For patients with higher grade and/or higher stage disease, these tests, and others such as pelvic or endorectal coil MRI, may be indicated and may provide guidance for further management.

### Treatment of Localized Prostate Cancer

Several treatments exist for those with low-to-intermediate risk localized prostate cancer: radical prostatectomy (RP), external beam radiation therapy, or brachytherapy (radiation seeds). Active surveillance (close monitoring without definitive treatment) is an additional, and often preferable, option for low-risk patients. Once the decision is made to treat, all approaches offer excellent chance for favorable cancer-related outcomes. A patient with a Gleason 6, low volume prostate cancer with a PSA  $>10$  ng/mL (a common scenario in the PSA era) has a  $>90\%$  chance of remaining disease free at 5 years based on one large retrospective series.

The major long-term complications from local treatment are erectile and urinary dysfunction. The prospect of these life-altering side effects influences treatment decisions for the low-risk patient. Based on large prospective series, active surveillance provides the opportunity to avoid, or at least forestall, these complications with little impact on 10-year cancer-related outcomes.

For patients with localized prostate cancer with high-risk features, emerging data suggest that adjuvant treatments improve outcomes. In particular, adding androgen-deprivation therapy (ADT), usually a luteinizing hormone-releasing hormone agonist, to standard radiation therapy consistently proves superior to radiation alone in randomized trials. Side effects associated with ADT include hot flashes, erectile dysfunction, loss of libido, fatigue, decreased bone density, and increased risk of cardiovascular events. These effects largely resolve upon discontinuation of treatment, but quality of life is diminished during therapy.

### Treatment of Prostate Cancer Recurrence and Advanced Disease

Despite definitive local treatment, prostate cancer often recurs. Recurrence may be local or distal. The distinction is important because the site of recurrence could dictate the next steps in treatment. Local recurrences after RP, for example, can be successfully salvaged with radiation therapy. Patients with distally recurrent disease, on the other hand, are unlikely to benefit from postsurgical radiation to the pelvis.

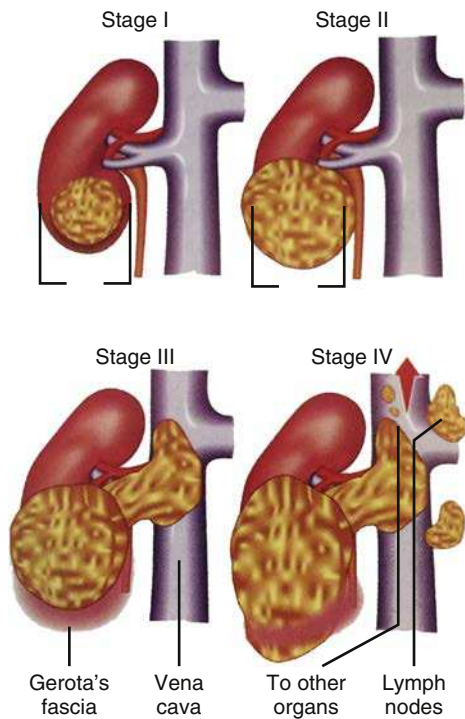

Many men who receive aggressive local therapy, including salvage radiation treatment, recur. Some men present with metastatic disease and are not candidates for any localized therapy. These scenarios represent advanced disease, and ADT remains the standard of care. Although ADT is not curative, approximately 90% of men respond with a decrease in PSA and alleviation of any prostate cancer-related symptoms. Emerging data indicate that ADT-naïve men presenting with widespread metastatic disease benefit from an upfront course of chemotherapy in addition to ADT.

Resistance to ADT ultimately develops in a median time to progression of 1 to 24 months. Nonetheless, patients may still respond to further hormonal manipulation. Agents such as antiandrogens, 17,20 lyase inhibitors, taxane-based chemotherapy, immunotherapy, and radiopharmaceuticals have all been shown to improve overall survival among castration-resistant patients.

## Renal Cell Carcinoma

### Epidemiology

Approximately 64,000 Americans are diagnosed with renal cell carcinoma (RCC) each year. The disease is the sixth leading cause of cancer-related death in the United States. Risk factors for RCC include smoking, obesity, and hypertension. There are also inherited syndromes associated with high risk of RCC, including von Hippel-Lindau disease and tuberous sclerosis.

• **Fig. 13.1** Renal cell carcinoma staging.

### • BOX 13.1 Renal Cell Carcinoma Cancer Staging

- Stage 1: <7 cm in greatest dimension, limited to the kidney; 5-year survival 95%
- Stage 2: >7 cm in greatest dimension, limited to the kidney; 5-year survival 88%
- Stage 3: Tumor in major veins or adrenal gland, tumor within Gerota's fascia, or 1 regional lymph node involved; 5-year survival 59%
- Stage 4: Tumor beyond Gerota's fascia, or >1 regional lymph node involved; 5-year survival 20%

Over 80% of RCCs originate in the renal cortex and are considered primary renal neoplasms, whereas 8% to 10% are transitional cell carcinomas, originating in the renal pelvis and, similar to bladder cancer, are of urothelial carcinomas. Most RCCs have clear cell histology (75%–85%), 10% to 15% are papillary RCCs, and 5% to 10% are chromophobe tumors.

The 5-year survival rates among patients with RCC are associated with stage (Fig. 13.1, Box 13.1). Stage I patients have a 95% 5-year survival. Stage II and III RCC have a 75% to 90% and 59% to 70% 5-year survival, respectively. Median survival for stage IV disease is generally <4 years.

### Clinical Presentation and Diagnosis

Most RCCs are asymptomatic and do not present until the disease is advanced. The most common presenting symptoms are hematuria, abdominal mass, pain, weight loss, or sequelae from metastases. Increasingly, RCCs (particularly curable lesions diagnosed at an early stage) are discovered

incidentally when scans are performed for another indication. Rarer presenting signs and symptoms of RCC are a palpable flank mass, scrotal varicoceles, anemia, hypercalcemia, or edema from inferior vena cava involvement. Paraneoplastic symptoms resulting, for example, from production of erythropoietin are occasionally observed.

CT scans are recommended in the presence of symptoms or signs suggestive of RCC. Ultrasonography or MRI also may be useful for distinguishing a benign cyst from a renal tumor. In the setting of a concerning solid mass, most patients undergo nephrectomy or partial nephrectomy rather than biopsy, because these procedures are therapeutic as well as diagnostic. For nonsurgical candidates or those requiring immediate medical treatment for advanced disease, biopsy is important for establishing RCC histology, although biopsy of a metastatic site is preferred. When RCC is presumed, staging should be performed with CT of the chest, abdomen, and pelvis. MRI can provide superior imaging of the inferior vena cava if there is locally advanced disease.

There is no known role for RCC screening via CT scan, except for patients from families with hereditary kidney cancer syndromes such as Von Hippel-Lindau syndrome or tuberous sclerosis. Patients with a long history of end-stage renal disease on dialysis for 3 to 5 years may also benefit from screening.

### Treatment

With the increase in incidental diagnosis of RCC, the disease is commonly discovered at an early stage when curable. Although size does not predict presence or absence of RCC, localized lesions <4 cm generally have a more favorable prognosis. When lesions are very small, <1 cm, an active surveillance approach is often recommended. When suspicious kidney lesions are between 1 to 4 cm and the patient has a >5-year life expectancy, surgery (often partial nephrectomy, thermal ablation, or cryoablation) is recommended.

For patients with a resectable stage I (>4 cm), stage II, or stage III RCC, radical nephrectomy is generally recommended as the primary treatment approach. Surgery is recommended for locally advanced disease as well. Cure remains possible in the setting of local invasion into the perinephric fat, adrenal gland, or renal vein and vena cava. There have been several large series exploring the efficacy of adjuvant therapy, but data remain inconclusive, and postnephrectomy systemic treatment is not recommended outside of a clinical trial.

Patients with advanced, incurable disease, including those with widespread metastases, benefit from nephrectomy. Temporary regression of disease and/or decrease in pace of metastatic progression are frequently observed after resection of the primary lesion. Systemic treatment is inevitably required for metastatic RCC, and the regimens used differ from most other carcinomas. RCC is not as vulnerable to traditional chemotherapy as most other carcinomas. Immunotherapy has long had a known role in RCC. High-dose interleukin-2 (IL-2) has a very modest response rate (<10%–20%) but can

### • BOX 13.2 Bladder Cancer

Sixth most frequent cancer with 430,000 new cases in United States each year

Risk factors: smoking, family history, prior radiation therapy, frequent bladder infections, and exposure to certain chemicals

Most common type: transitional cell

Diagnosis: cystoscopy and tissue biopsy

induce prolonged remissions. It produces a cytokine storm that is associated with profound short-term morbidity and therefore is recommended only for younger patients with a good performance status. More recently, immune checkpoint inhibition with agents such as nivolumab has been shown to have activity in RCC. These medications are more tolerable with higher response rates, although remissions are not as durable as those induced by IL-2.

Advanced RCC also responds to molecularly targeted agents, particularly tyrosine kinase inhibitors and medications with antiangiogenic properties. These are frequently used in the first line, with checkpoint inhibition in the second line. In general, clinical trials are recommended, when feasible, for advanced RCC patients at each line of therapy.

## Bladder Cancer

### Epidemiology

Over 90% of urinary tract malignancies in the United States are urothelial (transitional cell) carcinoma, typically arising in the bladder. Other histologies, such as squamous cell carcinoma or adenocarcinoma, are rare. Urothelial carcinoma is usually caused by exposure to carcinogens. Half of new cases in the United States are associated with smoking, and an additional 20% are associated with occupational exposures to particular chemicals. The disease typically affects older patients and has a 3-fold higher incidence in men than women (Box 13.2).

### Clinical Presentation and Diagnosis

The majority of patients diagnosed with urothelial carcinoma present with painless hematuria. Hematuria without a clear etiology in any patient age >40 years requires workup for possible malignancy. Investigation begins with flexible cystoscopy and biopsy of any suspicious regions of bladder epithelium. If no suspicious lesions are identified, sampling of normal-appearing tissue is indicated. Urine cytology is typically performed along with initial cystoscopy. This aids in detection of in situ bladder lesions not visualized by the scope as well as lesions of the upper urinary tract.

Upon discovery of a bladder cancer, a transurethral resection of bladder tumor (TURBT) is performed under anesthesia. Extensive resection allows thorough analysis for histology and, critically, depth of tumor invasion. Prognosis and management decisions hinge on the presence or absence of tumor invasion through the muscularis mucosa layer of bladder epithelium. A CT scan is then

recommended to assess for locally advanced or metastatic disease.

### Treatment

Treatment decisions depend to a large extent on bladder cancer stage (Fig. 13.2). Tumors that do not invade the muscle layer are considered superficial. Treatment recommendations for superficial disease post-TURBT depend upon extent and histologic grade of the bladder tumors. For low-risk patients, a single instillation of Bacillus Calmette–Guérin (BCG) into the bladder is performed. For intermediate- and high-risk patients, maintenance therapy with periodic instillations follows BCG induction for 1 to 3 years. Follow-up includes serial cystoscopy examinations and TURBTs as well as periodic urine cytology and imaging of the upper urinary tract.

For patients with muscle-invasive bladder cancer, radical cystectomy is the standard treatment recommendation. Neoadjuvant therapy before surgery has been shown to increase chance for cure compared with cystectomy alone. With surgery alone, 5-year survival rates for tumors that invade merely the muscularis mucosa approach 80%. For tumors invading beyond muscle into the perivesical fat, 5-year survival is approximately 60%. Chemotherapy can improve these numbers by 5% to 10%.

An alternative for localized disease is chemoradiation therapy as bladder-preserving therapy. It has the risk of leaving a relatively small bladder with a limited capacity to contain urine, resulting in increased urinary frequency. This approach entails aggressive TURBT followed by combined chemotherapy and radiation. If after the first 6 weeks the patient has no evidence of disease at biopsy, consolidate with more chemoradiation. If there is residual disease after the first 6 weeks, a cystectomy is performed. Five-year survival using this approach ranges from 58% to 81%. Data suggest that only 40% of patients who undergo this bladder-preservation strategy are alive and maintain an intact bladder.

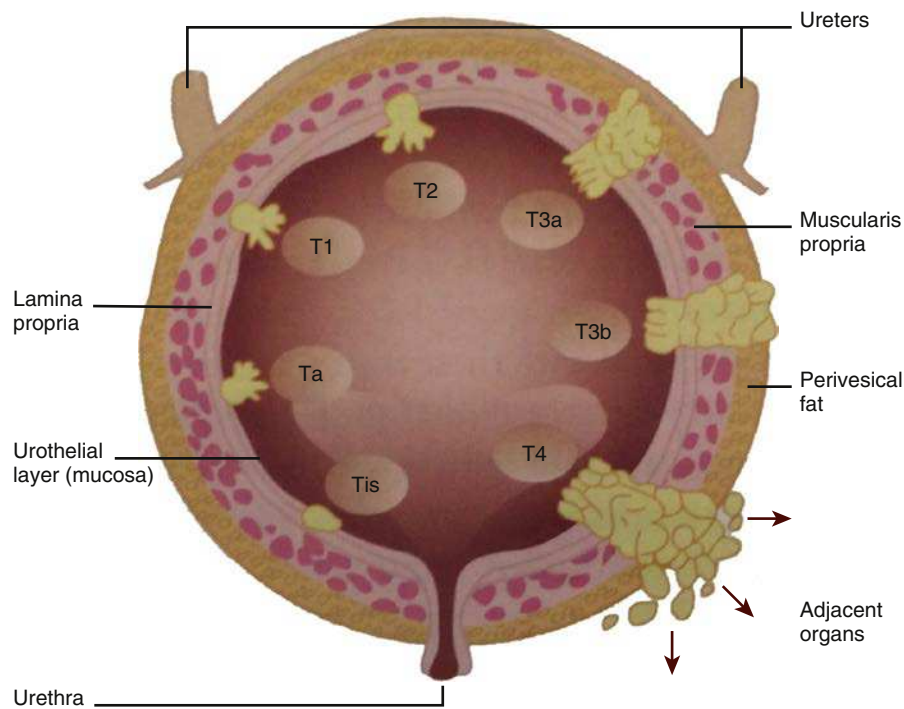

For patients with metastatic bladder cancer, cisplatin-based chemotherapy is the standard first-line treatment. Although most patients initially respond to this form of treatment, progression inevitably develops. Median survival in the metastatic setting is 15 months, with 15% 5-year survival. Immunotherapy is emerging as a second-line treatment when patients become refractory to platinum-based treatment.

## Testicular Cancer

### Epidemiology

Testicular cancer is rare, accounting for only 1% of male cancers in the United States, but it is the most solid tumor in males age 15 to 35 years (Box 13.3). More than 95% of testicular cancers are germ cell tumors (GCTs). The remaining 5% arise from spread from other sources, such as lymphoma, or from other testicular structures such Sertoli cell or Leydig cell cancers. Most GCTs develop in the absence

• Fig. 13.2 Bladder cancer staging.

### • BOX 13.3 Testicular Cancer

Most common cancer among men age 15–35 years  
 Lifetime risk in males 1 in 263 males  
 7500–8500 new cases in United States  
 Risk factors: prior history, family history of testicular cancer,  
 and undescended testes  
 95.4% survival at 5 years

of any known risk factors. GCT has a modest heritable component, although the vast majority of patients report no family history of the disease. Cryptorchidism at birth confers significant risk of GCT, and a history of this condition is noted in about 10% of cases. GCT is exceptional among human solid malignancies because it remains highly curable, even in the setting of widespread metastatic disease. In modern series, 5-year survival rates for testicular GCTs exceed 95%.

### Clinical Presentation and Diagnosis

Most men diagnosed with testicular GCT initially seek medical attention because of a palpable, hard, painless testicular mass. A minority report testicular pain or achiness. Other presenting symptoms include gynecomastia or sequel from metastases, such as back/flank pain.

When a suspicious testicular mass is detected on physical examination, the first diagnostic test to order is a testicular ultrasound. Ultrasound is specific for tumor and can distinguish a solid mass from other conditions such as hydrocele or epididymitis. If ultrasound is positive, baseline GCT serum tumor markers (beta subunit of human chorionic

gonadotropin, alpha fetoprotein, and lactate dehydrogenase) should be tested. CT scan of the abdomen and pelvis along with chest x-ray or CT chest are required to assess for metastases. The most common site of metastasis for testicular GCT is the retroperitoneal lymph nodes. The lungs are the next most common metastatic site.

No testicular biopsy is indicated in the setting of a positive ultrasound. After blood draw for tumor markers, patients are referred for radical inguinal orchiectomy. Sperm banking should be considered before surgery and is almost always indicated before any systemic treatment. Orchiectomy is indicated, even in the setting of metastases (if clinically feasible), because surgery provides histologic diagnosis, and the testicle is a sanctuary site that may shield the primary tumor from systemic treatment.

The extent of local or metastatic disease, along with tumor marker levels, determines the disease stage. Tumor stage and histology, in turn, determine disease aggressiveness and treatment recommendations.

### Treatment

For patients with stage I GCT (disease limited to the testicle based on scans and tumor markers normalizing postorchiectomy), cure rates are exceedingly high. Observation is often recommended in this setting because metastatic recurrences are reliably salvageable with chemotherapy. Adjuvant treatment with short-course chemotherapy, radiation to the retroperitoneum for seminoma, or retroperitoneal lymph node dissection (RPLND) for nonseminoma can appreciably decrease the odds that full-course chemotherapy will be necessary upon long-term follow-up. However, these adjuvant treatments are associated with some morbidity. With

a cure rate of 75% to 85% from orchiectomy alone, these are often avoided. Adjuvant treatments are considered for men at higher risk of recurrence (e.g., a large, locally invasive tumor) or who cannot dependably follow-up with serial blood work and scans as part of an observational protocol. Patients with stage II GCT (retroperitoneal lymph node involvement) are treated with full course chemotherapy or radiation to the retroperitoneum (for seminoma) or retroperitoneal lymph node dissection (for nonseminoma).

Men with metastatic disease are stratified into good-, intermediate-, and high-risk categories based on sites of metastases and tumor marker levels. Standard treatment for good-risk disease is three cycles of bleomycin, etoposide, and cisplatin (BEP) or four cycles etoposide/cisplatin. Intermediate- and high-risk patients receive four cycles of BEP. Alternative regimens are available for patients with compromised pulmonary function who are at increased risk of bleomycin-induced lung injury. Following chemotherapy for GCT, men are referred for surgery, typically RPLND, to consider resection of any masses visible by posttreatment CT scan, which can consolidate a cure. Such masses may

represent teratoma (a differentiated histology that does not respond to chemotherapy but could proliferate and transform), viable GCT, or, most commonly, scar tissue from a successfully treated tumor. For men who recur after chemotherapy, cure is less likely, but salvage therapies, including autologous stem cell transplant, can meaningfully prolong survival.

Surveillance is critical for men treated for all stages of GCT. Monitoring includes serial blood draws for tumor markers, periodic CT scans of the abdomen/pelvis, and chest x-rays. Recurrence after 2 years is exceedingly unlikely, and routine follow-up for recurrence can be discontinued after 5 to 10 years. Nonetheless, GCT survivors require careful long-term care because this population faces higher mortality rates from certain noncancer related causes compared with the general population. GCT patients are at higher risk for infertility and hypogonadism. A history of chemotherapy or radiation therapy for GCT is associated with increased risk of cardiovascular disease, pulmonary disease, renal dysfunction, peripheral neuropathy, or a second malignancy.

## Chapter Review

### Questions

1. A healthy 66-year-old European-American with no known family history of prostate cancer undergoes routine PSA screening. The PSA elevated from 3.2 ng/mL last year to 4.2 ng/mL this year. The PSA was repeated and the level returned to 4.1 ng/mL. He was referred to urology, and a biopsy was performed. Adenocarcinoma of the prostate was detected in 2/12 prostate needles cores, both in the left lobe of the gland, involving 5% of each of the two cores. Given this diagnosis, which treatment option is most appropriate?
  - A. ADT with a GnRH agonist
  - B. External-beam radiation therapy with neoadjuvant ADT
  - C. Watchful waiting with continued yearly PSAs
  - D. Resection of the left lobe of the prostate in a partial prostatectomy
  - E. Active surveillance with quarterly PSAs and repeat biopsy within 1 year
2. A 56-year-old presents to his primary care physician with a cough and productive sputum. Chest x-ray is performed to assess for pneumonia. The chest radiograph incidentally shows sclerotic lesions in the ribs bilaterally. Given concern for metastatic cancer, follow-up staging with bone scan and CT scan was remarkable for multiple blastic bony lesions in the pelvis, sacrum, and ribs bilaterally. No soft tissue disease is visualized. The PSA was drawn demonstrating a level of 630 ng/mL. Prostate biopsy reveals voluminous high-grade prostate cancer. What is the optimal treatment for this patient?
  - A. Combination chemotherapy with cisplatin and etoposide
  - B. Radical prostatectomy followed by radiation therapy to all visible sites of disease
  - C. Observation until onset of cancer-related symptoms
  - D. ADT and six cycles docetaxel chemotherapy
  - E. Immunotherapy with a prostate cancer vaccine
3. A 69-year-old smoker presents to her primary care physician with recent onset hematuria. She reports no fever or dysuria. Urinalysis confirms presence of red blood cells. Urinalysis is negative for white blood cells or nitrite. What is the appropriate next step in her management?
  - A. Observation for two weeks and repeat urinalysis
  - B. CT urography and urology referral for cystoscopy
  - C. A 7- to 10-day course of nitrofurantoin
  - D. Ultrasound of the bladder and urinary tract
  - E. Urine cytology for bladder cancer

## Leukemia

JACQUELINE S. GARCIA AND JOSEPH H. ANTIN

A lifetime of sustained lymphohematopoiesis requires a stem cell compartment that produces maturing progeny with immaculate fidelity over almost a century. The hematopoietic stem cell (HSC) gives rise to progenitor cells that are committed to either lymphoid or myeloid development. These HSCs perpetually replenish all blood cell classes through a series of lineage restriction steps and a progressive loss of differentiation potential to other cell lineages. A variety of mutations can occur in either the stem cell or in a more committed cell, which result in excessive proliferation, failure of differentiation, or both. These cumulative events result in the development of leukemia. An estimated 333,975 people are currently living with leukemia in the United States ([National Cancer Institute, 2013](#)). This chapter reviews some of the more common forms of leukemia, including chronic myelogenous leukemia (CML), acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), chronic lymphocytic leukemia (CLL), and other B-cell leukemias.

### Chronic Myelogenous Leukemia

The hallmark of CML is a balanced translocation of chromosomes 9 and 22 (t[9;22]) or Philadelphia chromosome. This anomaly was first observed in the 1960s by Nowell and Hungerford and, using cytogenetic banding techniques, was identified as a reciprocal translocation between the long arms of chromosomes 9 and 22 by Rowley. The translocation links the *ABL* oncogene to *BCR*, an unrelated gene. A new fusion peptide is transcribed called BCR/ABL. The BCR component causes BCR/ABL to tetramerize, which allows the ABL component of the fusion peptide to function as an autonomous tyrosine kinase with transforming ability. The resulting leukemic cells grow without regulation and are resistant to apoptosis, resulting in accumulation of cells in the marrow and blood. In contrast to acute leukemia, there is no defect in maturation, so the cells mature normally and carry on their specific functions without compromise. This is a genetically unstable condition. If untreated, new mutations will be acquired that result in failure of differentiation and transformation into acute leukemia. The latter acute phase is called *blast transformation* or *blast crisis*.

CML is an uncommon disease. It affects all races equally at an incidence of about 1.8 cases per 100,000 per year. The median age is 64 years, and the gender ratio is 1:1. There are no geographic or exposure associations with the possible exception of nuclear weapon survivors.

### Diagnosis

CML presents in three phases: chronic, accelerated, and blast. Typically, the onset is insidious. Clinical manifestations are summarized in [Table 14.1](#). The generally preserved ability of the hematopoietic cells to mature and function results in long asymptomatic periods.

Presentation in accelerated phase (AP) may occur, although it is unusual. AP is associated with weight loss, fever, bone pain, extramedullary disease, increased treatment requirements, increasing blasts, increasing basophils, anemia or thrombocytopenia, marrow fibrosis, and additional chromosomal abnormalities (especially a second Philadelphia chromosome or iso[17]). AP portends a poor prognosis and evolution into blast transformation.

Blast transformation is a form of acute leukemia and manifests with weight loss, manifestations of anemia and thrombocytopenia, fever, bruising, and abdominal pain. When blast crisis occurs, approximately two-thirds of the time the leukemic blasts are AML and one-third of the time they are ALL. This is an ominous event with a median survival of 6 months.

### Therapy and Prognosis

Historically the two principal treatments were oral busulfan and hydroxyurea. Busulfan is almost never used any more. Hydroxyurea is a palliative therapy, not a remission-inducing agent, primarily used to control progressive leukocytosis. On the other hand, interferon- $\alpha$  is a remission-inducing agent, although only a minority of patients enter remission. In 20% of patients, the number of Philadelphia chromosome-positive metaphases in the marrow declines to <35%, and when these good responses are observed there may be a survival advantage. The responders have a median survival of 7 to 10 years compared with 3 to 5 years in nonresponders. Interferon toxicity is substantial. Flu-like syndrome, insomnia,

**TABLE 14.1 Clinical Manifestations of Chronic Myelogenous Leukemia**

Clinical or Laboratory Finding	Frequency
Diagnosis in chronic phase	85%–90%
Asymptomatic	50%
Symptoms are often nonspecific	
Fatigue	80%
Weight loss	60%
Abdominal discomfort	40%
Easy bruising	35%
Leukostasis, priapism, thrombosis	Unusual
Laboratory	
WBC >100,000/mL	~30%
Left shift. Presence of basophilia is very helpful	100%
Philadelphia chromosome, t(9;22)	100%
Mild anemia (Hb <12 g/dL)	65%
Platelets	
>700,000/mL	25%
<150,000/mL	5%
Increased vitamin B <sub>12</sub> , B <sub>12</sub> binding capacity	100%

*Hb*, Hemoglobin; *WBC*, white blood cell.

autoimmune manifestations, depression, alopecia, and neurotoxicity limit its use, and 20% of patients are intolerant. It is rarely used in current management.

Recognition of the dysregulated tyrosine kinase activity of the fusion BCR/ABL protein led to the development of imatinib (Gleevec) as the principal therapy for CML. This is a remission-inducing tyrosine kinase inhibitor (TKI) with an excellent toxicity profile. It is administered orally and may be associated with fluid retention, rash, or nausea, but most people tolerate it very well. Disease response to treatment is evaluated at the hematologic, cytogenetic, and molecular level. Most responses occur within 30 days of starting therapy, and 95% of patients in chronic phase will have a clinical response. Major cytogenetic responses are more likely to occur in patients with less advanced disease. Patients who achieve at least a major molecular response (defined as a 3-log or higher reduction in *BCR-ABL1* mRNA from the standardized baseline, as measured by quantitative polymerase chain reaction [PCR]) at 12 months avoid progression to AP or blast phase. Further achievement of a major molecular response after 18 months of TKI therapy is associated with a durable remission including a 95% event-free survival at 7 years. In fact, an early response (faster and deeper) at 3 months predicts for a 3-year overall survival of >96%. Second-generation TKIs are now available, including dasatinib (Sprycel) and nilotinib (Tasigna) that may be offered to patients with higher-risk disease features (significant splenomegaly or basophilia). These patients are not cured, but the relapse rate is extremely small on continued therapy. In accelerated

and blast phase, higher doses of imatinib are necessary, but ultimately patients relapse. In advanced disease, the TKI may be a bridge to allogeneic hematopoietic stem cell transplantation (HSCT). Some patients develop primary resistance to TKI therapy, including mutations in the ABL1 kinase domain. Newer agents including bosutinib (Bosulif), omacetaxine mepesuccinate (Synribo), and ponatinib (Iclusig) may be useful in many instances, but usually HSCT is required in eligible individuals.

HSCT remains the only curative therapy (60%–80% long-term disease-free survival in chronic phase), but the success of imatinib and now the second-generation TKIs have relegated HSCT to a secondary role. It is used primarily in patients with resistant or advanced disease or who are intolerant to TKIs. HSCT is also the only known curative therapy in AP and blast crisis CML, although the outcomes are less encouraging. Matched sibling HSCT outcomes are dependent on age, cytomegalovirus (CMV) status, disease stage, and the presence of comorbidities. Young patients (<50 years) with fully matched donors transplanted in stable phase generally do the best. Unrelated donor HSCT outcome data are asymptotically approaching matched sibling donor HSCT outcomes as human leukocyte antigen (HLA) technology has improved.

## Acute Myelogenous Leukemia

AML is rare, with an incidence of approximately 4 cases per 100,000 per year. It is a disease of aging, and the incidence increases in individuals over 65 years of age to as many as 25 cases per 100,000 per year.

Most cases of AML are sporadic and occur without known predisposing cause, but there are well-established factors or conditions that increase the risk of AML: exposure to benzene, ionizing radiation, chemotherapy (especially alkylating agents), congenital disorders such as Down syndrome, and antecedent hematologic disorders such as polycythemia vera or myelodysplastic syndrome. There are rare cases of germ-line inheritance of *RUNX1*, *GATA2*, or *CEBPA* mutations that result in a predisposition to myeloid malignancies. Somatic mutations (or a second hit) are required for progression to myelodysplastic syndromes and AML in these familial cases.

In contrast to CML, in which cellular maturation is normal but proliferation is excessive, AML requires two defects: a proliferation signal (such as CML), and failure of cellular maturation. Specific genetic abnormalities are associated with specific disease phenotypes. For example, acute promyelocytic leukemia (APML) is known to involve a balanced translocation involving the retinoic acid receptor alpha and a partner gene called *PML* (t[15;17]). This translocation is definitive for APML, and it results in a maturation block, locking the myeloid cells in a promyelocyte stage of differentiation. However, a second mutation is necessary that provides the proliferative thrust for APML to develop. In some cases, this is caused by a mutation in the gene *FLT3*, which encodes a tyrosine kinase involved in cellular proliferation.

Thus all-*trans* retinoic acid (ATRA) is an extremely adjunctive therapy for APML, a disease that, not coincidentally, involves the retinoic acid receptor.

## Diagnosis

Usually signs and symptoms are associated with bone marrow failure—for instance, pallor, fatigue, mucosal bleeding, bruising, or fever and infection. Leukemic infiltrates of the skin, mucous membranes, and meninges are common. Very high blast counts are associated with cerebral or pulmonary leukostasis. Hyperuricemia resulting from tumor lysis may cause renal failure. Disseminated intravascular coagulation (DIC) can occur with any of the subsets of AML but is most prominent in APML.

The diagnosis is made on examination of the peripheral blood smear and/or bone marrow. Typical leukemic blast morphology is supplemented by flow cytometry, cytogenetics, and molecular analysis. Morphology and cytochemistries were the principal criteria to distinguish subtypes of AML in the past. AML is now classified into four main groups using the World Health Organization classification system based on a combination of morphology, immunophenotype, genetics, and clinical features. These groups include AML with recurrent genetic abnormalities, AML with myelodysplasia-related features, therapy-related myeloid neoplasm, and AML, not otherwise specified.

## Therapy

Standard therapy for remission induction in patients under age 60 years (excluding APML) is a combination of an anthracycline (e.g., daunorubicin) and cytarabine (Ara-C). This is an intensive regimen and typically requires a prolonged hospital stay to deal with complications of tumor lysis syndrome, DIC, severe cytopenias, and infections. Approximately 70% of younger patients will enter remission. The results are much less favorable in patients >60 years of age where toxicity tends to be higher, remissions less frequent (45%), and long-term outcome poorer. In the elderly, intensive regimens are not typically used. When possible, there should be consideration for treatment on a clinical trial because there has yet to be an optimal therapy for the older patient population. Once remission is achieved, consolidation therapy is administered. In favorable disease (e.g., t[8;21] or inv[16]) the consolidation therapy includes four courses of high-dose cytarabine. In adverse risk disease, eligible patients typically undergo allogeneic HSCT or clinical trials. APML is a special case where therapy consists of ATRA-based therapy, including ATRA plus arsenic trioxide in low-risk APML and ATRA plus intensive chemotherapy followed by maintenance therapy with ATRA, and a regimen of antimetabolites in high-risk APML. Patients with APML experience excellent long-term survival. A potentially fatal complication of ATRA-based therapies includes differentiation syndrome (previously called *retinoic acid syndrome*), which is characterized by fever, peripheral edema, pulmonary infiltrates, hypoxemia, and respiratory distress

**TABLE 14.2 Acute Myelogenous Leukemia Prognostic Factors**

Good Prognosis	Poor Prognosis
Age <60 years	Age >60 years
<i>De novo</i> acute myelogenous leukemia	Secondary to underlying hematologic disorder Secondary to prior therapy
Cytogenetics and mutations

inv(16) bi-allelic CEPB- $\alpha$	Complex cytogenetics inv(3) or t(3;3)
Failure to achieve an initial complete remission	
African-American men have a lower remission rate and overall survival when other prognostic factors are considered	
Less important: high WBC or LDH at diagnosis	
<i>LDH</i> , Lactate dehydrogenase; <i>WBC</i> , white blood cell.	

triggered by a cytokine storm, which occurs in up to one-quarter of the patients with APML during induction. Glucocorticoids are used to treat and prevent differentiation syndrome.

## Prognosis

There are well-defined factors that contribute to prognosis in AML (Table 14.2). A principal factor is increasing age. The outcome for older adults (generally greater than age 60 years) is markedly inferior to that in younger adults with the same disease. Reasons for the poor results in the older cohort include poor stem cell reserve, comorbid disease, and intrinsic resistance to chemotherapy marked by adverse risk cytogenetics. For patients <60 years of age the complete remission rate is approximately 70%, with an overall survival of about 30%. However, for patients >60 years of age, the remission rate is only 45% and the survival rate is 10%.

Cytogenetics and molecular markers are critical determinants of outcome in younger patients. For instance, in the presence of t(15;17) or t(8;21) there is a 60% to 80% long-term disease-free survival, whereas monosomy 7 results in a <10% long-term disease-free survival. Recurrence of AML (or disease relapse) remains the primary treatment problem. Further, approximately 10% to 40% of newly diagnosed AML do not achieve a complete remission despite intensive induction therapy. Relapsed or refractory disease is associated with an extremely poor prognosis. Recent data using deep sequencing technology suggest that AML relapse is associated with the addition of new mutations and clonal evolution, which is partly influenced by chemotherapy.

## Acute Lymphoblastic Leukemia

ALL is primarily a disease of childhood; however, one-third of cases occur in adults. There are approximately 1000 cases per year in adults with a slight increase in incidence over the age of 50 years. Males are slightly more affected than females, and African Americans have a 60% lower risk. Exposure associations are less clear than in AML. There does seem to be an increased risk in industrialized countries.

ALL derives from primitive lymphoid cells of either B-cell or T-cell lineage, although B lineage disease is more common. ALL is divided into pre-B-cell, T-cell, and B-cell disease. Pre-B-cell ALL is the most frequent form of ALL, representing malignant transformation of a lymphoid progenitor that has undergone incomplete maturation along the B-cell lineage. T-cell ALL has similarly become transformed before full T-cell maturation has occurred. In contrast, B-cell ALL, the least common type of ALL, is the leukemic phase of Burkitt lymphoma. In contrast to pre-B-cell ALL, the cells have matured adequately to express cell surface immunoglobulins.

### Diagnosis

Usually signs and symptoms are associated with bone marrow failure: pallor, fatigue, mucosal bleeding, bruising, or fever and infection. Leukemic infiltrates of the meninges are common, although usually later in the course. T-cell ALL presents with the highest white blood counts and has a specific association with mediastinal masses.

The diagnosis is made on examination of the peripheral blood smear and/or bone marrow. Typical leukemic blast morphology is supplemented by flow cytometry, cytogenetics, and molecular analysis. Morphologically they appear somewhat different from AML, having fewer granules and less cytoplasm. Pre-B-cell ALL is characterized by cell surface CD10, CD19, cytoplasmic terminal deoxynucleotidyl transferase (TdT), and immunoglobulin gene rearrangements. Chromosome abnormalities include hyperdiploidy and hypodiploidy as well as specific translocations. In 30% of adults there is a variant of the Philadelphia chromosome that produces a smaller BCR/ABL fusion transcript (p190) than that occurring in CML. Many of the other chromosomal abnormalities include translocations involving the immunoglobulin gene locus or the *MLL* gene. T-cell ALL is characterized by expression of TdT, cell surface T-cell markers such as CD7, T-cell receptor gene rearrangement, and chromosomal abnormalities involving the T-cell receptor rather than immunoglobulin genes. In contrast to pre-B ALL, B-cell ALL expresses surface immunoglobulin and has translocations involving one of the immunoglobulin gene loci and the *MYC* oncogene on chromosome 8.

### Therapy

In general, principles of therapy are similar to AML, except that risk of central nervous system (CNS) relapse is much higher and requires specific prophylaxis. Typically, induction therapy consists of a combination of anthracycline,

vincristine, prednisone, cyclophosphamide, and L-asparaginase. Induction is followed by a complex series of treatments including CNS prophylaxis, intensified postremission therapy, and 1 to 2 years of maintenance chemotherapy. These multiagent combination chemotherapy regimens result in complete remission rates >80%. Alternative multiagent regimens (e.g., hyper-CVAD [cyclophosphamide, vincristine, doxorubicin, and dexamethasone]) are similarly effective. Patients who have t(9;22) are treated with imatinib or dasatinib in addition to intensive chemotherapy. Despite high remission rates, one-third of patients with standard risk ALL and two-thirds of high-risk patients relapse. Adults with ALL have disease-free survival (DFS) rates of 30% to 40% long term, whereas children with ALL have DFS rates of greater than 80%. There is a trend toward using intensive pediatric-inspired regimens featuring pegylated-asparaginase in the upfront treatment of adults aged 50 years and under. Although long-term follow-up is not yet available, the 3-year DFS is 73% and the 3-year overall survival is 75% for those who achieve complete remission with this regimen. Allogeneic HSCT continues to play an important role in the management of ALL. A recent international collaboration of the Eastern Cooperative Oncology Group and the Medical Research Council of Great Britain demonstrated that allogeneic HSCT improves outcome in patients with standard-risk disease. All patients with t(9;22) should be offered HSCT if feasible.

Immunotherapies including monoclonal antibodies and adoptive T-cell therapies are newer agents in the ALL treatment arsenal. Monoclonal antibodies have demonstrated high response rates and survival benefits in the relapsed and refractory setting with drugs targeting CD20 (i.e., rituximab [Rituxan]), CD22 (i.e., inotuzumab ozogamicin), and CD19 (i.e., blinatumomab [Blinicyto]). More recently, T-cell therapy with tumor-targeted chimeric antigen receptor (CAR)-modified T cells has emerged as a promising therapy with profound activity in refractory patients. In CAR-T-cell therapy, patient-derived T cells are genetically modified to express a protein receptor that recognizes a particular antigen found on ALL cells. This therapy is associated with risk for cytokine release syndrome, which is characterized by high-grade fever, hypotension, hypoxia, and neurologic disturbances.

### Prognosis

The prognosis of adult ALL has not yet approached the high cure rates observed in childhood ALL. This reflects in part a higher prevalence of high-risk cytogenetic variants in adults as well as reluctance or inability on the part of adult hematologist-oncologists to use asparaginase-containing regimens. Intensive chemotherapy combined with allogeneic HSCT results in long-term DFS of >50% in adults with pre-B ALL. If the Philadelphia chromosome is present, outcomes are less favorable. The recent addition of imatinib or dasatinib to conventional chemotherapy or to prednisone alone is promising, although results are less mature. The genetic basis of T-cell ALL has only recently been uncovered with identification of

a mutation in the *NOTCH1* gene (whose protein is critical in T-cell differentiation) in up to 60% of cases, and thus may represent an attractive therapeutic target.

## Chronic Lymphocytic Leukemia

CLL originates from antigen-stimulated mature B lymphocytes, which either avoid apoptotic death or undergo apoptosis, followed by replacement from a pool of precursor cells. CLL is the most frequent and prevalent leukemia. There are more than 15,000 new cases per year in the United States. There are no known etiologic factors, although there is a tendency for patients to have a family history of a hematologic malignancy. CLL is a disease of aging; the median age is greater than 60 years, and only 10% to 15% of patients are less than 50 years of age.

### Diagnosis and Staging

The diagnosis of CLL is commonly incidental, and approximately half of patients are asymptomatic. Other patients may have some combination of lymphadenopathy, splenomegaly, anemia, thrombocytopenia, and hypogammaglobulinemia. Examination of the blood reveals mature-appearing lymphocytes, although some cells will be damaged in processing the slide resulting in “smudge cells.” Immunophenotyping is normally used to differentiate CLL from other lymphoid malignancies in a leukemic phase. CLL typically expresses the B-cell antigens CD5, CD19, and CD20, as

well as clonal immunoglobulin light chains. The two common staging systems are Rai (stage 0-4) and Binet (stage A, B, C) as shown in Table 14.3.

### Therapy

Those patients who are asymptomatic and who have better prognosis disease (e.g., 13q-) may be safely followed without therapy. In general, treatment is indicated when there is progressive lymphadenopathy or hepatosplenomegaly, disease-related symptoms, or autoimmune hemolytic anemia or thrombocytopenia unresponsive to corticosteroids. Lymphocytosis per se is not a criterion for treatment.

Fludarabine-based therapy has largely replaced chlorambucil (Leukeran) as the mainstay of treatment. Fludarabine is often used in combination with rituximab (anti-CD20 monoclonal antibody). However, chlorambucil is inexpensive, nontoxic, and easy to administer, making it appealing for some elderly patients. In addition to rituximab the monoclonal antibody alemtuzumab (Campath, anti-CD52) may be used in fludarabine-refractory CLL. This drug is highly immunosuppressive, and its use mandates pneumocystis prophylaxis and close monitoring for CMV reactivation. Combination chemoimmunotherapy regimens are now recommended for front-line treatment of CLL. Bendamustine (Treanda), an alkylating agent, has shown high response rates in combination with chlorambucil and with rituximab (Rituxan). Combination fludarabine, cyclophosphamide,

11g-				6–7 years	
17p-				2–3 years	
<sup>a</sup> Anemia and thrombocytopenia are not immune mediated.					

and rituximab remains the first-line treatment option for patients with CLL eligible for intensive therapies.

There are newer oral therapies that have shown significant improvement in the outcomes of patients with relapsed or refractory CLL. Ibrutinib (Imbruvica), an irreversible inhibitor of *Bruton tyrosine kinase* that targets the B-cell receptor signaling pathway, has significant monotherapy activity in patients with del(17p), who are poor risk. Treatment with ibrutinib results in a transient lymphocytosis from CLL cells egressing from the lymph nodes. Idelalisib (Zydelig), an isoform-selective oral inhibitor of PI3K-delta, has promising clinical activity as monotherapy and in combination with rituximab. Both ibrutinib and idelalisib-based treatments induce response in patients in whom chemoimmunotherapy has failed. Persistent disease remains a concern because of the potential development of resistance that is driven by the constitutive expression of BCL-2, an anti-apoptotic protein. Venetoclax, a selective BCL-2 inhibitor, is a newer agent that has demonstrated significant clinical activity including in patients with poor prognostic features. Patients must be monitored for tumor lysis syndrome when initiating venetoclax because of a rapid reduction in tumor volume.

Currently, the only curative therapy for CLL is allogeneic HSCT. There is increasing data indicating that reduced intensity regimens that are tolerable to older people control the disease immunologically via a graft-versus-leukemia effect, although opportunistic infections and graft-versus-host disease remain problematic. Patient selection and the timing of this treatment must be undertaken carefully.

## Prognosis

Younger patients with stage 0 disease or good prognosis chromosomes often have a survival that is similar to an age-matched population. Older patients particularly with more indolent disease tend to die of causes independent of CLL. Patients with more advanced disease may have a median survival of 6 to 7 years, whereas patients with the most aggressive forms have a median survival of 1 to 3 years. Prognosis is related to staging, but cytogenetic abnormalities as established by fluorescence in situ hybridization have proven to be more helpful. The most common abnormality is deletion of 13q. It is observed in about 40% of patients and is the most favorable. Normal karyotypes and trisomy 12 are the next most common and have intermediate outcomes. Deletions of 17p or of 11q as well as complex abnormalities have the worst outcome but fortunately are least common as well (see Table 14.3). IGHV mutational status is an important predictor of survival outcome, with unmutated status being associated with poor prognosis compared with mutated status despite stage of disease. Expression of ZAP-70 is also associated with shorter survival outcomes. Abnormalities in *TP53* independently predict for decreased survival and resistance to chemotherapy.

A frequent cause of morbidity and mortality is infections related to hypogammaglobulinemia. The most common

bacterial pathogens are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*; however, particularly after chemotherapy there is an increased risk of candidiasis, listeriosis, *Pneumocystis jiroveci*, and herpesvirus infections such as CMV and herpes simplex virus. All fevers must be taken seriously with appropriate diagnostic testing. Patients receiving highly immunosuppressive regimens should be monitored for CMV reactivation, but prophylactic intravenous immunoglobulins are reserved for patients with recurrent bacterial infections.

Coombs-positive hemolytic anemia and/or immune thrombocytopenia occur in about 20% of patients. These sometimes develop after the initiation of therapy and reflect immunologic dysregulation because the clone does not produce the antibodies. Failure of immune surveillance results in an increased risk of solid tumors such as skin and colon cancers. Moreover, transformation to large cell lymphoma (so-called Richter transformation) occurs in 15% of patients. It is heralded by increasing lymphadenopathy, hepatosplenomegaly, fever, abdominal pain, weight loss, anemia, and thrombocytopenia with a rapid rise in lactate dehydrogenase, and it has a poor prognosis.

## Related B-Cell Leukemias

Although rare, two additional B-cell leukemias (prolymphocytic leukemia and hairy cell leukemia) should be considered in the differential diagnosis of CLL. Prolymphocytic leukemia may be of either B-cell or T-cell lineage. It occurs in somewhat older patients than those presenting with CLL and tends to be more advanced at presentation. Symptoms include weight loss, fever, and abdominal pain from splenomegaly. The white blood count tends to be quite high, and the smear is characteristically different from CLL; the cells are larger with a more prominent nucleolus. The immunophenotype distinguishes it from CLL by stronger expression of surface immunoglobulins, and they are less likely to express CD5. This disease responds poorly to therapy, with a median survival of 1 to 3 years.

Patients with hairy cell leukemia often have symptoms related to marrow depression with little in the way of leukocytosis, although characteristic hairy cells are usually seen in the blood. Similar to CLL, the cells express the B-cell antigens CD19 and CD20 but also the monocyte antigen CD11c and characteristically CD103. Treatment is indicated in the setting of massive or progressive splenomegaly, serious cytopenias, recurrent infections, or bulky lymphadenopathy. The purine analogs cladribine (Leukostatin) and pentostatin (Nipent) are extremely effective, resulting in long remissions in 70% to 80% of patients with little disease-related mortality. The BRAF V600E mutation is present in the overwhelming majority of patients with classic hairy cell leukemia, and there has been encouraging clinical activity with the low-dose BRAF inhibitor, vemurafenib, in the refractory setting.

## Chapter Review

### Questions

- A 35-year-old man calls because he noted large bruises on his arms and legs. He had been playing touch football but felt that the bruising was unexpectedly severe. He had no fever or weight loss. Physical examination confirmed several 5- to 10-cm ecchymoses on the arms and legs including bruises on the medial surfaces. Examination was otherwise normal. White blood count was 1300/dL with 25% polymorphonuclear leukocytes (PMN), 55% lymphocytes, and 20% atypical cells. Hemoglobin is (Hb) 13.6 g/dL, platelets 22,000/dL, international normalized ratio (INR) 2.2, partial thromboplastin time (PTT) 50 s, and D-dimer is elevated. Which of the following is true?

  - Postviral immune thrombocytopenic purpura is the most likely diagnosis, and a course of prednisone is warranted.
  - The low white blood count precludes the diagnosis of AML.
  - Pancytopenia plus evidence of DIC are suspicious for promyelocytic leukemia.
  - HLA typing should be obtained immediately in anticipation of stem cell transplantation.
  - Cytogenetics is likely to show evidence of a translocation involving the *MYC* oncogene.
- Which of the following statements about CLL is correct?

  - CLL uniformly requires therapy.
  - Staging of CLL requires a bone marrow aspirate.
  - A subset of patients with CLL will have disease transformation into another lymphoproliferative disorder, which represents a terminal event.
  - Chromosomal abnormalities such as del(13q) and trisomy 12 are poor prognostic findings of CLL.
  - Decreased levels of zeta chain-associated protein 70 (ZAP 70) denotes a poor prognosis.
- A 70-year-old man is found to have an enlarged spleen (5 cm below the costal margin) on routine annual evaluation. He has been feeling well, although on close questioning may have lost 5 pounds in the last 6 months, and he has had a few episodes of night sweats. Laboratory studies show white blood count 56,000/dL, with 50% PMN, 15% bands, 10% lymphocytes, 5% monocytes, 5% basophils, 3% metamyelocytes, 5% myelocytes, 2% promyelocytes, and 5% blasts. Hb is 13.8 g/dL, platelets 1,250,000/dL. Which of the following statements is true?

  - Prognosis is grim, with 2-year survival of 10%.
  - The most appropriate therapy is lifetime daily interferon- $\alpha$ .
  - Cytogenetic analysis of the bone marrow is unlikely to provide useful information.
  - Imatinib therapy has a 95% chance of normalizing hematopoiesis within 3 months.
  - DIC is a common complication of therapy.
- A 30-year-old woman presents with a diagnosis of CML in chronic phase, confirmed by cytogenetic analysis and molecular testing for the BCR-ABL1 transcript. She is started on dasatinib 100 mg daily. At her routine 3-month visit, she achieves complete hematologic remission and her BCR-ABL1 transcript level is less than 10% by quantitative PCR methods (using International Scale). Six months later, she reports having fatigue with gradual, increased shortness of breath and pleuritic chest discomfort. She is afebrile. What should you do next?

  - A bone marrow biopsy because she likely has transformed to blast-phase CML.
  - Perform an infectious workup, and immediately start intravenous antibiotics because she is at high risk for bacterial infections.
  - A stat referral to cardiology for cardiac catheterization because she is at high risk for a myocardial infarction.
  - A chest x-ray and consideration of diuretics plus supportive care for suspected pleural effusion.
- Which of the following statements about Philadelphia-positive (Ph<sup>+</sup>) ALL in adults is correct?

  - Patients with Ph<sup>+</sup> ALL have an excellent prognosis.
  - Nonintensive therapies for Ph<sup>+</sup> ALL include steroids plus a TKI of BCR-ABL.
  - Patients with Ph<sup>+</sup> ALL have a low risk of CNS involvement.
  - If inducing with an intensive chemotherapy regimen, a TKI of BCR-ABL may be omitted from therapy.

## Non-Hodgkin and Hodgkin Lymphoma

OREOFE O. ODEJIDE AND ANN S. LACASCE

**L**ymphomas are malignancies of lymphoid cells. These neoplasms originate from cells in the B lymphocyte and T lymphocyte/natural killer (NK) cell lineages. Broadly they are categorized into non-Hodgkin (NHL) and Hodgkin lymphomas (HL). The World Health Organization (WHO) recognizes over 40 major types of NHLs and 5 major types of HLs.

### Overview of the Lymphatic System and Lymphocyte Immunology

The lymphatic system is composed of central and peripheral lymphoid organs (Fig. 15.1). Central lymphoid organs are the sites where immature lymphoid cells develop into mature B and T cells; these sites are the bone marrow (for B-cell development) and the thymus (for T-cell development). Peripheral lymphoid organs are sites where mature lymphoid cells aggregate into functioning units; these sites are the lymph nodes, spleen, and mucosa-associated lymphoid tissues (MALT).

Immature lymphoid cells in the bone marrow differentiate into pro-B and pro-T cells. The former complete development into mature B cells in the bone marrow, whereas the latter undergo subsequent maturation in the thymus. Mature B and T cells exit the bone marrow and thymus, respectively, and migrate to the peripheral lymphoid organs. Mature B and T cells bear cell surface immunoglobulins (Ig, containing heavy-chain and light-chain proteins) and T-cell receptors (TCR, containing alpha and beta, or delta and gamma, subunits), respectively, that en masse possess an infinite repertoire of antigenic specificities. The molecular basis for Ig and TCR antigenic diversity is the process of V(D)J recombination that occurs during B-cell and T-cell development, whereby variable (V), diversity (D), and joining (J) gene segments of Ig and TCR genes are assembled together in semirandom fashion to generate the mature genes. Somatic hypermutation of mature rearranged Ig genes further modifies the repertoire of antigenic specificities in activated B cells.

Within each lymph node a fibrous capsule surrounds a central parenchyma, which is divided into an outer cortex, a paracortex, and an inner medulla. The cortex contains primary follicles with mostly unstimulated B cells and secondary follicles with antigen-stimulated, activated B cells. Secondary

follicles are further partitioned into a germinal center containing activated B cells, surrounded by a mantle zone of mostly unstimulated B cells and a few T cells. The lymph node paracortex contains mostly T cells. The medulla contains mostly macrophages and Ig-secreting plasma cells.

### Non-Hodgkin Lymphoma

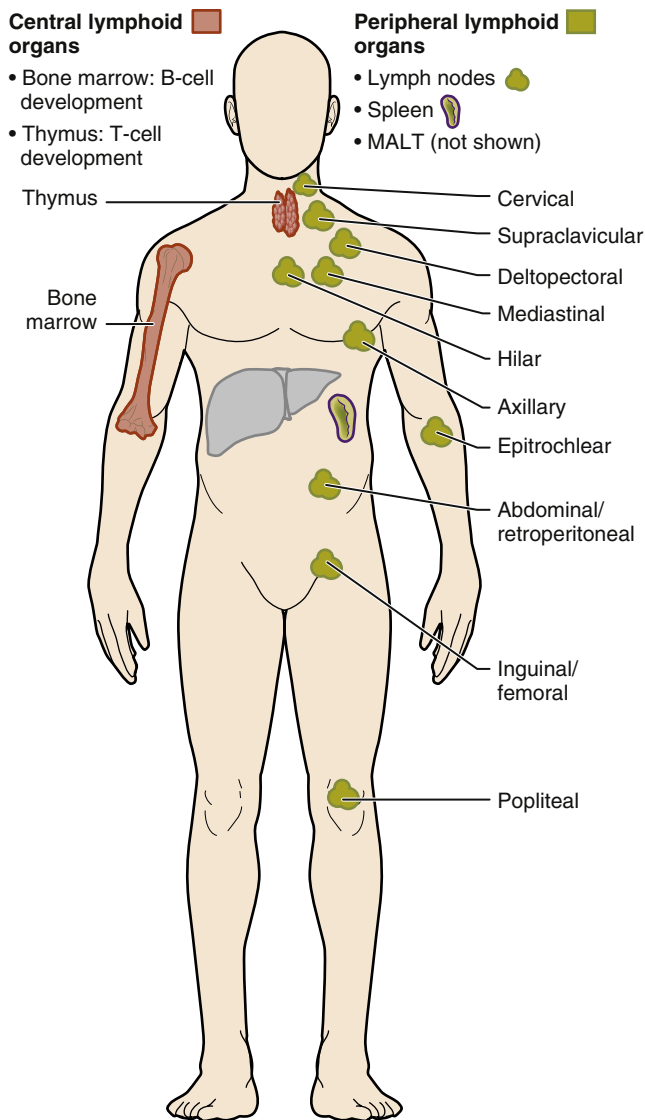

NHL is the seventh most common cancer and the most common hematologic malignancy in the United States, with approximately 71,000 new cases diagnosed each year. NHL is also the seventh most common cause of cancer-related deaths in the United States, accounting for approximately 19,000 deaths per year.

### Clinical Presentation Non-Hodgkin Lymphoma

- Lymphadenopathy is present in over two-thirds of patients with NHL, with the rapidity of lymph node enlargement reflecting the aggressiveness of the underlying lymphoma.
- B symptoms are defined as fever  $>100.4^{\circ}\text{F}$ , drenching night sweats requiring a change of clothes, and weight loss of  $>10\%$  baseline body weight over a 6- to 12-month period. B symptoms are observed in about 45% of aggressive or highly aggressive NHL and in  $<25\%$  of indolent NHL; when present in the setting of an indolent NHL, B symptoms tend to indicate a large burden of disease or transformation into aggressive lymphoma.
- Local symptoms reflect the degree to which a lymphoma impairs the function of involved or adjacent tissues, with different NHLs displaying varying degrees of extranodal (i.e., external to the lymph nodes) involvement. Common sites of extranodal disease include the liver, spleen, gastrointestinal tract, skin, bone marrow, and central nervous system (CNS); rare sites include the kidneys, bladder, adrenals, heart (particularly the pericardial space), lungs, breast, testes, and thyroid.

### Evaluation of Non-Hodgkin Lymphoma

Evaluation of a new or suspected diagnosis of NHL requires a thorough history, physical examination, laboratory evaluation, imaging analysis, and tissue sampling for pathology review (Fig. 15.2).

• **Fig. 15.1** Overview of the lymphatic system. Central lymphoid organs (red) are the bone marrow, where B-cell development occurs, and the thymus, where T-cell development occurs. Peripheral lymphoid organs (green) are the lymph nodes, spleen, and mucosa-associated lymphoid tissues (MALT). The major lymph node regions are shown (green clovers).

## History

A comprehensive history in the evaluation of a new or suspected diagnosis of NHL should assess for B symptoms and for factors known to be associated with NHL, including the following:

- **Autoimmune and inflammatory diseases:** Examples are systemic lupus erythematosus, rheumatoid arthritis, inflammatory bowel disease, dermatomyositis, and Sjögren syndrome, all of which may be associated with NHL and, occasionally, HL. Celiac disease is associated with enteropathy-associated T-cell lymphoma, autoimmune thyroiditis with extranodal marginal zone lymphoma (MZL), and cryoglobulinemia with NHL. Sarcoidosis is both associated with and may mimic NHL by virtue of lymphadenopathy.

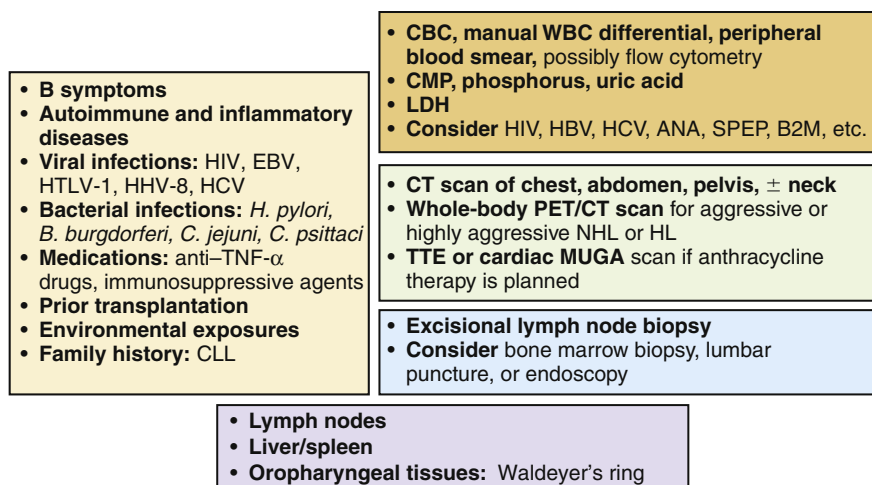

- **Viral infections:** Examples include human immunodeficiency virus (HIV), associated with diffuse large B-cell lymphoma (DLBCL), Burkitt lymphoma (BL), primary CNS lymphoma, primary effusion lymphoma, plasmablastic lymphoma, and HL; Epstein-Barr virus (EBV), associated with DLBCL, BL, NK- and T-cell lymphomas, and HL; human T lymphotropic virus type 1 (HTLV-1), is associated with adult T-cell lymphoma/leukemia; human herpesvirus 8 (HHV-8), associated with HIV+ primary effusion lymphoma and with HIV+ plasmablastic lymphoma; and hepatitis C virus (HCV), associated with splenic and extranodal MZLs.
- **Bacterial infections:** The major association of bacterial infections is with extranodal MZLs in various organs. The most common infections are *Helicobacter pylori* (stomach, also known as gastric MALToma), *Borrelia burgdorferi* (skin), *Campylobacter jejuni* (small intestine), and *Chlamydia psittaci* (eye).
- **Medications:** The most important medications associated with NHL are immunosuppressive agents (e.g., methotrexate, infliximab, 6-mercaptopurine, azathioprine, tacrolimus, cyclosporine, and mycophenolate) and targeted therapies against tumor necrosis factor-alpha (e.g., infliximab [Remicade], adalimumab [HUMIRA], and etanercept [Enbrel]).
- **History of prior transplantation,** associated with B- or T-cell posttransplant lymphoproliferative disease.
- **Environmental exposure** to pesticides, solvents, chemicals, or chemotherapy.
- **Family history** of lymphoma (particularly chronic lymphocytic leukemia [CLL]), leukemia, or other hematologic diseases.

## Physical Examination

- **Lymph node examination:** The major peripheral lymph node groups are the cervical (anterior and posterior), supraclavicular, axillary, epitrochlear, inguinal, and popliteal nodes. Features suggestive of malignancy include nodes that are >1 cm in diameter; have a firm, rubbery consistency; are fixed or immobile; are nontender to palpation; are located in the posterior cervical, supraclavicular, or epitrochlear chains; or are diffusely distributed.
- **Liver and spleen examination:** Every patient with a new or suspected diagnosis of NHL or HL should be evaluated for hepatomegaly or splenomegaly, because the liver and spleen are common sites of extranodal involvement.
- **Oropharyngeal examination:** Waldeyer's ring, a region of lymphoid tissue encompassing the tonsils, base of tongue, and nasopharynx, may be involved by various lymphomas, particularly mantle cell lymphoma (MCL). Aphthous ulcers may rarely be manifestations of oral lymphoma. Oral petechiae may indicate thrombocytopenia or disseminated intravascular coagulation.

## Laboratory Evaluation

- **Complete blood count (CBC):** Anemia or thrombocytopenia may reflect marrow infiltration or an associated

• **Fig. 15.2** Evaluation of non-Hodgkin lymphoma (NHL). Shown are components of history (yellow), physical examination (purple), laboratory investigation (orange), imaging (light green), and tissue analysis (blue) that should be explored in evaluation of new cases of NHL. ANA, Antinuclear antibody; B2M, beta-2 microglobulin; CBC, complete blood count; CLL, chronic lymphocytic leukemia; CMP, comprehensive metabolic panel; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV-8, human herpesvirus 8; HL, Hodgkin lymphoma; HTLV-1, human T lymphotropic virus type 1; LDH, lactate dehydrogenase; MUGA, multigated acquisition; PET, positron emission tomography; SPEP, serum protein electrophoresis; TTE, transthoracic echocardiogram; WBC, white blood cell.

autoimmune process such as autoimmune hemolytic anemia (AIHA) or immune thrombocytopenia (ITP), both of which may be seen with CLL. The white blood cell (WBC) differential should be manually counted to assess for lymphocytosis. Peripheral blood smear should be examined for unusual lymphoid cell morphologies. In select cases, flow cytometry may be performed to evaluate for circulating monoclonal lymphoid populations.

- *Comprehensive metabolic panel*, phosphorus, and uric acid. Creatinine and liver function tests assess for end-organ damage caused by lymphomatous infiltration. Calcium, potassium, phosphorus, and uric acid assess for tumor lysis, which may be seen with aggressive or highly aggressive lymphomas.
- *Lactate dehydrogenase (LDH)*: The serum LDH level is a marker of tumor lysis in aggressive or highly aggressive NHL and serves as an important prognostic factor in many NHL subtypes. It may also be an indicator of transformation from indolent into aggressive NHL.
- *Additional laboratory tests* may include specific serologic, polymerase chain reaction, and culture studies for infectious or autoimmune processes as indicated by the clinical scenario. Examples are HIV, EBV, HTLV-1, hepatitis B virus, HCV, *H. pylori*, antinuclear antibody (ANA), rheumatoid factor (RF), serum protein electrophoresis, beta-2 microglobulin (B2M), cryoglobulin, and Coombs testing.

### Imaging Evaluation

The imaging study of choice in the evaluation of NHL is a CT scan of the chest, abdomen, and pelvis. CT scan of the neck may be performed if there is suspicion for cervical or upper oropharyngeal disease.

- For aggressive and highly aggressive NHL (and HL), whole-body fluorodeoxyglucose positron emission tomography in combination with CT (PET/CT) is routinely obtained in the initial staging and subsequent evaluation of response to therapy. In general, rapidly growing malignancies are exquisitely sensitive to detection on PET imaging because of robust uptake of fluorodeoxyglucose. The role of PET/CT in the evaluation of indolent NHL is less clear.
- Transthoracic echocardiogram or cardiac multigated acquisition scan should be performed in all patients who will be receiving chemotherapy containing anthracyclines (e.g., doxorubicin [Adriamycin]).

### Tissue Evaluation

- Full excisional biopsy of an involved lymph node is the preferred procedure for obtaining tissue for pathologic review in evaluation of lymphoma. In patients with multiple enlarged peripheral lymph nodes, supraclavicular nodes have the highest diagnostic yield, followed by cervical or axillary nodes. Inguinal nodes are of low diagnostic utility because their enlargement is often reactive.
- CT-guided core needle biopsy may be performed in cases where excisional lymph node biopsy is not feasible. Because of the small size of tissue obtained, diagnostic ability is reduced with core needle biopsy as compared with excisional biopsy.
- Fine-needle aspiration of an involved lymph node is not recommended in the evaluation of lymphoma because cytology samples do not allow for evaluation of lymph node architecture.
- Bone marrow biopsy is performed in the majority of patients with aggressive or highly aggressive NHL and in some patients with indolent NHL.

<ul style="list-style-type: none"> <li>• <b>B-cell markers:</b> CD19, CD20, CD22, CD79a. <i>The most important B-cell marker is CD20, the molecular target of rituximab.</i></li> <li>• <b>T-cell markers:</b> CD3, CD4, CD5, CD8, CD5. <i>The most important T-cell marker is CD5, as CD5 positivity in a B-cell NHL restricts the differential diagnosis to CLL and MCL.</i></li> <li>• <b>Surface Ig expression:</b> IgG, IgM, IgA, IgD, <math>\kappa</math> light chain, <math>\lambda</math> light chain.</li> <li>• <b>CD52:</b> all mature B and T cells. <i>CD52 is the molecular target of alemtuzumab, used in the treatment of CLL.</i></li> <li>• <b>CD138:</b> plasma cells (<i>myeloma</i>), lymphoplasmacytic cells (<i>Waldenstrom macroglobulinemia</i>).</li> <li>• <b>CD10:</b> germinal center–derived B cells (<i>Burkitt lymphoma, B lymphoblastic lymphoma/leukemia, FL subset of DLBCL</i>).</li> <li>• <b>CD30/CD15:</b> <i>either marker may be expressed in some subsets of peripheral T-cell lymphoma. CD30 is expressed in anaplastic large cell lymphoma. Both are expressed in classical HL.</i></li> <li>• <b>TdT (terminal deoxynucleotidyl transferase):</b> <i>B-lymphoblastic lymphoma/leukemia, T-lymphoblastic leukemia/lymphoma.</i></li> <li>• <b>cyclin D1:</b> <i>MCL.</i></li> </ul>
<ul style="list-style-type: none"> <li>• <b>t(8;14), t(2;8), or t(8;22):</b> <i>BL. These translocations place c-myc protooncogene (chromosome 8) next to the enhancer elements of the Ig heavy chain (chromosome 14), <math>\kappa</math> light chain (chromosome 8), or <math>\lambda</math> light chain (chromosome 22).</i></li> <li>• <b>t(14;18):</b> <i>FL. This generates a tyrosine kinase that is the molecular target of imatinib (Gleevec).</i></li> </ul>

• **Fig. 15.3** Major immunophenotypic (*light yellow*) and cytogenetic (*darker yellow*) markers in non-Hodgkin lymphoma. *BL*, Burkitt lymphoma; *CLL*, chronic lymphocytic leukemia; *DLBCL*, diffuse large B-cell lymphoma; *FL*, follicular lymphoma; *HL*, Hodgkin lymphoma; *Ig*, immunoglobulin; *MCL*, mantle cell lymphoma.

- Lumbar puncture may be performed in patients with highly aggressive NHL who have suspicious neurologic manifestations or risk factors for CNS involvement (e.g., elevated LDH at initial presentation, involvement of more than one extranodal site, or infiltration of bone marrow, testes, paranasal sinuses, kidneys, or adrenal glands). In cases where the suspicion for CNS involvement is high, or where there may be concern for possible hematogenous seeding of the CNS by circulating lymphoma cells during lumbar puncture, intrathecal chemotherapy may be administered.
- Endoscopic evaluation of the gastrointestinal tract may be performed if there are suspicious gastrointestinal symptoms (e.g., dysphagia, abdominal pain, diarrhea, or constipation). At many academic centers, endoscopy has become part of the routine staging evaluation of MCL irrespective of symptoms, caused by the high incidence of gastrointestinal involvement with this disease. Direct visualization and laryngoscopy may be performed if examination of Waldeyer’s ring is clinically indicated.

### Pathologic Characterization of Non-Hodgkin Lymphoma

- **Histology:** Pathologic characterization of NHL begins with a histologic review of tissue. Individual lymphoid and nonlymphoid cells are observed for malignant characteristics such as irregular shape, uniform or monotonous appearance, or nucleoli. Global lymphoid

architecture is also evaluated because normal follicular lymph node architecture is often preserved in follicular lymphoma (FL) and other indolent NHL subtypes but may be disrupted in DLBCL, BL, and other aggressive or highly aggressive NHLs.

- **Immunophenotyping (Fig. 15.3):** The immunophenotype is the unique signature of cell surface proteins displayed by each type of NHL. Immunophenotyping may be performed by immunohistochemistry or flow cytometry; these techniques measure binding of antibodies directed against specific molecular targets. For B-cell NHL the most important cell surface marker is CD20, which serves as the molecular target of the anti-CD20 antibody rituximab (Rituxan) used in the treatment of a variety of B-cell NHLs.
- **Cytogenetic analysis (see Fig. 15.3):** Specific cytogenetic abnormalities, particularly translocations, are associated with different NHLs. Cytogenetic analysis is performed by karyotyping or fluorescent in situ hybridization (FISH).
- **Ki-67 or MIB-1 fraction:** Staining for Ki-67 or MIB-1 identifies actively dividing cells. The Ki-67 index or MIB-1 fraction may help distinguish the clinical aggressiveness of different NHL subtypes and may have prognostic significance in specific NHLs (e.g., MCL).

### Staging of Non-Hodgkin Lymphoma

Staging for NHL (Table 15.1) uses the Ann Arbor Staging System, originally devised for HL.

**TABLE 15.1 Ann Arbor Staging System for Non-Hodgkin Lymphoma (NHL) and Hodgkin Lymphoma (HL)**

Stage	Clinical Features
I	Single lymph node or lymph node area on one side of diaphragm
II	Two or more involved lymph node areas on same side of diaphragm
III	Disease on both sides of diaphragm, contained within nodal tissues (including spleen)
IV	Extranodal involvement (marrow, liver, lung)

For NHL and HL, the following subscript is commonly used:  
E: involvement of one extranodal site

For HL, four additional subscripts are used:  
A: absence of B symptoms  
B: presence of B symptoms  
X: bulky disease, defined as a nodal mass >10 cm in greatest transverse diameter, or a mediastinal mass whose maximum width is more than one-third the thoracic diameter at the level of the T5 to T6 intercostal space  
S: splenic involvement

From Rosenberg SA. Validity of the Ann Arbor staging classification for the non-Hodgkin's lymphomas. *Cancer Treat Rep.* 1977;61(6):1023–1027.

## Classification of Non-Hodgkin Lymphoma

WHO classifies NHL according to the parental cell type of origin and recognizes four broad categories of NHL: precursor lymphoid neoplasms, mature B-cell neoplasms, mature T-cell and NK-cell neoplasms, and posttransplant lymphoproliferative disorders. For practical reasons, and from the perspective of the general internist, the different NHL subtypes may be classified as indolent, aggressive, or highly aggressive (Box 15.1). Survival of untreated indolent NHL is generally on the order of years; aggressive NHL, months; and highly aggressive NHL, weeks. Major NHL subtypes are presented subsequently.

### Highly Aggressive Non-Hodgkin Lymphoma

#### B Lymphoblastic Leukemia/Lymphoma

B lymphoblastic leukemia/lymphoma is the lymphomatous counterpart of pre-B acute lymphoblastic leukemia (pre-B ALL) and is evaluated and treated similarly. The disease is defined as leukemia if the bone marrow is >25% involved. B lymphoblastic leukemia/lymphoma is more common in children but may present in older adults. Both B lymphoblastic leukemia/lymphoma and pre-B ALL express terminal deoxynucleotidyl transferase, which is unique to these diseases and to T lymphoblastic leukemia/lymphoma, distinguishing these disorders from mature B-cell and T-cell lymphomas. B lymphoblastic leukemia/lymphoma and pre-B ALL are also associated with a number of translocations, the most important being the t(9;22) translocation (Philadelphia chromosome). Whereas pediatric cases have a favorable prognosis, the clinical course in adult patients is generally unfavorable, particularly for t(9;22)+ disease. First-line treatment is a combined approach incorporating

### • BOX 15.1 Major Non-Hodgkin Lymphoma Subtypes Classified by Clinical Aggressiveness

Indolent: median survival of several years (untreated)

Follicular lymphoma  
Chronic lymphocytic leukemia/small lymphocytic lymphoma  
Marginal zone lymphoma  
Mantle cell lymphoma (MCL)<sup>a</sup>  
Lymphoplasmacytic lymphoma/Waldenström macroglobulinemia

Aggressive: median survival of a few to several months (untreated)

Diffuse large B-cell lymphoma  
Peripheral T- and natural killer-cell lymphoma  
Anaplastic large cell lymphoma

Highly aggressive: median survival of a few weeks (untreated)

B lymphoblastic leukemia/lymphoma  
T lymphoblastic leukemia/lymphoma  
Adult T-cell leukemia/lymphoma  
Burkitt lymphoma

<sup>a</sup>MCL is classified as indolent but behaves as aggressive non-Hodgkin lymphoma.

intensive chemotherapy, prophylactic CNS therapy, and allogeneic stem cell transplant; the tyrosine kinase inhibitor imatinib (Gleevec) is added in t(9;22)+ cases.

#### T Lymphoblastic Leukemia/Lymphoma

T lymphoblastic leukemia/lymphoma is the T-cell counterpart to B lymphoblastic leukemia/lymphoma and is treated similarly. It typically presents in young males with a mediastinal mass.

#### Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is caused by the HTLV-1 virus, endemic to southern Japan and the Caribbean, and also found in Africa, Latin America, and the Middle East. About 5% of HTLV-1+ patients develop ATLL, usually following a latency period of over 30 years. Although there are indolent and smoldering subsets, the majority of patients present with aggressive disease and have a poor prognosis. Treatment approaches include intensive chemotherapy, allogeneic stem cell transplant, and in some cases antiviral agents such as interferon-alpha or zidovudine.

#### Burkitt Lymphoma

BL represents more than one-half of pediatric NHL and <5% of all adult NHL in the United States.

**Pathologic Features.** BL is characterized by medium-sized B cells with round nuclei containing multiple nucleoli and cytoplasmic vacuoles. Owing to a high proliferative rate, spontaneous cell destruction and necrosis are common. With macrophages recruited to remove cellular debris, the overall appearance is of sheets of lymphoma cells with interspersed macrophages, forming a “starry sky” pattern (Fig. 15.4). By definition, BL cells harbor translocations involving the

• **Fig. 15.4** Histologies of select non-Hodgkin lymphoma and Hodgkin lymphoma subtypes. (A) The starry sky pattern of Burkitt lymphoma. Hematoxylin and eosin stain. (Modified from Harris NL, Horning SJ. Burkitt's lymphoma. The message from microarrays. *N Engl J Med.* 2006;354(23):2495–2498.) (B) Peripheral blood smear of chronic lymphocytic leukemia, showing lymphocytes, thrombocytopenia, and smudge cells (arrows). (From the American Society of Hematology Image Bank. Lazarchick J (2001). Chronic lymphocytic leukemia: thrombocytopenia. Image #00001359.) (C) Owl's eye nuclei of RS cell in classical Hodgkin lymphoma, nodular sclerosis subtype. (From American Society of Hematology Image Bank. Kadin M (2002). Hodgkin lymphoma. Image #00001741.)

*c-myc* protooncogene on chromosome 8, the most common being the t(8;14) translocation, which positions *c-myc* close to the Ig heavy chain enhancer on chromosome 14, leading to *c-myc* overexpression. The t(8;14) translocation accounts in part for the very high proliferative index of BL cells, with Ki-67 staining 100% of cells.

**Clinical Presentation.** The three major subtypes of BL are endemic, sporadic (nonendemic), and immunodeficiency-associated BL. Endemic BL is found in Africa, mostly in the pediatric population, is strongly associated with EBV infection, and presents as a jaw tumor with bone marrow, CNS, and other multiorgan involvement. Sporadic BL is found throughout the world, is associated with EBV in 30% of cases, and presents as disseminated disease with abdominal lymphadenopathy, ascites, and often bone marrow and/or CNS involvement. Immunodeficiency-associated BL occurs primarily in association with HIV, with only a subset being EBV+.

**Prognosis.** BL is potentially curable, although bone marrow and CNS involvement at presentation are adverse features and predict a higher risk of relapse. Response rates to chemotherapy are very high, in part reflecting the high proliferative rate of BL cells. Children with BL have an excellent prognosis with high rates of durable remission, whereas adults have a less favorable course because of an increased risk of relapsed disease.

**Treatment.** First-line treatment is intensive combination chemotherapy. Two commonly used chemotherapy regimens are hyper-CVAD (cyclophosphamide, vincristine, doxorubicin, dexamethasone) and the modified Magrath regimen (CODOX-M/IVAC: cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate, ifosfamide, cytarabine, etoposide), both of which incorporate prophylactic CNS therapy. Rituximab has been combined with both regimens, with encouraging results of improved outcomes.

**TABLE 15.2 International Prognostic Index for Diffuse Large B-Cell Lymphoma**

Adverse prognostic factors (“APLES”):  
 Advanced age (>60 years)  
 Poor performance status  
 Elevated lactate dehydrogenase  
 Extranodal disease (≥2 sites)  
 Stage III or IV disease

**Treatment Without Rituximab<sup>a</sup>**

No. of Risk Factors	Complete Remission	5-Year Relapse-Free Survival	5-Year Overall Survival
0–1 Low risk	87%	70%	73%
2 Low-intermediate risk	67%	50%	51%
3 High-intermediate risk	55%	49%	43%
4–5 High risk	44%	40%	26%

**Treatment With Rituximab<sup>b</sup>**

No. of Risk Factors	4-Year Progression-Free Survival	4-Year Overall Survival
0 Very good risk	94%	94%
1–2 Good risk	80%	79%
3–5 Poor risk	53%	55%

<sup>a</sup>From the International Non-Hodgkin's Lymphoma Prognostic Factors Project. A predictive model for aggressive non-Hodgkin's lymphoma. *N Engl J Med.* 1993;329(14):987–994.

<sup>b</sup>From Sehn LH, Berry B, Chhanabhai M, et al. The Revised International Prognostic Index (R-IPI) is a better predictor of outcome than the standard IPI for patients with diffuse large B-cell lymphoma treated with R-CHOP. *Blood.* 2007;109(5):1857–1861.

**Aggressive Non-Hodgkin Lymphoma****Diffuse Large B-Cell Lymphoma**

DLBCL is the most common subtype of NHL, accounting for approximately 30% of all NHLs.

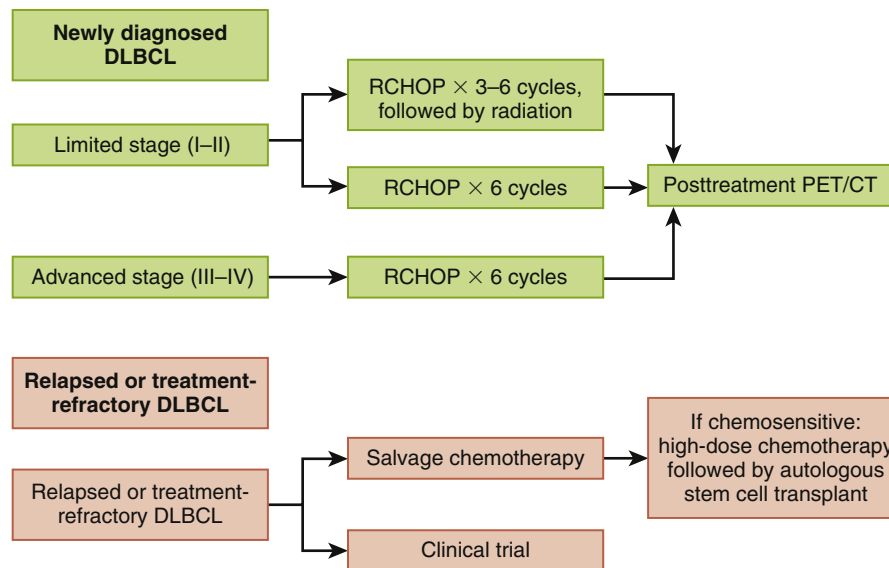

**Pathologic Features.** DLBCL is characterized by heterogeneous large B cells that proliferate in a diffuse pattern, disrupting normal lymph node architecture. The Ki-67 index is typically around 70%; cases with a Ki-67 index >90% may occur, particularly in association with translocations involving or overexpression of *c-myc*, which can cloud histologic distinction from BL. About one-third of DLBCL cases bear the t(14;18) translocation of FL, which may indicate transformation from an earlier FL.

**Clinical Course.** The median age of DLBCL is 64 years. The majority of patients present with advanced-stage (III or IV) disease. About 40% have extranodal involvement at the time of initial presentation, including gastrointestinal, skin, bone, CNS, thyroid, or testicular infiltration. Another 10% to 20% have bone marrow involvement. B symptoms and elevated LDH are common. In some cases, DLBCL may arise from a prior indolent NHL such as FL or CLL; the

latter is known as *Richter transformation* and has an aggressive clinical course. Intravascular large B-cell lymphoma is a rare subtype of DLBCL in which the malignant cells infiltrate small blood vessels distributed across multiple organs; the classic presentation is of a “vasculitic disease without vasculitis,” with neurologic symptoms being common; prognosis is poor, in part because the disease is often not suspected until late in the course. Double-hit lymphoma is a subset of DLBCL characterized by concurrent chromosomal abnormalities affecting MYC (8q24) and BCL2 (18q21) or BCL6 (3q27). Prognosis is very poor, with resistance to standard chemotherapy and early disease relapse.

**Prognosis.** Prognosis of DLBCL is determined by the International Prognostic Index (IPI; Table 15.2). Before the introduction of rituximab into standard therapy for DLBCL, 5-year overall survival of DLBCL ranged from 26% to 73% depending on the number of IPI risk factors. Both disease-free and overall survival has increased by 10% to 15% with the addition of rituximab to standard therapy for DLBCL.

**Treatment.** The prognosis of treated DLBCL is favorable, with a high rate of durable responses after chemotherapy

• **Fig. 15.5** Treatment of diffuse large B-cell lymphoma (DLBCL). PET/CT, Positron emission tomography/computed tomography; RCHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone plus rituximab. (From Zelenetz AD, Abramson JS, Advani RH, et al. Non-Hodgkin's lymphomas. *J Natl Compr Canc Netw*. 2011;9(5):484–560.)

reflecting, in part, the high proliferative rate of DLBCL cells. Treatment of DLBCL depends on disease stage (Fig. 15.5). For advanced-stage (III or IV) DLBCL, first-line treatment is combination chemotherapy with addition of rituximab. A phase III study of advanced-stage DLBCL compared combination CHOP chemotherapy (cyclophosphamide, doxorubicin, vincristine, prednisone) with more intensive regimens and found decreased toxicity of CHOP without differences in efficacy. A landmark study from the French Study Group of the Adult Lymphoma compared CHOP with or without rituximab in the treatment of advanced-stage DLBCL and found an increase in overall survival with CHOP plus rituximab (RCHOP) without a significant increase in toxicity. RCHOP is therefore first-line therapy for advanced-stage DLBCL, with a typical course being six cycles administered every 3 weeks. DLBCL patients with risk factors for CNS disease (discussed earlier; see “Tissue Evaluation” under “Evaluation of Non-Hodgkin Lymphoma”) may benefit from prophylactic CNS therapy using intrathecal chemotherapy or high-dose systemic methotrexate. For limited stage (I or II) nonbulky DLBCL, first-line treatment options include either abbreviated rituximab-containing chemotherapy with radiation or an extended course (six cycles) of rituximab-containing chemotherapy without radiotherapy. Following completion of first-line therapy, a posttreatment PET/CT scan is performed, with complete remission defined as reduction in the size of the initial lesions on CT and absence of fluorodeoxyglucose uptake on PET. For patients with stage III to IV disease who attain complete remission, routine surveillance CT scans may be performed every 6 to 12 months for the first 2 years to monitor for relapsed disease. Notably, the efficacy of surveillance radiography of DLBCL in first remission in the

absence of symptoms is uncertain and is increasingly being challenged by concerns regarding radiation exposure from excessive radiographic imaging.

Patients who do not have a complete response to first-line treatment with RCHOP or who develop relapsed DLBCL within 1 year after therapy have a poor prognosis. For relapsed or treatment-refractory DLBCL, the standard approach is salvage chemotherapy followed by high-dose chemotherapy and autologous stem cell transplant for patients with chemosensitive disease, based on a seminal randomized clinical trial from the Parma study group; alternately, such patients may be evaluated for clinical trials.

#### Peripheral T-Cell and Natural Killer-Cell Lymphomas

Peripheral T- and NK-cell lymphomas comprise a heterogeneous collection of malignancies that include peripheral T-cell lymphoma, angioimmunoblastic T-cell lymphoma, extranodal NK/T-cell lymphoma of nasal type, subcutaneous panniculitis-like T-cell lymphoma, enteropathy-associated T-cell lymphoma, hepatosplenic gamma/delta T-cell lymphoma, cutaneous T-cell lymphoma, and anaplastic large cell lymphoma (ALCL). In general, CHOP is used as first-line chemotherapy for peripheral T- and NK-cell lymphomas, although the efficacy is significantly lower than in the B-cell lymphomas. The role of stem cell transplantation in first remission is under investigation.

Angioimmunoblastic T-cell lymphoma presents with fever, generalized lymphadenopathy, hepatosplenomegaly, B symptoms, marrow involvement, and a vasculitic rash. It is associated with HIV, EBV, polyclonal gammopathy, and AIHA. Prognosis is poor, although high-dose chemotherapy with autologous stem cell transplant may offer long-term disease control.

Cutaneous T-cell lymphoma manifests as a plaque-like rash with associated erythroderma. It represents a spectrum of disease ranging from mycosis fungoides (an indolent disease mostly but not exclusively limited to the skin) to Sézary syndrome, an aggressive malignancy with circulating lymphoma cells. Multiple skin biopsies may be required to establish a definitive diagnosis. Treatment approaches include radiation, topical chemotherapy, systemic retinoids, systemic phototherapy, and chemotherapy, depending on the extent and responsiveness of disease.

ALCL has cutaneous and systemic subtypes. Systemic ALCL may be further classified according to anaplastic lymphoma kinase (ALK) expression, with ALK-positive ALCL showing a more favorable prognosis than ALK-negative ALCL. Standard treatment is anthracycline-containing combination chemotherapy (e.g., CHOP), which yields a high overall survival in patients with ALK+ disease. Brentuximab, an antibody-drug conjugate that targets CD30 (a cell surface protein expressed in ALCL) was approved in 2011 for treatment of relapsed systemic ALCL based on a multicenter trial demonstrating improved outcomes.

### Indolent Non-Hodgkin Lymphoma

#### Follicular Lymphoma

FL is the second most common subtype of NHL, accounting for 20% of all NHLs.

**Pathologic Features.** FL cells are small B cells with cleaved nuclei (“butt cells”) that in aggregate preserve the follicular architecture of involved lymph nodes. FL is categorized into three different histologic grades (I–III), with grade IIIB FL demonstrating an aggressive clinical course similar to DLBCL.

Ninety percent of FL cases carry the t(14;18) translocation, which positions the antiapoptotic *bcl-2* gene on chromosome 18 near the Ig heavy-chain enhancer element.

**Clinical Presentation.** The median age of FL is 65 years. Between 70% and 80% have advanced-stage (III–IV) disease at the time of initial presentation; 40% to 70% have bone marrow involvement. Lymphadenopathy may wax and wane. Median survival from the time of diagnosis is >10 years; most patients die from FL even after appropriate therapy because of decreased chemoresponsiveness and reduced durable remission rates following treatment. Spontaneous remissions may occasionally occur. One-third of patients transform into an aggressive disease NHL, such as DLBCL.

**Prognosis.** Prognosis of FL is gauged by the Follicular Lymphoma International Prognostic Index (FLIPI; Table 15.3). The original prognostic index (FLIPI-1), performed in the prirituximab era, identified age, stage III or IV disease, a large number of involved nodes, anemia, and high LDH as the most important prognostic factors, with 10-year median survivals ranging from 36% to 71%. Following the introduction of rituximab to standard therapy, an updated prognostic index (FLIPI-2) identified age, anemia, B2M, size of the largest involved lymph node, and presence of bone marrow involvement

as the factors with greatest prognostic significance in FL, with 5-year progression-free survival ranging from 19% to 80%.

**Treatment.** For asymptomatic patients with advanced-stage (III–IV) FL, early initiation of therapy has not been conclusively shown to improve outcomes compared with observation. Asymptomatic advanced-stage FL may be managed expectantly with observation until patients become symptomatic or show evidence of end-organ compromise, at which point a variety of treatment options may be used including rituximab alone or in combination with bendamustine. RCHOP and RCVP (rituximab, cyclophosphamide, vincristine, and prednisone) remain options but are associated with inferior progression-free survival compared with bendamustine plus rituximab (BR). The addition of rituximab as “maintenance” therapy after initial front-line chemoimmunotherapy with RCHOP or RCVP improves progression-free survival but not overall survival and has not been studied following BR. Limited stage (I–II) FL is treated with radiotherapy. For relapsed disease, options include chemoimmunotherapy, lenalidomide with or without rituximab or idelalisib, (a novel, oral PI3 kinase inhibitor). High-dose chemotherapy followed by autologous stem cell transplant and nonmyeloablative allogeneic stem cell transplant are used in selected patients with relapsed or refractory disease. Notably, treatment practices for FL vary considerably among clinicians across the United States, reflecting regional and institutional variation along with patient preferences.

#### B-Cell Small Lymphocytic Lymphoma

B-cell small lymphocytic lymphoma (B-SLL) is the lymphomatous counterpart of CLL. CLL is the most common adult leukemia in the Western world.

**Pathologic Features.** CLL/B-SLL is characterized by a monomorphic population of small round lymphocytes that invade multiple tissues including peripheral blood, lymph nodes, and bone marrow. The malignant cells have a unique immunophenotype (CD5+ CD23+ CD19+ CD20<sup>weak</sup> surface Ig+) requiring that flow cytometry or other immunohistochemical studies be used to establish the diagnosis. Of the various cell surface markers, CD5 positivity is conceptually important because it necessitates distinction between CLL (CD5+ CD23+) and MCL (CD5+ CD23–). CLL is defined by a malignant population of CLL cells with a circulating absolute lymphocyte count of  $\geq 5000/\text{mL}$ . B-SLL is diagnosed when there is lymph node involvement by CLL cells with a circulating absolute lymphocyte count of  $< 5000/\text{mL}$ . The premalignant condition of monoclonal B-cell lymphocytosis is defined by the presence of circulating CLL cells with an absolute lymphocyte count that is  $< 5000/\text{mL}$  and no evidence of lymph node or other organ involvement. Examination of the peripheral blood smear characteristically shows an increased number of lymphocytes, smudge cells representing lymphocytes smashed in the

<sup>b</sup>From Federico M, Bellei M, Marcheselli L, et al. Follicular lymphoma international prognostic index 2: a new prognostic index for follicular lymphoma developed by the International Follicular Lymphoma Prognostic Factor Project. *J Clin Oncol*. 2009;27(27):4555–4562.

smear-making process (see Fig. 15.4), and in some cases, a small population of large, irregularly shaped precursor prolymphocytes.

**Clinical Course.** The median age of CLL/B-SLL onset is 72 years. There is a strong correlation with family history; no known environmental, radiation, or drug associations have been definitively demonstrated. The most commonly used staging system is the Rai staging system, with stage 0 disease defined by lymphocytosis; stage I is defined by lymphadenopathy, stage II by hepatosplenomegaly, stage III by anemia, and stage IV by thrombocytopenia. Median survival ranges from 19 to 150 months depending on Rai stage. High-risk clinical features in addition to advanced Rai stage include systemic symptoms, progressive lymphadenopathy or splenomegaly, a 50% increase in circulating lymphocyte count over a 2-month period, and a doubling of absolute lymphocyte count in <6 to

12 months. High-risk molecular markers include absence of somatic hypermutation in the Ig heavy-chain variable region, deletion of 11q23, deletion of 17p or mutation of the *p53* gene located on chromosome 17p, CD38 positivity, increased expression of thymidine kinase, and expression of ZAP-70. The most significant favorable molecular prognostic feature is the presence of a deletion in 13q as the sole chromosomal abnormality.

Three clinical features specific to CLL/B-SLL merit discussion. First, patients with CLL/B-SLL may develop AIHA or ITP (of note, only nonimmune anemia or thrombocytopenia meets criteria for stage III or IV disease in the Rai staging system). Purine analogs, used as therapy in CLL/B-SLL, further increase the risk of these phenomena (see Treatment section later). AIHA in CLL is predominantly a warm agglutinin (IgG-mediated) disease, although cold agglutinin (IgM-mediated) disease

can occur. Second, patients with CLL/B-SLL have an increased risk of infection caused by hypogammaglobulinemia, CLL/B-SLL–mediated immune dysfunction, and the immunosuppressive effects of purine analog treatment. Prophylactic intravenous immune globulin decreases the infectious rate in CLL/B-SLL patients with recurrent bacterial infections. Third, roughly 5% of CLL/B-SLL patients develop a Richter transformation into DLBCL, which carries a poor prognosis (see DLBCL discussion earlier, section on Clinical Course). A smaller percentage transform into HL.

**Treatment.** Treatment of CLL/B-SLL is indicated for Rai stage III or IV disease and for symptoms related to disease including painful lymphadenopathy or B symptoms, high-risk clinical features (enumerated previously), recurrent infections, AIHA, or ITP. High-risk molecular features alone are not an indication for treatment. Similarly, asymptomatic patients with Rai stage I or II disease do not require treatment. Historically, chlorambucil, an alkylating agent, was the standard of care for treatment of CLL/B-SLL and can be combined with the humanized type II anti-CD20 antibody, obinutuzumab. In the past decade, the purine analog fludarabine and fludarabine-containing therapies (e.g., FCR [fludarabine, cyclophosphamide, rituximab]) have emerged as first-line therapy for CLL/B-SLL; bendamustine with or without rituximab is another widely used first-line therapy. The Bruton tyrosine kinase inhibitor, ibrutinib was also recently approved as a first-line treatment of CLL/B-SLL based on a multicenter phase 3 trial that demonstrated significantly improved progression-free and overall survival of ibrutinib over chlorambucil. It is a reasonable treatment option for frail CLL patients with significant comorbidities who are unable to tolerate intensive fludarabine-containing therapies. Purine analogs exhibit a number of specific side effects including persistent neutropenia, CD4+ T-cell lymphopenia, and an increased risk of infections; AIHA and, rarely, ITP may also be associated. These same regimens may also be used for relapsed or treatment-refractory disease. Alemtuzumab (Campath), a monoclonal antibody against the CD52 antigen expressed on the surfaces of all mature lymphocytes, has favorable activity in first-line treatment of CLL/B-SLL, particularly in cases with unfavorable cytogenetic abnormalities (i.e., deletions of 11q23 or 17p) although its efficacy is limited in nodal disease. The major side effect of alemtuzumab is infection, with a 50% rate of cytomegalovirus reactivation. The second-generation humanized anti-CD20 monoclonal antibody ofatumumab is another option for CLL that is refractory to fludarabine and alemtuzumab. Nonmyeloablative allogeneic stem cell transplant may be effective in patients with treatment-refractory disease and is the only effective cure for CLL.

### Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma (LPL), more commonly referred to as Waldenström macroglobulinemia (WM), is a B-cell lymphoproliferative disease in which the malignant

cells are morphologically and immunophenotypically intermediate between lymphocytes and plasma cells. LPL/WM cells secrete IgM, which forms pentavalent aggregates causing hyperviscosity symptoms including bleeding (particularly epistaxis), ocular abnormalities (e.g., blurring, retinal hemorrhages, retinal vein thrombosis, and tortuous retinal vessels), cryoglobulinemia, and cold agglutinin AIHA. LPL/WM may also be associated with amyloidosis, peripheral demyelinating neuropathy, and an increased risk of infections. All patients have marrow involvement; 20% to 30% have lymphadenopathy and/or hepatosplenomegaly. As with FL, CLL, and other indolent lymphomas, treatment of LPL/WM is deferred for asymptomatic patients. For those with symptomatic or progressive LPL/WM, plasmapheresis is used for control of hyperviscosity symptoms; rituximab, fludarabine, steroids, the nuclear factor kappa-B inhibitor bortezomib (Velcade), and combinations of these with other chemotherapy agents (e.g., fludarabine/rituximab with or without cyclophosphamide, RCVP, RCHOP, BR, bortezomib/rituximab, bortezomib/dexamethasone/rituximab) have all been successfully used. Of note, treatment with rituximab-containing regimens may precipitate an IgM flare, particularly if single-agent rituximab is used. Ibrutinib has been shown to be effective in patients with relapsed/refractory LPL/WM and was recently approved for this indication.

### Mantle Cell Lymphoma

MCL comprises approximately 7% of all NHLs. It has an aggressive clinical course despite its classification as an indolent NHL.

**Pathologic Features.** MCL consists of small- or medium-sized B cells that resemble CLL, FL, or MZL. Immunophenotypically, MCL cells express CD5, necessitating distinction from CLL/B-SLL (see CLL/B-SLL earlier, under Pathologic Features). The most important molecular feature of MCL is translocation t(11;14), which positions the cell cycle gene cyclin D1 on chromosome 11 next to the Ig heavy chain locus, leading to overproduction of cyclin D1.

**Clinical Course.** MCL is a disease of older men, with a median age of 68 years. Roughly 70% present with stage IV disease, including over 60% with bone marrow infiltration. A substantial proportion of patients have gastrointestinal involvement, some with intestinal polyposis, prompting routine endoscopy of such patients at many academic centers. Historical studies showed median survivals on the order of 3 to 4 years; prognosis has improved with newer therapies, particularly with incorporation of high-dose chemotherapy and autologous stem cell transplant. A high Ki-67 index in MCL is a prognostic marker of aggressive disease. A minority of patients may develop an aggressive variant known as blastoid MCL characterized by a high proliferative index and circulating MCL cells with a blast-like appearance.

**Treatment.** Standard treatment for MCL is either intensive chemotherapy (e.g., hyper-CVAD) or combination chemotherapy with rituximab (e.g., RCHOP alternating with high-dose cytarabine) followed by high-dose chemotherapy

and autologous stem cell transplant. RCHOP followed by maintenance rituximab or BR is a treatment option that offers prolonged remission for frail, elderly patients who are unable to tolerate intensive high-dose chemotherapy. Ibrutinib, bortezomib, lenalidomide, and allogeneic stem cell transplant have also been used, particularly in relapsed or treatment-refractory disease.

### Marginal Zone Lymphomas

The MZLs include splenic MZL with or without villous lymphocytes, extranodal MZL of MALT type, and nodal MZL. The classic pathologic description of MZL is of malignant B cells with lymphoplasmacytic differentiation (similar to LPL/WM) that are immunophenotypically negative for multiple cell surface markers (e.g., CD5–CD10–CD23–), except for major B-cell markers such as CD20+ and CD79a+.

Splenic MZL is a disease of older men. Patients present with massive splenomegaly; 40% have hepatomegaly. Most patients have bone marrow involvement. Lymphadenopathy is rare. The disease is associated with HCV infection. Median survival is >10 years. Standard treatment for splenic MZL is either splenectomy or single-agent rituximab, which are beneficial in relieving abdominal symptoms and cytopenias.

Extranodal MALT lymphoma consists of a heterogeneous population of B lymphocytes and plasma cells occupying MALT sites distributed throughout the body. Anatomic involvement is varied and is frequently associated with local inflammation or infection. The most common site of disease is the gastrointestinal tract (also known as gastric MALToma), particularly the stomach in association with *H. pylori* infection. Other sites include the thyroid, ocular adnexa, lungs, salivary gland, and breast. Local lymph node involvement is common; one-third of patients have monoclonal gammopathy. First-line treatment of *H. pylori* + gastric MALToma is antibiotics, which induces remission in the majority of cases. For other disease sites, chemotherapy or local radiation may be used.

Nodal MZL is similar to extranodal MALToma except that the disease is restricted to lymph nodes, and in many cases the bone marrow, without other extranodal involvement. Management is similar to that of FL.

## Hodgkin Lymphoma

Compared with NHL, HL is a far less common disease, with about 9000 new cases and approximately 1000 deaths in the United States each year.

### Clinical Presentation of Hodgkin Lymphoma

#### Epidemiology

HL has a bimodal age distribution with one peak presenting between the ages of 15 and 34 years, another peak age >50 years, and a median age in the mid-20s. An increased incidence is observed in industrialized countries and among persons of increasing socioeconomic status. A

minority of cases are associated with EBV or with HIV. Correlations with family history and human leukocyte antigen genotype have also been reported.

### Systemic Symptoms

As with NHL, the most important systemic symptoms in HL are B symptoms. The classic B symptom is Pel-Ebstein fever, a cyclic fever occurring in intervals of 1 to 2 weeks. Two additional, albeit uncommon, symptoms characteristic of HL are pruritus without rash and pain after alcohol consumption, the latter localized to sites of disease.

### Patterns of Lymph Node Involvement

The most common presentation of HL is of a young person with painless lymphadenopathy in the neck. Cervical or supraclavicular lymph nodes are involved in 75% of cases, followed by mediastinal, paraaortic, axillary, and inguinal nodes (in order of decreasing frequency). HL spreads anatomically through contiguous lymph nodes, infiltrating the spleen before spreading systemically and invading the bone marrow, as reflected by the Ann Arbor staging system.

### Evaluation of Hodgkin Lymphoma

The evaluation of HL is similar to that of NHL and includes physical examination, with careful attention to peripheral lymph nodes and hepatosplenic enlargement, laboratory evaluation, radiographic imaging, and tissue analysis. All patients with HL should have a comprehensive metabolic panel, a CBC with a peripheral blood differential, and erythrocyte sedimentation rate, the latter of which is prognostic in early stage (I–IIA) HL. HL may be associated with a number of laboratory abnormalities including anemia, leukocytosis, lymphopenia, monocytosis, and hypoalbuminemia. LDH is rarely elevated in advanced-stage HL and is therefore not routinely checked in the evaluation of HL. The imaging study of choice in the workup of HL is a whole-body PET/CT scan, which is integral in initial staging and response assessment in HL. An excisional biopsy of an involved lymph node is the gold standard for tissue evaluation. Bone marrow biopsy may be performed under certain circumstances.

### Staging of Hodgkin Lymphoma

Staging of HL uses the Ann Arbor staging system (see Table 15.1).

### Classifications of Hodgkin Lymphoma

WHO recognizes two distinct disease entities of HL: classical HL and nodular lymphocyte-predominant HL (NLPHL). The former includes the histologic subtypes of nodular sclerosis, lymphocyte-rich, mixed cellularity, and lymphocyte-depleted HL.

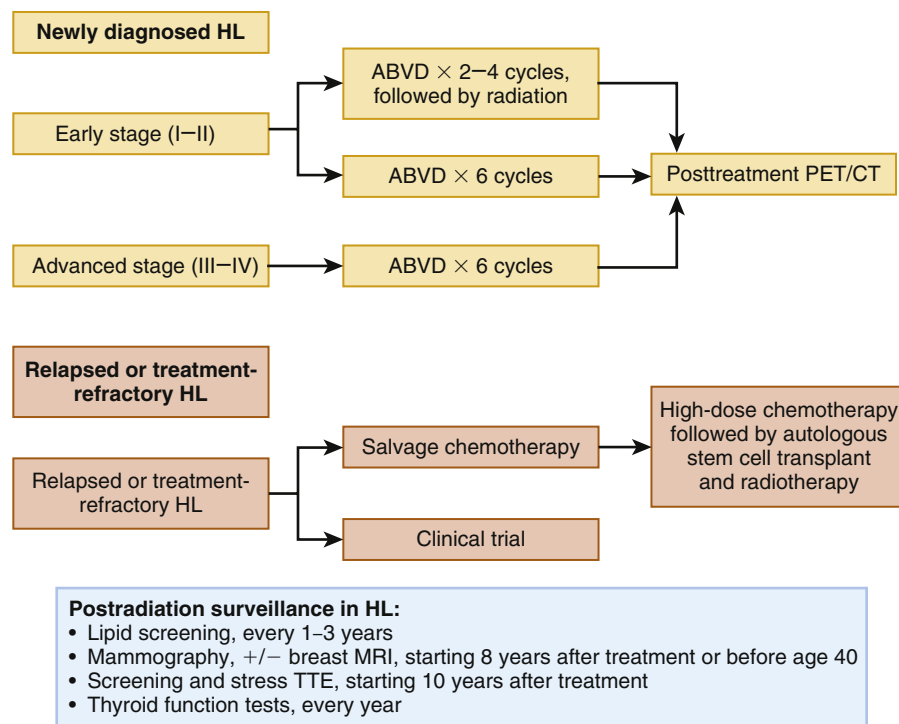

## Pathology of Hodgkin Lymphoma

The neoplastic cell in classical HL is the Reed-Sternberg (RS) cell, characterized by a bilobed (“owl’s eyes”) nucleus (see Fig. 15.4). RS cells are of B-cell origin but have an unusual immunophenotype (CD20+/- CD15+ CD30+). Histologically, RS cells occupy only a very small fraction of the total cellularity of an involved lymph node, rendering full excisional lymph node biopsy essential in diagnostic evaluation. In nodular sclerosis HL, RS cells are scattered among a fibrous nodular architectural pattern, whereas in the other histologic subtypes of classical HL, varying degrees of infiltration by other lymphocytes are seen. The neoplastic cell in NLP HL is a variant of the RS cell known as the “popcorn” or lymphocyte-predominant (LP) cell, with an immunophenotype (CD20+ CD15- CD30-) that differs from classical RS cells.

## Treatment of Classical Hodgkin Lymphoma

In the modern era, treatment of classical HL uses a combination of chemotherapy with or without limited radiation fields (Fig. 15.6). Advanced-stage (IIB-IV) classical HL is treated with chemotherapy alone; radiation may be added to sites of bulky disease or in cases where a partial rather than complete remission is achieved. Prognosis in advanced HL is gauged by the International Prognostic Score (IPS) comprising seven factors that predict poor

prognosis (Table 15.4). Between 40% and 85% of patients with advanced-stage classical HL achieve long-term disease control with standard chemotherapy, depending on IPS risk factors. Early stage (I-IIA) classical HL is typically treated with a combination of chemotherapy and radiation; chemotherapy alone may alternately be used in many centers for patients with nonbulky disease, defined as a mass <10 cm or less than one-third the maximal intrathoracic diameter on chest x-ray. More than 85% of patients with early-stage classical HL will be cured following initial therapy. PET/CT scans are performed in the middle of therapy to assess the interim response (which may have prognostic value, although this is controversial) and at the end of therapy. The use of interim PET/CT scans to guide decisions regarding therapy is presently under investigation. Complete remission is gauged by the end-of-treatment PET/CT scan, using the same criteria as for DLBCL (see DLBCL previously, in section on Treatment). HL patients in first remission are frequently subjected to routine surveillance CT scans, although surveillance radiography in HL is costly and is associated with significant radiation exposures. Relapsed or treatment-refractory classical HL is treated with a combined approach of salvage chemotherapy followed by high-dose chemotherapy, autologous stem cell transplant, and radiation therapy. Brentuximab is used to treat relapsed classical HL after failure of autologous stem cell transplant, as well as patients who are not transplant candidates who have failed at least two combination chemotherapy regimens. It can

• **Fig. 15.6** Treatment of Hodgkin lymphoma (HL). ABVD, Doxorubicin, bleomycin, vinblastine, and dacarbazine; PET/CT, positron emission tomography/computed tomography; TTE, transthoracic echocardiogram. (From Ng AK, Abramson JS, Digumarthy SR, et al. A 56-year-old woman with a history of Hodgkin’s lymphoma and sudden onset of dyspnea and shock. *N Engl J Med.* 2010;363:664–675.)

also be used for consolidation treatment after autologous stem cell transplant for patients who are at high risk for relapse or progression. Nivolumab, a check-point inhibitor of programmed cell death-1, was also approved in 2016 for treatment of relapsed classical HL after autologous stem cell transplantation and posttransplantation brentuximab based on two multicenter trials that demonstrated overall response rates of 65% after a median of five prior systemic therapies.

### Chemotherapy Regimens

The first successful combination chemotherapy regimen in classical HL was MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone), which cured approximately one-half of patients with advanced disease. Long-term toxicities, including infertility and secondary leukemia, eventually led to the replacement of MOPP by the more effective and less toxic regimen of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine). Two other, more intensive chemotherapy regimens currently in use are BEACOPP (bleomycin, etoposide, adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone), used in Germany, and the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, vincristine, bleomycin, etoposide, and prednisone), used at Stanford University. Both regimens incorporate radiation therapy for bulky disease. Recent clinical trials have found no difference in overall survival of patients with early-stage or advanced-stage HL treated with either Stanford V or ABVD.

### Long-Term Consequences of Radiation Therapy

Radiation therapy to the chest, particularly when administered in a “mantle distribution” encompassing the mediastinum and thorax, has been associated with extensive long-term toxicities including secondary malignancies (e.g., leukemia and cancers of the breast, lung, and thyroid), cardiac disease (congestive heart failure, early coronary artery disease, valvular heart disease, arrhythmias, and pericarditis), hypothyroidism, and lung disease (radiation pneumonitis and pulmonary fibrosis). The importance of long-term complications from thoracic radiation is underscored by the observation that deaths from radiotherapy-related complications ultimately exceed those from relapsed HL in recipients of mantle radiation. Significant efforts have been made in the modern era to limit radiation fields in HL patients who require radiotherapy. Recipients of mantle or other thoracic radiation are advised to undergo comprehensive surveillance for secondary malignancies and for cardiovascular and pulmonary disease (see Fig. 15.6).

### Treatment of Nodular Lymphocyte-Predominant Hodgkin Lymphoma

For NLPHL, early-stage (I–IIA) disease is treated with radiation, whereas advanced-stage (IIB–IV) disease is treated with chemotherapy with or without radiation. Rituximab may have a therapeutic role, owing to CD20 expression by LP cells. The clinical course of NLPHL is generally favorable, particularly for early-stage disease.

**TABLE 15.4 International Prognostic Score for Advanced (Stage IIB–IV) Hodgkin Lymphoma**

Adverse factors (WALMASH):  
 Elevated white blood cell count  
 Age  $\geq$ 45 years

## Chapter Review

### Questions

- A 31-year-old woman presents with painless lymphadenopathy in her neck, intermittent pruritus, and night sweats. Biopsy of a left supraclavicular lymph node reveals classical HL. Staging PET/CT scans show a large mediastinal mass in addition to supraclavicular lymphadenopathy. She is treated with combination chemotherapy followed by radiation therapy to the mediastinum and attains complete remission. Which of the following is the most appropriate follow-up plan for her?

  - PET-CT scans every 3 months for the next 5 years to monitor for disease recurrence
  - Start annual screening mammography approximately 8 years after completion of therapy
  - Start screening colonoscopy 5 years after completion of therapy
  - High-dose chemotherapy and autologous stem cell transplant to increase her likelihood of cure
  - Check serum LDH level every 6 months
- A 65-year-old woman notices new asymptomatic right inguinal lymphadenopathy while showering. She presents to her physician and subsequent biopsy of the lymph node reveals grade 1 FL. Staging CT scans demonstrate multiple enlarged lymph nodes in the neck, axillae, mesentery, and pelvis. The largest lymph node is <3 cm, and there is no compression of surrounding organs. She does not have fever, drenching night sweats, or unintentional weight loss. Her CBC and differential are normal. What is the most appropriate management plan for the patient?

  - Rituximab alone
  - Rituximab combined with chemotherapy
  - Close observation with repeat CT scans in about 6 months
  - High-dose chemotherapy followed by autologous stem cell transplant
  - Radiation therapy
- An 80-year-old female presents with a history of a rapidly growing swelling on the left lateral border of the tongue of 1 month's duration. She reports unintentional weight loss of 15 lb in the preceding month but denies fever or drenching night sweats. Local examination shows a 4-cm × 3-cm firm nodular lesion involving the lateral margin of the left half of the tongue. Other parts of the oral cavity, oropharynx, and neck are normal, as are examinations of the lungs, heart, abdomen, and nervous system. Biopsy of the tongue lesion shows NHL. Which of the following is the best next step in management?

  - Whole-body PET/CT scan
  - Initiate radiation therapy to treat tongue lesion
  - Initiate chemotherapy
  - Check erythrocyte sedimentation rate
  - Check serum LDH level
- A 60-year-old male presents with nonpainful swelling on the left side of his neck of 3 week's duration. He denies weight loss, fever, and night sweats. Physical examination reveals an enlarged left cervical lymph node, measuring 3 cm × 2 cm. There is no other enlarged peripheral lymphadenopathy on examination. Excisional biopsy shows a diffuse infiltrate of large atypical lymphoid cells, with immunophenotype consistent with diffuse large B-cell lymphoma. Staging with PET/CT scan and bone marrow biopsy reveal no other sites of disease. The patient's CBC and LDH levels are normal. Which of the following is an appropriate treatment plan?

  - Neck dissection to obtain wide margin around excised lymph node
  - Radiation therapy to the neck
  - An abbreviated course of rituximab-containing chemotherapy (RCHOP) followed by radiation therapy
  - Rituximab alone
  - Neck dissection followed by radiation therapy
- A 63-year-old woman presents to her primary care physician with months of intermittent abdominal pain. She reports that pain is typically in the upper abdomen and is exacerbated by eating. She undergoes an upper endoscopy as part of her evaluation that reveals gastric nodularity as well as nonbleeding gastric ulceration. Biopsies of the abnormal areas are consistent with gastric extranodal gastric MALT lymphoma; *H. pylori* stains are also positive. An endoscopic ultrasound shows that the lymphoma is limited to the gastric mucosa with no adjacent enlarged gastric lymph nodes. In addition, contrast-enhanced CT scans of the chest, abdomen, and pelvis are negative for distant spread of the lymphoma. Which of the following is the best next step in management?

  - Radiation to the stomach
  - Gastrectomy with lymph node dissection
  - Intensive multiagent chemotherapy
  - H. pylori*-directed antibiotic therapy
  - Treat with histamine 2-receptor antagonist

## Multiple Myeloma

CONSTANTINE S. MITSIADES, KENNETH C. ANDERSON, AND PAUL G. RICHARDSON

**M**ultiple myeloma (MM) is a clonal accumulation of malignant plasma cells (PCs) that typically produce a monoclonal immunoglobulin (or fragment thereof) termed *M-protein*, detectable in the serum or urine. Despite recent advances in its treatment (median overall survival is now 5–7 years compared with 2–3 years for patients diagnosed  $\geq 10$  years ago), MM remains incurable. Monoclonal gammopathy of undetermined significance (MGUS) is a premalignant condition in which a clonal population of PCs accumulates in the bone marrow (BM). MGUS is asymptomatic and does not otherwise meet diagnostic criteria for MM, but it can develop into MM, other PC dyscrasia, or lymphoproliferative disease with a transformation rate of approximately 2% per year.

### Epidemiology

MM is the second most commonly diagnosed hematologic malignancy in the Western world (with >19,000 new cases annually in the United States compared with 5000 per annum for either chronic lymphocytic leukemia or chronic myeloid leukemia). MM represents approximately 1% of all cases of malignancy, 2% of cancer deaths, and approximately 10% of all hematologic malignancies in the United States, with a prevalence of about 60,000. The annual incidence of MM is currently approximately 4 in 100,000, and some data suggest a recent increase in incidence rates. This may reflect increased access and use of medical services, improved diagnostic testing, and awareness of the disease and its management rather than a true increase in incidence, as suggested by studies from Olmsted County, Minnesota. However, more recent studies from Taiwan point to a 5-fold increase in the last 25 years. The median age at diagnosis is 65 years, and although patients age <40 years are estimated to be about 2% of the MM patient population, MM is not exclusively a disease of the elderly in that a sizable proportion of patients are 40 to 60 years old. There are reports of higher incidence of MM in African Americans, Afro-Caribbeans, and Pacific Islanders compared with Caucasians, as well as higher incidence in certain other populations and a greater age-adjusted incidence in men versus women (4% vs. 2.7%). Occupational and lifestyle-related risk factors include agricultural

work, exposure to pesticides, herbicides (e.g., Agent Orange), petroleum products, woodworkers, paper producers, furniture manufacturers, and health care workers. Families with multiple affected members have also been reported, but familial MM appears rare.

### Diagnostic Criteria: Clinical Presentation

A key goal in the diagnostic evaluation of a patient with possible MM is to distinguish the presence of MM (which can have nonspecific symptoms in its early stages) from other symptoms of advancing age in an otherwise healthy individual. It is also important to distinguish MM from other gammopathies and dysproteinemias (e.g., MGUS, Waldenstrom macroglobulinemia, primary amyloidosis, heavy chain disease, cryoglobulinemia, idiopathic cold agglutinin disease) or B-cell neoplasias (e.g., non-Hodgkin lymphoma). The formal diagnosis of MM (and whether it is active or smoldering) versus MGUS is based on criteria (Table 16.1) related to histologic evidence of PC accumulation (as PC infiltration in the BM or plasmacytomas), detection of monoclonal immunoglobulin, and the presence or absence of end-organ damage. The older Durie-Salmon classification has now been simplified by the introduction of International Myeloma Working Group criteria, which are based on the original system but easier to apply and now widely used (Box 16.1).

When serologic and histologic criteria for MM are met but a patient has no evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia, or skeletal lesions) and/or symptoms attributable to MM, then the condition is defined as smoldering MM (SMM) or asymptomatic MM. SMM has a 10% to 20% per year risk of progression to symptomatic MM.

### Clinical Presentation

The diagnosis of MM should be considered in patients who present with a constellation of fatigue, bone pain, recurrent infections, and symptoms compatible with renal impairment and/or hypercalcemia (Box 16.2). In the past, retrospective analyses of case series of MM patients indicated

**TABLE 16.1** Criteria for Multiple Myeloma Diagnosis

Major Criteria	Minor Criteria
1. Plasmacytomas on tissue biopsy	a. BM plasmacytosis (10%–30% PCs)
2. BM plasmacytosis (>30% PCs)	b. Monoclonal immunoglobulin spike present but of lesser magnitude than for major criterion 1
3. Monoclonal immunoglobulin spike on serum electrophoresis: IgG >3.5 g/dL or IgA >2.0 g/dL, kappa or lambda light-chain excretion >1.0 g/d on 24-hour urine electrophoresis	c. Lytic bone lesions
	d. Suppressed normal uninvolved immunoglobulins (i.e., IgM, IgA, or IgG <50, <100, or <600 mg/dL, respectively)
MM diagnosis is confirmed by any of the following:	
<ul style="list-style-type: none"> <li>• Any two major criteria</li> <li>• Major criterion 1 + minor criteria b, c, or d</li> <li>• Minor criteria a, b, and c or a, b, and d</li> </ul>

### • BOX 16.1 Criteria for the Classification of Monoclonal Gammopathies, Multiple Myeloma, and Related Disorders: a Report of the International Myeloma Working Group

#### Monoclonal Gammopathy of Undetermined Significance

M-protein in serum <30 g/L  
 Bone marrow (BM) clonal plasma cells <10% and low level of plasma cell infiltration in a trephine biopsy (if done)  
 No evidence of other B-cell proliferative disorders  
 No related organ or tissue impairment (no end-organ damage, including bone lesions)

#### Myeloma-Related Organ or Tissue Impairment (End-Organ Damage) Caused by the Plasma Cell Proliferative Process

Calcium levels increased: serum calcium >0.25 mmol/L above the upper limit of normal or >2.75 mmol/L  
 Renal insufficiency: creatinine >173 mmol/L  
 Anemia: hemoglobin 2 g/dL below the lower limit of normal or hemoglobin <10 g/dL  
 Bone lesions: lytic lesions or osteoporosis with compression fractures (MRI or CT may clarify)  
 Other: symptomatic hyperviscosity, amyloidosis, recurrent bacterial infections (>2 episodes in 12 months)  
 CRAB (calcium, renal insufficiency, anemia, or bone lesions)

#### Asymptomatic Myeloma (Smoldering Myeloma)

M-protein in serum  $\geq$ 30 g/L and/or BM clonal plasma cells  $\geq$ 10%<sup>a</sup>  
 No related organ or tissue impairment (no end-organ damage, including bone lesions) or symptoms

#### Symptomatic Multiple Myeloma

M-protein in serum and/or urine  
 BM (clonal) plasma cells<sup>a</sup> or plasmacytoma  
 Related organ or tissue impairment (end-organ damage, including bone lesions)

#### Nonsecretory Myeloma

No M-protein in serum and/or urine with immunofixation  
 BM clonal plasmacytosis  $\geq$ 10% or plasmacytoma

Related organ or tissue impairment (end-organ damage, including bone lesions)

#### Solitary Plasmacytoma of Bone

No M-protein in serum and/or urine<sup>a</sup>  
 Single area of bone destruction caused by clonal plasma cells  
 BM not consistent with multiple myeloma  
 Normal skeletal survey (and MRI of spine and pelvis if done)  
 No related organ or tissue impairment (no end-organ damage other than solitary bone lesion)<sup>a</sup>

#### Extramedullary Plasmacytoma

No M-protein in serum and/or urine<sup>a</sup>  
 Extramedullary tumor of clonal plasma cells  
 Normal BM  
 Normal skeletal survey  
 No related organ or tissue impairment (no end-organ damage, including bone lesions)

#### Multiple Solitary Plasmacytomas ( $\pm$ Recurrent)

No M-protein in serum and/or urine<sup>a</sup>  
 More than one localized area of bone destruction or extramedullary tumor of clonal plasma cells, which may be recurrent  
 Normal BM  
 Normal skeletal survey and MRI of spine and pelvis if done  
 No related organ or tissue impairment (no end-organ damage other than the localized bone lesions)

#### Plasma Cell Leukemia (PCL)

Peripheral blood absolute plasma cell count of at least  $2.0 \times 10^9/L$  and >20% plasma cells in the peripheral blood differential white cell count  
 PCL may be primary (when it presents in the leukemic phase) or secondary (leukemic transformation of a previously recognized multiple myeloma); approximately 60% of patients with PCL have the primary type

<sup>a</sup>A small M-component may sometimes be present.

that at the time of diagnosis, 98% of patients were age >40 years, 88% had dysproteinemia, 79% had skeletal abnormalities on x-rays, 49% had Bence Jones proteinuria, 68% reported bone pain, 62% had anemia, 55% had renal insufficiency, 30% had hypercalcemia, 21% had hepatomegaly on examination, and 5% were found to have splenomegaly. More recent studies indicate that about 70% of MM patients have anemia, and 97% have detectable M-protein in the serum or urine at the time of diagnosis, with lytic

#### • BOX 16.2 Diagnostic Workup in Patients With Suspected Multiple Myeloma

History and physical examination  
 Hemoglobin, white blood cell with differential count, platelets  
 Serum creatinine, calcium, uric acid, beta-2 microglobulin, albumin  
 Serum C-reactive protein, lactate dehydrogenase values (useful but not required for formal diagnosis)  
 Radiographic skeletal survey (including humeri and femurs)  
 MRI of the thoracolumbar spine (especially in the presence of symptoms, such as back pain)  
 CT imaging of the chest and abdomen (including positron emission tomography/CT if appropriate)  
 Serum protein electrophoresis with immunofixation  
 Quantification of immunoglobulins  
 Serum free light-chain determination  
 Bone marrow aspirate and biopsy  
 Urinalysis  
 Electrophoresis and immunofixation of an adequately concentrated aliquot from a 24-hour urine specimen  
 If available, cytogenetics, fluorescent in situ hybridization of bone marrow

lesions, osteoporosis, or fractures present in 80%. It should be noted, however, that the precise percentage of some of the presenting features may change considerably in the coming years with increased awareness about MM diagnosis and treatment, as well as the trend for more widespread use of serum protein electrophoresis in routine workups, which may significantly increase the proportion of patients diagnosed earlier in the course of the disease and thus without many of these presenting features. Conversely, the absence of these presenting symptoms does not preclude the diagnosis of MM.

### Staging Systems

The most commonly used staging systems for MM are the Durie-Salmon (D-S) system (Table 16.2) and the International Staging System (ISS; Table 16.3) or its revised version (R-ISS). The D-S system classifies patients according to several parameters that reflect tumor volume directly (e.g., M-protein levels, lytic bone lesions) or indirectly (impact of disease on hemoglobin [Hb], calcium [Ca<sup>2+</sup>], and renal function). The ISS applies specific cutoff points to baseline albumin and beta-2-microglobulin values that identified, in retrospective evaluation of a large series of patients, three subgroups of patients with favorable (stage I), less favorable (stage III), and intermediate (stage II) prognosis in terms of their overall survival. The recently developed R-ISS defines again three prognostic subgroups of MM patients based on the ISS criteria plus evaluation of serum lactate dehydrogenase (LDH) levels and detection of chromosomal abnormalities (CA) by interphase fluorescent in situ hybridization (FISH).

**TABLE 16.2 Durie-Salmon Myeloma Staging System Criteria**

Stage I	Stage II	Stage III
<p>All of the following:</p> <ul style="list-style-type: none"> <li>Hb &gt;10 g/dL</li> <li>Serum Ca<sup>2+</sup> normal (&lt;12 mg/dL)</li> <li>X-rays: normal bone structure or solitary bone plasmacytoma only</li> <li>Low M-component production rates IgG value &lt;5 g/dL IgA value &lt;3 g/dL</li> </ul> <p>Urine light-chain M-component on electrophoresis &lt;4 g/24 hours</p> <p>Subclassification:</p> <p>A, Relatively normal renal function (serum creatinine value &lt;2.0 mg/dL)</p> <p>B, Abnormal renal function (serum creatinine &gt;2.0 mg/dL)</p> <p>Ca<sup>2+</sup>, Calcium; Hb, hemoglobin.</p>	<p>Overall data are minimally abnormal as shown for stage I and no single value as abnormal as defined for stage III</p>	<p>One or more of the following:</p> <ul style="list-style-type: none"> <li>Hb &lt;8.5 g/dL</li> <li>Serum Ca<sup>2+</sup> &gt;12 g/dL</li> <li>Advanced lytic bone lesions (scale 3)</li> <li>High M-component production rates IgG value &gt;7 g/dL IgA value &gt;5 g/dL</li> </ul> <p>Urine light-chain M-component on electrophoresis &gt;12 g/24 hours</p>

A large variety of candidate prognostic factors have been proposed for MM. These include plasmablastic morphology; high serum levels of beta-2 microglobulin, interleukin-6 (IL-6) or soluble IL-6 receptor, LDH, or C-reactive protein; increased PC labeling index (PCLI); abnormal karyotype of MM cells in metaphase; cell surface markers on MM cells (e.g., CD56); serum levels of cytokines, such as hepatocyte growth factor; presence of *RAS* or *p53* mutations in MM cells; detection of malignant PCs in the peripheral blood (especially when the absolute count is  $\geq 2000$ , which defines PC leukemia); and various sets of transcripts identified by oligonucleotide microarray or RNA-sequencing analysis of MM cells; all of these have been previously proposed in at least one study to correlate with inferior clinical outcome in MM and/or to have significant differences between MM patients with early-stage disease versus advanced MM.

Although some of these parameters (such as beta-2 microglobulin, LDH, cytogenetics, and, in some centers, PCLI) are routinely used in the workup of MM patients, the optimal set of markers for prognostication in MM remains to be defined, because of the continuous progress in both the methods to evaluate some of these markers and the therapeutic management. For instance, chromosome 13 deletion, which is associated with inferior outcome to conventional anti-multiple myeloma (anti-MM) treatments such as glucocorticoids and standard or high-dose cytotoxic chemotherapy, does not confer an adverse prognostic role

in patients treated with bortezomib. This indicates that the association of a candidate marker with clinical outcome is dependent on the treatment that is being administered. As the therapeutic algorithm for MM continues to evolve with the introduction of new therapeutic classes (e.g., thalidomide and its analogues, proteasome inhibitors, and the monoclonal antibodies daratumumab and elotuzumab), the role of various prognostic markers needs to be evaluated in prospective studies of patients homogeneously treated with these new regimens.

## General Algorithm for Therapeutic Management

Patients with MGUS or asymptomatic (smoldering) myeloma can be observed, often for years, without need for treatment, although it is notable that the latter group is at a significantly higher risk of progression to symptomatic disease. Historically, early treatment of asymptomatic MM patients has not been pursued because of absence of data that it can prolong overall survival. However, some studies have suggested clinical benefit from the use of bisphosphonates, especially in patients with very early bone disease and/or osteopenia. Furthermore, recent studies indicate that early treatment of high-risk smoldering MM patients with lenalidomide plus dexamethasone (Dex) delays progression to active disease and increases overall survival.

A key question in the therapeutic management of a newly diagnosed symptomatic MM patient pertains to his/her eligibility for autologous stem cell transplant (auto-SCT).

Transplant-eligible patients can be treated with a variety of regimens, the choice of which is dictated by the goal of decreasing the pretransplant tumor burden so that the steep dose-response curve of myeloablative doses of alkylation in the transplant's conditioning regimen can maximize the depth and durability of disease control. Patients' recovery from the transplant depends on the rapid reengraftment of reinfused autologous stem cells, which in turn depends on their quantity and quality at their pretransplant collection. Consequently, the induction treatment for a transplant-eligible patient should be conducted with agents that impose the minimum damage to hematopoietic stem cells. This is not a requirement for patients ineligible for transplant, and, depending on the patient's hematopoietic reserve, stem-cell-targeting drugs such as melphalan can be an important part of treatment.

Eligibility for auto-SCT is determined in many institutions by an age cutoff of age  $\geq 65$  years, especially in Europe. However, this limit can seem arbitrary because patients in their late 60s or older may also be transplant eligible if they are relatively healthy. Insufficient functional reserve for the liver (e.g., direct bilirubin  $> 2.0$  mg/dL) or kidneys (e.g., serum creatinine  $> 3.0$  mg/dL), pulmonary insufficiency, or Eastern Cooperative Oncology

**TABLE 16.3** International Staging System Stage Criteria

Stage	Beta-2-M and Albumin Levels	Median Survival (Months)
I	Beta-2-M $< 3.5$ mg/L Albumin $\geq 3.5$ g/dL	62
II	Neither stage I nor III <sup>a</sup>	44
III	Beta-2-M $\geq 5.5$ mg/L	29
Revised ISS (R-ISS) Stage	Beta-2-M and Albumin Levels <sup>b</sup>	5-Year Overall Survival Rates
I	ISS stage I No high-risk CA Normal LDH level	82
II	Neither R-ISS stage I nor III <sup>b</sup>	62
III	ISS stage III and high-risk CA or high LDH level	40

<sup>a</sup>There are two subcategories for stage II: serum beta-2 microglobulin  $< 3.5$  mg/L but serum albumin  $< 3.5$  g/dL and serum beta-2 microglobulin 3.5 to  $< 5.5$  mg/L irrespective of the serum albumin level.

<sup>b</sup>High-risk CA includes any of del(17p), t(4;14), or t(14;16), whereas normal LDH level is less than the upper limit of normal range.

Beta-2-M, Beta-2 microglobulin; CA, chromosomal abnormalities; ISS, international staging system; LDH, lactate dehydrogenase.

**TABLE 16.4** Criteria for Response

Response	Criteria for Response
Complete response (CR)	Requires all of the following: Disappearance of the original monoclonal protein from the blood and urine on at least two determinations for a minimum of 6 weeks by immunofixation studies <5% plasma cells in the BM on at least two determinations for a minimum of 6 weeks No increase in the size or number of lytic bone lesions (development of a compression fracture does not exclude response) Disappearance of soft tissue plasmacytomas for at least 6 weeks
Partial response (PR)	PR includes patients in whom some, but not all, criteria for CR are fulfilled providing the remaining criteria satisfy the requirements for PR. Requires all of the following: 50% reduction in the level of serum M-protein for at least two determinations 6 weeks apart If present, reduction in 24-hour urinary light-chain excretion by either >90% or to <200 mg for at least two determinations 6 weeks apart ≥50% reduction in the size of soft tissue plasmacytomas (by clinical or applicable radiographic examination; i.e., two-dimensional MRI or CT scan) No increase in size or number of lytic bone lesions (development of compression fracture does not exclude response)
Minimal response (MR)	MR includes patients in whom some, but not all, criteria for PR are fulfilled providing the remaining criteria satisfy the requirement for MR. Requires all of the following: ≥25%–<50% reduction in the level of serum monoclonal protein for at least two determinations If present, a 50%–89% reduction in 24-hour light-chain excretion, which still exceeds 200 mg/24 hours for at least two determinations 6 weeks apart A 25%–49% reduction in the size of plasmacytomas (by clinical or applicable radiographic examination, i.e., two-dimensional magnetic resonance imaging or CT scan) No increase in size or number of lytic bone lesions (development of compression fracture does not exclude response)
No change (NC)	Not meeting the criteria for MR or PD
Progressive disease (PD) for patients not in CR	Requires one or more of the following: >25% increase in the level of monoclonal paraprotein, which must also be an absolute increase of at least 5 g/L and confirmed on repeat investigation 1–3 weeks later >25% increase in 24-hour urinary light-chain excretion, which must also be an absolute increase of at least 200 mg/24 hours and confirmed on a repeat investigation in 1–3 weeks >25% increase in plasma cells in a BM aspiration or on trephine biopsy, which must also be an absolute increase of at least 10% Definite increase in the size of existing lytic bone lesions or soft tissue plasmacytomas Development of new bone lesions or soft tissue plasmacytomas (not including compression fractures) Development of hypercalcemia (corrected serum Ca <sup>2+</sup> >11.5 mg/dL, not attributable to other causes)
Relapse from CR	Requires at least one of the following: Reappearance of monoclonal paraprotein on immunofixation or routine electrophoresis to an absolute value >5 g/L confirmed by at least one follow-up 6 weeks later and excluding oligoclonal immune reconstitution; >5% plasma cells in a BM aspirate or biopsy Development of new lytic bone lesions or soft tissue plasmacytomas or definite increase in the size of residual bone lesions (not including compression fractures) Development of hypercalcemia (corrected serum Ca <sup>2+</sup> >11.5 mg/dL, not attributable to other causes)

*BM, Bone marrow; Ca<sup>2+</sup>, Calcium.*  
From Blade J, Samson D, Reece D, et al. Criteria for evaluating disease response and progression in patients with multiple myeloma treated by high-dose therapy and haemopoietic stem cell transplantation. Myeloma Subcommittee of the EBMT. European Group for Blood and Marrow Transplant. *Br J Haematol.* 1998;102(5):1115–1123.

Group (ECOG) performance status 3 or 4 (unless caused by bone pain) or New York Heart Association functional status class III or IV confers a high risk of complications with transplant and is usually considered not compatible with successful SCT, although younger and otherwise well dialysis-dependent patients can be transplanted at selected SCT centers where the requisite expertise may reside.

### Response Criteria

The response of MM patients to a given therapy is assessed on the basis of decrease in the serum and/or urine levels of M-protein produced by the MM cells. The two main systems of criteria used for evaluation of response are the Blade criteria (Table 16.4) and the recently developed International Myeloma Working Group uniform response criteria (Table 16.5).

**TABLE 16.5 International Myeloma Working Group Uniform Response Criteria: Complete and Other Response Categories**

Response Subcategory	Response Criteria <sup>a</sup>
CR	Negative immunofixation on the serum and urine <i>and</i> Disappearance of any soft tissue plasmacytomas <i>and</i> ≤5% plasma cells in BM <sup>b</sup>
sCR	CR as defined above <i>plus</i> Normal FLC ratio <i>and</i> Absence of clonal cells in BM <sup>b</sup> by immunohistochemistry or immunofluorescence <sup>c</sup>
VGPR	Serum and urine M-component detectable by immunofixation but not on electrophoresis or ≥90 reduction in serum M-component <i>plus</i> Urine M-component <100 mg per 24 hours
PR	≥50% reduction of serum M-protein and reduction in 24-hour urinary M-protein by ≥90% or to <200 mg per 24 hours  If the serum and urine M-protein are unmeasurable, a ≥50% decrease in the difference between involved and uninvolved FLC levels is required in place of the M-protein criteria  If serum and urine M-protein are unmeasurable, and serum free light assay is also unmeasurable, ≥50% reduction in plasma cells is required in place of M-protein, provided baseline BM plasma cell percentage was ≥30%  In addition to the above listed criteria, if present at baseline, a ≥50% reduction in the size of soft tissue plasmacytomas is also required
SD	Not meeting criteria for CR, VGPR, PR, or progressive disease

<sup>a</sup>All response categories require two consecutive assessments made at any time before the institution of any new therapy; complete and PR and SD categories also require no known evidence of progressive or new bone lesions if radiographic studies were performed. Radiographic studies are not required to satisfy these response requirements.

<sup>b</sup>Confirmation with repeat bone marrow biopsy not needed.

<sup>c</sup>Presence/absence of clonal cells is based upon the k/ratio. An abnormal k/ratio by immunohistochemistry and/or immunofluorescence requires a minimum of 100 plasma cells for analysis. An abnormal ratio reflecting presence of an abnormal clone is k/of >4:1 or <1:2. Alternatively, the absence of clonal plasma cells can be defined based on the investigation of phenotypically aberrant plasma cells. The sensitivity level is 10<sup>-3</sup> (less than one phenotypically aberrant plasma cell within a total of 1000 plasma cells). Examples of aberrant phenotypes include (1) CD38+dim and CD56+strong and CD19- and CD45-; (2) CD38+dim and CD138+ and CD56++ and CD28+; (3) CD138+, CD19-, CD56++, and CD117+.

CR, Complete response; FLC, free light chain; PR, partial response; SD, stable disease; sCR, stringent complete response; VGPR, very good partial response. From Rajkumar SV, Buadi F. Multiple myeloma: new staging systems for diagnosis, prognosis and response evaluation. *Best Pract Res Clin Haematol*. 2007; 20(4):665-680.

## Key Drug Classes Used for Multiple Myeloma Therapy

### Established Conventional Agents (Glucocorticoids, Alkylators, Anthracyclines)

Until the late 1990s, MM treatment at all stages of the disease was based on combinations of glucocorticoids and DNA-damaging chemotherapy, specifically alkylators (such as melphalan/cyclophosphamide) and anthracyclines (doxorubicin/adriamycin). Melphalan-prednisone (MP) was shown to be as effective as the more complex combinations of multiple chemotherapeutics with glucocorticoids that had been evaluated for transplant-ineligible patients. The VAD (vincristine, adriamycin, Dex) combination was also used, primarily as induction therapy for transplant-eligible patients and to achieve more rapid reduction of tumor burden when deemed clinically necessary. The biggest proportion of the tumor-debulking properties of these regimens was attributed to the glucocorticoid component. Melphalan (typically at 200 mg/m<sup>2</sup>) also became a standard

conditioning regimen for auto-SCT. Side effects were consistent with those of glucocorticoids and DNA-damaging chemotherapy with some important distinctions: melphalan is more stem-cell toxic than cyclophosphamide, or adriamycin (and less so cyclophosphamide) can be cardiotoxic, and vincristine can cause significant peripheral neuropathy. Most patients would generally respond at least to some extent to these regimens, but resistance would invariably eventually develop. Until the advent of thalidomide, the lack of other non-cross-resistant drug classes for MM therapy meant that regimens used at relapse were again based on steroids plus DNA-damaging agents, resulting in a progressive decrease in the rate, depth, and durability of response seen with each successive round of salvage treatment attempted.

### Novel Agents (Proteasome Inhibitors; Thalidomide and Its Derivatives; Monoclonal Antibodies)

The landscape of MM treatment changed radically with the development of thalidomide (first used in the late 1990s and US Food and Drug Administration [FDA] approved

in 2006); its derivatives lenalidomide and pomalidomide (FDA approved in 2006 and 2013, respectively); proteasome inhibitors, such as bortezomib, carfilzomib, and ixazomib (FDA approved in 2003, 2012, and 2015, respectively); and several combinations of these agents. These drug classes target MM tumor cells (although with mechanisms different from classical DNA-damaging chemotherapy or from glucocorticoids) and also target the critical interaction of MM cells with the local microenvironment of the BM milieu. Thalidomide, lenalidomide, and pomalidomide have direct antitumor effects, as well as immunomodulatory properties. Bortezomib (formerly known as PS-341) binds reversibly to the beta-5 subunit of the 20S core of the proteasome and blocks one (specifically the chymotryptic-like activity) of the three proteolytic activities of the proteasome. This activity regulates the expression and function of many regulators of tumor cell proliferation, survival, and drug resistance, and its inhibition by bortezomib kills MM cells both potently and rapidly. Carfilzomib is considered an irreversible inhibitor of the 20S proteasome. Ixazomib is an orally bioavailable reversible inhibitor of the 20S proteasome.

Recently, two monoclonal antibodies were also FDA approved: daratumumab (anti-CD38) as single-agent (2015) or combined with lenalidomide-Dex or bortezomib-Dex (2016) and elotuzumab (anti-CS1/SLAMF7) in combination with lenalidomide-Dex. The development of these monoclonal antibodies represents an important paradigm change in the treatment of MM.

Proteasome inhibitors and thalidomide and its analogues share several pharmacologic features distinct from conventional chemotherapy:

- All these novel anti-MM agents can induce, as single agents, objective clinical responses in large proportions of patients resistant or even refractory to prethalidomide regimens (including high-dose alkylation with auto-SCT).
- Either as single agents (bortezomib) or when combined with conventional agents (e.g., thalidomide + Dex, lenalidomide + Dex, pomalidomide + Dex, bortezomib + MP, bortezomib + liposomal doxorubicin, bortezomib + the histone deacetylase inhibitor panobinostat), proteasome inhibitors and thalidomide derivatives offer improved rates, depth, and durability of clinical responses and, importantly, can prolong progression-free or overall survival of patients compared with conventional agents in randomized phase III clinical trials.
- The side-effect profiles of proteasome inhibitors and thalidomide derivatives are distinct from those of conventional chemotherapy. Nausea, vomiting, and alopecia are typically absent, and diarrhea, although sometimes present with bortezomib (or with lenalidomide), is usually manageable. Lenalidomide and pomalidomide can cause neutropenia/thrombocytopenia, and bortezomib can cause thrombocytopenia, but these are usually not associated with significant increase in infectious risk or clinically significant bleeding and typically respond favorably to dose/schedule modifications, transfusion, and/or myeloid growth factor support.

Bortezomib and thalidomide use does not compromise stem cell collection, thereby allowing their use in induction regimens for transplant-eligible patients. Lenalidomide is not considered toxic to hematopoietic stem cells per se, but early data suggested that it modulates adhesion of hematopoietic cells in the BM and could influence the yield of stem cell collection, making early stem cell collection and the use of cyclophosphamide-based mobilization (vs. growth factor alone) potentially important.

Importantly, these novel agents cause certain side effects not typically associated with the conventional anti-MM agents. Thalidomide and bortezomib can both cause a significant peripheral sensory neuropathy (PN), although with some difference in their clinical features—for example, PN that is more polymorphic (with occasional facial and truncal involvement) with thalidomide compared with the involvement of feet and then hands with centripetal progression using bortezomib. Carfilzomib is typically not associated with peripheral neuropathy, but cardiopulmonary adverse events (including heart failure, ischemia, pulmonary hypertension, and even deaths) were reported in early clinical trials; the FDA recommends caution with the use of this agent.

Thalidomide also causes somnolence and constipation. Although structurally related to thalidomide, lenalidomide is devoid of significant PN, somnolence, or constipation. On the other hand, combinations of either thalidomide or lenalidomide with glucocorticoids are associated with increased risk for thromboembolic events.

Thalidomide, lenalidomide, and pomalidomide are oral agents administered typically once daily (thalidomide typically is administered at night before sleep, given its sedative properties), whereas bortezomib is given intravenously (or subcutaneously) typically twice weekly (72 hours must elapse between successive doses). Carfilzomib is administered intravenously on two consecutive days weekly (for 3 weeks, followed by a 12-day rest period, of a typical treatment cycle).

It is notable that some of these agents (e.g., pomalidomide, carfilzomib, or monoclonal antibodies) are not available in all countries outside the United States. For instance, some restrictions exist for the use of both bortezomib and lenalidomide in the United Kingdom.

### **Management of Transplant-Eligible Patients in the Era of Novel Agents**

For newly diagnosed MM patients age <65 years who have normal renal function and are fit to undergo auto-SCT, the procedure-related mortality is <5% and usually of the order of 1% to 2%. In this group of patients, randomized studies have confirmed that auto-SCT offers superior clinical outcome to conventional-dose combination chemotherapy, with longer progression-free survival as well as a significant increase in median overall survival by approximately 1 to 2 years.

The introduction of novel agents for MM therapy has led to more available options for pretransplant induction

regimens: currently available first-line therapeutic options include thalidomide plus Dex, lenalidomide plus Dex, bortezomib plus Dex, or the triple combination of bortezomib, thalidomide, and Dex (VTD), and most recently lenalidomide, bortezomib, and Dex (RVD), with response rates of partial response or better in all patients (100%) treated at maximal doses.

The precise choice of regimen is determined by several considerations, including the extent and clinical aggressiveness of the disease (as determined by Durie-Salmon and/or ISS staging, cytogenetics, and other clinical features associated with worse outcome); the extent of bone disease (which, if pronounced, merits consideration for use of a bortezomib-based regimen); the status of concomitant end-organ dysfunction (e.g., renal insufficiency, neuropathy) and risk factors for side effects to each of the potential anti-MM agents, including thromboembolism; and regional differences in practice patterns and approval status of a particular agent, as well as the patient's preference for oral therapy versus regimens with infusional components. Importantly, randomized trials have supported the role of bortezomib therapy in any patient going forward to auto-SCT.

Randomized trials indicate that lenalidomide as maintenance therapy after auto-SCT is associated with prolonged progression-free and overall survival. These studies also raised concerns about possible increase in risk for second primary malignancies, although this may potentially be influenced by the use of DNA-damaging alkylating agents in pre-SCT induction regimens that are used now less commonly.

The role of allogeneic SCT in MM remains the topic of intense research. Allogeneic SCT following myeloablative conditioning regimens can induce molecular remissions, and in some studies about one-third of MM patients remain disease free for 6 years. These cases of long-term remission are attributed to the immune response of the donor's lymphoid cells against the host's MM cells, termed *graft-versus-myeloma* (GVM) *effect*, and have supported the notion that allogeneic SCT, in at least a subset of patients, may have the potential to cure MM or at least provide a platform for the long-term control of the disease. However, the toxicity of fully ablative allogeneic SCT is very high, with treatment-related mortality (mostly related to infections and graft-versus-host disease [GVHD]-related complications) of up to 50% in some studies of previously treated MM patients. As a result, allogeneic SCT is not proposed for patients age >50 to 55 years. Reduced-intensity conditioning (RIC) allogeneic SCT has been developed with the goal to reduce transplant-related mortality while sustaining a GVM effect. However, RIC regimens that induce less GVHD are associated with higher rates of relapse, suggesting that the relationship between GVM and GVHD is very close and difficult to manipulate therapeutically at this point.

### Management of Patients Not Eligible for Transplant

The fundamental difference in the management of transplant-ineligible MM patients compared with those eligible

for the auto-SCT procedure is that the former do not have to receive extensive alkylator-free first-line therapy. Therefore in addition to all other possible treatment induction regimens that are applicable to transplant-eligible patients, the noneligible patients can also receive melphalan-containing combinations such as MP, melphalan-prednisone-thalidomide (MPT), melphalan-prednisone-bortezomib (MPV), or melphalan-prednisone-lenalidomide (MPR). Again, the precise choice of regimen is determined by a series of considerations including the extent and clinical aggressiveness of the disease (as determined by Durie-Salmon and/or ISS staging, cytogenetics, etc.), the extent of bone disease (which, if pronounced, merits consideration for use of a bortezomib-based regimen), the status of concomitant end-organ dysfunction (e.g., renal insufficiency where bortezomib-based therapy is currently preferred, underlying neuropathy, such that lenalidomide may be preferred), and other risk factors for side effects to each of the potential anti-MM agents, regional differences in practice patterns, and approval status of a particular agent, as well as patient's preference for oral therapy versus regimens with infusional components. Again, response rates have proven dramatic with overall response rates of 90% now being reported.

### Relapsed and Refractory Multiple Myeloma

The term *relapsed myeloma* refers to patients who have initially responded to a treatment and then have disease progression. In those patients, the disease may be sensitive to a rechallenge with their last treatment, but this usually requires additional agents. Relapsed patients who develop resistance while on treatment with an active regimen (or within 60 days of completion of their last treatment) are classified as having "relapsed and refractory" or "refractory" myeloma. In the prethalidomide era, this latter group of patients had a uniformly unfavorable outcome with short overall survival. However, with the development of proteasome inhibitors and thalidomide derivatives, the management of relapsed and refractory MM has improved dramatically: studies of single-agent treatment with members of these two drug classes have shown that they can be active in patients with disease refractory to conventional or high-dose chemotherapy. Therefore with the emergence of these newly established agents, the significance of the term *relapsed and refractory MM* also changes because it directly depends on the specific agents to which the term applies: patients with refractoriness to conventional or high-dose chemotherapy often respond to bortezomib-based, thalidomide-based, or lenalidomide-based therapies. Patients refractory to one of these new drug classes may still respond to one of the others, whereas patients refractory to multiple new agents may still respond to combinations of new and conventional agents (e.g., RVD or VTD). Refractoriness to combinations of proteasome inhibitors with thalidomide derivatives (especially in patients also refractory to alkylator/anthracycline treatment) represents a challenging clinical setting for which new treatment approaches are urgently needed.

### Recent Developments and Future Perspectives from Investigational Agents

The therapeutic management of MM represents a rapidly changing field. In the last 15 years, proteasome inhibitors, thalidomide and its derivatives, and new monoclonal antibodies, as well as combination regimens based on at least one of these classes of therapeutics, have drastically altered the management for this disease, and the overall survival of patients has significantly improved, compared with the prethalidomide era. Importantly, this improvement in clinical outcomes does not yet fully reflect the very recent development of some of these agents, for example, daratumumab.

Intensive basic and clinical research efforts are taking place to further expand the therapeutic armamentarium for this disease. Some of the many options currently explored in the clinical trial setting have yielded encouraging early results and may perhaps soon be added to the rapidly evolving standard of care. It is not possible to specifically predict which of these encouraging leads will successfully translate to FDA approval and how they may impact the MM field.

However, some interesting themes have evolved and are likely to be central to the management of MM in the coming years. Recent results from European centers suggest that bortezomib as part of the preauto-SCT regimen plays an important role in improving the auto-SCT outcome. Furthermore, results from the Velcade as Initial Standard Therapy in Multiple Myeloma (VISTA) trial support the use of bortezomib plus MP as a major option for upfront therapy of nontransplant candidates. An Eastern Cooperative Oncology Group (ECOG) trial showed that lenalidomide plus low-dose Dex is better tolerated and has better overall survival than lenalidomide combination with high-dose Dex, indicating that combinations of conventional or novel agents with lenalidomide should incorporate low-dose Dex in an effort to improve response rates without conferring increased treatment-related mortality and/or morbidity. Finally, clinical trials of the triplet RVD indicate encouraging tolerability, high response rates, and favorable duration of responses in both the relapsed/refractory and the newly diagnosed setting, suggesting that the RVD combination may become the therapeutic backbone for other more complex combination regimens designed to improve the depth and durability of clinical responses in MM patients. After its FDA approval, pomalidomide is also being incorporated into diverse combination regimens, including combinations with proteasome inhibitors. Given its potent anti-MM clinical activity and manageable safety profile, daratumumab is also expected to become a key component of many combination regimens.

## General Management and Supportive Care

### Supportive Management

#### Anemia

Low Hb is a frequent feature at presentation but can also develop eventually during the course of the disease. The etiology can be multifactorial (BM infiltration by MM cells;

anemia of chronic disease, sometimes further complicated by anemia related to MM-associated renal dysfunction). Erythropoietin (Epogen, Procrit) decreases transfusion requirements and increases Hb levels in over half of MM patients, with the higher probability of response among MM patients with low baseline serum erythropoietin levels. Most physicians proceed with a trial of erythropoietin (Epogen, Procrit), 150 U/kg three times weekly, or 40,000 U once a week. Darbepoetin, a long-lasting erythropoietin (Aranesp), may be given weekly or biweekly. Recombinant erythropoietin should be used with caution, not only because of its association with increased risk for cardiovascular events in other settings but also because its administration in thalidomide/lenalidomide patients increases the risk of thromboembolism.

It is also worth noting that monoclonal M-protein exerts an osmotic effect that (especially at high M-protein levels) tends to increase plasma volume and spuriously lower both Hb and hematocrit levels.

### Skeletal Lesions

Bone lesions with pain and fractures (spontaneous or trauma-induced fractures) are frequently the first manifestation of MM and can also become a major problem during the disease course. MM can cause not only discrete lytic lesions but also diffuse osteopenia in areas of the skeleton macroscopically unaffected by tumor cells. The management of bone disease in MM involves skeletal radiographic surveys that should be performed at least at yearly intervals (or earlier, if new pain develops), and bisphosphonate therapy is recommended for all MM patients with lytic lesions, pathologic fractures, or severe osteopenia. In the United States, the bisphosphonates typically chosen for MM treatment are zoledronate (zoledronic acid or Zometa, 4 mg intravenously [IV] over 15 minutes every 4 weeks) or pamidronate (Aredia, 90 mg IV over 2 hours every 4 weeks). These regimens have comparable efficacy, but the shorter duration of infusion is a potential advantage of zoledronate. Bisphosphonates can cause renal dysfunction and even nephritic-range proteinuria. Therefore the monitoring of serum creatinine and 24-hour urine protein is necessary, and the drug dose should be reduced or omitted according to the level of renal insufficiency. Because MM patients now survive longer, the issue of osteonecrosis of the jaw has been recognized, making the duration and frequency of longer-term bisphosphonate therapy a matter of ongoing debate. It has been proposed that after 2 years of IV bisphosphonate, if there is no evidence of progressive skeletal disease, the frequency of doses should be adjusted to every 3 months. Moreover, once in complete response (CR), additional bisphosphonate can be deferred as long as the patient's bone disease is quiescent.

Some novel therapies (e.g., proteasome inhibitors) conceivably help MM bone disease by suppressing the tumor clone that triggers it and inhibiting osteoclast activation directly. For instance, independent of its effect on the tumor, bortezomib appears to potently suppress bone resorption (by affecting osteoclast maturation) and trigger

new bone formation (by stimulating osteoblast function). Consequently, bortezomib is a reasonable option for treatment of patients with extensive bone lesions.

Vertebroplasty and/or kyphoplasty may be helpful for patients with compression fracture of the spine. Patients should be encouraged to be as active as possible, because confinement to bed increases demineralization of the skeleton. Trauma must be avoided because even mild stress may result in a fracture. Fixation of long bone fractures or impending fractures with an intramedullary rod and methyl methacrylate can give excellent results.

### **Osteonecrosis of the Jaw**

Osteonecrosis of the jaw has been reported in patients receiving bisphosphonates for MM or other cancers (incidence estimated between 1.5% among patients treated for 4–12 months to 7.7% for treatment of 37–48 months). Etiology is unclear. Complete dental evaluation and preventive dental treatments should take place before onset of bisphosphonate therapy. During bisphosphonate treatment, careful oral hygiene should be practiced, and invasive procedures, particularly dental extractions, are not recommended. Osteonecrosis of the jaw should be managed conservatively.

### **Renal Insufficiency**

Up to 20% of MM patients have serum creatinine levels  $>2.0$  mg/dL at diagnosis. Myeloma M-protein itself (particularly light chains) and MM-related hypercalcemia are two major causes of renal impairment in this setting. Other contributing factors include dehydration (e.g., in relationship to hypercalcemia or independently of it), infection, nonsteroidal antiinflammatory drug use (e.g., for relief of MM bone pain), contrast for radiographic studies, hyperuricemia, or amyloid deposition. Acute (or subacute) renal failure in MM requires prompt fluid and electrolyte replacement as well as active anti-MM treatment to decrease the tumor burden, the release of M-protein, and their impact on renal function. Although Dex, thalidomide, and their combination (or even VAD, in the prethalidomide era) have been used for cytoreduction in the context of renal impairment, a bortezomib-containing regimen (e.g., bortezomib-Dex or bortezomib-thal-Dex) has emerged recently as a reasonable and very active option for such settings because bortezomib is not excreted renally and does not further compromise renal function. It exerts a rapid cytotoxic effect on MM cells, thus being more conducive to the goal for rapid cytoreduction and light-chain removal. A direct protective effect of bortezomib has been hypothesized but has not yet been formally proven. The use of plasmapheresis can be attempted to prevent the need for chronic dialysis, but randomized data are conflicting in terms of benefit. Patients with symptomatic azotemia or other indications for renal replacement therapy can receive either hemodialysis or peritoneal dialysis, which have comparable efficacy in this setting. Kidney transplantation for renal failure in the context of MM has been followed by prolonged survival, but the decision to perform the procedure has to take into account

the probability for long-term control; limited data so far suggest the procedure can be challenging.

In general, MM patients, and in particular those with Bence Jones proteinuria, need to maintain high fluid intake to prevent renal failure. A reasonable target for fluid intake leads to 24-hour urine volume of approximately 3 L in patients with Bence Jones proteinuria. In the event of hyperuricemia, allopurinol (at a dose of up to 300 mg daily) is an effective therapy. CT with IV contrast should be avoided.

### **Hypercalcemia**

Hypercalcemia must be suspected in cases of MM patients with anorexia, nausea, vomiting, polyuria, constipation, weakness, confusion, stupor, or coma. If left untreated, hypercalcemia in MM patients can precipitate serious renal insufficiency. Therefore hydration with isotonic saline and prednisone (e.g., at a dose of 25 mg orally four times daily) is effective in most patients. The dosage of prednisone must be reduced and discontinued as soon as possible. After hydration has been achieved, furosemide may be helpful; a bisphosphonate such as zoledronic acid or pamidronate constitutes a standard of care in this setting.

### **Infections**

Compared with the general population, MM patients are at higher risk for bacterial infections; such infections remain the most common direct cause of death in MM patients overall.

This risk has multifactorial etiology: suppression of uninvolved immunoglobulins by high levels of M-protein, neutropenia caused by BM infiltration and/or therapy, and defects in antigen-presenting function of dendritic cells. This infection risk is higher during the first 2 months after initiation of induction chemotherapy. Sinopulmonary bacterial infections are among the most common infections in MM patients.

Even if MM can be associated with suboptimal antibody response to antigen challenge, pneumococcal and influenza immunization should be given to all MM patients.

Prophylactic antibiotics may be useful, and commonly used agents include trimethoprim-sulfamethoxazole (Bactrim, Septra) or prophylactic daily oral penicillin (which may benefit patients with recurrent pneumococcal infections). Prophylactic levofloxacin has good bioavailability in sinopulmonary tissues where infections commonly occur in MM patients, but this advantage has to be carefully weighed against the risk for emergence of fluoroquinolone resistance. Intravenous immunoglobulin administration may be useful for short-term treatment of recurrent infections, especially in the context of selective IgG subclass deficiency. Appropriate cultures, chest x-rays, and empirical antibiotic therapy are warranted not only for febrile MM patients but also for nonfebrile MM patients with pronounced neutropenia.

Fungal infections, particularly in the context of prolonged steroid use, are an important consideration. Finally, herpes zoster virus has been shown to occur in MM patients receiving the agent bortezomib, possibly through effects on

the immunoproteasome. Viral prophylaxis with acyclovir or its equivalent is therefore recommended.

### Radiation Therapy

Palliative radiation (XRT) is used for patients with significant pain because of well-defined focal involvement of MM that does not respond to systemic pharmacologic treatment. The combination of analgesics with specific therapy directed against the MM itself can also provide control of pain, which may not be limited to one particular site, therefore providing an advantage over radiation therapy. The cumulative myelosuppression by radiotherapy and chemotherapy should be taken into account when considering palliative radiotherapy, but XRT can often be safely combined with thalidomide, glucocorticoids, and bortezomib.

### Thromboembolic Complications

Malignancies in general can be associated with increased risk for thromboembolic events. In MM, these complications have been associated mostly with treatment with combinations of Dex with thalidomide or lenalidomide. Reports suggest that this risk is increased by administration of erythropoietin and decreased by bortezomib-containing regimens. Patients should receive low-molecular-weight heparin or warfarin in therapeutic doses. Aspirin may reduce the risk of thromboembolic complications and is an alternative in patients who cannot or do not want to receive anticoagulation.

### Hyperviscosity Syndrome

Hyperviscosity syndrome can be manifested as oronasal or gastrointestinal bleeding, blurred vision, neurologic symptoms, or congestive heart failure. It is more common with the rare form of IgM myeloma, less common with IgA myeloma, and even less common in IgG myeloma. The clinical manifestations are not directly proportional to serum viscosity measurement, but symptoms are more likely to appear when serum viscosity reaches values of  $>4$  cP. It is important to note that in general the decision to perform plasmapheresis, which promptly relieves the symptoms of hyperviscosity, should be made on clinical grounds rather than serum viscosity level alone.

### Spinal Cord Compression

This important complication should always be suspected and ruled out in MM patients with lower extremity weakness, difficulty in urinary voiding or defecation, or sudden onset of severe radicular or severe back pain. Workup must include MRI or CT, and, if diagnosis of spinal cord compression is confirmed, radiation therapy with Dex to decrease edema is appropriate.

### Emotional Support

MM patients must receive continuing emotional support. It is important to inform patients and family members of the major progress achieved in the field in recent years and the fact that there has been a consistent trend for improved

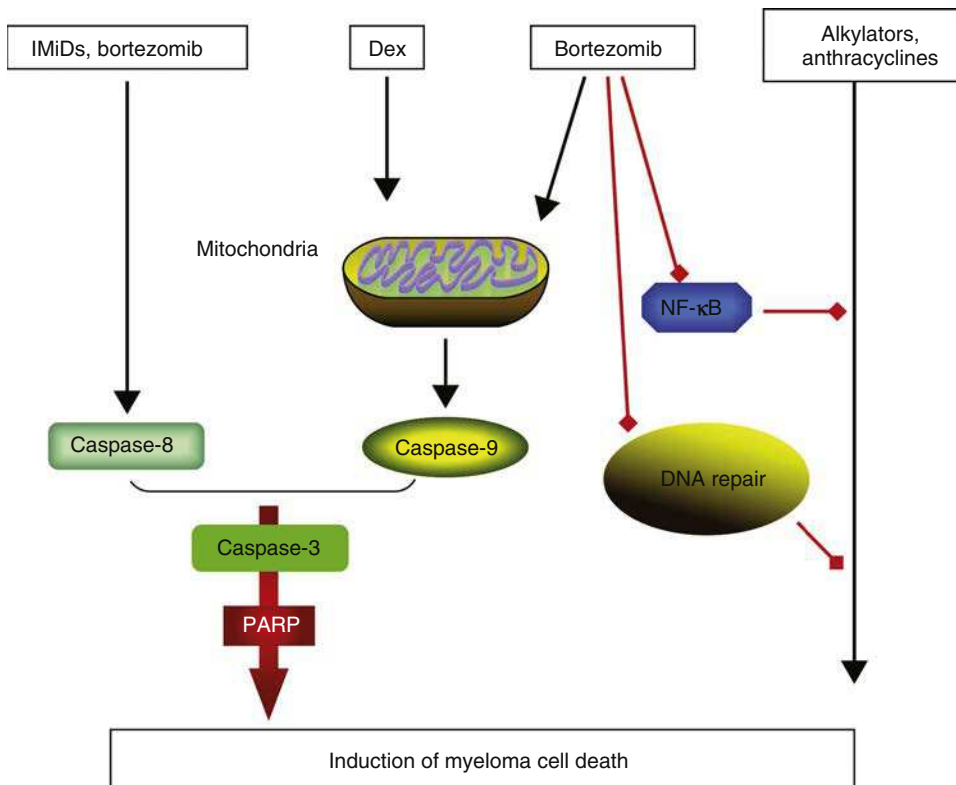

survival since the introduction of new drugs and supportive measures. An increasing proportion of MM patients survive for 10 years or more. However, the disease is unfortunately still considered incurable. Therefore it is necessary to establish with patients and family members an appropriate and not unrealistic level of expectation about long-term outcome, based on the clinical and laboratory evidence for each patient and the responsiveness seen to administered therapies. The support of medical social workers and experienced psychiatrists is invaluable, especially given the complexity of an incurable malignancy combined with the profound psychotropic effects of steroid-based therapy.

## Some Clinical Pearls in the Management of Multiple Myeloma Patients

- The advent of proteasome inhibitors, thalidomide and its derivatives, which target the myeloma and its micro-environment, has transformed the management of this disease (Fig. 16.1).
- The choice of thalidomide versus lenalidomide use in diabetics and other patients with neuropathy should take into account the lack of significant neuropathy with lenalidomide use.
- Recombinant erythropoietin in MM patients may increase the risk of thromboembolic events when used with thalidomide or lenalidomide, especially when combined with steroids.
- Patients with light-chain disease can be especially responsive to bortezomib and are more likely to achieve CR compared with bortezomib responders with intact monoclonal immunoglobulin.
- Serum free light-chain measurement is a useful tool if careful serial measurements are followed up over time and the test is used in patients with oligosecretory or hyposecretory disease. Sometimes it can detect a relapse earlier than conventional measurements; however, results can fluctuate considerably. Thus it is important to interpret “spot” measurements cautiously.
- Rechallenge with novel and conventional agents (including Dex, alkylating agents, and anthracyclines) is feasible and can often be effective, especially when using combinations with a therapeutic “backbone” of proteasome inhibition (bortezomib) with thalidomide or its derivative lenalidomide (Fig. 16.2).
- It is sometimes advisable not to change treatments too rapidly in the face of mild-to-moderate treatment-emergent side effects: managing toxicities proactively and facilitating patients remaining on a particular regimen can be important, since duration of therapy correlates with clinical benefit including improved response rate and increased time to disease progression.
- The use of amino-bisphosphonates in the management of myeloma-related bone involvement and hypercalcemia remains a cornerstone of disease management, but be aware of potential side effects both short and long term.

• **Fig. 16.1** Schematic representation of how the proteasome inhibitor bortezomib, as an example of a novel anti-multiple myeloma (anti-MM) agent, influences key molecular pathways in MM cells as well as how it interacts with nonmalignant cells of the bone marrow microenvironment.

• **Fig. 16.2** Schematic representation of how the proteasome inhibitor bortezomib can complement the molecular mechanisms of action of other anti-multiple myeloma agents. *Dex*, Dexamethasone; *IMiDs*, immunomodulatory drugs; *NF*, nuclear factor; *PARP*, polyadenosine diphosphate ribose polymerase.

## Future Directions

The management of MM has undergone radical changes in the last 15 years. Given the pace of preclinical and translational research in the field, more major changes are also likely to occur in the near future. Recent studies of RVD or other combinations of proteasome inhibitors, thalidomide

derivatives, and Dex suggest that this triplet could become a backbone for treatment. More complex combinations with other agents, including daratumumab and next-generation proteasome inhibitors or histone deacetylase inhibitors, as well as immune checkpoint inhibitors and cell-based immunotherapies (e.g., chimeric antigen receptor T cells), are also being evaluated.

## Chapter Review

### Questions

- Which of the following is a recognized side effect observed with lenalidomide?
  - Peripheral sensory neuropathy
  - Somnolence
  - Constipation
  - Thrombocytopenia
  - Alopecia
- Which of the following statements regarding MM is correct?
  - Pathologic fractures are highly uncommon in MM.
  - Bacterial infections are not a common direct cause of death in MM patients.
  - The median age at diagnosis for myeloma patients is age 65 years, but this is not exclusively a disease of the elderly, and a sizable proportion of patients are between age 40 and 60 years.
  - Serum beta-2 microglobulin levels higher than 5.5 mg/L and LDH levels above the upper limit of normal range are typically associated with favorable clinical outcome.
  - Plain radiography is no longer considered a standard imaging modality procedure for staging newly diagnosed and relapsed myeloma.
- Which of the following statements about adjunctive therapy for MM is correct?
  - Radiation therapy is recommended in areas of pain or existing pathologic fracture but not in areas of impending pathologic fracture.
  - Pamidronate and zoledronate have comparable efficacy, but pamidronate has the advantage of a shorter duration of infusion.
  - Anticoagulation is typically not required for patients being treated with combinations of dexamethasone with thalidomide or lenalidomide.
  - The improvements in supportive care for MM have been the primary driver for the improvement of clinical outcomes in this disease during the last 2 decades.
  - Pneumococcal and influenza immunization should be given to all MM patients, despite the fact that MM patients may mount suboptimal antibody responses to antigen challenge.
- Which of the following agents is approved by the FDA for treatment of MM?
  - Brentuximab
  - Cetuximab
  - Daratumumab
  - Infliximab
  - Rituximab

## Oncologic Emergencies

EDWIN ALYEA III AND DANIEL J. DEANGELO

**M**edical emergencies related to cancer are often related to (1) the anatomic localization of the tumor resulting in obstruction or mass effect, (2) metabolic or hormonal derangements, or (3) complications of cancer therapy. Common presentations of severe oncologic complications and their treatment will be discussed in this chapter.

### Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome results from reduction in venous blood flow from the head, neck, and upper extremities caused by either extrinsic compression or invasion of the venous system by a mass. The most common tumors associated with SVC syndrome are lung cancer, lymphoma, and metastatic tumors. Lung cancer accounts for approximately 85% of all cases. Less common etiologies include benign tumors, thyroid enlargement, vascular abnormalities such as aneurysms and thrombosis, or fibrosing mediastinitis. Rarely, vascular thrombosis caused by a central line may result in an SVC-like syndrome.

Swelling of the head and neck is the most common presenting symptom in patients with SVC syndrome. Other symptoms may include cough, dyspnea, headache, pain, dizziness, nightmares, and syncope. Symptoms are often made worse by either bending forward or lying down. On examination, in addition to the facial and neck fullness, the neck veins may be dilated, and collateral vessels covering the anterior chest may be noted. In severe cases, the patient may present with tracheal or bronchial obstruction, vascular collapse, or obtundation.

Diagnosis of SVC syndrome is made on a clinical basis. Radiologic imaging of the chest may demonstrate widening of the mediastinum. Pleural effusions are present in about 25% of cases. A CT scan provides the best imaging and can help define the anatomy of the obstructing lesion. In patients without a diagnosis of cancer, a biopsy is mandatory to establish a diagnosis. If the only site of disease is the mediastinal mass, a needle biopsy or preferentially a surgical biopsy should be obtained by skilled providers. In patients with a known history of cancer, appropriate treatment may be initiated without a need for a biopsy.

Emergent treatment includes stabilization of the cardiopulmonary system. The primary treatment modality depends on the tumor histology. For patients with lung cancer, radiation therapy is the treatment of choice. For patients with lymphoma, small cell lung cancer, and germ cell tumors, chemotherapy may be indicated following initial stabilization.

### Spinal Cord Compression

Prompt recognition of the signs and symptoms associated with spinal cord compression and the initiation of urgent therapy can in some cases prevent catastrophic complications such as paralysis. Epidural compression of the spinal cord resulting in cord injury is the most common etiology. Less commonly, direct extension through the foramen may occur. Metastatic tumors involving the vertebral bodies are often responsible. Common cancers with metastasis to the bone include lung, prostate, and breast cancer as well as multiple myeloma. Compression can occur at any point along the spinal cord. The thoracic spine is the most common site, representing 70% of lesions, followed by the lumbosacral spine at 20% and the cervical spine at 10%. It is important to recognize that multiple sites of compression may be present at the same time.

The most common presenting symptom of spinal cord compression is pain. Pain may be either localized back pain or, in some cases, radicular pain caused by compression of a nerve root. Pain is usually present for days or even months before the development of neurologic symptoms. The importance of recognizing pain as the presenting symptom of cord compression cannot be overemphasized because the development of neurologic symptoms is ominous, and the outcome for patients with neurologic impairment is poor. Patients and families should be educated about the signs and symptoms of cord compression to allow early detection. A recent study from 2010 suggests that this education may allow for an earlier diagnosis of cord compression with 62% of patients being ambulatory at the time of diagnosis.

Signs of cord compression on physical examination include numbness, weakness in the extremities, or loss of bladder or bowel function. Motor weakness or numbness

with loss of sense to pinprick may be present. The upper limit of the sensory loss is often one or two vertebrae below the site of cord compression. Deep tendon reflexes may be brisk. In advanced cases of cord compression, an extensor plantar reflex may be present. Loss of motor and sensory function often precedes sphincter dysfunction.

If cord compression is suspected, an MRI of the spine should be performed immediately to confirm or exclude the diagnosis (Box 17.1). An MRI of the entire spine should be performed if possible to assess if there are multiple sites of disease. Myelography, in addition to CT scanning, may also be used when an MRI cannot be obtained. In patients with a known diagnosis of cancer, treatment should be initiated immediately. For patients without a diagnosis, a biopsy should be performed while initiating therapy.

The goals of treatment are the relief of pain and preservation of neurologic function. Most commonly, treatment of cord compression includes the administration of steroids in addition to radiation therapy. The optimal dose of steroids has not been defined. Prompt therapy is critical because outcome for patients who are ambulatory at the time of diagnosis is good. Unfortunately, for patients who have already developed paralysis at the time of diagnosis, only 10% of these patients will resume ambulation. The role of surgical intervention in the treatment of spinal cord compression has evolved over the last several years. Early studies did not demonstrate a benefit of decompressive laminectomy compared with radiation therapy alone. A randomized trial demonstrated an improved outcome for patients receiving resection and radiation therapy compared with radiation therapy alone in terms of regaining and maintaining

ambulation. A more recent matched pair analysis performed in 2010 looked at the outcome of 108 patients receiving surgery in addition to radiation therapy compared with 216 patients receiving radiation therapy alone. This analysis found a similar outcome for both groups questioning the need for surgery. Given the significant complications of the surgery, careful selection of patients with a good performance status and adequate life expectancy is needed. For patients with recurrent spinal cord compression, surgery and chemotherapy may be considered. Chemotherapy is often only useful in patients with tumors that respond well to chemotherapy. The need for immediate treatment must be emphasized because pretreatment neurologic status is the most important predictor for response to therapy.

## Brain Metastasis

Central nervous system involvement by cancer can be found in 25% of patients. Cancers that most commonly metastasize to the brain are lung cancer, breast cancer, renal cell cancer, and melanoma. Brain metastasis often occurs in the presence of systemic disease. Brain metastasis results in significant morbidity. There is an increased incidence in brain metastasis in several solid tumors as advances in control of systemic disease have occurred.

Presenting signs of central nervous system involvement include headache, nausea, vomiting, new onset seizures, and focal neurologic deficits. Behavioral changes may also be noted in some patients. Abrupt presentations resembling a stroke may occur in the setting of hemorrhage associated with metastasis. This is most common in melanoma or hypervascular tumors such as germ cell tumors and renal cell cancers. Edema resulting from metastatic lesion results in increased intracranial pressure. On examination, patients may demonstrate decreased mental alertness. They may have papilledema and neck stiffness or cranial nerve findings. Muscular weakness is also common, depending on the location of the lesion.

CT with contrast or MRI is effective in diagnosing brain metastasis. MRI is more sensitive than CT scan at identifying small lesions as well as leptomeningeal disease. A biopsy should be obtained especially if this represents the only site of disease. The importance of obtaining a biopsy is highlighted by a study where 6 of 48 patients were found to have other causes for a brain lesion including infection and lymphoma.

Emergent treatment includes steroid administration. Steroids lead to a reduction in edema associated with the metastatic lesion and improvement in the patient's condition. In patients with multiple brain metastases, whole brain radiation therapy should be initiated. For patients with a single brain metastasis and controlled systemic disease, surgical excision followed by radiation therapy may be considered for younger individuals. Tumors that are not responsive to radiation therapy should also be considered for resection. Stereotactic radiosurgery may be used in treating tumors that have recurred or are in an anatomically sensitive location.

## Pericardial Effusion and Tamponade

The most common cancers associated with pericardial involvement include lung cancer, breast cancer, leukemia, and lymphoma. Malignant pericardial disease is common and may be present at autopsy in up to 10% of patients with cancer. Patients with symptomatic pericardial disease or tamponade may present with complaints of dyspnea, cough, or orthopnea. Other signs include sinus tachycardia, jugular venous distention, hepatomegaly, and peripheral edema. Chest radiograph often demonstrates an enlarged cardiac silhouette. The electrocardiogram (EKG) may demonstrate abnormalities such as low voltage or electrical alternans. Echocardiography should be performed to confirm the diagnosis. Treatment is pericardiocentesis. Placement of a pericardial window and, in some cases, pericardial stripping may be required. Acute pericardial tamponade with hemodynamic instability is a medical emergency and requires immediate drainage.

## Intestinal or Urinary Tract Obstruction

Intestinal obstruction may be a complication associated with advanced cancers particularly colorectal, gastric, and ovarian carcinoma. Other cancers such as melanoma, breast cancer, and lung cancer that have metastasized to the abdomen can also be associated with obstruction. There are often multiple sites of obstruction present simultaneously. Symptoms of obstruction typically include pain, which is colicky in nature, or abdominal distention. Physical examination may be notable for a palpable tumor mass or distention. Treatment includes decompression. Conservative management may be used in patients with advanced cancer. In other cases, surgical correction or stent placement may be used.

Urinary tract obstruction occurs most commonly in patients with either prostate, bladder, or gynecologic cancers. Other etiologies include extrinsic compression from lymphoma and sarcoma in the retroperitoneum. Less commonly, radiation therapy to the pelvis or retroperitoneum may result in fibrosis leading to obstruction. The most common symptom is flank pain. Patients with bilateral obstruction may develop renal failure. Treatment includes internal stent placement or percutaneous nephrostomy. In cases of bladder outlet obstruction, a suprapubic cystostomy tube may be needed for urinary drainage.

## Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is the collection of electrolyte abnormalities that occur as a result of the rapid release of intracellular contents into the bloodstream. TLS is characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia, which may result in metabolic acidosis and acute renal failure. The release of intracellular potassium and organic as well as inorganic phosphate into the bloodstream from cells undergoing apoptosis results in the development of hyperkalemia and hyperphosphatemia,

respectively. Prolonged and severe hyperphosphatemia may result in a marked decrease of the serum calcium concentration, but symptomatic hypocalcemia rarely develops. However, hypocalcemia may develop from overzealous alkalization and thus one needs to exercise caution when using intravenous (IV) fluids with bicarbonate.

Patients with large tumor burdens are at an increased risk for TLS, especially if the tumor is chemotherapy sensitive. These disorders include acute myeloid and lymphoblastic leukemia, especially those with high circulating blast counts, Burkitt lymphoma, and other high-grade lymphoproliferative disorders. Large bulky solid tumors that undergo rapid cellular destruction also place patients at a significant risk for the development of TLS. TLS is more common in patients with elevated lactate dehydrogenase (LDH) levels. Although extremely rare, TLS has also been described after the use of nonchemotherapy agents such as  $\alpha$ -interferon or with hormonal therapy for breast cancer. Older patients with poor renal function are at an increased risk of developing TLS. These patients have a lower glomerular filtration rate and are more susceptible to electrolyte disturbances as compared with patients with normal renal function.

## Hyperuricemia

Xanthine oxidase catalyzes the breakdown of hypoxanthine and xanthine to uric acid. Purine nucleotides and deoxynucleotides are broken down within the liver. The  $pK_a$  of uric acid is approximately 5.75 at 37°C. Therefore in the serum, uric acid is present in the acid soluble form. However, within the acidic environment of the renal tubules, uric acid may be present in the nonionized less soluble form. Renal insufficiency may develop because of the development of uric acid crystals in the renal tubules as well as the distal renal collecting system. Nephrolithiasis caused by the development of uric acid stones is uncommon and usually develops only in patients with chronic hyperuricemia. Many medications, especially diuretics such as thiazides as well as antituberculous drugs, IV contrast dye, and certain cytotoxic agents, can aggravate hyperuricemia.

The most important factor to prevent hyperuricemia is to recognize patients who are most at risk for its development and then initiate appropriate prophylactic measures (Table 17.1). Drugs that elevate serum uric acid levels should be discontinued if possible and IV hydration should be initiated, preferably before the start of chemotherapy. Any preexisting intravascular volume deficits must be corrected. The focus in the treatment of hyperuricemia is to maintain adequate urinary volume. Alkalinization of the urine will further decrease uric acid solubility, which is usually achieved by the addition of sodium bicarbonate (50–100 mmol/L) to the IV fluids. The admixture should be adjusted so that the urine pH is maintained above 7 without over alkalinizing the serum because this will lead to hypocalcemia. The most important factor in decreasing uric acid levels is the maintenance of adequate urine output; alkalization is a secondary factor. Although furosemide increases the renal tubular

**TABLE 17.1** Signs and Symptoms of Tumor Lysis Syndrome

Laboratory Abnormality	Clinical Symptoms
Hyperuricemia	Nausea, vomiting, diarrhea, joint pain, oliguria, anuria, azotemia, flank pain, hematuria, crystalluria
Hyperkalemia	Muscle cramps, nausea, weakness, paresthesias, paralysis, electrocardiogram changes, bradyarrhythmias, tachyarrhythmias, cardiac arrest
Hyperphosphatemia	Oliguria, anuria, azotemia, renal failure
Hypocalcemia	Muscle twitching, tetany, laryngospasm, paresthesias, hypotension, ventricular arrhythmias, heart block

reabsorption of uric acid, this is offset by the preservation of increased urinary flow rates. Therefore furosemide can be safely used to maintain a proper total body fluid balance.

Allopurinol is the standard treatment for both the prevention and treatment of hyperuricemia. Allopurinol is an inhibitor of xanthine oxidase and is extremely well tolerated. The most common adverse reaction is an erythematous skin rash caused by a hypersensitivity reaction. There have also been rare reports of interstitial nephritis developing after the administration of allopurinol. Allopurinol is usually administered orally at a dose of between 200 and 300 mg/m<sup>2</sup>/d with typical doses of 300 to 600 mg/d with a maximum oral dose of 800 mg/d. Allopurinol is cleared renally, and the dose should be adjusted in older patients or patients with chronic renal failure. Allopurinol is also available IV, and the typical dose is 200 to 400 mg/m<sup>2</sup>/d with a maximum adult dose of 600 mg/d. Both azathioprine and 6-mercaptopurine are metabolized by xanthine oxidase; therefore use of these agents should be avoided.

Rasburicase is a recombinant urate oxidase enzyme that catalyzes the enzymatic oxidation of uric acid into its inactive, water-soluble metabolite, allantoin. The approved dose of rasburicase is 0.15 to 0.2 mg/kg IV over 30 minutes daily for 5 days; however, lower doses of rasburicase such as a fixed dose of 6 mg have been used with excellent efficacy. Data from preclinical studies suggested that rasburicase remains active *ex vivo*, leading to spuriously low uric acid levels in the absence of specialized handling: sample collection in prechilled heparin tubes, transportation to the laboratory and centrifugation at 4°C, and testing within 30 minutes. These studies were conducted using healthy donor samples spiked with rasburicase *in vitro*. However, an independent study of these requirements in treated patient samples has not been well established. Alkalinization is not necessary with recombinant urate oxidase therapy. Rapid and early consultation of the nephrology team should be initiated if the renal function starts to deteriorate or in the case of severe hypervolemia that is not responsive to loop diuretics.

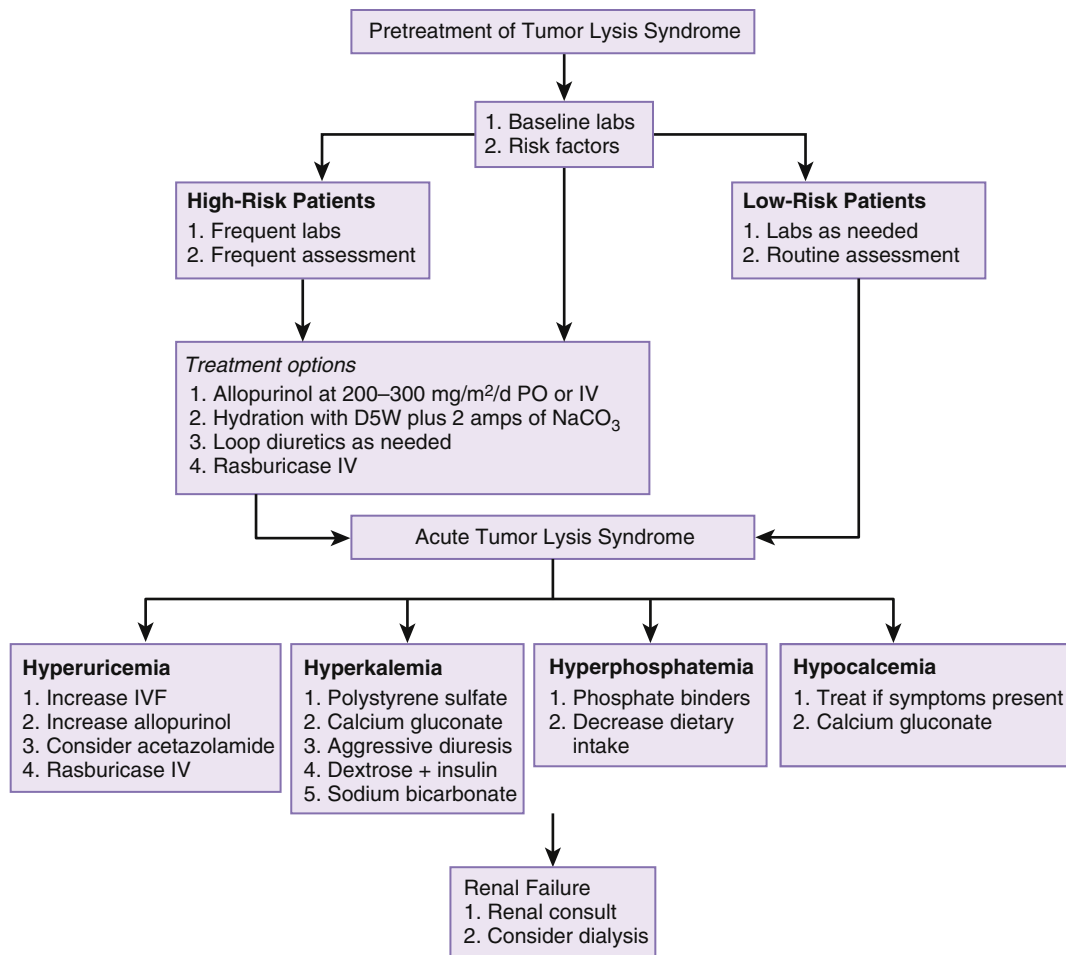

## Hyperkalemia

Hyperkalemia is the most important, life-threatening electrolyte abnormality that develops during tumor lysis syndrome. Hyperkalemia results from the release of large intracellular stores caused by cell lysis. Pseudohyperkalemia

may result from poor phlebotomy technique, hemolysis, or because of marked leukocytosis or thrombocytosis. Measuring the plasma potassium using a heparinized tube may be required in the setting of a markedly elevated platelet count.

The intracellular and extracellular potassium ion concentrations maintain the resting membrane potential. Hyperkalemia leads to the partial depolarization of the resting cell membrane potential, and prolonged depolarization will eventually lead to impaired excitability resulting in muscular weakness, which may progress to flaccid paralysis. The most serious, life-threatening manifestation of hyperkalemia is ventricular arrhythmia. Unfortunately, cardiac toxicity does not correlate with the degree of hyperkalemia. The initial electrocardiographic abnormalities include increased amplitude of the T waves, which are often referred to as “peaked” T waves. Subsequent EKG changes include prolongation of the PR and QRS intervals, A-V conduction blocks, and flattening of the P waves. Eventually the QRS complex will merge with the T wave resulting in a sine-wave pattern, which will often terminate in ventricular fibrillation or asystole. Fatal hyperkalemia rarely occurs at a plasma potassium concentration <7.5 mmol/L.

The treatment of hyperkalemia largely depends upon the potassium serum concentration (Fig. 17.1). All patients with hyperkalemia regardless of the degree of elevation require an EKG. Furthermore, medications that interfere with potassium metabolism such as nonsteroidal antiinflammatory drugs and angiotensin-converting enzyme inhibitors should be discontinued. Oral cation-exchange resins promote the exchange of potassium and sodium ions within the lumen of the gastrointestinal tract. This is an easy and effective initial strategy for patients with mild asymptomatic hyperkalemia. A dose of 15 to 30 g of sodium polystyrene sulfonate will generally lower the serum potassium concentration by 0.5 to 1.0 mmol/L within 1 to 2 hours and last for about 4 hours. Severe hyperkalemia requires more emergent treatment. Calcium gluconate should be given to decrease cellular membrane excitability. The usual dose is 10 mL of a 10% solution administered over 1 to 3 minutes. The effect, which can be seen in minutes, is unfortunately short lived. The administration of insulin with glucose will cause potassium to shift into cells. The usual combination is 10 to 20 U

• **Fig. 17.1** Pretreatment of tumor lysis syndrome. *IV*, Intravenously; *IVF*, intravenous fluid; *PO*, orally.

of regular insulin with 25 to 50 g of glucose. Glucose should be avoided if the patient is already severely hyperglycemic. This method will typically result in the lowering of the serum potassium concentration by 0.5 to 1.5 mmol/L and will last for several hours. Alkalinization of the serum with bicarbonate will also lead to a shift of potassium into cells. Hemodialysis and continuous venous-venous hemofiltration are the most effective methods for effectively lowering the serum potassium levels especially in patients with either preexisting or acute renal failure. Peritoneal dialysis is not as effective as hemodialysis in lowering the serum potassium level, and its initiation should be avoided in patients receiving chemotherapy.

## Hyperphosphatemia

Hyperphosphatemia results from the release of intracellular phosphate stores into the serum as a result of cell lysis and is defined as a serum phosphate level above 1.67 mmol/L (5.0 mg/dL). Spurious hyperphosphatemia may be seen in patients with a marked paraprotein level. Hyperphosphatemia is a potentially dangerous condition caused by extraosseous calcification. Although it should only serve as a guideline, a calcium-phosphorus product (serum Ca [mg/dL] × serum

P [mg/dL]) >70 suggests a potential risk of metastatic calcification. Prolonged hyperphosphatemia may result in lowering the serum calcium levels. Except in those patients with renal failure, the initial treatment of hyperphosphatemia includes volume expansion (see Fig. 17.1). This will effectively result in the increase of the fractional clearance of phosphorus by the kidney. Aluminum-based antacids bind to phosphorus in the gut and prevent further absorption. Although the chronic use of these agents may lead to aluminum toxicity, they are safe and effective for short-term use. Other phosphate binders such as calcium acetate or sevelamer may also be used. Calcium acetate is dispensed as two tablets or gel caps (667 mg) with each meal, and the dose can be increased as long as hypercalcemia does not develop. Sevelamer, a cross-linked polyallylamine hydrochloride, is a cationic polymer that binds intestinal phosphate. The treatment of hyperphosphatemia in the setting of renal failure often requires hemodialysis.

## Hypocalcemia

Unlike the other metabolic alterations resulting from TLS, hypocalcemia is a direct manifestation of hyperphosphatemia. Many oncology patients will have hypocalcemia with hypoalbuminemia as the principal cause in severely

ill patients. Over alkalization of the serum will increase the binding of calcium to proteins and result in a further reduction of the serum calcium level. In these cases, an ionized calcium level should be measured. Transient hypocalcemia may also arise from repeated transfusions of blood products because of the use of citrate as an anticoagulant. Transient hypocalcemia is seldom clinically significant, but, if long-standing, it can lead to several serious clinical manifestations. The QT interval on the EKG can become prolonged, which may lead to serious ventricular arrhythmias. Rarely, patients may become irritable, depressed, or psychotic as a result of severe prolonged hypocalcemia. Calcium supplementation with oral calcium or calcium gluconate in severe symptomatic cases must be taken with caution, especially if the calcium-phosphate product is  $>70$ . In general, calcium should not be given in asymptomatic patients as this may precipitate calcium phosphate deposition.

## Hypercalcemia

Hypercalcemia is the single most common metabolic disorder in patients with cancer. Hypercalcemia caused by an underlying malignancy must be differentiated from hypercalcemia because of primary hyperparathyroidism. The association of elevated serum calcium with a low or normal parathyroid hormone level excludes the diagnosis of primary hyperparathyroidism.

Serum calcium is highly bound to albumin; therefore the total serum concentration will vary depending on serum protein concentrations. Measurement of the ionized calcium level can often assist in sorting out difficult cases. An adjustment for the total serum calcium concentration based on the serum albumin concentration can be made as follows: Corrected calcium = serum calcium +  $0.8 \times (\text{normal albumin} - \text{patient albumin})$ .

Clinical symptoms that arise from hypercalcemia are as a direct result of both the rate of rise and the absolute serum calcium level (Table 17.2). The most common constitutional symptoms include weight loss, anorexia, polydipsia, which may progress into nausea, vomiting, polyuria, azotemia, renal failure, constipation, ileus, abdominal pain, and

even obstipation. With continued rise, patients may begin to experience neurologic symptoms such as fatigue, lethargy, muscle weakness, confusion, seizure, and even coma. Cardiac symptoms are rare but when they occur can lead to fatal arrhythmias. The initial electrocardiographic changes include bradycardia, prolonged PR interval, shortened QT interval, and widening of the T wave.

The treatment of cancer-related hypercalcemia should be directed at the underlying malignancy. Hypercalcemia most commonly affects patients with underlying renal insufficiency. Immobilization can exacerbate hypercalcemia, and it is important to review the patient's medication list to avoid drugs that inhibit ordinary calcium excretion such as thiazide diuretics and nonsteroidal antiinflammatory agents as well as histamine receptor antagonists.

Most patients with hypercalcemia present with marked dehydration caused by anorexia, nausea, and vomiting as well as polyuria caused by calciuresis. Therefore aggressive fluid repletion with normal saline is the first line of therapy. Appropriate volume expansion will not only increase renal blood flow but also improve calcium excretion. Once euolemia has been established, forced diuresis with furosemide can be initiated. The bisphosphonates pamidronate and zoledronic acid are most commonly used in the treatment of cancer-related hypercalcemia. The typical onset of action is within 24 to 48 hours. Bisphosphonates absorb to the surface of hydroxyapatite and inhibit the release of calcium from bone. Bisphosphonates also interfere with the metabolic activity of osteoclasts.

Pamidronate is typically infused at a dose of 60 to 90 mg over 2 to 4 hours, and zoledronic acid is administered at a dose of 4 mg in patients with normal renal function. Peak levels of both pamidronate and zoledronic acid have been associated with renal tubular dysfunction. Zoledronic acid was initially infused at a rate of  $<15$  minutes. However, infusion rates of 30 to 45 minutes are now recommended, and the dose should be reduced in patients with renal insufficiency. The use of steroids is most useful in patients with malignancies that are steroid responsive, such as multiple myeloma and lymphoma as well as acute lymphoblastic leukemia.

**TABLE 17.2** Signs and Symptoms of Hypercalcemia

Category	Clinical Symptoms
Constitutional	Weight loss, anorexia, polydipsia
Neurologic	Fatigue, lethargy, muscle weakness, confusion, seizure, coma
Gastrointestinal	Nausea, vomiting, constipation, ileus, abdominal pain, obstipation
Renal	Polyuria, azotemia, renal failure
Cardiac	Bradycardia, prolonged PR interval, shortened QT interval, wide T wave, arrhythmias

## Syndrome of Inappropriate Antidiuretic Hormone

Hyponatremia is a potentially life-threatening abnormality that has many causes, but first one must exclude pseudohyponatremia. The most common causes of pseudohyponatremia are hyperproteinemia, hyperlipidemia, and hyperglycemia. The differential diagnosis of hyponatremia cannot be made until the patient's volume status is accurately determined. Hypotonic hyponatremia is the result of primary water gain or sodium loss. To determine the cause of hyponatremia, it is important to measure plasma osmolality, urine osmolality, and urine sodium concentration as well as urine potassium concentration. In patients with

hypervolemia hyponatremia, the expanded extracellular fluid status is caused by a decrease in the effective circulating volume. This can be seen in patients with congestive heart failure, hepatic cirrhosis, or nephrotic syndrome.

The syndrome of inappropriate antidiuretic hormones secretion (SIADH) is the most common cause of hyponatremia that occurs in the euvoletic state. SIADH is a result of the nonphysiologic release of arginine vasopressin (AVP) either secreted from the posterior pituitary or an ectopic source. SIADH is usually caused by the production of an ADH-like substance through ectopic production, although nonmalignant causes must be excluded. Approximately 10% to 15% of patients with small cell lung cancer will present with SIADH. SIADH can be caused by a variety of other tumors including nonsmall cell lung cancer, head and neck tumors, brain tumors, and, rarely, hematologic malignancies such as leukemia and lymphoma. There are several nonmalignant causes of SIADH such as central nervous system infections, vasculitis, and pulmonary infections as well as a wide variety of drugs. Tumor-associated SIADH remains a diagnosis of exclusion; however, the treatment of both tumor-related SIADH and SIADH from other causes is similar.

The clinical manifestations of hyponatremia are a direct relationship to the rate of change in the serum plasma sodium concentration. Plasma sodium concentrations that fall slowly over long periods of time are often well tolerated, and patients usually remain asymptomatic. As the plasma sodium concentration falls to  $<120$  mmol/L, patients may develop neurologic symptoms, which include headache, lethargy, and confusion and, if left uncorrected, may develop into seizures and coma. The goal of therapy is to slowly increase the serum sodium concentration. In patients with mild-to-moderate hyponatremia, this can be efficiently corrected by restricting the patients free water intake. If free water restriction is ineffective, demeclocycline can be used. Demeclocycline inhibits the effect of AVP on the kidneys. The typical dose of demeclocycline is 600 mg/d. In patients with severe hyponatremia with the development of neurologic symptoms, it may be necessary to administer hypertonic saline. One must be extremely careful with the administration of hypertonic saline to avoid central pontine myelinolysis. This devastating neurologic syndrome can be avoided by ensuring that the plasma sodium concentration is raised by no greater than 1 to 2 mmol/L per hour.

## Complications Related to Cancer Treatment

### Fever and Neutropenia

Infections occurring in the setting of neutropenia are one of the most common complications of cancer therapy. The degree and duration of neutropenia are directly related to the incidence of febrile neutropenia. Normal barriers to

infections such as mucosal surfaces and luminal epithelial cells in the gastrointestinal tract may be disrupted by chemotherapy and provide a portal of entry for bacteria. Development of fever in a neutropenic patient is a medical emergency requiring hospitalization and prompt administration of broad-spectrum antibiotics.

Patients may be infected with multiple organisms simultaneously. The epidemiology and antibiotic resistance pattern in the hospital should direct initial antibiotic coverage. Gram-negative rod infections are of most concern; therefore antibiotics with anti-*Pseudomonas* coverage should be used. A third-generation cephalosporin is often appropriate in this situation. Alternatives include a semisynthetic penicillin in combination with an aminoglycoside. If a skin source or line-associated source is suspected, administration of antibiotics with gram-positive coverage, such as vancomycin, should also be considered. Patients should remain on broad-spectrum antibiotics until resolution of neutropenia. If an organism is identified, antibiotics should be altered to assure activity against this organism, but broad-spectrum antibiotics should be continued because other pathogens not identified may also be present. For patients with prolonged neutropenia and persistent fever, the addition of antifungal agents should be considered. The most common fungal infections in this setting include *Candida albicans* and *Aspergillus* species.

### Typhlitis

Neutropenic enterocolitis, or typhlitis, is the necrosis of the cecum and adjacent colon. This condition is most commonly identified in patients undergoing chemotherapy for acute leukemia. Patients often present with right lower quadrant abdominal pain that may progress to rebound tenderness and abdominal distention. Patients also commonly have diarrhea that may be bloody. CT scanning demonstrates bowel wall thickening in the cecum. Treatment includes the administration of broad-spectrum antibiotics and bowel rest. Surgical intervention may be required if there is no improvement or in cases of perforation.

### Pulmonary Complications

Pneumonia is the most common cause of pulmonary complication in patients receiving treatment for cancer. In patients with lung cancer or other cancers involving the mediastinum and lung, postobstructive pneumonia may develop. Broad-spectrum antibiotics including treatment of anaerobic organisms are often needed in these situations. Relief of the obstruction either using chemotherapy, radiation therapy, or stenting may be required. In severely immune-suppressed patients, such as those receiving high-dose corticosteroids or those who have undergone stem cell transplantation, *Pseudomonas (carinii) jiroveci* infection should be considered. Diagnostic bronchoscopy may be required to establish a diagnosis.

Noninfectious pulmonary complications include radiation pneumonitis and drug toxicity. Radiation pneumonitis usually develops within 2 to 6 months after the completion of radiation therapy. Patients may present with dyspnea, cough, and low-grade fever. Chest x-ray often demonstrates an infiltrate confined to the radiation field. Bronchoscopy or lung biopsy may be needed to exclude other diagnoses. Steroids are the treatment for radiation pneumonitis.

Several chemotherapeutic agents are associated with pulmonary toxicity. These agents can include bleomycin, methotrexate, and busulfan. Symptoms may include dyspnea; cough and fever may also be present. Physical examination may demonstrate diffuse crackles. Chest x-ray often demonstrates an interstitial infiltrate. As with radiation pneumonitis, bronchoscopy may be required to exclude infectious etiologies. Steroids may be helpful in the treatment of some patients.

## Cytokine Release Syndrome

Cytokine release syndrome (CRS) is a systemic inflammatory response that results from blinatumomab administration and chimeric antigen receptor (CAR) T-cell activation and proliferation. CRS is associated with high fevers, hypoxemia, hypotension, capillary leak, and multiorgan dysfunction (Table 17.3). CRS generally occurs within the first couple of days after starting blinatumomab or with dose escalation and during the first two weeks after CAR T-cell infusion. CRS is sometimes mild and managed with fluids and antipyretics. In other cases, the initial fever, which can exceed 104°F to 105°F, is followed quickly by distributive shock, respiratory distress, and organ failure. The clinical syndrome of CRS is associated with laboratory evidence of inflammation including elevation of acute phase reactants (ferritin, C-reactive protein), effector cytokines (interferon- $\gamma$ , soluble IL-2 receptor- $\alpha$ ), and cytokines associated with macrophage activation (IL-6 and IL-10).

## Chapter Review

### Questions

1. A 61-year-old woman with metastatic squamous cell lung cancer presents with increasing lethargy, confusion, and somnolence over a period of 2 weeks. Over the past month, she has steadily increased her narcotic intake because of worsening pain from several bony metastases. In the emergency department (ED), her temperature (T) is 99.2°F, heart rate (HR) is 104 beats per minute, blood pressure (BP) is 110/70 mm Hg, respiratory rate (RR) is 18 breaths per minute, and oxygen saturation (SaO<sub>2</sub>) is 96% on room air. She is obtunded but transiently arousable to voice. Examination is otherwise unremarkable. Pertinent laboratory results include sodium (Na) 135, potassium (K) 4.2, blood urea nitrogen (BUN) 30, creatinine (Cr) 1.4, calcium (Ca) 13, and albumin (Alb) 2.6; complete blood count (CBC) and liver function tests (LFTs) are within normal limits.

**TABLE 17.3** Signs and Symptoms of Cytokine Release Syndrome

Category	Clinical Symptoms
Constitutional	Fever with or without rigors, malaise, fatigue, anorexia, arthralgias, myalgias
Skin	Rash
Gastrointestinal	Nausea, vomiting, diarrhea
Renal	Azotemia, renal failure
Cardiac	Tachycardia, hypotension
Pulmonary	Tachypnea, hypoxemia
Neurologic	Headache, altered mental status, confusion, delirium, word-finding difficulties, aphasia, hallucinations, tremors, dysmetria, altered gait, seizure

The major predictor for CRS is disease burden. The National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events grading scale for CRS was developed for CRS syndromes associated with antibody-based therapy, such as blinatumomab. Given that CAR T cells cannot be turned off like infusion therapies, a need to create grading systems that better reflect the toxicity of CAR T-cell–related CRS was recognized, and the two systems that are most commonly used are the 2014 NCI consensus grading system and a grading system developed by the University of Pennsylvania/Children’s Hospital of Philadelphia group.

Steroids are the mainstay of management for CRS secondary to blinatumomab. In the case of CAR T cells, tocilizumab, an anti-IL6 receptor antibody, was found to be effective and is the backbone of management of severe CRS secondary to CAR T cells. Tocilizumab is well tolerated and rapidly effective in most cases decreasing rates of severe CRS without affecting efficacy or T-cell engraftment and persistence.

The most likely cause of her altered mental status is:

- Dehydration
  - Opiate overdose
  - Uremia
  - Hypercalcemia
  - Brain metastases
2. A 61-year-old woman with metastatic nonsmall cell lung cancer presents with increasing nausea, lethargy, and confusion over a period of 2 weeks. She has been receiving a platinum-based chemotherapy regimen. Over the past month, she has steadily increased her MS Contin intake because of worsening pain from several bony metastases. In the ED, her temperature is 99.2°F, HR is 80 beats per minute, BP is 110/70 mm Hg, RR is 18 breaths per minute, and SaO<sub>2</sub> is 96% on room air. She is obtunded but transiently arousable to voice. Examination is otherwise unremarkable; she appears euvolemic. Pertinent

laboratory results include Na 120, K 4.2, BUN 20, Cr 1.4, Ca 8.8, Alb 2.6, and CBC and LFTs within normal limits. Urine sodium (Na) = 46.

The most likely cause of her SIADH is:

- A. Brain metastases
  - B. Pneumonia
  - C. Morphine
  - D. Platinum
  - E. Primary tumor
3. A 23-year-old man with metastatic medulloblastoma presents with decreased urine output. He has extensive extracerebral disease, involving the liver, mediastinal and abdominal nodes, and the bone marrow. He is on day 2 of chemotherapy with cisplatin and etoposide. His examination reveals mild pedal edema but is otherwise unremarkable. His BUN is 36, and his Cr is 4.4, up from 1.1 before treatment. His LDH is markedly elevated at >8000.

The most likely etiology of this patient's renal failure is:

- A. Cisplatin-mediated nephrotoxicity
  - B. Tumor lysis syndrome
  - C. Postrenal obstruction by tumor
  - D. Prerenal azotemia
4. A 61-year-old woman with multiple myeloma presents with increasing headache, lethargy, and confusion over a period of 2 weeks. Over the past month, she has steadily increased her MS Contin intake because of worsening pain from several skeletal lesions. She is taking thalidomide daily for her myeloma. In the ED, her temperature is 99.2°F, HR is 80 beats per minute, BP is 110/70 mm Hg, RR is 18 breaths per minute, and SaO<sub>2</sub> is 96% on room air. She is obtunded but transiently arousable to voice. Examination is otherwise unremarkable. Pertinent laboratory results include Na 140, K 4.2, BUN 20, Cr 1.4, Ca 7.8, Alb 1.9, TP 12.4, WBC 6.0, and hematocrit 24. Platelets and coagulation are within normal limits.

The most likely “unifying diagnosis” in this case is:

- A. Coagulopathy
  - B. Morphine overdose
  - C. Hyperviscosity syndrome
  - D. Leukostasis
  - E. Thalidomide toxicity
5. A 51-year-old woman with a past medical history of hypertension and asthma presents with chest pain and shortness of breath. These symptoms progressed over 1 week and were accompanied by orthopnea and paroxysmal nocturnal dyspnea. Over the past day, her symptoms have worsened to the point where she feels very short of breath even at rest. She takes no medications and has a 20 pack-year tobacco history, although she quit years ago. Both parents died of cancer. In the ED, her RR is 40 to 44 breaths per minute, and systolic BP is 100 mm Hg. Her examination is notable for a Kussmaul sign and a pulsatile liver. Laboratory results are notable for bicarbonate 16, AG 22, BUN 24, Cr 1.5, serum glutamic-pyruvic transaminase 269, serum glutamic oxaloacetic transaminase 321, and total bilirubin 2.1. Her WBC is 15.6, D-dimer >1000, and PT 15.6.
- What is the most likely diagnosis?
- A. Multiple pulmonary emboli
  - B. Atypical pneumonia
  - C. Congestive heart failure
  - D. Malignant cardiac tamponade
  - E. Metabolic acidosis

## Disorders of Platelets and Coagulation

ELISABETH M. BATTINELLI AND ROBERT I. HANDIN

The blood platelet, interacting with a complex network of coagulation proteins, makes up the hemostatic system, which provides the major body defense against excess bleeding after injury, surgery, or other invasive episodes. Disorders of the hemostatic system are a mixture of common and rare, inherited and acquired, mild or life-threatening illnesses. Furthermore, although excess bleeding is caused by a failure in the hemostatic system, patients who present with thrombosis may have a defect in the regulatory mechanisms that normally limit the hemostatic response. There has been substantial progress in both the diagnosis and treatment of hemostatic disorders. In addition, highly effective antiplatelet and anticoagulant drugs have been developed for treating patients with venous and arterial thromboembolism including coronary artery and cerebrovascular disease.

This chapter begins with an outline of the process of normal hemostasis and reviews the laboratory tests used to assess hemostasis. It then reviews the pathophysiology, clinical presentation, diagnosis, and treatment of the most important hemostatic disorders. Although diagnosis and treatment rely heavily on laboratory tests, it is crucial to emphasize the critical importance of the history and physical examination in assessing patients suspected of having a hemostatic disorder. A careful history will provide an assessment of the likelihood of a disorder and is sometimes positive even when initial screening tests are normal. In addition, the history can help focus the workup on platelets or coagulation proteins. The physical examination can provide important clues to the nature of the bleeding disorder and should not be overlooked.

### Normal Hemostasis

The process of normal hemostasis is initiated when there is disruption of the normal endothelial cell barrier that lines all blood vessels. When endothelial cells are detached following vascular injury, flowing blood is exposed to vascular subendothelial proteins (principally collagen). Circulating platelets promptly adhere to exposed collagen; become activated and undergo dramatic change in shape and secrete their granule contents; and recruit additional platelets to the site of injury, forming a platelet aggregate or hemostatic

plug that temporarily stops the flow of blood out of the damaged vessel. This process is often referred to as *primary hemostasis* and is initiated within a few seconds of injury.

At the same time, the coagulation system is activated, leading to the formation of a fibrin meshwork that engulfs and stabilizes the platelet plug. Blood coagulation is initiated by the interaction of flowing blood with tissue factor and involves a series of linked proteolytic reactions. The final coagulation event is the generation of sufficient thrombin to convert plasma fibrinogen to fibrin. This process has been called *secondary hemostasis* and is complete several minutes after injury. Hours to days later, the definitive fibrin/platelet plug is slowly dissolved by the fibrinolytic pathway so that blood flow can be reestablished in the newly endothelialized vessel.

Thrombosis is the pathologic equivalent of normal hemostasis and has been called *hemostasis at the wrong time or in the wrong place*. Just as it is impossible to develop immunosuppressive drugs that do not perturb the normal immune and inflammatory process, drugs designed to prevent or limit thrombus formation inevitably increase the risk of bleeding. In arterial thrombosis the triggering event, rather than vascular injury, is pathology within the vascular endothelium or subendothelium. The rupture of an atherosclerotic plaque is the most common arterial pathology. In venous thrombosis, there may be a combination of excess thrombin generation and more subtle endothelial injury.

Platelets are critically important for hemostasis in the microvasculature and in skin and mucous membranes. Hence, platelet disorders tend to cause bleeding primarily in these areas. In contrast, the coagulation pathway is needed for optimal hemostasis in larger vessels and in joints and muscle, so that deficiencies lead to characteristic deep delayed bleeding and hemarthroses.

Coagulation was initially divided into intrinsic or contact-dependent and extrinsic or tissue factor-dependent limbs. It is now clear that this separation is artificial and does not reflect how the reactions proceed in vivo. At present, there is a consensus that basal coagulation is driven by the formation of a tissue factor–VIIa complex, which activates factors IX and X with equal efficiency. In addition, traces of thrombin generated from these reactions can feed back and activate factor XI. The role of contact activation

via factor XII (Hageman factor) in normal coagulation is now less clear.

## Clinical Evaluation and Coagulation Tests

The key points to cover in the history of any patient suspected of having a hemostatic disorder can be summarized in these seven questions:

1. Has the patient bled on multiple occasions and from multiple sites?
2. Has any of the bleeding been severe enough to require blood transfusion?
3. What types of surgery or trauma precipitated the bleeding?
4. How long after injury did the bleeding occur?
5. Is there a pattern or specific location of the bleeding?
6. Is there a family history of abnormal bleeding, and what is the pattern of inheritance?
7. What, if any, medication does the patient take?

Key elements of the physical examination include the following:

1. Any evidence of skin or mucous membrane bleeding (petechiae, ecchymoses)
2. Evidence of swelling, fluid accumulation, limited range of motion, or synovial thickening of a joint: hips, knees, ankles, shoulders, elbows are most often affected in hemophilia A and B (factors VIII and IX deficiency)
3. Hematomas in deep subcutaneous tissues or muscle as well as bleeding into the head, airways, or retroperitoneum that is out of proportion to known trauma or pathology
4. Vascular lesions such as the nasal and lip hemangiomas seen in Osler-Weber-Rendu disease or the abnormal skin laxity and joint hyperextensibility seen in Ehlers-Danlos syndrome

## Screening Tests of Hemostasis

Basic screening tests should include the following:

1. Complete blood count (CBC)
2. Prothrombin time (PT), partial thromboplastin time (PTT)
3. Mixing studies to rule out an inhibitor and/or identify factor abnormalities if either PT or PTT is prolonged
4. von Willebrand factor (vWF) level/activity in patients with suspected primary hemostatic defect by history
5. Platelet aggregation in patients with suspected inherited, acquired, or drug-induced primary hemostatic defect

## Specific Disorders

### von Willebrand Disease

von Willebrand disease (vWD) is one of the most common inherited disorders, affecting an estimate of 1 in 100 individuals. Many patients are minimally affected and may live their entire lives without untoward bleeding. vWD is an

• **Fig. 18.1** This schematic represents the relationship between von Willebrand factor (vWF) with platelets and the endothelium.

autosomal dominant disorder affecting males and females with equal frequency, presenting as bleeding after surgery or dental procedures, menorrhagia, or easy bruising.

The vWF is a very large, heterogeneous plasma protein synthesized in endothelial cells and megakaryocytes and secreted into plasma as well as the vascular subendothelium. It is stored in unique endothelial organelles called *Weibel-Palade bodies* or in platelet alpha granules. vWF has two major functions: to stabilize platelet adhesion to the vessel wall under high-flow/high-shear conditions by binding to collagen and the platelet GpIb/IX/V complex, and to serve as an intravascular carrier for the antihemophilic protein factor VIII (Fig. 18.1).

The vast majority (85%) of patients with vWD have type 1 disease caused by missense mutations that perturb multimer assembly (Table 18.1). They have a parallel decrease in vWF antigen, vWF activity measured as ristocetin cofactor activity, and factor VIII. vWF levels are influenced by a number of physiologic/pathologic states or additional genes. For example, acute or chronic inflammation can raise the vWF level, whereas hypothyroidism lowers the vWF level. The unique hormonal milieu present during pregnancy can completely normalize the vWF level, allowing for easy labor and delivery. vWF protein contains ABO blood group molecules that influence the rate of vWF clearance from plasma. Type O vWF is cleared most rapidly, types A and B less so, and type AB the slowest. Thus type O patients have the lowest plasma levels of vWF and are more likely to have bleeding when they have inherited a mutant vWD allele.

Most of the remaining patients have type 2 vWD characterized by specific mutations in the vWF A1 domain

TABLE 18.1

Laboratory Characterization of Types of von Willebrand Disease

Type	FVII	vWF:Ag	vWF:RCo	RIPA	Multimer Analysis
1	Decreased	Decreased	Decreased	Decreased	All forms present
2A	Normal	Decreased	Decreased	Decreased	Decreased high and intermediate MW multimers
2B	Normal	Decreased	Decreased	Decreased	Decreased high MW multimers
2M	Normal	Normal	Decreased	Decreased	All forms present
2N	Decreased	Normal	Normal	Normal	All forms present
3	Decreased	Decreased	Decreased	Decreased	All forms absent

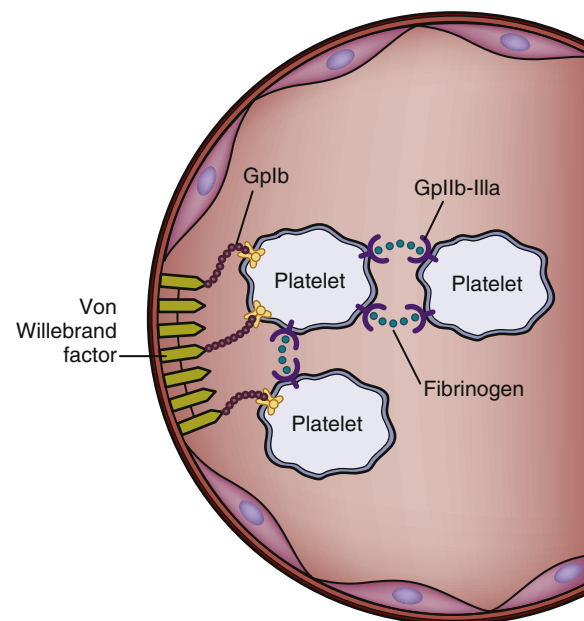

Ag, Antigen; MW, molecular weight; RCo, ristocetin cofactor; RIPA, ristocetin-induced platelet aggregation; vWF, von Willebrand factor.

that make the molecule abnormally sensitive to proteolytic degradation (type 2a disease) or partially activated and continually binding to circulating platelets (type 2b). There are some rare patients with mutations that inactivate the site in the A1 domain that binds to GpIb (type 2M disease). Some patients have a disorder that has been called *autosomal hemophilia* and have a mutation in the region of vWF that binds to and stabilizes factor VIII (type 2N disease). When a type 2N allele is combined with a type 1 mutant allele, the resulting double heterozygote patient can have very low factor VIII levels and present with hemarthroses that mimic classic hemophilia. Because the platelet adhesive function of vWF is preserved, there is no mucosal bleeding. An autosomal inheritance pattern can provide the clue to diagnosis and distinguish this condition from classic hemophilia A. There are a small number of patients with type 3 disease, which is caused by large deletions in the *vWF* gene. These patients have inherited two abnormal alleles and have severe lifelong bleeding with no detectable vWF in their plasma.

### Qualitative Platelet Disorders

The qualitative platelet disorders are a heterogeneous group of abnormalities affecting many different steps in platelet adhesion, signaling, granule packaging, and secretion and aggregation. Some disorders are quite common, whereas others are exceedingly rare, and one may spend an entire career in a primary care or subspecialty practice without seeing a patient with one of these disorders. Some abnormalities occur in isolation, whereas others are a manifestation of a multiorgan systemic disorder. It is convenient to link the disorders to specific steps in platelet function as shown in Fig. 18.2.

Platelet membrane disorders affecting adhesion or aggregation, two critical steps in platelet function, are the result of cooperative activity between a membrane glycoprotein and a plasma glycoprotein. The interaction of vWF with the GpIb/IX/V complex facilitates platelet adhesion, whereas the binding of fibrinogen to GpIIb/IIIa regulates platelet aggregation. Rare patients with mutations in GpIb a or b

• Fig. 18.2 Platelet function.

polypeptides or GpIX fail to synthesize the GpIb/IX/V complex, a condition called *Bernard-Soulier syndrome*. It is characterized by abnormally large platelets, mild-to-moderate thrombocytopenia, and an inability to support vWF-dependent adhesion. It is an autosomal recessive trait and causes lifelong bleeding. In a similar vein, patients with mutations in the GpIIb or GpIIIa polypeptides fail to synthesize the platelet GpIIb/IIIa complex and have platelets that cannot bind fibrinogen or aggregate. This disorder, called *Glanzmann thrombasthenia*, is also an autosomal recessive trait. It differs from Bernard-Soulier syndrome in that patients have a normal platelet count and normal-sized platelets. Similar to Bernard-Soulier patients, they also have severe, recurrent lifelong hemorrhage. In both cases, repeated platelet transfusions can lead to alloimmunization because of antibodies directed against the missing proteins, which can both limit the effectiveness of platelet transfusions in the future.

Patients have been identified with selective defects in the transport and packaging of materials in platelet granules. Patients with dense body or delta storage pool disease have low levels of granule adenosine triphosphate, adenosine diphosphate (ADP), calcium, and serotonin and have defective secondary platelet aggregation. In contrast, patients with alpha granule or alpha storage pool disease have normal or near-normal aggregation. Patients with combined alpha/delta disease have platelets that have the appearance of Swiss cheese with multiple holes representing the limiting membrane of empty granules. They have a hemostatic defect and can also develop marrow fibrosis as proteins such as the platelet-derived growth factor leak from megakaryocytes and stimulate the growth of marrow fibroblasts.

Patients with oculocutaneous albinism and patients with the Chédiak-Higashi syndrome, who may also be partial albinos, have a generalized granule packaging defect that extends to the platelet and presents as delta storage pool disease. Patients with Hermansky-Pudlak syndrome have delta storage pool disease and often develop severe pulmonary fibrosis. Many of these patients end up requiring continuous oxygen therapy and eventual lung transplants.

Patients have been identified with mutations in the P<sub>2</sub>Y<sub>12</sub> ADP receptor and in some of the important intraplatelet signaling molecules. A mutation in a myosin isoform, MyH9, causes the May-Hegglin anomaly, which is characterized by very large platelets, moderate thrombocytopenia, and Dohle bodies in their leukocytes but no hemostatic defect.

In clinical practice the most common platelet abnormalities are those caused by the administration of antithrombotic medications. Aspirin is the most commonly administered drug and induces a mild hemostatic defect. Because it irreversibly inactivates platelet cyclooxygenase, a single dose can perturb hemostasis for 5 to 7 days. Other nonsteroidal antiinflammatory drugs (NSAIDs) such as naproxen or ibuprofen are transient reversible cyclooxygenase inhibitors and rarely cause clinical bleeding. Of far more importance is their competition with aspirin for cyclooxygenase binding. Simultaneous ingestion of sodium naproxen or ibuprofen and aspirin will block the desired cardiovascular effect of aspirin and is one of the leading causes of aspirin resistance. Patients need to be instructed to take aspirin first and to wait at least 30 minutes before taking an NSAID.

Clopidogrel and prasugrel are both P<sub>2</sub>Y<sub>12</sub> inhibitors that block ADP-induced aggregation. They are prodrugs whose active metabolites are irreversible inhibitors, so their effect is also prolonged. Two other popular drugs, integrilin and abciximab (Rheo Pro), bind to the GpII/IIIa complex and block platelet fibrinogen binding and platelet aggregation. Integrilin has a short biological half-life and can be rapidly reversed by stopping its infusion. The effect of abciximab can persist for several days.

## Hemophilia A

Although patients have been described with deficits in each of the known coagulation proteins, three diseases

predominate and account for well over 90% of patients with inherited coagulation disorders—deficiencies in factors VIII, IX, and XI. They are also known as hemophilias A, B, and C. Factors VIII and IX deficiency are X-linked disorders primarily affecting males, whereas factor XI deficiency is an autosomal recessive disorder that can affect both males and females.

Factor VIII deficiency occurs in 1 in 10,000 male births and causes lifelong recurrent soft tissue, muscle, and, most importantly, joint bleeding or hemarthroses. There is a close relationship between factor VIII level and severity of bleeding. Patients with <1% activity have severe disease with frequent, life-threatening bleeding. Patients with 1% to 5% activity have moderate disease with bleeding weekly or even monthly. Patients with levels over 5% have milder disease with infrequent bleeding.

Treatment of hemophiliacs has steadily improved. At present, many children and adolescents receive prophylactic therapy several times a week and have few major bleeds; almost all children and adults self-administer coagulation factor concentrates at home on demand with minimal medical supervision; and most patients use highly purified recombinant factor concentrates that are free of all known viruses. Recent advances in treatment options for hemophilia A may revolutionize current approaches through the development of a factor VIII mimetic (emicizumab). Shima and colleagues (2016) recently demonstrated that emicizumab, a drug that functions as a conformational replica of factor VIII by binding to factors IX and X in a thrombin-generating complex, has efficacy in treatment of severe hemophilia. Certainly, this would advance the field not only by providing a different approach to therapy but also offering a treatment that is associated with fewer factor VIII neutralizing antibodies as discussed subsequently.

Although the life expectancy of a hemophilia patient is near normal and many patients have few damaged joints, there are unresolved health issues such as the increased incidence of hypertension and the enormous expense of optimal therapy. Perhaps the most dreaded complication of hemophilia at present is the development of an inhibitor to factor VIII. This occurs in 15% to 20% of patients and both complicates therapy and reduces the patient's quality of life. Recently, Peyvandi and colleagues (2016) demonstrated that the cumulative incidence of inhibitor development in children with severe hemophilia A was higher in those who received recombinant factor VIII products as compared with plasma-derived factor VIII containing vWF. This study has implications for clinical decision making regarding replacement therapy in hemophiliacs with severe disease albeit the rate of inhibitor development is still low.

## Hemophilia B and C

Almost everything written earlier about factor VIII deficiency holds true for factor IX deficiency. It is less common, appearing in 1 in 50,000 births, and the protein has a longer

plasma half-life so infusions are less frequent. Otherwise the diseases are nearly identical.

Factor XI deficiency is, however, quite distinct. First, it is autosomal recessive and usually presents as postoperative bleeding. It is more common in Ashkenazi Jewish populations. Also, the correlation between factor level and bleeding is not very strong for unknown reasons. Finally, in the United States, the only available treatment is infusion with fresh frozen plasma because factor XI concentrate has not been approved because of concerns for increased thrombotic risk.

### Acquired Hemophilia and von Willebrand Disease

Rarely, patients with perfectly normal hemostasis for their entire lives can develop a severe hemostatic defect caused by acquisition of an antibody inhibitor to a particular coagulation factor, the adsorption of a coagulation factor onto a tumor surface, or an abnormal protein. These disorders present particular challenges and can at times cause very severe, sometimes lethal bleeding.

Acquired hemophilia is usually caused by an antibody to factor VIII. It is seen in patients with an autoimmune disorder such as systemic lupus, in pregnant women, and in otherwise healthy elderly individuals. The presentation in otherwise healthy older patients is the most common event. Patients require intensive support with factor VIII concentrates and, more recently, recombinant factor VIIa. With immunosuppressive therapy using agents like rituximab (Rituxan), along with the passage of time, most of these inhibitors will disappear and patients make a complete recovery.

The first example of coagulation factor adsorption causing an acquired deficiency is the interaction of factor X with amyloid protein in patients with primary light-chain amyloidosis. Subsequently, various groups have noted acquired vWD because of adsorption of vWF onto tumor surfaces. This is particularly common in patients with lymphoproliferative disorders. Effective therapy requires reduction of the tumor mass.

Patients with monoclonal gammopathy of uncertain significance may have antibodies against the vWF protein and significant bleeding. A substantial number of patients with Waldenstrom macroglobulinemia, myeloma, and other lymphoproliferative disorders will develop anti-vWF antibodies and acquired vWD.

Finally, patients with aortic stenosis, patients with ventricular assist devices, and patients with myeloproliferative disorders may unfold and then proteolyze vWF and develop mild-to-moderate vWD.

### Immune Thrombocytopenia

Immune thrombocytopenia, formerly called *idiopathic thrombocytopenic purpura* (ITP), is the most common autoimmune disorder. In young children, it is a transient disorder that follows a viral infection. In adults, ITP is usually a chronic problem, affecting otherwise healthy women three

times as often as men. Patients may rarely have other autoimmune phenomena. For example, the simultaneous or sequential appearance of autoimmune hemolytic anemia and thrombocytopenia is referred to as *Evan syndrome*. Although ITP is rarely fatal, it can cause recurrent and sometimes serious mucocutaneous and occasional intracerebral bleeding.

The most frequent target antigen is the platelet GpIIb/IIIa complex. A small number of patients have antibodies to the GpIb/IX/V complex or other platelet cell surface proteins. In most cases the antibodies act as opsonins and increase the clearance of platelets from the circulation without perturbing platelet function. Occasionally the antibody may perturb fibrinogen binding, and patients will have both thrombocytopenia and platelet dysfunction that mimics Glanzmann disease. There have been multiple attempts to develop laboratory tests for platelet autoantibodies in ITP patients. None of the tests has been successful for myriad reasons, including a high level of background IgG on the platelet surface and the presence of Fc receptors, which may bind immunoglobulins or immune complexes in a nonspecific manner.

The typical patient with ITP presents with a history of easy bruising, mucocutaneous bleeding, and, if the platelet count is sufficiently low, petechiae, which arise from the movement of red cells through leaky capillaries into the skin. Most patients have no pathognomonic physical findings or laboratory tests, and ITP remains a diagnosis of exclusion. In contrast with patients who have autoimmune hemolytic anemia, ITP patients have a normal-sized spleen. Typically, other than thrombocytopenia, the blood count is normal, although some patients may have atypical lymphocytes, suggesting a recent viral infection. There is debate about what constitutes an adequate workup for ITP. Most hematologists have stopped performing bone marrow examinations in ITP patients unless a more global hematologic abnormality is suspected. Because of the association with autoimmune disease, the workup usually includes an antinuclear antibody test, which is often normal. Many practitioners routinely order HIV testing in all patients who are sexually active, whereas others order it only if the patient has engaged in a high-risk behavior. Serologic panels for toxoplasmosis, cytomegalovirus, and other viral disorders are rarely positive and not recommended unless clinically indicated at time of presentation. Chronic ITP is defined as thrombocytopenia that has been present for at least 3 months. The likelihood of a viral etiology or a spontaneous remission is extremely low after 3 months.

For many years, the standard initial therapy has been administration of large doses of glucocorticoids, usually 50 mg of prednisone or equivalent daily. In most patients, the platelet count will return to normal after several doses of prednisone, but it falls to pretreatment values as the steroid dose is reduced. If the count remains low after several months of prednisone therapy, the well-established second-line therapy is splenectomy. In most large centers this is a laparoscopic procedure with minimal morbidity and mortality. Patients are immunized against encapsulated organisms such as pneumococcus, meningococcus, and *Haemophilus influenzae* that are cleared primarily in the spleen. The only remaining infection that is worsened by splenectomy is babesiosis. In adults

the spleen seems to be dispensable, and immune function is largely preserved. Splenectomy raises the platelet count to normal in approximately 70% of ITP patients.

Patients who fail splenectomy and have dangerously low platelet counts ( $<50,000/\mu\text{L}$ ) are usually given the immunosuppressive medications azathioprine (Imuran) or oral cyclophosphamide. Recently, the favored drug is the anti-CD20 monoclonal antibody rituximab. It will induce a remission in 70% of patients who have failed corticosteroids and splenectomy but may require a second course of treatment within a year in 25% of initial responders. Although the complication rate is low, opportunistic infections are a potential problem; several patients have developed progressive multifocal leukoencephalopathy after rituximab treatment, so caution is advised.

There is a great desire among patients and treating physicians to avoid splenectomy. One new approach is the administration of pulses of very high-dose dexamethasone given for 4 days a month. After several months of therapy, a small percentage of patients go into remission. The remission rate may increase when patients are given both dexamethasone pulses and four doses of rituximab as initial therapy. Although this regimen may induce remissions in 70% of patients, the ability to spare patients from splenectomy needs to be balanced against the known and unknown risks of these potent medications.

For patients who cannot be put into remission, there are several drugs that can transiently raise the platelet count. Large dose of intravenous immunoglobulin (IVIG) or the anti-RhD immunoglobulin RhoGam have both been used for many years. They both appear to reduce the clearance of antibody-coated platelets. RhoGam is not effective after splenectomy. Because of their expense, the need to administer them intravenously, and their short duration of action, they are recommended only for emergency use or to prepare patients for surgery.

Recently, two thrombopoietin (TPO) mimetics, romiplostim and eltrombopag, have received US Food and Drug Administration approval. Both drugs will stimulate marrow production of megakaryocytes, which is suboptimal in many ITP patients, and thereby raise the platelet count. Romiplostim is a novel peptibody TPO mimetic, given as a weekly subcutaneous injection, that binds to the same site on the TPO receptor as native TPO. Eltrombopag is a small molecule, administered orally, that binds to the transmembrane domain of the TPO receptor. These drugs may be useful as substitutes for IVIG and RhoGam or for the small number of ITP patients who cannot be put into remission with splenectomy and immunosuppressive medication. The drugs may cause a reversible increase in marrow reticulin and collagen with prolonged use, and there are reports of thrombotic events in association with their use.

### Heparin-Induced Thrombocytopenia

Heparin is the most common cause of thrombocytopenia in hospitalized patients, affecting 15% to 20% of patients receiving unfractionated heparin. Heparin-induced thrombocytopenia (HIT) is caused by an antibody directed against a complex

of heparin and the heparin-neutralizing protein, platelet factor 4 (PF4). The heparin-PF4 antibody complex binds to the platelet Fc receptor, which induces both platelet activation and secretion and thrombocytopenia. The spectrum of HIT ranges from patients with mild nonprogressive thrombocytopenia to patients who develop profound thrombocytopenia and to an occasional patient who develops life-threatening thrombosis despite being fully anticoagulated. There is an increased risk of thrombus formation in all HIT patients, which persists for several months after heparin is discontinued.

HIT is diagnosed by a combination of clinical observation and judicious laboratory testing. The four key features are the degree of thrombocytopenia, the timing of thrombocytopenia, the presence of concomitant thrombosis, and the absence of other obvious causes of thrombocytopenia. A fall of over 50% of the platelet count since starting heparin with a nadir  $>20,000/\mu\text{L}$ ; onset of thrombocytopenia 5 to 14 days after starting heparin, 48 hours if previously exposed to heparin within 30 days; and new thrombosis, skin necrosis, or anaphylactic reaction to heparin infusion are all considered strong predictors of HIT. If HIT is suspected, a heparin-PF4 enzyme-linked immunosorbent assay (ELISA) test should be ordered. The test has a reported sensitivity of 95% and thus a high negative predictive value. The limitation of the test is that it does not distinguish between IgM and IgA antibodies or the IgG antibodies that cause platelet activation. The reported specificity of 50% can be improved by looking at the optical density (OD) of the ELISA test. An OD  $>1.00$  is more likely to be caused by a pathologic IgG antibody. Newer tests are being introduced using IgG-specific antisera that should increase the specificity of the test. A second set of tests that measure platelet activation, such as the serotonin release assay, can identify those antibodies that are most likely to cause HIT and are said to have  $>90\%$  sensitivity and specificity. The test is quite specialized, not widely available, and may only be run once or twice a week even in large reference laboratories.

Once HIT is identified, heparin infusion should be immediately discontinued and patients switched to a direct thrombin inhibitor. The two drugs most often used to treat HIT are argatroban, a small-molecule derivative of L-arginine with a plasma half-life of 45 minutes and lepirudin (recombinant hirudin), which has a half-life of 2 hours. Both drugs are given by intravenous infusion and monitored by measuring the PTT. When the platelet count has returned to  $>150,000/\mu\text{L}$ , patients are bridged to warfarin, which is continued for 30 days in patients with no thrombosis and 3 to 6 months in patients with heparin-induced thrombocytopenia with thrombosis.

The incidence of HIT should decrease and eventually disappear as newer forms of heparin are introduced that are less immunogenic. For example, the incidence of HIT is  $<1\%$  for low-molecular-weight heparins such as enoxaparin (Lovenox) or dalteparin (Fragmin). Only a handful of HIT cases have been reported in patients receiving the synthetic pentasaccharide fondaparinux (Arixtra). Given the efficacy and safety of the new heparins, unfractionated heparin should probably be reserved for patients who require

minute-to-minute titration of heparin dose and prompt reversibility. Unfractionated heparin should only be needed for cardiac catheterization, cardiopulmonary bypass, in intensive care units, and, perhaps, in patients with impaired renal function.

### Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a relatively rare disorder characterized by thrombocytopenia, microangiopathic hemolytic anemia, varying degrees of renal failure, and fluctuating neurologic symptoms. Most patients with sporadic TTP have an acquired deficiency in ADAMTS13, a plasma metalloprotease enzyme that remodels the vWF secreted by endothelial cells. In the absence of this enzyme, superlarge vWF multimers interact with circulating platelets and form the hyaline thrombi characteristic of TTP. Although there are rare patients who have a congenital deficiency in ADAMTS13, most patients with acquired deficiency have an autoantibody inhibitor. Patients who develop TTP after stem cell transplantation or drug ingestion have normal levels of ADAMTS13 and may have endothelial damage or dysfunction that induces the release of large quantities of large multimers.

Patients with the abrupt onset of thrombocytopenia, anemia, elevated blood urea nitrogen and creatinine, and neurologic abnormalities (usually fluctuating levels of

consciousness or fluctuating focal findings) are good candidates for TTP. The blood smear should show the presence of schistocytes, whereas coagulation parameters including PT, PTT, fibrinogen, and D-dimer levels are normal. Elevated lactate dehydrogenase (LDH) is a cardinal feature. Blood should be sent to a reference laboratory for ADAMTS13 activity and inhibitor levels, although the results may not be available for several days or a week.

The best therapy for TTP is intensive plasmapheresis accompanied by infusion of fresh frozen plasma. Although the therapy was derived empirically, it is rational. Plasmapheresis may remove antibody or antibody-enzyme complexes, whereas plasma infusion replaces ADAMTS13. Once initiated, daily plasmapheresis should be continued until neurologic symptoms have abated and the creatinine returns to normal along with the platelet count and LDH. Approximately 20% of patients may relapse immediately after plasmapheresis is stopped and may require retreatment. Within a year of initial treatment, 20% of patients may relapse and require additional plasmapheresis. Before the advent of plasmapheresis and plasma replacement, the mortality of TTP was close to 100%. Now it is down to 10% to 15%.

There is a long list of therapies that have not been effective in TTP (Fig. 18.3). They include antiplatelet drugs, splenectomy, and some of the older immunosuppressive medications such as prednisone and azathioprine. Recently

• **Fig. 18.3** Schematic of the role of von Willebrand factor and platelet adhesion. TTP, Thrombotic thrombocytopenic purpura.

there has been evidence that the anti-CD20 monoclonal antibody rituximab may be beneficial in TTP and certainly should be tried in patients with relapsing forms of the disorder. In addition, an anti-vWF humanized single-variable-domain immunoglobulin named *caplacizumab* has been developed and generated initially promising results. Peyvandi and colleagues (2016) recently published results from a phase 2 controlled study in patients with acquired TTP who received caplacizumab and demonstrated a faster resolution of acute TTP episodes compared with the placebo group.

The most common drugs causing TTP are the thienopyrimidines ticlopidine and its close derivative clopidogrel, which bind to the platelet P<sub>2</sub>Y<sub>12</sub> (ADP) receptor. Although they are very effective antithrombotic agents, the incidence of TTP following administration of ticlopidine was so high that the drug was taken off the market. TTP has been described after the administration of clopidogrel, but considering the widespread use of this drug the incidence is quite low. The mortality in patients with drug-induced TTP is higher than in sporadic cases and approaches 50%. Although plasmapheresis is prescribed, it is less clear that it is effective in this subset of TTP.

### Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is caused by the unregulated activation of the coagulation pathway. It is most commonly seen during labor and delivery and in patients with sepsis or malignancy. The trigger for DIC can be endotoxin from bacteria, a tissue factor, or other activators of coagulation and contact of blood with incompatible surfaces or membranes. Unregulated coagulation leads to excess thrombin generation, which causes the rapid conversion of plasma fibrinogen to fibrin. Platelets become trapped in the fibrin thrombi, and red blood cells become skewered on fibrin strands. The fibrinolytic response to massive fibrin deposition in the microcirculation leads to additional coagulation abnormalities.

Classic laboratory findings include thrombocytopenia, anemia with schistocytes on the blood smear, a prolonged PT and PTT, and a low fibrinogen. Patients also have elevated fibrinogen/fibrin degradation products. The most common assay in use today is the D-dimer assay, which uses a fibrin-specific monoclonal antibody to detect cross-linked fibrin degradation products.

DIC is easily differentiated from TTP, but it may be more difficult to distinguish DIC from a primary fibrinolytic state. Primary fibrinolysis is a rare event seen with some malignancies that have high concentrations of fibrinolytic activators, such as carcinoma of the prostate, or in patients with advanced cirrhosis who fail to clear fibrinolytic activators from their blood. Although in theory, patients with fibrinolysis should have normal platelet counts, no schistocytes, and normal D-dimer assays, in clinical situations these distinctions may get blurred,

perhaps because of a combination of DIC and primary fibrinolysis, limitations in the D-dimer assay, or the effects of plasmin on platelets.

Patients with DIC may present with small vessel thrombosis, often in digits, extremities, skin, or genitalia, with fulminant hemorrhage from multiple sites or with some combination of bleeding and thrombosis. Patients with DIC secondary to sepsis seem to have more prominent thrombosis, whereas patients with obstetric DIC tend to have massive uncontrollable bleeding. Many patients with cancer have low-grade chronic DIC but may develop more active disease if they undergo tumor resection or other surgery. Patients with epithelial tumors that have metastasized to blood vessels can develop fulminant, intractable DIC.

The treatment of DIC varies with the clinical manifestation. Patients who have thrombosis are best treated with heparin. Prompt heparinization can be lifesaving and prevent subsequent tissue necrosis and amputation. Patients with bleeding are usually treated with platelets, red cells, and fresh frozen plasma to replace depleted coagulation factors. After this initial resuscitation, the most important next step is to try to treat the underlying pathology that is inducing DIC. In pregnant women, the causes are placenta previa, premature placental separation with retroplacental clot, severe eclampsia, or retained products of conception. With delivery of the fetus and the placenta, DIC can disappear quite rapidly. Treatment of gram-negative or other forms of sepsis can help to reverse DIC and stop bleeding. Although this should be attempted, there is no evidence that treatment of DIC per se improves the prognosis in septic patients. Patients with metastatic tumor provide the greatest challenge because there may be no effective therapy for the underlying tumor. If the patient develops acute DIC in association with surgery, replacement therapy may help to stop bleeding although low-grade DIC may persist. Heparin can be used as an adjunct to replacement therapy if fibrinogen and platelets are persistently low despite adequate replacement. Patients with DIC should be followed closely with serial measurements of fibrinogen level, D-dimer, or any other measure of fibrinogen/fibrin degradation products. The platelet count may lag behind these other parameters.

### Hypercoagulable States

Patients with cancer, congestive heart failure, prolonged immobility, or patients undergoing surgical procedures have an increased risk of thrombosis. The mechanisms are not well understood and are multifactorial. There is increasing use of prophylactic anticoagulation with heparin and/or warfarin in these patients. Most notable are the marked reductions in postoperative venous thromboembolism in orthopedic patients with hip fracture or hip or knee replacement following the universal use of warfarin in the perioperative period.

A group of genetic traits has been identified that increase the risk of venous thromboembolism and, collectively, may account for up to 70% of patients with recurrent deep vein thrombosis (DVT) or pulmonary emboli (PE). These mutations also heighten the risk of thrombosis in patients who are pregnant, use oral contraceptives, have malignancy, or are taking certain medications. In addition, the mutations are sufficiently common that patients often coinhere two of the defects heightening their risk of thrombosis. Each of these disorders, reviewed later, has its own unique natural history, pathophysiology, and response to therapy (Table 18.2).

1. Antithrombin (AT) deficiency: This was the first of this group of disorders to be identified. It is an autosomal dominant trait and occurs in approximately 1 in 2000 individuals. Because patients only have one affected allele (gene), they have only a modest deficiency in AT. No patients have been identified with two defective alleles; therefore we believe that homozygosity is an embryonic lethal condition. Most patients with AT deficiency will develop symptoms of DVT or PE before they are 30 years old. Although there are AT concentrates available for replacement therapy, most patients have only a modest decrease in AT level and respond normally to heparin. The rare patient with a missense mutation that perturbs heparin binding or heparin-induced AT activation or a mutation in the AT active site will require replacement therapy. Because the risk of recurrence is quite high, patients who have an initial thrombotic event should be on lifelong oral anticoagulation with warfarin or its equivalent. Relatives of a patient with known AT deficiency should be tested and, if they carry the mutation, should avoid oral contraceptives and receive prophylaxis with elective surgery.
2. Protein S and C deficiency: These two proteins, similar to coagulation factors II, VII, IX, and X, are synthesized in the liver and require a posttranslational modification (gamma carboxylation of specific glutamic acids) for biological activity. Anything that perturbs gamma carboxylation such as liver disease, vitamin K deficiency, or oral anticoagulants of the warfarin class will reduce

the levels of proteins C and S. Protein C binds to the endothelial cell surface protein thrombomodulin, where it is activated by thrombin. Activated protein C catalyzes the inactivation of factors V and VIII, two critical cofactors in the coagulation pathway, in concert with protein S and the endothelial surface protein thrombomodulin. Deficiencies in proteins C and S are very common, with estimates for protein C as common as 1 in 200 individuals. Most affected individuals are asymptomatic or minimally affected and may never develop venous thrombosis or embolism. However, the disorders do increase the lifetime risk of DVT/PE several-fold. Babies with homozygous protein C or S deficiency develop fulminant DIC just after birth and require lifelong plasma infusions to replace protein C or S. Parents of these severely affected children are often completely asymptomatic and have only a mild decrease in protein C or S. Protein C levels are reduced in patients taking warfarin. Because protein C has a short plasma half-life, during the initiation of warfarin therapy its level drops before factors II, VII, IX, or X, creating a transient prothrombotic state. It is especially pronounced in patients who are started on warfarin and have protein C deficiency. This prothrombotic state is thought to cause the rare complication of warfarin-induced skin necrosis. This serious complication is, fortunately, very rare because most patients starting on warfarin are on heparin and are thus protected.

Protein S acts as a high-molecular-weight cofactor and forms a complex with protein C and thrombomodulin to facilitate the inactivation of factors V and VIII. It exists in two forms: an active fraction that is free in plasma, and an inactive fraction bound to a steroid-binding globulin. Pregnancy and the use of oral contraceptives can increase the level of this protein and thereby induce or exacerbate protein S deficiency. This reduction in protein S, when combined with another mild defect such as the factor V Leiden or prothrombin gene mutation, may account for the increase in DVT/PE in pregnancy and in users of oral contraceptives who were previously asymptomatic.

3. Factor V Leiden: This mutation R506Q is present in 5% of the Caucasian population but is uncommon in Africans, Asians, and Latinos. The mutation modifies one of the two protease-sensitive sites in factor V that are cleaved by activated protein C and thereby results in excess thrombin generation. Despite a lot of speculation, we do not know how this invariant mutation arose and was propagated. Carrying the mutation increases the lifetime risk of DVT/PE approximately 3-fold, from 1 in 1000 individuals to 1 in 250 individuals. In case-control studies, patients who present with DVT/PE on oral contraceptives or during pregnancy often have this mutation. Homozygosity at this locus (inheritance of two defective genes) increases the risk of DVT/PE 30-fold to 80-fold, to 1 in 12 individuals.

**TABLE 18.2** Hypercoagulable State and Type of Thrombosis

Abnormality	Arterial	Venous
Factor V Leiden	–	+
Prothrombin G20210A	–	+
Antithrombin deficiency	–	+
Protein C deficiency	–	+
Protein S deficiency	–	+
Antiphospholipid syndrome	+	+

4. Prothrombin gene: The prothrombin gene mutation G20210A occurs in the 3' untranslated region of the gene rather than in the coding sequence. It stabilizes prothrombin mRNA levels and thereby increases the steady-state level of prothrombin in plasma by 25% to 30%. This results in increased thrombin generation. The clinical course is quite similar to factor V Leiden. It is a second example of an invariant mutation that has become common in the Caucasian population. Again, the possible advantage of carrying this mutation and maintaining it in the population is unknown. There are a few reports that patients with the prothrombin gene mutation may have a higher incidence of PE than those with the factor V Leiden defect.

### Antiphospholipid Antibody

The antiphospholipid antibody syndrome, also called the *anticardiolipin antibody* or *lupus/lupus-like anticoagulant syndrome*, is an autoimmune disorder that increases patient risk of both venous and arterial thrombosis (Table 18.3). The mechanism of induction of a hypercoagulable state remains speculative, and many patients have the disorder but remain asymptomatic. The two most commonly ordered tests are measurement of anticardiolipin antibody and screening

for a lupus-like inhibitor. If the screening test is positive, a confirmatory test using hexagonal phase phospholipid is performed. Anti-B2GPI and antiprothrombin antibody tests are also available. There is some evidence that patients with anticardiolipin antibodies that also react with B2GPI are more prone to thrombosis. The serology is complicated, although most but not all patients are positive in both the lupus anticoagulants and anticardiolipin tests.

Once a patient has an initial thrombotic event, the risk of recurrence is sufficiently high that patients are usually placed on indefinite/lifelong anticoagulation. Most patients have DVT or PE, a stroke, or a coronary arterial event. Rare patients may develop a more aggressive disorder; the catastrophic antiphospholipid antibody syndrome, with life-threatening thrombosis at multiple sites. Plasmapheresis is recommended, in addition to vigorous anticoagulation, for these patients.

Although the standard therapy for a thrombotic event is heparin followed by maintenance on a warfarin anticoagulant, there is some evidence that a course of the anti-CD20 antibody rituximab may reduce or eliminate anticardiolipin antibodies and reduce the risk of thromboembolism. In some small, published series, approximately 50% of treated patients responded and were able to discontinue anticoagulant therapy.

**TABLE 18.3**

**Relationship Between Thrombophilic Status and Risk of Venous Thromboembolism**

Thrombophilic Status	Relative Risk of Venous Thrombosis	
Normal	1	
OCP use	4	
Factor V Leiden, heterozygous	5–7	
Factor V Leiden, heterozygous + OCP	30–35	
Factor V Leiden, homozygous	80	
Factor V Leiden, homozygous + OCP	???	>100
Prothrombin gene mutation, heterozygous	3	
Prothrombin gene mutation, homozygous	???	possible risk of arterial thrombosis
Prothrombin gene mutation, heterozygous + OCP	16	
Protein C deficiency, heterozygous	7	
Protein C deficiency, homozygous		Severe thrombosis at birth
Protein S deficiency, heterozygous	6	
Protein S deficiency, homozygous		Severe thrombosis at birth
Antithrombin deficiency, heterozygous	5	
Antithrombin deficiency, homozygous		Thought to be lethal before birth
Platelets	23,000/mm <sup>3</sup>	(150,000–450,000)
Creatinine	0.7 mg/dL	(0.7–1.3)
LDH	176 IU/L	(107–231)

*LDH*, Lactate dehydrogenase; *OCP*, oral contraceptive.

## Chapter Review

### Questions

1. A 25-year-old woman comes for her first clinic visit after a recent flu-like illness. Her past medical history is only remarkable for occasional migraine headaches that usually occur around the time of her menstrual period. These are generally relieved by ibuprofen. She takes no other medications. On review of systems she notes that her last menstrual period was heavier than usual. Physical examination is unremarkable. Laboratory studies reveal the following:

White blood cell count	7400/mm <sup>3</sup>	(4000–10,000)
Hematocrit	36%	(36–48)
Platelets	23,000/mm <sup>3</sup>	(150,000–450,000)
Creatinine	0.7 mg/dL	(0.7–1.3)
LDH	176 IU/L	(107–231)

Peripheral blood smear reveals normal red and white cell morphology and decreased platelets.

The most appropriate next step should be:

- Immediate hospitalization for intravenous gammaglobulin
  - Send HIV test, advise the patient to discontinue ibuprofen, treat with dexamethasone 40 mg for 4 days.
  - Obtain surgical consultation for splenectomy.
  - Observation
2. A 76-year-old woman on warfarin for chronic atrial fibrillation normally anticoagulated to an international normalized ratio (INR) of 2.5 is found to have an INR of 5.8 on routine testing. She is otherwise asymptomatic. The most appropriate next step is:
- Decrease dose of warfarin by 50%.
  - Hold warfarin, and administer 1 mg vitamin K subcutaneously.
  - Hold warfarin, and administer 2.5 mg vitamin K orally.
  - Hold warfarin for 1 day, and restart at 50% of previous dose the next day.
  - Hold warfarin, and recheck INR in 1 to 2 days before restarting therapy.
3. A 32-year-old Caucasian male is found to have a right popliteal DVT after injuring his leg playing football. Of the following heritable conditions, which is most likely to be found on diagnostic evaluation?
- Antithrombin III deficiency
  - Protein C deficiency
  - Homocystinemia
  - Factor V Leiden
  - Prothrombin gene mutation (G20210A)
4. Which of the following statements is true regarding low-molecular-weight heparins?
- They should never be used for the management of pulmonary embolus.
  - The incidence of treatment failure for DVT is higher with low-molecular-weight heparins.
  - All the available preparations have similar pharmacologic properties.
  - The incidence of heparin-associated thrombocytopenia in previously untreated patients is <1%.
  - They can be used in any patient regardless of other underlying conditions.
5. A 28-year-old woman is seen for evaluation in the clinic. Her past medical history is notable for significant bleeding after extraction of her wisdom teeth, such that additional sutures were required. She takes no medications regularly and does not smoke cigarettes or drink alcohol. Her family history is notable for the fact that her mother required blood transfusions several days after the birth of each of her two children. Her sister also had major bleeding several days after the birth of her child. The patient wants to become pregnant, but she is concerned because of her family history.

An appropriate evaluation now would include:

- PT, PTT, and fibrinogen assays
- No evaluation necessary, perform testing for vWD if patient becomes pregnant
- von Willebrand antigen level, ristocetin cofactor level, and factor VIII level
- Urea clot solubility test

## Anemia and Hemoglobinopathies

MAUREEN M. ACHEBE

Anemia is defined as a hemoglobin (or hematocrit [Hct]) below the lower limit of the normal range for age and sex of an individual. About 40 years ago, a World Health Organization expert committee suggested 12 g/dL as the lower limit of normal for nonpregnant women and 13 g/dL as the lower limit for adult men, values that continue to be used in many studies as the definition of normal. The right values for the upper and lower limits of normal remain a subject of intense debate but certainly vary by age, race, and gender.

Erythrocyte development starts in the bone marrow where the earliest erythroid precursor, the pronormoblast, develops through a series of maturation steps and finally extrudes its nucleus to become a reticulocyte. The reticulocyte then enters the bloodstream, loses its remaining RNA, and in 1 to 2 days becomes a mature red blood cell (RBC). The life span of the RBC in circulation is approximately 120 days, after which it is cleared by the reticuloendothelial system, primarily in the spleen. Hemoglobin, which is made up of two alpha chains and two beta chains, makes up 90% of the protein in the RBC and is responsible for the most important function of the RBC, oxygen delivery. In the absence of blood loss, the number of RBCs in circulation is a function of the rate of production of RBCs (and incorporation of hemoglobin) in the bone marrow and the rate of destruction or clearing by the spleen.

### Evaluation of Anemia

An organized approach to the evaluation of anemia is essential to reaching an accurate diagnosis. Every case of anemia has an underlying cause that should be sought and identified. The evaluation of anemia should start with a focused history and physical examination, an exclusion of blood loss, a determination of the reticulocyte index (RI), and examination of the blood smear (Fig. 19.1). Regardless of the cause of anemia, patients present with symptoms caused by reduced oxygen delivery to tissues: dizziness, dyspnea on exertion, palpitations, headaches, nausea, and presyncope or syncope.

The RI is the reticulocyte count corrected for the degree of anemia in an individual. It is calculated as follows:

$$\text{RI} = \text{reticulocyte count} \times \text{patient's Hct}/40$$

where 40% is a normal Hct.

The RI broadly divides anemias into hypoproliferative anemias resulting from inadequate production of RBCs by the bone marrow, associated with a low RI, and hyperproliferative anemias resulting from increased clearing of RBCs by the spleen or frank blood loss, associated with a high RI. The RI in the normal healthy adult is between 1 and 2 (Fig. 19.2).

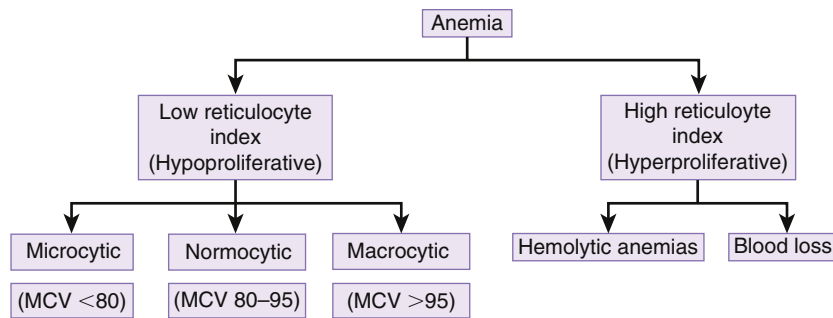

The treatment of anemias in general entails treating the underlying cause and providing supportive care including administration of blood transfusions in unstable or high-risk patients.

### Hypoproliferative Anemias

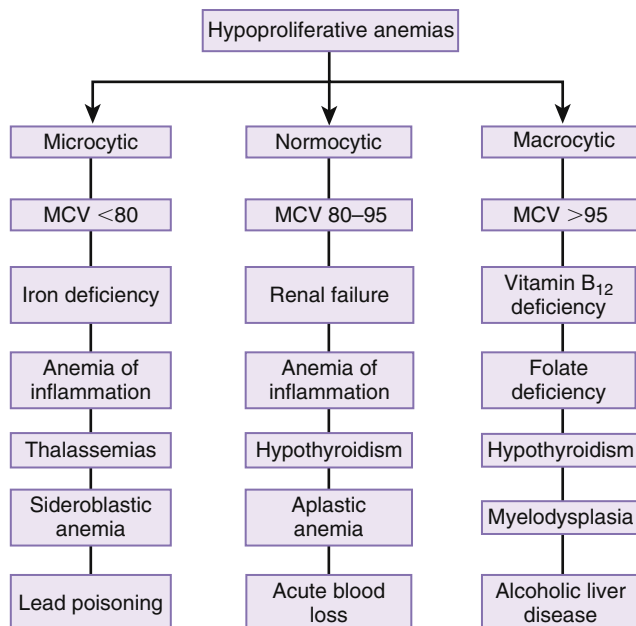

The hypoproliferative anemias result from the inadequate production of RBCs by the bone marrow. This may be the result of a primary bone marrow pathology such as red cell aplasia, aplastic anemia, or Fanconi anemia, or from an inadequate supply of the ingredients needed by the bone marrow to produce RBCs, principally iron, vitamin B<sub>12</sub>, folate, and erythropoietin, or from a dysregulation of cytokines that influence the bone marrow to make RBCs. The RI in these instances is <1. These anemias can be classified based on the average size of the cells, the mean corpuscular volume (MCV), into microcytic, macrocytic, and normocytic anemias (Fig. 19.3).

• Fig. 19.1 Normal blood smear.

• **Fig. 19.2** Initial evaluation of anemia. *MCV*, Mean corpuscular volume.

• **Fig. 19.3** Classification of anemia by red cell size. *MCV*, Mean corpuscular volume.

## Microcytic Hypochromic Anemias

*Microcytosis* refers to the size of the RBC being small relative to the nucleus of a normal mature lymphocyte, and *hypochromia* refers to the central pallor of the RBC being greater than one-third the diameter of the RBC. The differential diagnosis of microcytic anemia includes iron deficiency, thalassemias and other hemoglobinopathies, anemia of inflammation, sideroblastic anemia, and lead poisoning.

### Iron Deficiency Anemia

Iron deficiency anemia is the most common hematologic problem encountered in general practice. The causes of iron deficiency include blood loss, decreased gastrointestinal (GI) absorption (e.g., celiac disease or after bariatric surgery), or increased iron requirements (during pregnancy or with exogenous erythropoietin use). In addition to the general clinical features of all anemias,

• **Fig. 19.4** Iron deficiency.

iron deficiency is associated with symptoms in rapidly proliferating tissues: glossitis, angular stomatitis, gastric atrophy, koilonychia (spoon-shaped nails), and pica. The blood smear in iron deficiency shows microcytic hypochromic RBCs as well as pencil (shaped) cells and cells of all sizes and shapes (anisopoikilocytosis) (Fig. 19.4). The best single test for making a diagnosis of iron deficiency is the ferritin (the storage form of iron). A ferritin level  $<30 \mu\text{g/mL}$  is generally diagnostic. Other indices that aid a diagnosis are a low serum iron and a high total iron binding capacity (TIBC). The TIBC reflects transferrin availability, transferrin being the protein that transports iron in the plasma. Iron deficiency is also associated with a high RBC distribution width (RDW), which is a quantitative measure of the variation in RBC size, and a high serum soluble transferrin receptor level. Anemia is a late feature of iron deficiency, and although iron deficiency is very often a hypochromic microcytic anemia, it may present as a normocytic anemia. Fig. 19.5 shows the stages of iron deficiency. Once a diagnosis of iron deficiency has been made, a thorough search for the underlying cause should be undertaken and blood loss must be ruled out.

Treatment for iron deficiency is either with oral or intravenous replacement. Oral iron comes as iron sulfate, iron gluconate, or iron lactate. Ferrous sulfate, 325 mg twice

• Fig. 19.5 Stages of iron deficiency. TIBC, Total iron binding capacity.

daily, is a standard dose. Intravenous formulations (in the United States) include low molecular weight iron dextran, iron sucrose, ferric gluconate, ferumoxytol, and ferric carboxymaltose. Intravenous iron should be used particularly if the patient is unable to absorb iron (malabsorption, celiac disease, etc.); unable to tolerate oral iron (severe constipation or other GI upset); or to improve response to erythropoiesis-stimulating agents such as in patients on renal dialysis. The American Society of Hematology recommends a total repletion of 1 to 1.5 g. Oral repletion usually takes 4 to 6 months to return ferritin to midnormal range.

### Normocytic Normochromic Anemias

The differential diagnosis of normocytic anemias includes acute blood loss, anemia of inflammation, anemia of renal failure, hypothyroidism, aplastic anemia, and hemolysis.

#### Anemia of Inflammation

Anemia of inflammation (formerly termed *anemia of chronic disease*) is the second most common form of anemia. Anemia of inflammation is characterized by impaired absorption of iron from the GI tract and iron trapping in macrophages preventing the use of iron by the body. The features that define anemia of inflammation are mediated by the iron regulatory hormone, hepcidin, which is a 21-peptide hormone produced by the liver that is responsible for iron homeostasis. Hepcidin production is also stimulated by inflammation and binds to and causes the degradation of ferroportin. Ferroportin is the channel through which iron transverse to go from the enterocyte into the bloodstream and from the interior to the exterior of macrophages. Hepcidin, in inhibiting the function of ferroportin, blocks iron transportation across these membranes. Because anemia of inflammation results in iron-deficient erythropoiesis, various laboratory features are similar to those seen in iron deficiency. Table 19.1 shows the difference in laboratory values seen in anemia of inflammation, iron deficiency, and thalassemia minor. Anemia of inflammation and iron deficiency can be differentiated by the ferritin, TIBC, and soluble transferrin receptor. Efforts are under way to develop a hepcidin assay. Medical conditions commonly associated with anemia of inflammation include infective endocarditis, osteomyelitis, rheumatoid arthritis, tuberculosis, systemic lupus erythematosus, vasculitis, and cancer, although no conditions are exempt. Treatment of anemia of inflammation involves treating the underlying disease and exogenous erythropoietin administration (with or

without intravenous iron) to a goal hemoglobin not to exceed 11.5 g/dL.

### Macrocytic Anemias

The differential diagnoses of macrocytic anemias include vitamin B<sub>12</sub> and folate deficiency, myelodysplasia, alcoholic liver disease, reticulocytosis, hypothyroidism, and drugs that block folate metabolism (zidovudine, phenytoin, oral contraceptives, sulfasalazine, hydroxyurea).

#### Folate and Vitamin B<sub>12</sub> Deficiency

Folate and vitamin B<sub>12</sub> deficiency are the two most important causes of macrocytic anemia. Folate and B<sub>12</sub> deficiencies cause impaired DNA synthesis that results in macrocytic and megaloblastic RBCs as well as white blood cells (WBC) with hypersegmented (>5 lobes) nuclei.

Vitamin B<sub>12</sub> is found exclusively in animal proteins. On ingestion, vitamin B<sub>12</sub> is liberated from food (by pepsin and gastric juice) and binds to R-protein. In the duodenum, vitamin B<sub>12</sub> is released from R-protein by the action of pancreatic enzymes and is bound to intrinsic factor (IF) produced by the parietal cells in the stomach. Vitamin B<sub>12</sub>-IF complex then passes to the distal ileum where it is actively absorbed. It is then transported in the blood by transcobalamin for use in erythropoiesis. Dietary deficiency is rare except in the case of a strict vegan diet. Most causes of vitamin B<sub>12</sub> deficiency are related to ineffective absorption and include pernicious anemia (autoimmune destruction of parietal cells), partial gastrectomy, blind loop syndromes, fish tapeworm, pancreatic insufficiency, ileal resection, Crohn disease, and radiation enteritis. In addition to the general features of anemia, patients with deficiency can have GI symptoms such as diarrhea and glossitis and neurologic deficits ranging from paresthesias and loss of vibration and position sense, gait disturbances, to psychosis or dementia, so-called megaloblastic madness. Neurologic deficits from vitamin B<sub>12</sub> deficiency that go untreated for long durations may cause irreversible damage.

The Schilling test, which distinguishes among pernicious anemia, nutritional deficiency, and malabsorption, is no longer routinely used in clinical practice. The diagnosis of vitamin B<sub>12</sub> deficiency is made by the findings of low to low-normal levels of serum B<sub>12</sub> (lower limit of normal B<sub>12</sub> is 200 pg/mL) and elevated homocysteine and methylmalonic acid levels. An elevated lactate dehydrogenase (LDH) is also seen, caused by ineffective erythropoiesis. Vitamin B<sub>12</sub> levels are falsely low in pregnancy and

**TABLE 19.1** Laboratory Features of Iron Deficiency, Anemia of Inflammation, and Thalassemia Minor

	Iron Deficiency	Anemia of Chronic Disease	Thalassemia Minor
MCV	Low (70–80)	Normal or low	Low (<70)
RBC count	<5 × 10 <sup>12</sup> /L	<5 × 10 <sup>12</sup> /L	>5 × 10 <sup>12</sup> /L
RDW	High (>15)	High (>15)	Normal
Serum Fe	Low	Low	Normal
TIBC	High	Low	Normal
Transferrin saturation (Fe/TIBC)	Low (<9%)	Low or normal	Normal (>15%)
Ferritin	Very low	Normal or high	Normal or high
Soluble transferrin receptor	High	Normal	Normal

*MCV, Mean corpuscular volume.*

oral contraceptive use. Treatment of deficiency is traditionally with a loading dose of 1000 µg intramuscularly every week for 4 weeks followed by monthly injections of 1000 µg. Incidentally, oral repletion is also an option even in some cases of pernicious anemia at a dose of 1000 µg daily. Oral vitamin B<sub>12</sub> at this dose is absorbed by mass action.

Folate is found exclusively in plant sources, and folate bodily stores are minimal. Unlike vitamin B<sub>12</sub> deficiency, which takes 1 to 2 years to develop, in the absence of intake, folate deficiency may develop in 1 to 3 months. Deficiency results from poor dietary intake and increased bodily demands (such as in pregnancy and hemolysis). Patients with folate deficiency have similar symptoms to vitamin B<sub>12</sub> deficiency besides the neurologic features. Folate is not involved in myelin synthesis and so does not affect the neurologic system. Likewise, folate replacement may correct anemia arising from vitamin B<sub>12</sub> deficiency but will not affect the neurologic abnormalities. It is therefore important to differentiate vitamin B<sub>12</sub> deficiency from folate deficiency before treating with folate supplementation alone (Table 19.2).

## Hyperproliferative Anemias

These are anemias caused by inappropriate loss or premature destruction (hemolysis) of RBCs with an appropriate attempt by the bone marrow to compensate. The reticulocyte count and RI are therefore high. Hyperproliferative anemias are either of hereditary or acquired causes. The hereditary causes include defects in the RBC membrane, defects of RBC metabolism, and defects in hemoglobin. The acquired causes are of immune etiology and nonimmune etiology (Table 19.3).

### Acquired Hyperproliferative Anemias

Acquired causes of hyperproliferative anemias are distinguished from hereditary causes by the time of onset and lack of a family history. Clinically, in addition to the general signs and symptoms of anemia, patients have indirect hyperbilirubinemia, an elevated LDH, low haptoglobin, and reticulocytosis. The two most important tests in the evaluation of acquired hyperproliferative anemias are (1) a direct Coombs test (also known as the direct antiglobulin

**TABLE 19.3** Hyperproliferative Anemias

test), which detects the presence of antibodies or complement proteins bound to the RBC surface, and (2) an examination of the peripheral smear for the morphology of the RBCs (Table 19.4). The direct Coombs test differentiates immune from nonimmune causes.

### Immune Hemolytic Anemias (Coombs Positive)

#### Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia (AIHA) is defined as a Coombs-positive hemolytic anemia. In AIHA the patient produces antibodies against his or her RBC surface antigens. The antibody is most often IgG and less frequently IgM. Hemolysis in AIHA is caused by premature clearing of spherocytes by the spleen or complement-mediated hemolysis. Up to 15% of hospitalized patients may have a positive direct Coombs test of unknown significance.

#### IgG-Mediated Immune Hemolytic Anemia

IgG antibodies are called *warm antibodies* because they react with RBCs best at body temperature. The antigen-antibody complexes formed on the RBC membranes are nicked away in the spleen and produce the typical cells in AIHA, the spherocytes, which are then prematurely cleared by the spleen. Other conditions associated with spherocytes are hereditary spherocytosis, drug-induced hemolytic anemia, and hypophosphatemia. IgG also causes complement fixation, but this is usually inadequate to cause intravascular hemolysis. Most cases of warm AIHA are idiopathic, but AIHA can be secondary to lymphoproliferative diseases, ovarian cancer, viral infections, and other autoimmune disorders. The first-line treatment of choice is with corticosteroids starting at high doses of prednisone 1 mg/kg/day (which reduces the antibody production) and blood transfusions as needed for

• Fig. 19.6 Cold agglutinin disease.

symptoms. Splenectomy is reserved for patients who fail steroid treatment. Rituximab, a monoclonal antibody against the CD-20 antigen on B-lymphocytes can reduce or abolish hemolysis in AIHA. Immunosuppressive and cytotoxic drugs (azathioprine, cyclophosphamide, cyclosporine) also reduce the production of antibodies and are used in refractory cases.

### **IgM-Mediated Immune Hemolytic Anemia (Cold Hemagglutinin Disease)**

IgM antibodies are called *cold antibodies* because they typically react at room temperature. IgM is frequently directed against the “I” antigen on the RBC membrane causing complement activation. Because this happens at temperatures lower than body temperature, they are often clinically insignificant. Occasionally these antibodies have a wide thermal amplitude of activity and may then be clinically relevant. Besides the typical features of anemia, patients present with a dusky appearance to the skin and acrocyanosis of fingers, toes, ears, and nose tip. The direct Coombs test identifies complement (C3) binding on the RBC that is induced by IgM. The peripheral smear in cold agglutinin disease is classic (Fig. 19.6), and the agglutination disappears upon warming. Cold agglutinins are associated with *Mycoplasma pneumoniae* (anti-I), infectious mononucleosis (anti-i), lymphoproliferative disorders, and connective tissue diseases. Treatment includes keeping the patient warm and treating the underlying disease or infection. In severe cases, plasmapheresis may reduce the titer of the antibody, because IgM, unlike IgG, remains in the plasma.

### **Drug-Induced Immune Hemolytic Anemia**

Drugs can cause immune hemolysis in four ways: autoantibody type, hapten (drug-absorption) type, immune-complex type (innocent bystander), and nonspecific reactions. The diagnosis is made by careful history and examination, and treatment is by removal of the offending drug (Table 19.5).

### **Paroxysmal Cold Hemoglobinuria**

This is a much less common, self-limited, autoimmune hemolytic anemia in which there is IgG-activated complement mediated lysis. It is either idiopathic or secondary to infection (most commonly measles). Other infectious causes include mumps, chickenpox, and syphilis. Mainstay of treatment is keeping the patient warm and treating the underlying cause.

### **Nonimmune Hemolytic Anemias**

#### **Paroxysmal Nocturnal Hemoglobinuria**

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal hematopoietic stem cell disorder caused by a defective *PIG-A* gene, which results in the loss of glycosylphosphatidylinositol (GPI) anchors on RBCs, WBCs, and platelets and a loss of the protective proteins usually carried by these anchors. CD-55 (decay accelerating factor) and CD-59 (membrane inhibitor of reactive lysis) are two of these GPI-anchored proteins usually used in diagnosis. Other GPI anchor proteins include CD-14 and CD-16. Loss of the GPI-anchored proteins leaves RBCs unusually sensitive to complement-mediated lysis. Patients present with hemolysis, hemoglobinemia, hemoglobinuria (particularly in the morning because plasma is most acidotic at night), dysphagia, abdominal pain, iron deficiency, thrombocytopenia, and a predisposition to thrombosis in unusual sites. PNH may be accompanied by a bone marrow failure syndrome, myelodysplasia, or aplastic anemia, in which case pancytopenia accompanies the symptoms. Morbidity is from severe anemia, and mortality is primarily from thrombotic complications in the cerebral and abdominal veins that are present in up to 50% of cases for unclear reasons. The median survival of patients with PNH is 10 years. Diagnosis is by flow cytometry to detect a lack of cell surface markers CD-55 and CD-59. A new humanized monoclonal antibody, eculizumab (Soliris), is the only US Food and Drug Administration (FDA)-approved medication specifically for PNH. Eculizumab binds to C5 and prevents the cleavage of C5b required for the formation of the membrane attack complex of the complement system C5b-9. Eculizumab decreases hemolysis and the risk of thrombosis. Treatment also includes the use of steroids when there is brisk hemolysis. Steroids may inhibit activation of complement by the alternate pathway and cyclosporine. Blood transfusions are given as dictated by symptoms. The only treatment with a chance of cure is bone marrow transplant.

#### **Thrombotic Thrombocytopenic Purpura**

Thrombotic thrombocytopenic purpura (TTP) is a microangiopathic process in which uncleaved ultralarge von Willebrand factor (vWF) multimers aggressively bind platelets, causing profound thrombocytopenia and thrombotic complications. The pathogenesis centers around a reduction or absence of the vWF-cleaving protease (ADAMTS13), which typically limits the formation of very large vWF multimers. There are acquired and familial forms of TTP both defined

**TABLE 19.5** Mechanisms of Action in Drug-Induced Immune Hemolytic Anemia

Type	Mode of Action	Onset After Ingestion	Drug Examples
Autoantibody type (Aldomet)	Similar to idiopathic warm AIHA. 25% patients develop IgG against RBC Rh Ags, <5% patients develop hemolysis. The drug itself is not involved in the Ag-Ab reaction.	18 weeks to 4 years	$\alpha$ -Methyl dopa, procainamide, ibuprofen, cimetidine
Hapten type (drug-adsorption; high-dose PCN)	The drug or drug metabolite binds to the RBC and forms an RBC Ag-drug complex, which induces an immune response only to RBCs with drug coating.	7–10 days	High-dose penicillin, cephalosporins, tetracycline, cisplatin, quinidine
Immune-complex type; innocent bystander (quinidine)	This is an IgM Ab reaction. The drug binds to plasma proteins to form an immune complex. The complex then attaches to and cross-reacts with RBC Ags and activates complement causing intravascular hemolysis, hemoglobinemia, and hemoglobinuria.		Quinidine, quinine, acetaminophen, phenacetin, isoniazid, melphalan, sulfonyleureas, insulin, rifampin, HCTZ, sulfa drugs
Nonspecific reactions	Some drugs induce immune hemolytic reactions by more than one of the previous mechanisms or other mechanisms.		

*Ab, Antibody; Ags, antigens; AIHA, autoimmune hemolytic anemia; HCTZ, hydrochlorothiazide; IgG, immunoglobulin G; IgM, immunoglobulin M; PCN, penicillin; RBC, red blood cell.*

• **Fig. 19.7** Thrombotic thrombocytopenic purpura.

by the same final mechanism of limited ADAMTS13 activity. The classic pentad of TTP includes thrombocytopenia, renal failure, fever, neurologic changes, and microangiopathic hemolytic anemia (MAHA) with schistocytes. **Fig. 19.7** shows the smear of a patient with TTP; note the fragmented and distorted RBCs, some shaped like helmets, the absence of platelets, and the polychromatophilic cells. The diagnosis should be suspected in patients with thrombocytopenia and hemolytic anemia (dyad), because patients infrequently have all five features at presentation. The

#### • **BOX 19.1** Major Differential Diagnosis of Microangiopathic Hemolytic Anemia

Thrombotic thrombocytopenic purpura  
 Hemolytic uremic syndrome  
 HELLP (hypertension, elevated liver enzymes, and low platelets)  
 Eclampsia/preeclampsia  
 Malignant hypertension  
 Disseminated intravascular coagulopathy  
 Post bone marrow transplantation  
 Metastatic cancer  
 Prosthetic heart valves

 Autoimmune disease  
 HIV/AIDS  
 Drugs: quinine, ticlopidine, etc.

diagnosis is clinical, and therefore TTP must be differentiated from other causes of MAHA (**Box 19.1**). Without treatment, over 90% of patients with TTP die of multiorgan failure. The standard of care for treatment is urgent plasmapheresis, which has the advantage of potentially removing ADAMTS13 antibodies and replacing ADAMTS13 (from the donor plasma). Plasma infusions, which are thought to be less effective, replace missing ADAMT13 and may be given while plasmapheresis is being arranged. Platelet transfusions can worsen thrombosis and are contraindicated in TTP unless absolutely necessary in a bleeding patient.

• Fig. 19.8 Osmotic fragility.

## Hereditary Hemolytic Anemias

### Hereditary Conditions of the Red Blood Cell Membrane

#### Hereditary Spherocytosis

Hereditary spherocytosis (HS) is a hemolytic condition caused by defects in the red cell membrane proteins, ankyrin, spectrin, band 3, and protein 4.2 that cause abnormal interactions between the RBC cytoskeleton and bilipid membrane. The most frequent mutation causing this is in the ankyrin gene, a mutation that causes a loss of spectrin as well. This leads to fragility of the RBC membrane. Most cases (75%) are autosomal dominant, so there is often a family history. It is particularly common among Northern Europeans. Patients have chronic hemolysis, splenomegaly, bilirubin gallstones, and spherocytic RBCs on peripheral film causing an elevated mean corpuscular hemoglobin concentration (MCHC). Diagnosis is made by demonstrating increased osmotic fragility of RBCs when subjected to decreasing concentrations of saline (Fig. 19.8; the black lines are the limits of normal, the gray dots show the control sample, and the crossed-out gray dots show the patient), and confirmation is by membrane studies. Flow cytometric analysis for eosin-5'-maleimide-labeled intact RBCs has a sensitivity of 89% to 96% and specificity of 94% to 99% for HS, making it a superior screening test. Eosin-5'-maleimide interacts with the protein band 3 complex of the red cell membrane, directly targeting the structural lesion of this disease. Remember, tetrameric band 3 is bound to ankyrin, which is bound to spectrin. Fig. 19.9 is the smear of a patient with HS. Although there are spherocytes present, some RBCs maintain normal biconcavity. Treatment includes folic acid daily to support erythropoiesis and splenectomy, which

• Fig. 19.9 Hereditary spherocytosis.

decreases the rate of hemolysis. Asymptomatic patients with compensated hemolysis need no treatment.

### Hereditary Conditions of Red Blood Cell Metabolism (Enzymopathies)

#### Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common RBC enzyme deficiency. There are over 300 variants of deficiency, all inherited in an X-linked fashion. The variants lead to levels of activity of the enzyme varying from normal to severely deficient activity. Males are more typically affected, but heterozygous females may also show hemolysis. The hemolysis is caused by the inability of G6PD-deficient RBCs to produce enough nicotinamide adenine dinucleotide phosphate to reduce glutathione and

prevent oxidation and denaturation of hemoglobin by oxidant radicals. Denatured hemoglobin forms cytoplasmic inclusions (Heinz bodies), which are then pitted in the spleen, leading to bite-cell formation and hemolysis. Severity of the disease depends on the level of enzyme activity and the degree of oxidant stress. G6PD deficiency confers some protection against malaria. The increased oxidant stress is thought to be unfavorable to *Plasmodium falciparum*. Patients present with severe hemolytic anemia, hyperbilirubinemia, methemoglobinemia, and/or hemoglobinuria during an episode of hemolysis. The most common trigger of hemolysis is infection, commonly by *Pneumococcus*, *Salmonella*, and *Escherichia coli*. Other triggers include viral infections, drugs (chloroquine, primaquine, sulfonamides, aspirin, dapsone), ketoacidosis, liver disease, or kidney disease. Diagnosis is made by quantitative biochemical assays for G6PD. Note that false-negative results may be obtained if checked at a time of acute hemolysis because reticulocytes, which have relatively higher levels of G6PD than older RBCs, may be the predominant population during acute hemolysis. Diagnosis should be made months after an acute hemolytic episode. Management involves treating underlying infection/disease and/or withdrawing offending drugs.

### Hemoglobinopathies (Hereditary Conditions of Abnormal Hemoglobin)

The hemoglobinopathies refer to abnormalities in hemoglobin that are of clinical consequence. The hemoglobinopathies are the most common heritable hematologic diseases affecting mankind. The vast majority are caused by point mutations leading to amino acid substitutions. Over 500 structurally abnormal hemoglobins have been discovered. Hemoglobinopathies can result from one of the following: qualitative abnormalities as in the sickle cell syndromes; quantitative abnormalities as in the thalassemias; abnormalities of hemoglobin causing instability (to heat and alcohol in the laboratory); or unstable hemoglobins.

### Thalassemias

These are the most common hemoglobinopathies. Thalassemias are caused by a quantitative deficiency or absence of  $\alpha$  or  $\beta$  chains of hemoglobin referred to as  $\alpha$ -thalassemia and  $\beta$ -thalassemia, respectively. Decreased production of globin chains results in decreased normal hemoglobin production. In addition, the excess unpaired globin chains form homotetramers that precipitate in the erythroid precursors causing hemolysis and ineffective erythropoiesis that worsen the anemia. Rarer forms of thalassemia include  $\delta\beta$ -thalassemia and  $\epsilon\gamma\delta\beta$ -thalassemia.

#### $\beta$ -Thalassemia

$\beta$ -Thalassemia results from mutations of the  $\beta$ -globin gene complex of hemoglobin located on chromosome 11. The mutations may be nonsense mutations in which no  $\beta$ -globin is produced or mutations that alter splicing and cause decreased production of  $\beta$ -globin. The clinical manifestations depend on the number and severity of the

• Fig. 19.10  $\beta$ -Thalassemia intermedia.

abnormal  $\beta$ -globin gene(s) inherited. The peripheral smear in  $\beta$ -thalassemia characteristically shows hypochromic microcytic RBCs and target cells (Fig. 19.10) and therefore is the differential in cases of iron deficiency. Thalassemia minor and iron deficiency can be differentiated by the RBC count, RDW, and the hemoglobin A<sub>2</sub> (HbA<sub>2</sub>) on hemoglobin electrophoresis. Table 19.1 shows laboratory features that distinguish iron deficiency from thalassemia minor.

There are three clinical categories of  $\beta$ -thalassemia:  $\beta$ -thalassemia minor,  $\beta$ -thalassemia intermedia, and  $\beta$ -thalassemia major (Cooley anemia), defined strictly by clinical features (not mutational status).

**$\beta$ -Thalassemia Minor.** Patients are asymptomatic and have no clinical sequelae. Patients do have microcytosis (MCV usually below 70) but with only mild anemia or no anemia at all. Diagnosis is by hemoglobin electrophoresis that shows 2-fold to 3-fold elevation in levels of HbA<sub>2</sub> and mild elevations of fetal hemoglobin (HbF).

**$\beta$ -Thalassemia Intermedia.** Patients are severely anemic but are not chronically transfusion dependent. Patients inheriting homozygous  $\beta$ -0 alleles may present with thalassemia intermedia if modulating factors such as coinheritance of  $\alpha$ -thalassemia trait exist. Patients have ineffective erythropoiesis and so hyperabsorb iron, resulting in problems of iron overload. They often also have splenomegaly and bony expansion. Hemoglobin electrophoresis shows elevations of HbF and HbA<sub>2</sub>. Patients often need iron chelation, which is now available as oral formulations deferasirox (Exjade and Jadenu) 20 to 30 mg/kg/d and 14 to 28 mg/kg/d, respectively, or deferiprone (Ferroprox) 25 to 33 mg/kg three times a day. Before 2005 the only formulation available was deferoxamine (Desferal) given intravenously or subcutaneously as a continuous nightly infusion.

**$\beta$ -Thalassemia Major (Cooley Anemia).** Patients have essentially no production of  $\beta$ -globin chains. Severe anemia is seen early in life because of  $\alpha$ -chain homotetramer formation, which is toxic to erythroid precursors and causes ineffective erythropoiesis in the bone marrow and clearance of peripheral red cells by the spleen. Without RBC transfusions, patients

show marked bone marrow expansion of the skull and long bones producing a “chipmunk” facies, predisposition to fractures, growth retardation, and hepatosplenomegaly. Red cell transfusions suppress ineffective erythropoiesis and treat the anemia. Iron overload inevitably results from avid intestinal absorption of iron as well as from transfusions. Hemoglobin electrophoresis shows no HbA. Treatment is mainly supportive. Bone marrow transplant is the only curative approach.

### $\alpha$ -Thalassemia

$\alpha$ -Thalassemia results from defects of the  $\alpha$  genes located on chromosome 16. Human beings have duplicate copies of the  $\alpha$  gene on each chromosome; therefore the clinical manifestations of  $\alpha$ -thalassemia are more varied than those of  $\beta$ -thalassemia. Just as in  $\beta$ -thalassemia, the imbalance in globin chains leads to decreased hemoglobin and microcytosis. Although  $\alpha$ -thalassemia is associated with hemolysis, there is no significant ineffective erythropoiesis because homotetramers  $\beta_4$  and  $\gamma_4$  (seen in  $\alpha$ -thalassemia) are more soluble than  $\alpha_4$  (seen in  $\beta$ -thalassemia). RBCs are microcytic, but hemoglobin electrophoresis is normal in  $\alpha$ -thalassemia, and DNA analysis is required to make a diagnosis. The clinical syndromes of  $\alpha$ -thalassemia depend on the number of  $\alpha$ -chains missing (mutational status), as follows:

$\alpha$ -Thalassemia trait ( $-\alpha/\alpha$ ): These patients have one of four alleles absent. They are called *silent carriers* and are clinically normal.

$\alpha$ -Thalassemia minor ( $- -/\alpha\alpha$  or  $-\alpha/-\alpha$ ): These patients have two of four alleles missing. Patients are asymptomatic but have microcytosis and little or no anemia.

Hemoglobin H ( $- -/-\alpha$ ): These patients have varied presentations. All patients are anemic; most patients have a hemoglobin of 8 to 10 g/dL with moderate reticulocytosis. In severe forms patients exhibit transfusion dependence early in life, whereas other patients with milder disease are virtually asymptomatic until late adulthood.

Hemoglobin Bart ( $- -/- -$ ): Patients have an absolute absence of  $\alpha$ -genes. Instead, homotetramers of  $\gamma_4$  form and are able to carry oxygen but have such high oxygen affinity that oxygen is not delivered to tissues. This causes severe in utero hypoxia, hydrops fetalis, and death between 30 and 40 weeks of gestation or soon after birth. Hemoglobin Bart is incompatible with life.

## Sickle Cell Syndromes

The sickle cell gene results from a mutation at the sixth amino acid position of the  $\beta$ -globin gene of hemoglobin ( $\beta 6\text{Glu}\rightarrow\text{Val}$ ). The central abnormality in sickle hemoglobin is the tendency to polymerize in conditions of deoxygenation. Polymerized sickle hemoglobin causes RBC membrane stiffness, change in RBC shape to a crescent, abnormal RBC membrane permeability causing RBC dehydration, tissue ischemia, and tissue infarction. The peripheral smear shows numerous sickle (shaped) cells (Fig. 19.11). Patients

• Fig. 19.11 Sickle cell anemia.

with one of the sickle cell diseases frequently present with excruciating episodes of pain, often precipitated by infection, dehydration, acidosis, or other stressors. There is wide clinical variability in patients with sickle cell disease, with some patients living fairly asymptomatic lives. The reason for this variability is the subject of ongoing research.

### Sickle Cell Anemia

*Sickle cell anemia* refers to the homozygous inheritance of the sickle cell gene. It is in general the most severe form of the sickle cell syndromes. Patients present with severe anemia and jaundice from chronic hemolysis, hyposthenuria from renal microinfarctions, and leg ulcers. Splenic atrophy from chronic microinfarction causes predisposition to encapsulated organisms such as *Streptococcus pneumoniae*, *Klebsiella*, and *Neisseria meningitidis*. Every organ system is eventually affected by chronic hypoxia, some of which include the following: central nervous system (strokes, transient ischemic attack [TIA], cognitive impairment, proliferative and non-proliferative retinopathy, retinal detachment); cardiovascular system (cardiomegaly, high output failure); respiratory system (acute chest syndrome, pulmonary hypertension); GI system (bile gallstones, hepatic crisis); genitourinary system (isosthenuria, renal papillary necrosis, nephrotic syndrome, hematuria, focal segmental glomerulosclerosis, priapism); musculoskeletal system (avascular necrosis of long bones, fish-mouthed vertebrae, osteopenia/osteoporosis); skin (chronic leg ulcers); and bone marrow (aplastic anemia [precipitated by parvovirus B 19]).

Acute chest syndrome is a constellation of hypoxia, dyspnea, tachycardia, and a new infiltrate on chest x-ray in a patient with sickle cell disease. It is a frequent cause of mortality and an indication for urgent exchange blood transfusion to a goal hemoglobin S (HbS) level of 30% and a Hct of 30%. Laboratory diagnosis is by hemoglobin electrophoresis, which in the absence of recent RBC transfusion shows no HbA, 80% to 95% HbS, and varying quantities of HbF and HbA<sub>2</sub>. The primary chronic treatment modality is prevention of fever, dehydration, acidosis, high altitudes,

extreme temperatures, and infections. The treatment of acute pain episodes is supportive, with administration of intravenous fluids, intravenous pain medication, and blood transfusions and oxygen when indicated by symptoms. Evidence points to the P-selectin, an adhesion factor on endothelial cells and platelets in contributing to both vasoocclusion and sickle cell-related pain crises. Recently published data from a double-blind placebo controlled randomized trial using crizanlizumab, an antibody targeting P-selectin in patients with sickle cell disease shows a nearly 3-fold reduction in time to the first sickle crisis and was associated with a low incidence of adverse events. This contrasts with a lack of efficacy in a randomized trial of the platelet inhibitor prasugrel compared with placebo in reducing the rate of vasoocclusive crisis, a composite of painful crisis or acute chest syndrome. The indications for an exchange blood transfusion are acute chest syndrome and cerebrovascular accidents (strokes and TIAs). The goal is to reduce HbS to 30% and maintain Hct close to 30%. Hydroxyurea is the only FDA-approved medication for sickle cell disease. It is used in the chronic setting. The main mechanism of action of hydroxyurea in sickle cell disease is in the induction of HbF, which interferes with or participates in the polymerization of HbS, ameliorating the disease.

## Chapter Review

### Questions

- A 40-year-old man who refurbishes old city buildings presents for a routine physical. He is pale, has a discolored gum-tooth line, and has neuropathy.  
*Laboratory values:* WBC  $6.2 \times 10^3/\mu\text{L}$ , hemoglobin 10.3 g/dL, platelets  $232,000 \times 10^3/\mu\text{L}$   
*Smear:* microcytic hypochromic cells with basophilic stippling  
*Bone marrow:* Ringed sideroblasts  
 How would you manage this patient?

  - Ferrous sulfate 325 mg twice daily to replete ferritin
  - Vitamin B<sub>12</sub> shots and folic acid orally
  - Erythropoietin 40,000 units subcutaneous weekly to a goal Hct of 33%
  - Eliminate exposure, then give DMSA (oral chelator) to decrease lead levels  $<25 \mu\text{g/dL}$
- A 70-year-old woman develops tingling in her hands over 8 months. She is evaluated by a neurologist. Laboratory values were normal. She is then lost to follow-up until 2 years later, when she has increasing fatigue and incoordination. Examination reveals a positive Romberg test and absent position and vibration sense.  
*Laboratory values are as follows:* WBC  $2.3 \times 10^3/\mu\text{L}$ , hemoglobin 7.3 g/dL, Hct 20%. Platelet count is  $35,000 \times 10^3/\mu\text{L}$ , reticulocyte count is 0.4%. B<sub>12</sub> is 220 pg/mL (normal 200–800), and methylmalonic acid level is 0.51  $\mu\text{mol/L}$  (normal  $<0.4$ ).  
 The most likely diagnosis is which of the following?

  - Vitamin B<sub>12</sub> deficiency
  - Aplastic anemia
  - Anemia of inflammation
  - Folic acid deficiency
- A 60-year-old woman with rheumatoid arthritis presents with a 2-week history of worsening weakness and dizziness. Laboratory values are as follows: WBC  $4.7 \times 10^3/\mu\text{L}$ , hemoglobin 5.3 g/dL, Hct 5%, MCV 92 fL, MCHC 39 fL, platelet count  $177,000 \times 10^3/\mu\text{L}$ . Total bilirubin 3.1 mg/dL, direct bilirubin 0.2 mg/dL, reticulocyte count 23%, LDH 936 Units/L, haptoglobin  $<8$ , direct Coombs positive for IgG and complement.  
 You would expect which of the following?

  - Osmotic fragility to be abnormal
  - Treatment with steroids to be beneficial
  - Thrombosis in unusual sites
  - Schistocytes on her peripheral smear
  - None of the above
- A 39-year-old man is brought to the emergency room for acute onset of confusion. On physical examination he is afebrile, is pale, and has an altered mental status.  
*Laboratory values are as follows:* WBC  $7.1 \times 10^3/\mu\text{L}$ , hemoglobin 8 g/dL, Hct 26%, platelets  $21,000 \times 10^3/\mu\text{L}$ , blood urea nitrogen 30 mg/dL, creatinine 2.1 mg/dL, LDH 1040 Units/L, reticulocyte count 12%.  
 Laboratory data were normal during an annual physical 1 week earlier. How would you treat?

  - Steroids alone
  - Steroids followed by splenectomy
  - Platelet transfusion
  - Plasmapheresis
  - None of the above

## Hemoglobin SC Disease

This is the most common of the double heterozygous sickle cell diseases. Hemoglobin SC is caused by the coinheritance of HbS ( $\beta\text{6Glu}\rightarrow\text{Val}$ ) and HbC ( $\beta\text{6Glu}\rightarrow\text{Lys}$ ). Symptoms tend to be milder than in HbSS anemia, but patients have a particular predisposition to sickle retinopathy and avascular necrosis. Both HbS and HbC are seen on hemoglobin electrophoresis to make a diagnosis. Other double heterozygous states include HbS/ $\beta$ -thalassemia, HbSD, HbSE, and others. The clinical severity of each of these depends on the extent to which the other abnormal hemoglobin interferes with the polymerization of HbS. Treatment is supportive.

## Sickle Cell Trait

This is not one of the sickle cell syndromes and is not considered a disease. *Sickle cell trait* refers to the heterozygous inheritance of HbS with HbA. Patients are typically asymptomatic, although a few may have hematuria, isosthenuria, and renal papillary necrosis. Life expectancy of sickle cell trait is that of the general population.

5. A 32-year-old woman presents with 3-day history of colicky abdominal pain and fatigue. Laboratory values are as follows: hemoglobin 7.9 g/dL, Hct 22%, MCV 78, platelets  $60,000 \times 10^3/\mu\text{L}$ , reticulocyte count 9%, direct and indirect Coombs negative, ferritin 10. Abdominal ultrasound scan shows portal vein thrombosis. Urinalysis shows hemosiderin.

The most likely diagnosis is:

- A. Factor V Leiden mutation
- B. Paroxysmal cold hemoglobinuria

- C. Warm autoimmune hemolytic anemia
- D. Paroxysmal nocturnal hemoglobinuria
- E. Iron deficiency anemia

### Answers

- 1. D

## Board Simulation: Hematology

JULIE-AUORE LOSMAN AND BENJAMIN L. EBERT

### Questions

1. A 28-year-old woman is seen in clinic for evaluation. Her past medical history is notable only for an episode of prolonged bleeding after extraction of her wisdom teeth. She takes no medications regularly and does not smoke cigarettes or drink alcohol. Her family history is notable for the fact that her father has an “allergy” to aspirin characterized by extensive bruising, and her sister developed postpartum bleeding requiring a blood transfusion several days after the birth of each of her two children. The patient wants to become pregnant but is concerned because of her family history of bleeding.

An appropriate evaluation at this time would include:

- A. Prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen assays
  - B. Factor VIII and factor IX levels
  - C. von Willebrand antigen, ristocetin cofactor (RCo), and factor VIII levels
  - D. No evaluation necessary; perform testing for von Willebrand disease (vWD) if patient becomes pregnant
2. A healthy physically fit 25-year-old Caucasian woman with no significant past medical history develops a right popliteal deep venous thrombosis (DVT) several months after starting on oral contraception. She has no family history of spontaneous thrombosis, but her father did develop a pulmonary embolism (PE) after fracturing his leg in a motor vehicle accident several years ago. Of the following heritable conditions, which is most likely to have predisposed her to develop venous thrombosis?
    - A. Antithrombin III deficiency
    - B. Protein C deficiency
    - C. Hyperhomocysteinemia
    - D. Factor V Leiden (FVL)
    - E. Prothrombin gene mutation (G20210A)
  3. A 29-year-old African-American woman presents to the emergency department (ED) in acute respiratory distress and is found to have an oxygen saturation of 86% on room air. She undergoes a CT scan and is found to have bilateral pulmonary

emboli. She is immediately started on low-molecular-weight heparin and is admitted to the hospital. She reports that she has never been ill and takes no medications. Her only past medical history is a first-trimester spontaneous abortion several years ago. She has no family history of venous thromboembolic disease.

On the morning after admission, her laboratory studies are as follows:

White blood cell (WBC) count	12,600/mm <sup>3</sup>	(4000–10,000)
Hematocrit	34%	(36–48)
Mean corpuscular volume (MCV)	76 fL	(80–95)
Platelets	116,000/mm <sup>3</sup>	(150,000–450,000)
PT	11.6 s	(11–13)
PTT	44 s	(22–34)
Fibrinogen	230 mg/dL	(200–400)
Lactate dehydrogenase (LDH)	260 IU/L	(107–231)
Haptoglobin	96 mg/dL	(40–180)

An appropriate workup at this time would include:

- A. Serologic testing for heparin-induced thrombocytopenia (HIT) antibodies
  - B. Peripheral blood flow cytometry for CD55 and CD59
  - C. ADAMTS13 activity assay and serologic testing for antibodies to ADAMTS13
  - D. A lupus anticoagulant test and serologic testing for anticardiolipin and beta-2-glycoprotein antibodies
4. A 43-year-old woman comes to the ED complaining of fatigue, shortness of breath with exertion over the past 3 days, and a mild headache for the past several hours. She denies any other systemic symptoms. Her past medical history is unremarkable, and she takes no medications. She is afebrile, and her vital signs are stable. Her physical examination is entirely unremarkable, and she looks well.

Laboratory studies reveal:

WBC count	8200/mm <sup>3</sup>	(4000–10,000)
Hematocrit	26%	(36–48)
Platelets	31,000/mm <sup>3</sup>	(150,000– 450,000)
PT	12 s	(11–13)
PTT	29 s	(22–34)
Fibrinogen	320 mg/dL	(200–400)
Creatinine	0.9 mg/dL	(0.7–1.3)
LDH	652 IU/L	(107–231)

Peripheral blood smear reveals decreased platelets and a moderate number of schistocytes.

The most appropriate initial therapy is:

- A. Administer intravenous (IV) fluids and send stool studies for *Escherichia coli* 0157:H7.
  - B. Observe for now. Initiate plasmapheresis if the patient's platelet count falls below 20,000/mm<sup>3</sup>.
  - C. Observe for now. Initiate plasmapheresis if the patient clinically worsens or her creatinine rises.
  - D. Initiate plasmapheresis with plasma exchange as soon as possible.
5. A 19-year-old female college student comes for her first clinic visit after a recent flu-like illness. Her past medical history is remarkable only for occasional menstrual cramps that are relieved by ibuprofen. She takes no other medications. On review of systems she notes that her last menstrual period was heavier than usual, but she is currently not menstruating. Her physical examination is unremarkable, and she looks well.

Laboratory studies reveal:

WBC count	6200/mm <sup>3</sup>	(4000–10,000)
Hematocrit	34%	(36–48)
Platelets	19,000/mm <sup>3</sup>	(150,000– 450,000)
Creatinine	0.8 mg/dL	(0.7–1.3)
LDH	159 IU/L	(107–231)

Peripheral blood smear reveals normal red cell and white cell morphology, decreased platelets that appear somewhat larger than normal, and no schistocytes.

The most appropriate next steps are:

- A. Observe. Repeat platelet count in 3 to 5 days.
  - B. Request an HIV test. Advise patient to discontinue ibuprofen. Treat patient with dexamethasone 40 mg daily for 4 days as an outpatient with close follow-up.
  - C. Obtain a surgical consultation for consideration of splenectomy.
  - D. Hospitalize the patient, and treat her with IV gamma-globulin infusion.
6. A 71-year-old woman who recently underwent total hip replacement surgery is readmitted to the hospital with chest pain and acute-onset shortness of breath. She is found to have bilateral pulmonary emboli and

is started on unfractionated heparin. Her complete blood count is normal on admission, but by hospital day 5 her platelet count is noted to have drifted down to 80,000/mm<sup>3</sup>. An enzyme-linked immunosorbent assay (ELISA) for antibodies to the heparin–platelet factor 4 (PF4) complex is sent and is pending.

Which of the following management decisions is appropriate?

- A. Unfractionated heparin may be continued pending results of the heparin-PF4 antibody assay, and a search for other causes of thrombocytopenia should be initiated.
  - B. Unfractionated heparin should be discontinued immediately, and the patient should be started on anticoagulation with low-molecular-weight heparin.
  - C. Unfractionated heparin should be discontinued immediately, and the patient should be started on anticoagulation with warfarin.
  - D. Unfractionated heparin should be discontinued immediately, and the patient should be started on anticoagulation with a direct thrombin inhibitor.
7. A 74-year-old man comes to the ED complaining of 6 hours of fever, rigors, severe abdominal pain, and nausea and vomiting. His past medical history is remarkable for a myocardial infarction 3 years ago that required coronary artery bypass grafting as well as peripheral vascular disease that required femoral-popliteal bypass surgery 2 years ago. He is somewhat delirious and cannot provide a history, but his wife reports that he was “fine” when his primary care physician saw him 6 months ago. However, he had lost 25 pounds in the last 2 months because of severe postprandial “heartburn pain.” He takes several blood pressure and cholesterol-lowering medications, but she cannot recall their names. He is febrile, tachycardic, and hypotensive, and his physical examination is remarkable for moderate abdominal distension, severe abdominal pain with mild palpation, and diminished bowel sounds.

Laboratory studies reveal:

WBC count	14,300/mm <sup>3</sup>	(4000– 10,000)
Hematocrit	37%	(36–48)
Platelets	78,000/mm <sup>3</sup>	(150,000– 450,000)
PT	24 s	(11–13)
PTT	49 s	(22–34)
Fibrinogen	210 mg/dL	(200–400)
Creatinine	1.8 mg/dL	(0.7–1.3)
LDH	426 IU/L	(107–231)
Aspartate aminotransferase	634 IU/L	(10–50)
Alanine aminotransferase	786 IU/L	(10–50)
Lactate	19 mmol/L	(0.5–2.2)

Peripheral blood smear reveals neutrophils with toxic granulations and numerous bands, decreased platelets, and a moderate number of schistocytes.

His thrombocytopenia is most likely caused by:

- A. Drug-induced thrombocytopenia
- B. Immune thrombocytopenic purpura (ITP)
- C. Thrombotic thrombocytopenic purpura (TTP)
- D. Disseminated intravascular coagulation (DIC)
- E. Splenic platelet sequestration secondary to liver disease

8. An asymptomatic 43-year-old woman is noted on routine laboratory testing to have the following complete blood count:

WBC count	8200/mm <sup>3</sup>	(4000–10,000)
Hematocrit	38%	(36–48)
Platelets	863,000/mm <sup>3</sup>	(150,000–450,000)

The most appropriate next step is:

- A. Low-dose aspirin therapy should be started as soon as possible to prevent thrombotic complications.
  - B. Warfarin therapy should be started as soon as possible to prevent thrombotic complications.
  - C. Hydroxyurea therapy should be started to lower the platelet count to within the normal range.
  - D. The patient should be evaluated for the presence of iron deficiency, an inflammatory state, or a chronic myeloproliferative disorder.
  - E. The patient should be counseled about her risk of developing acute leukemia.
9. A 46-year-old African-American man is seen for follow-up 4 days after completing a course of trimethoprim/sulfamethoxazole for an episode of bacterial sinusitis. On review of systems, he notes that his sinus congestion has improved but that during the past week he has felt somewhat shorter of breath with exertion and more fatigued than usual.

Laboratory studies reveal:

WBC count	4100/mm <sup>3</sup>	(4000–10,000)
Hematocrit	26%	(36–48)
Reticulocyte count	9%	(0.5–2.5)
MCV	99 fL	(80–95)
Platelets	163,000/mm <sup>3</sup>	(150,000–450,000)

The most appropriate course of action at this time is:

- A. Observe and have the patient return in a few weeks for further laboratory tests.
- B. Send a dye decolorization test for glucose-6-phosphate dehydrogenase (G6PD) deficiency.
- C. Ask patient about any recent history of heavy alcohol use.
- D. Obtain patient's folate and vitamin B<sub>12</sub> levels.

10. A 39-year-old woman originally from the Dominican Republic comes to the clinic for her first visit. Her only past medical history is a diagnosis of iron deficiency anemia that was made 5 years ago, at the birth of her second child. At the time, she was told to take iron tablets twice daily. This is her only medication.

Laboratory studies reveal:

WBC count	4600/mm <sup>3</sup>	(4000–10,000)
Hematocrit	35%	(36–48)
MCV	66 fL	(80–95)
Platelets	256,000/mm <sup>3</sup>	(150,000–450,000)
Iron	142 µg/dL	(40–159)
Total iron binding capacity (TIBC)	320 µg/dL	(250–400)
Ferritin	220 ng/mL	(20–300)
Creatinine	0.7 mg/dL	(0.5–1.1)

The most appropriate management of this patient is to:

- A. Discontinue her iron replacement therapy, and initiate phlebotomy to reverse her hemochromatosis.
  - B. Discontinue her iron replacement therapy, and start her on erythropoietin therapy.
  - C. Discontinue her iron replacement therapy, and send a hemoglobin electrophoresis.
  - D. Switch her from oral to IV iron replacement therapy, and work her up for occult blood loss.
11. A 43-year-old man who underwent gastric bypass surgery for morbid obesity 2 years ago presents to clinic for the first time since recovering from his surgery. He is very happy about the fact that he has lost 150 pounds and reports that he has generally felt well since his surgery, but recently he has noticed that he is more fatigued and irritable than usual. He was finally prompted to come in for a checkup when, a few weeks ago, he began experiencing numbness and tingling in his fingers and toes.

Laboratory studies reveal:

WBC count	3900/mm <sup>3</sup>	(4000–10,000)
Hematocrit	32%	(36–48)
MCV	116 fL	(80–95)
Platelets	156,000/mm <sup>3</sup>	(150,000–450,000)

The most appropriate course of action at this time is:

- A. Check a hemoglobin A1c, and counsel the patient on management of diabetic peripheral neuropathy.
- B. Check a peripheral blood smear and reticulocyte count, and order folate and vitamin B<sub>12</sub> levels.

- C. Check a peripheral blood smear and reticulocyte count, order folate and vitamin B<sub>12</sub> levels, and start empirical treatment with folate.
- D. Recommend that the patient undergo screening tests for an occult malignancy.
12. A 61-year-old man with benign prostatic hypertrophy, diabetes mellitus (DM), and poorly controlled hypertension presents to clinic after a recent hospitalization for new-onset heart failure. He was switched from his oral diabetes medications to insulin and was started on several new blood-pressure-lowering agents as well as furosemide. A review of his records reveals that his hematocrit has been gradually declining over the past 3 years. Laboratory studies today reveal:

Hematocrit	29%	(36–48)
MCV	86 fL	(80–95)
Red cell distribution width (RDW)	14.1	(10–14.5)
Platelets	280,000/ mm <sup>3</sup>	(150,000– 450,000)
Blood urea nitrogen	31 mg/dL	(9–25)
Creatinine	1.8 mg/dL	(0.7–1.3)
LDH	221	(107–231)

Peripheral blood smear reveals normochromic, normocytic red blood cells, few reticulocytes, and normal-appearing platelets, lymphocytes, and neutrophils.

The most likely etiology of his anemia is:

- A. Medication effect of furosemide
- B. Erythropoietin deficiency
- C. Combined iron and vitamin B<sub>12</sub> deficiency
- D. Replacement of his bone marrow by metastatic prostate cancer
13. A 21-year-old man with sickle cell disease (SCD) and a baseline hematocrit of 26% comes back to the ED 1 week after his last ED visit for a simple pain crisis, reporting that his pain has returned. He reports that he is having his typical symptoms of back, hip, and thigh pain and says that he has been unable to eat or drink very much for the past 2 days. In the past day, he has developed fever and shortness of breath. In the ED, he is noted to have a temperature of 101.9°F, and his oxygen saturation is 94% on room air. On chest x-ray he has a right lower-lobe infiltrate that was not present 1 week ago. Laboratory studies reveal:

WBC count	18,000/mm <sup>3</sup>	(4000– 10,000)
Hematocrit	27%	(36–48)
Platelets	283,000/mm <sup>3</sup>	(150,000– 450,000)

Appropriate management of this patient should include:

- A. Intravenous fluids and pain medication in the ED until his pain has improved, then discharge home

with oral pain medication and a prescription for antibiotics for community-acquired pneumonia

- B. Intravenous fluids, oxygen supplementation, IV pain medication, and admission to the hospital for pain control
- C. Intravenous fluids, oxygen supplementation, antibiotics, IV pain medication, and admission to the hospital for monitoring and initiation of hydroxyurea
- D. Intravenous fluids, oxygen supplementation, antibiotics, IV pain medication, and admission to the hospital for monitoring and exchange transfusion
14. A 57-year-old woman with no significant past medical history presents to clinic after 4 days of worsening fatigue, dyspnea on exertion, and palpitations. She initially attributed her symptoms to being “out of shape,” but she noticed this morning that her eyes looked yellowish. She is on no medications and has no family history of hematologic diseases. Her mother and sister both had Graves disease.

Laboratory studies reveal:

WBC count	10,400/mm <sup>3</sup>	(4000– 10,000)
Hematocrit	16%	(36–48)
MCV	101 fL	(80–95)
Platelets	242,000/mm <sup>3</sup>	(150,000– 450,000)
Coombs test		Positive

Peripheral blood smear reveals a predominance of microspherocytes and increased numbers of reticulocytes but is otherwise normal.

Appropriate management of this patient involves:

- A. Initiation of high-dose oral steroids with follow-up the next day for a recheck of her hematocrit
- B. Admission to the hospital for initiation of high-dose steroids
- C. Admission to the hospital for initiation of rituximab therapy
- D. Immediate blood transfusion and admission to the hospital for high-dose steroids
- E. Immediate blood transfusion and admission to the hospital for initiation of rituximab therapy

### Answers

1. C. This patient’s personal and family histories are consistent with the diagnosis of vWD, which is caused by defects in the activity of von Willebrand factor (vWF), a central mediator of hemostasis. The vWF protein is synthesized by megakaryocytes and endothelial cells as a dimeric protein that then multimerizes, resulting in the formation of very large vWF complexes that are highly prothrombotic. When released into the circulation, these long vWF multimers are cleaved by the ADAMTS13 (*a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13*)

metalloprotease into smaller, less prothrombotic polypeptides. These polypeptides bind to platelets and the subendothelium, serving as a tether between platelets and sites of endothelial damage during platelet plug formation. vWF also contributes to fibrin clot formation by binding to and stabilizing factor VIII, a critical coagulation factor that has a very short half-life in the circulation when not bound to vWF.

vWD, which is caused by mutations in the vWF gene, is the most common inherited disorder of hemostasis. There are three types of vWD:

- a. Type I is an autosomal dominant condition caused by mutations that impair the synthesis of vWF, resulting in a partial deficiency of the vWF protein. Bleeding is typically mild to moderate.
- b. Type II is a (usually) autosomal dominant condition caused by mutations that result in impaired function of vWF. Bleeding is typically moderate to severe.
  - Type IIA is caused by mutations that disrupt normal intracellular processing of vWF, resulting in a relative deficiency of high-molecular-weight and intermediate-molecular-weight vWF multimers.
  - Type IIB is caused by mutations that increase binding of vWF to platelets. vWF-platelet aggregates are cleared, resulting in low-circulating vWF levels and thrombocytopenia.
  - Type IIM is caused by mutations that decrease the affinity of vWF for platelets.
  - Type IIN is caused by mutations in vWF that decrease the affinity of vWF for factor VIII.
- c. Type III is an autosomal recessive condition caused by mutations that result in complete deficiency of the vWF protein. These patients typically have severe bleeding.

vWD can also be an acquired disorder. Mechanisms of acquired vWD include development of autoantibodies to vWF in autoimmune and lymphoproliferative disorders, impaired vWF synthesis in hypothyroidism, aberrant vWF proteolysis in DIC, and sequestration of vWF by binding to tumors cells.

The diagnosis of vWD, especially mild cases, can be difficult to make. The range of normal vWF levels is wide, and normal individuals who are blood type O have 25% to 30% lower vWF levels compared with type AB individuals. In addition, many factors can influence vWF levels in normal individuals. Hypothyroidism decreases and exogenous estrogen increases vWF synthesis. Also vWF and factor VIII are both acute-phase reactants, and their levels can vary widely during periods of physiologic stress including strenuous exercise, inflammatory conditions, and pregnancy. vWF levels increase throughout pregnancy and decline rapidly postpartum. This can result in bleeding several days after delivery in patients with vWD.

Testing for vWD involves assessing both vWF levels and vWF function (Table 20.1).

- The vWF antigen assay determines the amount of vWF protein present.
- The RCo assay tests the ability of vWF to agglutinate platelets, thereby assessing the integrity of the platelet-dependent activity of vWF.
- The ratio of vWF antigen to vWF activity (vWF:RCo) can distinguish the different types of vWD.
- vWF multimer analysis can help to differentiate the subtypes of type II vWD.
- The factor VIII antigen assay tests the integrity of the factor VIII-stabilizing function of vWF.
- The activated partial thromboplastin time (aPTT) will be prolonged in cases of vWD where factor VIII levels are significantly decreased.

In Question 1, the patient's family history is suggestive of an autosomally inherited bleeding disorder and, epidemiologically, vWD the most likely diagnosis. The PT and fibrinogen levels are normal in patients with vWD, and the PTT is only affected in cases where the defect in vWF function is severe. These are therefore not effective screening tests for vWD, and answer A is incorrect. Given that the patient's sister is affected, the diagnosis of hemophilia A or B, which are X-linked deficiencies in factors VIII and IX, respectively, is unlikely. Answer B

**TABLE 20.1** Von Willebrand Disease Assay

vWD Type	vWF Ag	RCo	vWF: RCo	FVIII	Large Multimers
I	Low	Low	Normal	Proportional to vWF Ag	Proportional
IIA	Low	Lower	Low	Proportional to vWF Ag	Very low
IIB	Low	Lower	Low/normal	Proportional to vWF Ag	Low
IIM	Low/normal	Lower	Low	Proportional to vWF Ag	Proportional
IIN	Normal	Normal	Normal	Disproportionately low	Normal
III	Undetectable	Undetectable	-	Very low	Undetectable

Ag, Antigen; FVIII, factor VIII; RCo, ristocetin cofactor; vWD, von Willebrand disease; vWF, von Willebrand factor.

is therefore incorrect. Because vWF levels increase during pregnancy, testing for vWD during pregnancy can give falsely normal results. Women with suspected vWD should therefore be tested before they become pregnant. Answer D is therefore incorrect.

(Ng C, Motto DG, Di Paola J. Diagnostic approach to von Willebrand disease. *Blood*. 2015;125:2029–2037.)

2. D. The overall incidence of venous thromboembolism (VTE), which manifests clinically as DVT and PE, is 1 in 10 cases per 100,000 per year (0.01%) in the general population. This incidence increases significantly in patients with risk factors for thrombosis. In most patients with VTE, one or more of Virchow's triad of thrombotic risk factors (venous stasis, endothelial injury, hypercoagulability) can be identified. Causes of venous stasis include prolonged immobilization, extended air travel, pregnancy, and obesity. Causes of vascular endothelial injury include trauma, surgery, IV drug use, vasculitis, and sickle cell anemia. Hypercoagulable states can be acquired or inherited. Acquired hypercoagulable states include pregnancy, oral contraceptive (OCP) use, hormone replacement therapy, nephrotic syndrome, malignancy, clonal hematologic disorders (including polycythemia vera, essential thrombocythemia, and paroxysmal nocturnal hemoglobinuria), HIT, inflammatory conditions, and antiphospholipid syndrome. Inherited hypercoagulable conditions can be caused by mutations in factor V, prothrombin, methyltetrahydrofolate reductase, protein C and S, fibrinogen, and antithrombin III.

This patient does not appear to have venous stasis or a recent vascular injury. Given that her VTE occurred soon after she started on OCP therapy, it is likely that OCPs contributed to her VTE. However, it is important to note that OCP use alone increases the risk of VTE only ~5-fold, and the incidence of VTE in OCP users without any other thrombotic risk factors is therefore only 0.05%. On the other hand, in patients with underlying hereditary thrombophilias, OCP use increases the risk of VTE ~35-fold, resulting in an incidence of VTE of 0.35%. It is therefore reasonable to speculate that this patient may have developed a VTE because she is taking OCPs and also has a previously undiagnosed inherited hypercoagulable condition.

The FVL mutation is the most common familial thrombophilia. FVL is present in 4.8% of Caucasians and in 0.05% of Africans and Asians. The frequency of FVL in patients age <50 years with a family history of thrombosis or a history of recurrent thrombotic events and no acquired risk factors for thrombosis except pregnancy or oral contraceptive use is 40%. FVL is the result of a missense mutation that changes the arginine at position 506 of factor V to glutamine, which prevents inactivation of factor V by activated protein C. This impairs termination of activation of the coagulation cascade by protein C.

The second most common familial thrombophilia is the prothrombin G20210A mutation, which is a mutation in the 3'-untranslated region of prothrombin that results in overproduction of prothrombin. This results in elevated levels of circulating prothrombin. The prothrombin G20210A mutation is present in 2.7% of Caucasians and 0.06% of Africans and Asians, and the frequency of the prothrombin gene mutation in patients age <50 years with a family history of thrombosis or a history of recurrent thrombotic events and no acquired risk factors for thrombosis except pregnancy or oral contraceptive use is 16%.

Less common familial thrombophilias include antithrombin III deficiency, protein C deficiency, and protein S deficiency, which have a combined frequency of 13% in patients age <50 years with a family history of thrombosis or a history of recurrent thrombotic events and no acquired risk factors for thrombosis except pregnancy or oral contraceptive use. Other very rare familial thrombophilias include homozygosity for the C677T mutation in the methylenetetrahydrofolate reductase gene that results in elevated levels of homocysteine and mutations in fibrinogen that result in dysfibrinogenemia.

(Cushman M. Epidemiology and risk factors for venous thrombosis. *Semin Hematol*. 2007;44:62–69; Varga EA, Kujovich JL. Management of inherited thrombophilia: guide for genetics professionals. *Clin Genet*. 2012;81:7–17; Trenor CC 3rd, Chung RJ, Michelson AD, et al. Hormonal contraception and thrombotic risk: a multidisciplinary approach. *Pediatrics*. 2011;127:347–357.)

3. D. The patient's history is highly suggestive of antiphospholipid syndrome (APLS). APLS is an acquired hypercoagulable state characterized by the presence of autoantibodies to phospholipid binding proteins and by recurrent thrombosis. The thrombotic complications of APLS include venous thrombosis (DVT, PE, portal vein thrombosis), arterial thrombosis (myocardial infarction, limb necrosis), and spontaneous pregnancy loss. APLS can occur in the context of systemic lupus erythematosus and can also occur in isolation.

The patient's prolonged PTT is an additional clue to her diagnosis of APLS. She was treated with low-molecular-weight heparin, which does not affect the PTT. Her prolonged PTT is therefore not caused by her therapeutic anticoagulation. Rather, it is caused by the presence of antiphospholipid antibodies in her blood. The PTT test requires phospholipid as a cofactor. The antiphospholipid antibodies in patients with APLS bind to the phospholipids and interfere with the in vitro aPTT reaction, resulting in prolongation of the activated PTT (aPTT) in some patients. Her PTT is prolonged because of the presence of an inhibitor and not a factor deficiency; therefore her PTT would not correct upon mixing with normal plasma. Additional

testing, including the lupus anticoagulant test and the dRVVT (dilute Russell viper venom time) test, as well as direct serologic testing for the presence of antiphospholipid antibodies (anticardiolipin and anti-beta-2-glycoprotein), would help to confirm the diagnosis.

In this patient, the diagnosis of HIT is not consistent with her presentation or with the time course of her mild thrombocytopenia. HIT is a highly prothrombotic state that presents 5 to 10 days after initiation of heparin therapy in patients who develop autoantibodies to PF4–heparin complexes. The patient was on heparin for only 1 day when her blood tests were done, which is insufficient time for her to have developed HIT antibodies, and her thrombosis preceded her heparin exposure, making the diagnosis of HIT-associated thrombosis (HITT) implausible. However, there is one important caveat to this diagnostic reasoning. Although HIT and HITT typically manifest while patients are hospitalized, patients can develop HITT after they have been discharged from the hospital. In such cases, a patient is exposed to heparin in the hospital, which triggers HIT, but the patient is discharged before she has developed significant thrombocytopenia, and the HIT therefore goes unrecognized. After discharge, the patient is no longer exposed to heparin and her platelet count recovers, but she remains profoundly prothrombotic. If she develops HITT and is readmitted to the hospital for anticoagulation, reexposure to heparin will cause a precipitous drop in her platelet count caused by the presence of preformed PF4 antibodies. The diagnosis of HITT should therefore be considered in any patient who is admitted to the hospital with thrombosis after a recent hospitalization. In the case of this patient, this scenario is unlikely. She was previously well, with no known history of recent hospitalizations or heparin exposure. Moreover, HITT would not explain her prolonged PTT. Answer A is therefore incorrect.

Peripheral blood flow cytometry for CD55 and CD59 is done to evaluate patients suspected of having paroxysmal nocturnal hemoglobinuria (PNH). PNH is an acquired clonal disorder of red cell membranes in which red cells lack surface expression of glycosylphosphatidylinositol (GPI)-anchored proteins, including proteins that protect red cells from complement-mediated lysis. Patients with PNH have recurrent episodes of intravascular hemolysis and, for unclear reasons, are predisposed to venous thrombosis, in particular Budd-Chiari syndrome (hepatic vein thrombosis). The patient's normal haptoglobin level argues against the presence of any significant intravascular hemolysis, and the diagnosis of PNH would not explain her prolonged PTT or her history of spontaneous pregnancy loss. Answer B is therefore incorrect.

Measurement of ADAMTS13 activity and serologic testing for autoantibodies to ADAMTS13 are done in patients with suspected TTP to confirm the

diagnosis. TTP is classically characterized by a pentad of signs and symptoms—fever, neurologic changes, renal insufficiency, microangiopathic hemolytic anemia, and thrombocytopenia. Patients with TTP typically present with severe thrombocytopenia and very elevated LDH levels. This patient's mild thrombocytopenia, mildly elevated LDH, and normal haptoglobin are not consistent with the extensive platelet destruction and intravascular hemolysis that are hallmarks of TTP. In addition, TTP typically causes microvascular, not macrovascular, thrombosis, and the diagnosis of TTP would not explain her prolonged PTT or her history of spontaneous pregnancy loss. Answer C is therefore incorrect.

(Negrini S, Pappalardo F, Murdaca G, et al. The antiphospholipid syndrome: from pathophysiology to treatment. *Clin Exp Med*. 2016. [Epub ahead of print]; Warkentin TE, Anderson JA. How I treat patients with a history of heparin-induced thrombocytopenia. *Blood*. 2016;128:348–359; Brodsky RA. Paroxysmal nocturnal hemoglobinuria. *Blood*. 2014;124:2804–2811; Crawley JT, Scully MA. Thrombotic thrombocytopenic purpura: basic pathophysiology and therapeutic strategies. *Hematology Am Soc Hematol Educ Program*. 2013;2013:292–299.)

4. D. This patient meets the clinical criteria for TTP. TTP is classically characterized by a pentad of signs and symptoms: fever, neurologic changes (headaches, visual changes, paresthesias, delirium, seizures), renal dysfunction (hypertension, acute renal failure, proteinuria, microscopic hematuria), microangiopathic hemolytic anemia, and thrombocytopenia. However, in the appropriate clinical context, only microangiopathic hemolytic anemia and thrombocytopenia are required to make the diagnosis. Patients can also present with symptoms of cardiac (chest pain, arrhythmias, heart failure) and gastrointestinal (nausea, vomiting, abdominal pain, diarrhea) ischemia. [Fig. 20.1](#) shows a typical blood smear with schistocytes.

• **Fig. 20.1** Schistocytes. (Courtesy Dr. Lindsley Coleman.)

Under normal physiologic conditions, endothelial cells secrete unusually large multimers of vWF, which are tethered to the endothelial cell surface. These large multimers are cleaved into smaller fragments by the vWF-cleaving metalloprotease ADAMTS13. Cleavage releases the small vWF fragments into the circulation, where they help mediate platelet aggregation and clotting. In TTP, the activity of ADAMTS13 is inhibited by the presence of autoantibodies to the metalloprotease. The lack of ADAMTS13 activity results in the accumulation of membrane-bound, unusually large vWF multimers. These large multimers inappropriately bind to and activate circulating platelets, resulting in situ microvascular thrombus formation and tissue ischemia. If left untreated, TTP can cause irreversible tissue damage, particularly to the central nervous system (encephalopathy, stroke) and the kidneys (chronic renal failure). Note that the thrombocytopenia in TTP is rarely severe ( $<10,000/\text{mm}^3$ ), and platelet transfusions can exacerbate TTP-associated thrombosis. Platelet transfusions are therefore absolutely contraindicated in patients with TTP, except in cases of life-threatening hemorrhage.

The primary treatment for TTP is plasmapheresis, which is thought to work both by removing anti-ADAMTS13 antibodies as well as by providing a large infusion of active ADAMTS13 enzyme. Ninety percent of cases of TTP improve with plasmapheresis, although about 30% of patients will subsequently relapse and require additional courses of plasmapheresis. About 10% of patients have refractory disease and require additional therapeutic interventions, which may include splenectomy, cytotoxic agents, and/or rituximab (anti-B-cell therapy).

There are several diagnostic tests for TTP. These include in vitro enzymatic assays to measure ADAMTS13 activity; ELISA assays to measure ADAMTS13 antigen levels; and serologic tests to detect the presence of anti-ADAMTS13 autoantibodies. However, these assays are not universally available and have a slow turn-around time, which limits their utility in the acute setting. Treatment of suspected TTP should never be delayed awaiting laboratory tests. These assays are primarily used to confirm the diagnosis of TTP and to help guide clinical decision-making in patients who fail to respond to plasmapheresis.

Without immediate treatment, the morbidity and mortality of TTP are very high, and therapy should be initiated before permanent tissue damage occurs. Answers B and C are therefore incorrect. Answer A incorrectly presumes that the patient has hemolytic uremic syndrome (HUS). HUS is another thrombotic microangiopathy that is characterized by renal failure, microangiopathic hemolytic anemia, and thrombocytopenia, but it is caused by a strain of *E. coli* (*E. coli* 0157) that produces shiga toxin, a toxin that interferes with ADAMTS13 activity. HUS is classically a

disease of childhood and is rare in adults, and it is a self-limited condition for which plasmapheresis is not required. The age of the patient and the fact that she did not present with an antecedent diarrheal illness make HUS unlikely. Given the high morbidity and mortality of TTP and the lack of a rapid diagnostic test to differentiate HUS from TTP, adult patients who present with microangiopathic hemolytic anemia and thrombocytopenia should be presumed to have TTP and should be treated accordingly.

Other causes of microangiopathic hemolytic anemia and thrombocytopenia that should be considered in the differential diagnosis of this patient include DIC, HELLP syndrome of pregnancy (hemolysis, elevated liver enzymes, and low platelets), systemic vasculitides, malignant hypertension, advanced cancer, and drug effects. The patient is not on any medications and does not appear ill, and these conditions are therefore all less likely than TTP.

5. B. ITP is an acquired disorder in which platelets are destroyed in the peripheral circulation by an autoimmune mechanism. ITP is characterized by isolated thrombocytopenia with otherwise normal blood counts, no other abnormalities on peripheral blood smear, and the absence of an identifiable alternative cause for the low platelet count. ITP is commonly associated with other autoimmune diseases and can also occur in the setting of HIV infection, although the majority of cases are idiopathic. Patients with ITP can also present with Evans syndrome, in which ITP and Coombs-positive autoimmune hemolytic anemia occur concomitantly. ITP is a diagnosis of exclusion; there are no laboratory tests that can reliably confirm or rule out the diagnosis of ITP. Although antiplatelet antibody levels can be measured, the antibodies are neither sensitive nor highly specific for the diagnosis of ITP and are therefore of limited clinical utility.

The differential diagnosis of thrombocytopenia in ITP includes TTP (although microangiopathic hemolytic anemia is not present in ITP), DIC (although patients with DIC are typically ill-appearing and have abnormalities of coagulation, which are not present in ITP), drug-associated thrombocytopenia (commonly implicated drugs include alcohol, anticonvulsants, sulfonamides, quinine, penicillins), HIT, acute viral infections (HIV, Epstein-Barr virus, cytomegalovirus [CMV], hepatitis), hypersplenism, and primary bone

marrow disorders (although other hematologic abnormalities are typically present).

The choice of first-line treatment for ITP depends primarily on the presence or absence of active bleeding. In ITP, megakaryocytes respond to thrombocytopenia by producing larger-than-normal platelets that have enhanced function, and spontaneous bleeding is therefore rare at platelet counts above 10,000/mm<sup>3</sup>. However, when thrombocytopenia is very severe (platelet counts <10,000/mm<sup>3</sup>) and/or when patients with ITP are taking medications that interfere with platelet function (aspirin, nonsteroidal antiinflammatory drugs, clopidogrel), they can be at risk for spontaneous and even life-threatening bleeding. In patients who are not bleeding, ITP can be treated with dexamethasone, 40 mg by mouth for 4 days, or with prednisone, 1 mg/kg followed by a slow taper. Splenectomy, IV immunoglobulin (IVIG), Rh<sub>0</sub>(D) immune globulin, cytotoxic agents (cyclophosphamide, vincristine), rituximab, and thrombopoietin receptor agonists (eltrombopag and romiplostim) are reserved for second-line treatment of refractory ITP. In patients who are actively bleeding, IVIG in combination with steroids is a highly effective first-line treatment, although IVIG is contraindicated in patients with renal insufficiency. Rh<sub>0</sub>(D) immune globulin can also be used to treat severe ITP exacerbations in Rh+ patients, but, because Rh<sub>0</sub>(D) immune globulin binds the Rh+ red blood cells, it can precipitate an autoimmune hemolytic episode and is therefore contraindicated in Rh+ ITP patients with anemia. Platelet transfusions are typically not effective at raising the platelet count of patients with ITP and should be reserved for cases of life-threatening hemorrhage.

HIV-associated ITP is a clinical syndrome that deserves special mention because the pathophysiology and management of HIV-associated ITP are somewhat different than idiopathic ITP. HIV-associated ITP is the result of two processes: (1) direct infection of megakaryocytes by HIV, which suppresses platelet production, and (2) molecular mimicry between HIV envelope glycoproteins and platelet membrane glycoproteins (GPIIb/IIIa), which causes anti-HIV antibodies to cross-react with platelets and inappropriately clear them from the circulation. Because glucocorticoids can precipitate and/or exacerbate HIV-associated opportunistic infections (including oral candidiasis, herpes simplex virus and CMV reactivation, *Pneumocystis carinii* pneumonia, and tuberculosis), they should be used sparingly in patients with HIV-associated ITP, and IVIG is the mainstay of treatment in these patients. It should also be noted that HIV-associated ITP frequently responds to antiretroviral therapy, and suppression of HIV viral replication has been found to induce long-term remissions in many patients with HIV-associated ITP.

In children, ITP is typically triggered by viral infections and is an acute, self-limited process. However, in

adults, ITP tends to be persistent and recurrent and rarely resolves spontaneously. Without treatment, patients can be at risk for severe, even life-threatening bleeding. Answer A is therefore incorrect. Because this patient has not failed primary therapy with steroids and is not actively bleeding, answers C and D are also incorrect.

(Kistangari G, McCrae KR. Immune thrombocytopenia. *Hematol Oncology Clin North Am.* 2013;27:495–520; Passos AM, Treitinger A, Spada C. An overview of the mechanisms of HIV-related thrombocytopenia. *Acta Haematol.* 2010;124:13–18.)

6. D. This patient meets the clinical criteria for HIT. HIT is characterized clinically by the development of thrombocytopenia in patients on heparin, and the diagnosis should be considered in any patient whose platelet count drops by ≥50% within 5 to 10 days of initiation of heparin. HIT occurs in 1% to 10% of patients exposed to unfractionated heparin and in 0.1% to 0.5% of patients exposed to low-molecular-weight heparin. The incidence of HIT is highest in surgical patients undergoing cardiac and orthopedic procedures and lowest in obstetric patients.

HIT is an immune-mediated disorder in which autoantibodies develop to complexes of heparin and PF4, a factor secreted by activated platelets. The antibodies bind to the heparin-PF4 complexes and bind to the Fc receptors on the surface of platelets, which causes activation of the platelets and uncontrolled release by the platelets of procoagulant platelet microparticles. The activated platelets are cleared from the circulation by the spleen, resulting in thrombocytopenia, and the released procoagulant platelet microparticles bind to sites of endothelial injury and initiate uncontrolled thrombosis. It should be noted that, because HIT-associated thrombosis is driven by inappropriate activation of platelets, platelet transfusions can exacerbate the thrombosis. Platelet transfusions are therefore absolutely contraindicated in patients with HIT, except in cases of life-threatening hemorrhage. The morbidity and mortality associated with HIT are not consequences of thrombocytopenia, which is rarely severe, but from arterial and venous thrombosis, which occur in as many as 50% of patients with HIT. Common thrombotic complications of HIT include DVT/PE, cerebral vein thrombosis, lower-limb ischemia and limb loss, stroke, and myocardial infarction. Untreated HIT has a mortality of 20% to 30%.

There are two diagnostic tests for HIT. The immunoassay that detects the presence of antibodies to the heparin-PF4 complex is highly sensitive but only moderately specific, whereas the platelet activation assay that detects the presence of heparin-PF4 antibodies that can bind to platelets and cause platelet degranulation is both highly sensitive and highly specific. However, HIT remains a clinical diagnosis, and, given the high morbidity and mortality of HIT, appropriate management of patients suspected of having HIT

should never await results of laboratory tests. Answer A is therefore incorrect.

Management of suspected HIT consists of immediate cessation of all heparin products and immediate initiation of alternative anticoagulants. The only anticoagulants that are currently US Food and Drug Administration (FDA)–approved for the treatment of HIT are the direct thrombin inhibitors argatroban and bivalirudin, which are both intravenous. The currently available oral nonwarfarin anticoagulants, which include the direct thrombin inhibitor dabigatran and the anti-Xa inhibitors rivaroxaban and apixaban, have not been studied in patients with HIT and are not FDA approved for the treatment of HIT or HITT. Note that simple cessation of heparin is not adequate intervention in patients suspected of having HIT because patients with HIT continue to be significantly hypercoagulable after discontinuation of heparin and are at continued risk for catastrophic thrombosis; and although low-molecular-weight heparin has a lower incidence of causing HIT than unfractionated heparin, it is absolutely contraindicated in patients with HIT. Answer B is therefore incorrect. Anticoagulation with warfarin should not be started in patients with HIT until they are fully anticoagulated with a direct thrombin inhibitor and their platelet count has recovered. Premature initiation of anticoagulation with warfarin can result in the development of venous gangrene. Answer C is therefore incorrect.

(Warkentin T, Anderson JA. How I treat patients with a history of heparin-induced thrombocytopenia. *Blood*. 2016;128:348–359; Warkentin TE. Think of HIT. *Hematology Am Soc Hematol Educ Program*. 2006;2006:408–414.)

7. D. The patient's clinical presentation is consistent with DIC, likely secondary to acute mesenteric ischemia. DIC is a condition in which uncontrolled activation of the coagulation cascade in response to severe physiologic stress results in intravascular fibrin deposition and microvascular thrombosis, as well as consumption of platelets and clotting factors. DIC can occur in a number of different clinical settings in which large amounts of tissue factor are released into the circulation, including sepsis, obstetric complications, malignancy, and trauma. Patients with DIC typically have prolonged clotting times (PT and PTT), inappropriately low/normal fibrinogen levels (fibrinogen, as an acute phase reactant, should be elevated in acute illness), and elevated D-dimer levels. Clinically, patients with DIC present with varying degrees of intravascular hemolysis, bleeding, tissue ischemia and end-organ damage, including renal failure, hepatic dysfunction, acute respiratory distress syndrome, stroke, and shock. Treatment of DIC is supportive and involves maintaining organ perfusion and, in patients who are bleeding, transfusing blood products (red blood cells, platelets, fresh

frozen plasma, cryoprecipitate) until the underlying cause of the DIC can be treated and reversed.

The morbidity and mortality of DIC are high, and resolution of DIC requires treatment of the underlying condition. It is therefore important to distinguish DIC from other thrombotic microangiopathies and from other causes of coagulopathy and thrombocytopenia that might need different specific treatments. The principal conditions from which DIC must be distinguished are TTP and the coagulopathy of liver failure. In differentiating DIC from TTP remember that, although DIC results from the dysregulated activation and depletion of both platelets and clotting factors, TTP results from the inappropriate activation of platelets by uncleaved vWF without perturbation of the coagulation cascade. Clotting times as well as fibrinogen and D-dimer levels are therefore normal in TTP. In addition, TTP is a primary autoimmune disorder that typically occurs in patients who are otherwise well, whereas DIC occurs as a consequence of severe underlying physiologic stress, and patients are typically ill. Differentiating DIC from severe liver failure can be difficult and frequently relies on patient history and patient presentation. Liver failure, similar to DIC, is frequently associated with thrombocytopenia, caused in the case of liver failure by portal hypertension, splenomegaly, and splenic sequestration of platelets. Also because the liver synthesizes most of the coagulation factors, patients with severe liver disease frequently have elevated clotting times. Modest elevations in D-dimer levels are also frequently seen in patients with liver cirrhosis because D-dimer products are cleared by the liver, and clearance is impaired in the setting of liver failure. Of note, although the liver does synthesize fibrinogen, fibrinogen levels are typically maintained within the normal range in patients with liver disease until their liver failure becomes extremely severe, and a low fibrinogen level should therefore raise the suspicion for DIC even in patients with hepatic synthetic dysfunction.

In Question 7, although it is not clear from the patient's history whether he might be taking medications that are associated with HIT, a drug effect would not explain his overall presentation. Similarly, the diagnosis of ITP would not explain most of his laboratory findings or the severity of his presentation. Answers A and B are therefore incorrect. And although fever, acute renal failure, mental status changes, peripheral blood schistocytosis, and thrombocytopenia are all features of TTP, the diagnosis of TTP would not explain his abnormal coagulation studies, and the patient is too acutely ill for TTP to be the underlying cause of his presentation. Answer C is therefore incorrect. The patient does have elevated liver enzymes, but this is likely because of hepatic hypoperfusion, and there is nothing in his history to suggest that he has

underlying liver cirrhosis, portal hypertension, or splenomegaly. Answer E is therefore incorrect.

(Toh CH, Alhamdi Y. Current consideration and management of disseminated intravascular coagulation. *Hematology Am Soc Hematol Educ Program*. 2013;2013:286–291; Crawley JT, Scully MA. Thrombotic thrombocytopenic purpura: basic pathophysiology and therapeutic strategies. *Hematology Am Soc Hematol Educ Program*. 2013;2013:292–299.)

8. D. Even in people who have no apparent medical problems, the majority of cases of thrombocytosis are reactive, insofar as the elevated platelet count is secondary to an underlying medical condition. Common causes of reactive thrombocytosis include iron deficiency, acute and chronic infections, inflammatory conditions, allergic reactions, occult malignancies, hyposplenism, recent trauma or surgery, and count recovery after episodes of thrombocytopenia (such as postchemotherapy, postvitamin B<sub>12</sub>/folate repletion, and postalcohol cessation). Reactive thrombocytosis is rarely, even at very elevated platelet counts, associated with thrombosis or bleeding, and appropriate therapy for reactive thrombocytosis consists of treating the underlying medical condition, not the platelet count.

The initial workup of an elevated platelet count should include a careful patient history, measurement of iron saturation levels to rule out iron deficiency (which is very common in premenopausal women), and measurement of markers of inflammation such as the erythrocyte sedimentation rate and ferritin and C-reactive protein levels. In patients whose elevated platelet counts are sustained and who have none of the aforementioned medical conditions, a workup for primary causes of thrombocytosis is indicated. Causes of autonomous platelet production include the chronic myeloproliferative disorders (chronic myelogenous leukemia, polycythemia vera, essential thrombocythemia, and idiopathic myelofibrosis), the 5q–myelodysplastic syndrome, and hereditary thrombocythemia (which are caused by activating mutations in thrombopoietin and the thrombopoietin receptor). Many of these thrombocythemias are associated with increased risk of thrombotic complications, including DVT/PEs and the Budd-Chiari syndrome, and varying degrees of risk of progression to acute leukemia.

Essential thrombocythemia (ET) is one of the Philadelphia chromosome-negative chronic myeloproliferative disorders. It is characterized by a sustained elevated platelet count in the absence of evidence of reactive thrombocytosis or other causes of primary thrombocytosis. Although there is no single diagnostic laboratory test for ET, the majority of ET patients harbor activating mutations in one of three genes: *JAK2* (40%–60%), *calreticulin* (10%–25%), or *MPL* (~5%). However, activating mutations in *JAK2* (*JAK2*V617F and *JAK2* exon 12

mutations) are also present in over 90% of patients with polycythemia vera and in 40% to 60% of patients with idiopathic myelofibrosis, and *calreticulin*, and *MPL* mutations are also found in 30% to 35% and 5% to 10%, respectively, of patients with idiopathic myelofibrosis. None of these mutations are therefore diagnostic of ET. ET is associated with a low risk of thrombosis and bleeding and a very low risk of progression to marrow failure or acute leukemia, and the median survival of patients with ET approaches that of normal subjects. Many patients with ET do not require treatment, although elderly patients and patients who have risk factors for vascular disease are typically treated with low-dose aspirin even if they are asymptomatic. Indications for treatment with platelet-lowering agents include a platelet count >1,500,000/mm<sup>3</sup>; symptoms of vasomotor instability (headaches, flushing); bleeding, arterial, venous and/or microvascular thrombosis; and recurrent fetal loss. The most commonly used platelet-lowering agent in ET is hydroxyurea, which effectively lowers the platelet count and the risk of thrombosis in the majority of ET patients. The principal dose-limiting toxicity of hydroxyurea is leukopenia, and anagrelide is frequently used to treat symptomatic patients who cannot tolerate hydroxyurea.

In Question 8, until reactive thrombocytosis is ruled out, the initiation of any antiplatelet therapy would be premature. Answers A and C are therefore incorrect. The thrombosis in ET and the other primary thrombocythemias are platelet mediated, and warfarin, which targets the coagulation cascade, is therefore not an effective drug to decrease the risk of ET-associated thrombosis. Answer B is therefore incorrect. Finally, given the lack of a clear etiology for the patient's thrombocytosis, any discussion of her risk of developing leukemia would be premature. Answer E is therefore incorrect.

(Harrison CN, Bareford D, Butt N, et al. Guideline for investigation and management of adults and children presenting with a thrombocytosis. *Br J Haematol*. 2010;149:352–375; Klampfl T, Gisslinger H, Harutyunyan AS, et al. Somatic mutations of *calreticulin* in myeloproliferative neoplasms. *N Engl J Med*. 2013;369:2379–2390.)

9. A. This patient has G6PD deficiency. G6PD deficiency is an X-linked enzymatic disorder of red blood cells that results in a decreased ability of red blood cells to generate nicotinamide adenine dinucleotide phosphate (NADPH), a metabolic intermediate essential for the conversion of oxidized intracellular proteins to their reduced forms. When G6PD-deficient red blood cells are exposed to oxidative stress, the hemoglobin in the cells denatures and precipitates resulting in the formation of Heinz bodies (Fig. 20.2) that can be detected on peripheral blood smear. The oxidized

• **Fig. 20.2** Heinz bodies. (Courtesy Dr. Lindsley Coleman.)

red blood cells become rigid and nondeformable and are destroyed by the reticuloendothelial system of the liver, spleen, and bone marrow.

There are over 100 mutations associated with G6PD deficiency, but the two most common mutations are the A-variant, which is present in 10% of African Americans, and the Mediterranean variant, which is present in 5% of people of Mediterranean descent. The A-variant has normal enzymatic activity but is unstable and has a shorter half-life than the wild-type enzyme. When A-variant red blood cells are exposed to oxidative stress, only the older cells have insufficient G6PD and hemolyze, whereas reticulocytes and newly generated mature red blood cells survive. The A-variant is therefore generally associated with a mild, self-limited hemolysis. The Mediterranean variant is a mutation that results in very low baseline G6PD enzymatic activity and is associated with more severe hemolysis.

There are several diagnostic tests that quantify, with varying degrees of sensitivity, the level of G6PD activity in red blood cells. These include the dye decolorization test, the rapid fluorescence screening test, the G6PD-tetrazolium cytochemical test, and spectrophotometric tests that determine the rate of NADPH production by red blood cells. The ability of any of these tests to diagnose A-variant G6PD deficiency during or immediately after an acute hemolytic episode is limited by the fact that older G6PD-deficient red blood cells are preferentially hemolyzed, whereas younger cells that have near-normal levels of G6PD activity survive. These diagnostic tests should therefore be performed in patients with suspected A-variant G6PD deficiency only after they have recovered from their hemolytic episode, when their hematocrit and reticulocyte count have normalized. The red blood cells of patients with the Mediterranean variant of G6PD, on the other hand, will have abnormal G6PD activity throughout their

life span and will test positive even during an acute hemolytic episode.

Common oxidative stresses that have been associated with hemolytic crises in patients with G6PD deficiency include the following:

Antibacterial	Antima- larials	Misc. Agents/ Foods	Misc. Drugs
Dapsone	Primaquine	Fava beans	Doxorubicin
Nalidixic acid	Pamaquine	Naphthalene (mothballs)	Methylene blue
Nitrofurantoin		Toluene	Pyridium
Sulfamethox- azole			Phenylhy- drazine
Sulfapyridine			Probenecid

This patient likely has the A-variant of G6PD deficiency given his ethnicity. Sending a diagnostic test while he is still recovering from his acute hemolytic episode is likely to give a false-negative result. Answer B is therefore incorrect. Answers C and D refer to the fact that the patient's red blood cell MCV is slightly elevated, which can be seen with folate and vitamin B<sub>12</sub> deficiency and with chronic alcohol use—all causes of chronic anemia. However, the clinical scenario suggests none of these conditions. The patient's elevated MCV more likely reflects the fact that his bone marrow is responding to the acute drop in his hematocrit by producing increased numbers of reticulocytes, which have an MCV of 100 to 120.

(Luzzatto L, Seneca E. G6PD deficiency: a classic example of pharmacogenetics with on-going clinical implications. *Br J Haematol.* 2014;164:469–480; Howes RE, Battle KE, Satyagraha AW, et al. G6PD deficiency: global distribution, genetic variants and primaquine therapy. *Adv Parasitol.* 2013;81:133–201.)

10. C. This patient has a microcytic anemia in the presence of normal iron stores, which is highly suggestive of thalassemia. The thalassemias are a group of inherited disorders of hemoglobin production that are prevalent in people of Mediterranean, Asian, Middle Eastern, and Latin American descent. The thalassemias are caused by mutations in the regulatory elements of the globin genes resulting in decreased synthesis of either the alpha or the beta chain of hemoglobin. Microcytic anemia results from both a lack of normal  $\alpha_2\beta_2$  hemoglobin complexes as well as from precipitation of the excess unaffected subunit, which targets red blood cells for clearance by the reticuloendothelial system of the liver and spleen. The thalassemias are diagnosed by hemoglobin electrophoresis, which determines the relative abundance of the different hemoglobin complexes.  $\beta$ -thalassemia can be distinguished from  $\alpha$ -thalassemia by the presence of increased levels of hemoglobin A<sub>2</sub> ( $\alpha_2\delta_2$ ) in  $\beta$ -thalassemia.

In patients with suspected iron deficiency correctly interpret the results of iron studies before starting patients on iron replacement therapy. In patients who are otherwise well, the diagnosis of iron deficiency can be confidently made when the transferrin saturation (iron:TIBC ratio) is <15%. A ferritin level of <20 ng/dL confirms the diagnosis of iron deficiency. However, in patients who are chronically ill, especially those with chronic inflammatory conditions, serum iron levels can be low in the absence of iron deficiency. In such patients both serum iron and TIBC levels are proportionally decreased, and the transferrin saturation is therefore typically normal or near normal. Ferritin is an acute-phase reactant, and in inflammatory states the ferritin level may rise as high as 200 ng/dL in the presence of iron deficiency. Ferritin levels are therefore not an accurate measure of iron stores in patients with chronic inflammatory conditions. However, a ferritin level of <50 ng/dL in a patient with a chronic inflammatory condition is highly suggestive of iron deficiency.

If and when the diagnosis of iron deficiency is confirmed, investigate why the patient has low iron stores. Iron deficiency in men and in women who are not menstruating is usually indicative of an underlying medical condition. There are no physiologic mechanisms other than bleeding that remove significant amounts of iron from the circulation, and a diagnosis of iron deficiency should therefore prompt a workup for impaired iron absorption and for occult blood loss. Impaired iron absorption most commonly occurs in the setting of celiac disease and atrophic gastritis. Patients with impaired iron absorption, when given a therapeutic trial of oral iron, are unable to absorb the iron, and their iron levels do not increase. Such patients require IV iron replacement therapy. In patients with iron deficiency caused by occult blood loss, however, iron levels typically do increase after oral iron administration.

Occult blood loss most commonly occurs via the gastrointestinal (GI) tract and can be the presenting sign of an occult GI malignancy or occult inflammatory bowel disease.

This patient's presentation is consistent with thalassemia. Because her anemia is caused by inefficient red cell production, she would be unable to respond to erythropoietin by increasing her red cell production. Answer B is therefore incorrect. Her iron stores are not low, and continued iron replacement therapy would eventually result in her developing iron overload, especially if she were to stop menstruating. Answer D is therefore incorrect. Although her iron levels are somewhat high, she is not presently iron overloaded. Iron overload is associated with an iron:TIBC ratio of over 50%. Discontinuing her iron replacement therapy may be sufficient to prevent her from developing iron overload. Phlebotomy is not an appropriate approach

• **Fig. 20.3** Hypersegmented neutrophil. (Courtesy Dr. Franklin Bunn.)

to removing excessive iron in patients with abnormal hematopoiesis and who are anemic at baseline. Answer A is therefore incorrect.

(Martin A, Thompson AA. Thalassemias. *Pediatr Clin North Am.* 2013;60:1383–1391; Fraenkel PG. Anemia of inflammation: a review. *Med Clin North Am.* 2017;101:285–296.)

11. B. This patient presents with megaloblastic anemia caused by severe vitamin B<sub>12</sub> deficiency. Vitamin B<sub>12</sub> (cobalamin) and folate are two nutrients that are essential cofactors in DNA synthesis. They are required for conversion of deoxyuridylate to thymidylate, and nutritional deficiency in either cofactor causes nuclear maturation arrest, nuclear–cytoplasmic asynchrony, and impaired cell division. Cobalamin and folate deficiencies primarily impact rapidly dividing tissues, most notably the hematopoietic system and the gastrointestinal tract. The hematologic manifestations of cobalamin and folate deficiency include macrocytic anemia, hypersegmented (5+ lobes) neutrophils (Fig. 20.3) and, in severe cases, pancytopenia. Intestinal involvement results in glossitis and megaloblastic changes to the gut epithelium. In addition to its role in DNA synthesis, cobalamin (but not folate) plays a role in maintenance of neuronal myelination. Cobalamin deficiency can cause a myriad of neurologic problems including peripheral neuropathy, ataxia, personality changes, memory loss, and in severe cases dementia.

Consider the possible presence of cobalamin and folate deficiency even in patients without overt macrocytic anemia. A normal hematocrit and MCV do not exclude the presence of clinically significant vitamin deficiencies. In patients with concurrent microcytic anemia caused by, for example, iron deficiency, the macrocytosis of cobalamin and folate deficiency can be masked, and patients with cobalamin deficiency can develop neurologic complications before the development of anemia. Diagnosing cobalamin and folate deficiency is further complicated by the fact that blood cobalamin and folate levels have to be interpreted

carefully. Folate levels fluctuate significantly and do not necessarily accurately reflect total body folate levels, and what constitutes a “normal” cobalamin level is not clearly defined. Cobalamin levels <200 pg/mL are clearly low, and levels >300 pg/mL are unlikely to be associated with deficiency, but borderline levels between 200 and 300 pg/mL can be associated with clinically significant deficiency in some patients and not others.

In patients with borderline vitamin B<sub>12</sub> levels and patients suspected of having folate deficiency but who have normal serum folate levels, measurement of methylmalonic acid (MMA) and homocysteine levels can be diagnostically helpful. Vitamin B<sub>12</sub> deficiency results in high levels of both MMA and homocysteine, whereas folate deficiency results in high levels of homocysteine alone. Although MMA and homocysteine are very sensitive tests for folate and cobalamin deficiency, they are not 100% specific. Elevated homocysteine levels are present in familial hyperhomocysteinemia, and elevated levels of MMA are present in methylmalonic aciduria, hypovolemia, and renal failure.

The principal causes of folate and vitamin B<sub>12</sub> deficiencies differ. The body does not store folate to any significant degree, and inadequate dietary intake is the most common cause of folate deficiency, which can develop quickly in malnourished patients, particularly in people with poor dietary intake associated with alcoholism. Other causes of folate deficiency include gut malabsorption syndromes (celiac sprue, inflammatory bowel disease) and conditions associated with increased folate requirements, including hematologic recovery from severe anemia, growth spurts during infancy and adolescence, pregnancy, lactation, and exfoliative skin diseases. Certain drugs can also interfere with folate metabolism, most notably methotrexate, phenytoin, and nitrous oxide. Vitamin B<sub>12</sub>, on the other hand, is extensively stored by the liver, and vitamin B<sub>12</sub> deficiency takes years to develop. Vitamin B<sub>12</sub> deficiency caused by inadequate dietary intake is uncommon except in strict vegans and in patients who are severely malnourished for prolonged periods of time. The most common cause of vitamin B<sub>12</sub> deficiency is malabsorption. B<sub>12</sub>-containing proteins must be adequately cleaved in the acidic environment of the stomach. B<sub>12</sub> must then bind to intrinsic factor (IF), a protein released by the parietal cells of the gastric mucosa, and then the IF-B<sub>12</sub> complexes must be taken up by IF-receptor-expressing cells in the ileum. Perturbation of any step in cobalamin absorption can result in deficiency. Gastrectomy, atrophic gastritis, pancreatic insufficiency, and chronic use of proton-pump inhibitors can inhibit the release of cobalamin from foods. Pernicious anemia, the autoimmune destruction of gastric parietal cells, results in a lack of intrinsic factor, and Crohn disease, celiac sprue, ileitis, blind loop syndrome, and ileal resection can all

interfere with the uptake of IF-B<sub>12</sub> complexes by the small intestine. In addition, bacterial overgrowth and infection with fish tapeworms can result in depletion of nutritional cobalamin.

Vitamin B<sub>12</sub> and folate deficiency are treated by supplementation of dietary intake. Daily oral folate supplementation is generally sufficient to correct folate deficiency. Vitamin B<sub>12</sub> supplementation can be administered orally or by intramuscular injection. Even patients with impaired vitamin B<sub>12</sub> absorption will generally respond to high-dose oral vitamin B<sub>12</sub> because, in addition to specific intrinsic factor-mediated vitamin B<sub>12</sub> uptake, high levels of vitamin B<sub>12</sub> in the diet can also be absorbed by mass action.

This patient has a history of obesity, and, although diabetes could cause a peripheral neuropathy, diabetes would not explain his macrocytic anemia. Answer A is therefore incorrect. Whereas dramatic weight loss often prompts evaluation for occult malignancy, his weight loss occurred after gastric bypass surgery and is likely not pathologic. He should undergo age-appropriate routine cancer screening, but this is not a priority in light of his more urgent neurologic issues. Answer D is therefore incorrect. Based on his history and presenting symptoms, the patient's macrocytic anemia and neurologic complaints are most likely caused by vitamin B<sub>12</sub> deficiency. Although empiric treatment with folate may improve the macrocytic anemia somewhat, it will not ameliorate the neurologic symptoms. Moreover, several studies have found that high serum folate levels are associated with adverse neurologic outcomes in elderly patients with vitamin B<sub>12</sub> deficiency. It is not clear whether high folate levels are deleterious because they mask and delay the diagnosis of vitamin B<sub>12</sub> deficiency or whether a relative excess of folate actually exacerbates the neurologic impairment of vitamin B<sub>12</sub> deficiency. Regardless, in patients with vitamin B<sub>12</sub> deficiency, folate supplementation should only be initiated when folate levels are low or borderline, in combination with vitamin B<sub>12</sub> supplementation. Answer C is therefore incorrect.

(Stabler SP. Clinical practice. Vitamin B12 deficiency. *N Engl J Med*. 2013;368:149–160; Morris MS, Jacques PF, Rosenberg IH, et al. Folate and vitamin B-12 status in relation to anemia, macrocytosis, and cognitive impairment in older Americans in the age of folic acid fortification. *Am J Clin Nutr*. 2007;85:193–200.)

12. B. This patient has a normocytic anemia caused by his chronic kidney disease. Erythropoietin is primarily produced by the kidneys, in response to anemia and tissue hypoxia. The most common cause of erythropoietin deficiency is kidney failure. When renal function declines, there is a concomitant decrease in erythropoietin production. Patients with DM and even modestly abnormal renal function can be erythropoietin deficient and anemic.

The other common cause of normocytic anemia is chronic inflammation, which is characterized by underproduction of red blood cells (low reticulocyte count) and low-circulating levels of iron (low serum iron) despite the presence of high iron stores (high ferritin levels). Causes of chronic inflammation associated with anemia of chronic disease include connective tissue disorders (lupus, rheumatoid arthritis, inflammatory bowel diseases), chronic infections (osteomyelitis, tuberculosis, HIV, hepatitis), and metabolic disorders (uremia, cirrhosis, hypothyroidism). The cause of the anemia in chronic inflammatory states is not entirely clear, but it does appear to be mediated at least in part by hepcidin, a small polypeptide produced by the liver in response to cytokine (particularly interleukin-6) release. Hepcidin binds to and inhibits the activity of ferroportin, an iron-transport protein on macrophages, thereby inhibiting the release of iron from body iron stores. Lack of available iron inhibits erythropoiesis in the bone marrow.

Other less common causes of normocytic anemia include acute and chronic hemolytic anemias, including autoimmune hemolytic anemia, microangiopathic hemolytic anemias, sickle cell anemia, hereditary spherocytosis, G6PD deficiency, and drug-induced hemolysis; primary bone marrow failure syndromes, including aplastic anemia; and myelophthasic anemias, which are characterized by the presence of abnormally shaped red blood cells and nucleated red blood cells in the peripheral blood caused by replacement of the bone marrow by fibrosis and foreign cells. The cells can be malignant (leukemia, lymphoma, solid tumors) or reactive (sarcoidosis, tuberculosis, myelofibrosis).

Although many medications, including furosemide, can cause bone marrow suppression, the patient's anemia has been developing over several years, and he was only recently started on furosemide. Answer A is therefore incorrect. And although the concomitant presence of a microcytic and a macrocytic anemia can result in an apparent normocytic anemia with a normal mean corpuscular hemoglobin concentration (MCV), this patient has a normal RDW, which reflects the fact that his red blood cells are uniform in size. Answer C is therefore incorrect. Finally, the patient's relatively unremarkable peripheral blood smear strongly argues against marrow replacement as the etiology of his anemia. Answer D is therefore incorrect.

(Fraenkel PG. Anemia of inflammation: a review. *Med Clin North Am.* 2017;101:285–296; Ganz T. Hepcidin and iron regulation, 10 years later. *Blood.* 2011;117:4425–4433.)

13. D. This patient is presenting with evolving acute chest syndrome (ACS), a potentially fatal complication of SCD. ACS is characterized by the presence of fever, hypoxia, and new pulmonary infiltrates, although all three of these findings are not always apparent at the time of presentation. Distinguishing ACS from simple

pneumonia can be difficult. Although patients with ACS do not always have a bacterial pneumonia, the syndrome is often associated with infection with atypical organisms such as *Chlamydia* or *Mycoplasma*, and patients with suspected ACS should, in addition to oxygen, IV fluids, and pain medications, receive antibiotics. Patients with ACS and other life-threatening sickle cell crises also frequently require simple or exchange blood transfusions. The decision of whether to administer simple transfusions or to do an exchange transfusion in patients with SCD can be difficult. Frequent simple transfusions can result in iron overload and secondary hemochromatosis. In addition, increasing the hematocrit and blood viscosity of patients with SCD in crisis, all of whom have some degree of underlying microvascular disease, can worsen a pain crisis and precipitate strokes. Exchange transfusions, on the other hand, result in less iron overload and do not cause hyperviscosity; however, exposure of SCD patients to multiple units of blood and large numbers of alloantigens increases the risk of alloimmunization, which can complicate the management of future crises. The question of what type of transfusion to administer to patients with life-threatening sickle cell crises is frequently guided by the patient's hematocrit. Patients with a hematocrit of  $\leq 15\%$ , and patients whose hematocrit has dropped by  $>6\%$  from their baseline, are typically treated with simple transfusions to bring their hematocrit back to their baseline. Patients with less profound drops in their hematocrit are typically treated with exchange transfusions to prevent their hematocrit and blood viscosity from increasing to dangerous levels posttransfusion. In this case, the patient's hematocrit on presentation is at his baseline. Given his history of decreased oral intake for 2 days, it is likely that his preserved hematocrit is caused, at least in part, by hemoconcentration from dehydration, and his hematocrit will likely drop somewhat after he has received IV fluids. However, unless he becomes profoundly anemic after hydration, he will likely be managed with an exchange transfusion rather than a simple transfusion.

Keep in mind that the severity of a sickle cell crisis does not correlate with the patient's degree of acute-on-chronic anemia. ACS, strokes, bone marrow infarcts and other potentially life-threatening complications of SCD can occur in the absence of significant hemolysis, and a relatively normal (for the patient) hematocrit should never be used as evidence that the patient is not experiencing a severe complication of his SCD.

This patient is presenting with fever, hypoxia, and a new pulmonary infiltrate. Given that he is having a complicated sickle cell crisis, outpatient management and management of only his pain would be inappropriate. Answers A and B are therefore incorrect. And although hydroxyurea can be very effective in preventing future crises, it takes weeks to months to have an effect and does not have any role in the acute management of sickle crises. Answer C is therefore incorrect.

(Novelli EM, Gladwin MT. Crises in sickle cell disease. *Chest*. 2016;149:1082–1093; Kassim AA, Galadanci NA, Pruthi S, et al. How I treat and manage strokes in sickle cell disease. *Blood*. 2015;125:3401–3410.)

14. D. This patient is presenting with severe autoimmune hemolytic anemia (AIHA). In AIHA, patients develop autoantibodies to antigens on the surface of their own red blood cells. These antibody-coated red blood cells are recognized by the reticuloendothelial system of the liver and spleen and are phagocytosed by macrophages. Incomplete phagocytosis of red cells results in the “pinching off” of portions of the cell membrane, which disrupts the normal biconcave disc architecture of the red cells and leads to the formation of spherocytes, which are cleared from the circulation. This is a process referred to as *extravascular hemolysis*. The diagnosis of AIHA is strongly suggested by the presence of microspherocytes on peripheral blood smear and is confirmed by the direct Coombs test, which detects the presence of antibodies on the surface of the patient’s red blood cells. Patients with AIHA also characteristically have a significantly elevated reticulocyte count, provided that the patient has normal bone marrow function and is iron, vitamin B<sub>12</sub>, and folate replete.

AIHA is commonly idiopathic, although it is frequently associated with other autoimmune conditions including lupus, rheumatoid arthritis, Graves disease and Hashimoto thyroiditis, and ITP. The concomitant presence of AIHA and ITP is referred to as *Evans syndrome*. AIHA can also be associated with lymphoproliferative disorders, especially chronic lymphocytic leukemia. Although AIHA is frequently idiopathic, Coombs-positive immune hemolysis is also associated with exposure to certain drugs, including cephalosporins, penicillins, quinine, and methyl dopa. The mechanisms by which these drugs induce AIHA is not clear, but it is believed that the drugs bind to and alter proteins on the surface of red blood cells resulting in the formation of cryptic antigens that stimulate an immune response.

Most other conditions that cause hemolysis result in intravascular hemolysis and do not result in spherocytes formation. They include the following: severe liver disease, which is characterized by target cells, spur cells, and burr cells on peripheral blood smear; microangiopathic processes such as DIC, TTP, HUS, and malignant hypertension; infections including parasites (malaria, babesiosis) and *Clostridium perfringens*;

intrinsic red cell defects such as G6PD deficiency and PNH; and cold agglutinin disease, which is mediated by IgM autoantibodies that fix complement.

The treatment of AIHA is aimed at suppressing autoantibody production, and the mainstay of treatment is high-dose steroids. Responses to steroids are typically seen in 1 to 3 weeks, although some patients respond to steroids in just a few days. Treatment response is reflected by an increase in the hemoglobin concentration and hematocrit and a drop in the reticulocyte count. Once the hematocrit has recovered and is stable, steroids can gradually be tapered. It should also be noted that the dramatic increase in red blood cell production that occurs in the setting of AIHA can deplete body folate stores and, in the absence of folate supplementation, patients can become profoundly folate deficient. Patients with AIHA should therefore receive folate supplementation while they are recovering from their hemolytic crisis.

In this patient’s case, her low hematocrit and her symptoms make outpatient management of her AIHA unsafe. Answer A is therefore incorrect. Answer B would be correct if the patient’s hematocrit was not critically low and if she were minimally symptomatic from her anemia. However, steroids take at least a few days to have an effect, and she will continue to hemolyze her red blood cells until her AIHA remits. She is therefore at significant risk of developing cardiac ischemia, high-output heart failure, and other potentially life-threatening sequelae of severe anemia unless she receives blood transfusions. Although she will hemolyze some of the transfused red cells she receives, she should receive blood transfusions to maintain her hematocrit in a safe range until her hemolysis slows down. Answer B is therefore incorrect. Finally, although other immunosuppressive drugs including rituximab, cyclophosphamide, and azathioprine can be effective in the treatment of AIHA, they are not used as first-line treatment but are reserved for patients with steroid-refractory disease and for patients who persistently relapse with withdrawal of steroids. Answers C and E are therefore incorrect.

(Naik R. Warm autoimmune hemolytic anemia. *Hematol Oncol Clin North Am*. 2015;29:445–453; Arndt PA. Drug-induced immune hemolytic anemia: the last 30 years of changes. *Immunohematology*. 2014;30:44–54.)

### Chapter Review

#### Questions

1. A 63-year-old woman is 8 years status post lumpectomy and radiation therapy for a 1.5-cm, estrogen receptor–positive, node-negative breast cancer for which she had received 5 years of tamoxifen stopped 3 years ago. She presents to your office with severe, localized back pain. Physical examination is normal including the neurologic examination. The alkaline phosphatase is 330 U/L (elevated), and the cancer antigen 27.29 is 156 (elevated). A bone scan is positive in several areas of the thoracic and lumbar spine as well as in several ribs. The course of action at this point should be:
  - A. Combination chemotherapy
  - B. Tamoxifen therapy
  - C. MRI scan of the spine
  - D. Radiation therapy to areas of localized disease
  - E. Stem cell supported transplantation
2. A 68-year-old man presents with back pain, anemia, and fever. He has no lymphadenopathy or splenomegaly. Laboratory evaluation reveals hematocrit (Hct) 34%, platelet count 89,000/mm<sup>3</sup>, and a total protein of 9.8 g/dL (upper limit of normal, 7.5). The serum creatinine is 3.2 mg/dL, and the serum calcium is 12.3 mg/dL. Plain x-rays of the spine show generalized osteoporosis without focal defects. Which of the following best explains the situation?
  - A. Fever is a worrisome sign, and infection is a life-threatening risk for patients with this diagnosis.
  - B. Renal failure is uncommon and not likely to worsen.
  - C. Myeloma cannot be the diagnosis because lytic bone lesions are not seen.
  - D. Waldenstrom macroglobulinemia is never associated with lymphadenopathy and/or splenomegaly.
  - E. IgA and IgG paraproteins have similar serum viscosities and do not cause hyperviscosity syndrome.
3. A 46-year-old woman is concerned about the possibility of developing breast cancer and asks you about her risk factors. Which statement is most correct?
  - A. A previous biopsy that reveals lobular carcinoma in situ does not substantially increase her risk of developing breast cancer.
  - B. Presence of a *BRCA1* germline mutation will substantially increase her risk of developing breast cancer.
  - C. A maternal aunt with postmenopausal breast cancer will substantially increase her risk of developing breast cancer.
  - D. The majority of women with breast cancer have identifiable risk factors for developing breast cancer.
  - E. Duration and degree of estrogen (endogenous and exogenous) exposure are not associated with increased risk of developing breast cancer.
4. A 67-year-old man brought to the emergency department (ED) by his family is complaining of headaches, forgetfulness, and poor coordination. Several times over the past few weeks, he has had periods of confusion and urinary incontinence. He has a history of heavy smoking and hypertension for which he takes atenolol. You perform an emergency CT scan of the head, which reveals multiple round enhancing lesions. Chest x-ray shows a 2-cm lesion in the right midlung field. The most likely diagnosis is:
  - A. Prostate cancer metastatic to lung and brain
  - B. Pneumonia with brain abscesses
  - C. Colon cancer with lung and brain metastases
  - D. Adenocarcinoma of the lung with brain metastases
  - E. Gastric cancer with lung and brain metastases
5. A 26-year-old woman with Hodgkin lymphoma and a large mediastinal mass is treated with ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) and radiation to the mediastinum. Which of the following is true?
  - A. She is more likely to die of causes other than Hodgkin lymphoma.

- B. She is not at increased risk of developing breast cancer.
- C. She has an increased risk of developing leukemia.
- D. She is not likely to remain fertile after treatment.
- E. She is not at increased risk for heart disease.
6. A 46-year-old woman who never smoked is diagnosed with stage IV nonsmall cell lung cancer, metastatic to liver and bone. Which of the following is most correct?
- A. She is potentially curable with intensive modern chemotherapy.
- B. The likelihood of responding to an epidermal growth factor receptor (EGFR) kinase inhibitor is related to the presence of a gene mutation in the intracellular portion of the kinase region.
- C. The likelihood of having a mutation in the kinase region of EGFR is random and not related to gender or ethnic background.
- D. Cytotoxic chemotherapy is the only potentially beneficial treatment.
- E. Tumors initially sensitive to kinase inhibitors do not develop resistance to these kinase inhibitors.
7. A 22-year-old man, previously well, is found to have a left supraclavicular mass and an otherwise normal physical examination. Chest x-ray shows bilateral paratracheal adenopathy. Fine-needle aspiration cytology of the supraclavicular mass demonstrates undifferentiated carcinoma. The next clinical action should be:
- A. Institution of multiagent chemotherapy
- B. MRI scan of the chest
- C. Mediastinoscopy and biopsy of the paratracheal nodes
- D. Testicular ultrasound
- E. Institution of radiation therapy to the mediastinum and supraclavicular areas
8. Which of the following is true about the epidemiology of lung cancer?
- A. Adenocarcinoma has become the most common histologic subtype of lung cancer.
- B. Women who smoke develop lung cancer with a similar incidence and at a similar age as men.
- C. Asbestos does not add to the risk of developing lung cancer in smokers.
- D. Cigarette filters reduce the carcinogenic effect of cigarettes.
- E. 90% of patients with stage I nonsmall cell lung cancer will survive their cancer.
9. A 28-year-old man is admitted to the hospital with newly diagnosed acute lymphoblastic leukemia. Which of the following clinical characteristics would convey the worst prognosis?
- A. Peripheral blood blast count of  $200,000/\text{mm}^3$
- B. T-cell phenotype
- C. Mediastinal mass
- D. Philadelphia chromosome (t(9;22))
- E. Thrombocytopenia
10. A 51-year-old man is discovered to have a rectal cancer, which is then surgically resected. On pathology evaluation, the tumor penetrates the serosa of the bowel, and one regional lymph node shows involvement with metastatic carcinoma. There is no evidence of distant metastases. Optimal therapy should include which of the following?
- A. No postoperative therapy
- B. Re-resection of pelvic tissue surrounding the area of the original tumor
- C. Radiation therapy to the pelvis
- D. Systemic chemotherapy
- E. Both radiation to the pelvis and chemotherapy
11. A 46-year-old woman is found to have epithelial ovarian cancer and is taken to the operating room for surgical debulking. At the time of surgery, a 6-cm left ovarian mass and a 3-cm right ovarian mass are found. Multiple peritoneal nodules and omental nodules are seen, as well as ascitic fluid. All tumors that can be removed are removed, but tumor masses of 2 to 3 cm remain. There is no evidence of disease outside the peritoneal cavity. Postoperatively, the patient is treated with paclitaxel and carboplatin for six cycles of therapy. Which best describes the probable outcome?
- A. A very low chance of response to chemotherapy, and a very low chance of cure
- B. A high chance of complete clinical response, but a low chance for cure
- C. A high chance of response, and a high chance for cure
- D. The need for radiation therapy delivered to the whole abdomen
- E. The need for localized radiation therapy to the pelvis
12. A 72-year-old man presents with hematuria. Cystoscopy reveals multiple bladder nodules that are biopsied and reveal transitional cell carcinoma. The likelihood of developing metastatic bladder cancer is most closely related to:
- A. The size of the tumors in the bladder
- B. The number of tumors in the bladder
- C. History of smoking
- D. Family history
- E. Bladder wall muscle invasion by the tumor
13. A 32-year-old man presents with acute myelogenous leukemia. As postremission therapy, allogeneic bone marrow transplantation will most likely be recommended if a suitable donor can be found and if:
- A. His initial blast count is  $>100,000/\text{mm}^3$ .
- B. He is septic at presentation.
- C. He has M3/acute promyelocytic leukemia and disseminated intravascular coagulation.
- D. His leukemic blasts have a 7q-chromosomal deletion.
- E. His leukemic blasts have a t(8;21) chromosomal translocation.

14. You are evaluating a 52-year-old man with newly diagnosed nonsmall cell carcinoma of the right lung. Which of the following findings would not make him unresectable?
- Contralateral (N3) mediastinal adenopathy
  - Enlarged (4 cm) left adrenal gland
  - Ipsilateral pleural effusion
  - Ipsilateral (N2) mediastinal adenopathy
  - Enlarged supraclavicular lymph nodes
15. In regard to effects of tamoxifen and raloxifene, which of the following is most true?
- Raloxifene is a bone-strengthening agent, but tamoxifen is not.
  - Both increase the risk of endometrial cancer.
  - Both decrease the risk of developing a future breast cancer in women.
  - Tamoxifen increases the rate of hot flashes, but raloxifene does not.
16. A 42-year-old woman is diagnosed with a 3-cm poorly differentiated breast cancer with five involved axillary lymph nodes. The cancer is negative for estrogen receptors and positive for human epidermal growth factor receptor 2 (HER2). Which of the following is most true?
- The presence of HER2 on breast cancer cells does not affect prognosis.
  - Adjuvant chemotherapy is not effective in reducing the risk of developing metastatic cancer for women with this type of breast cancer.
  - Trastuzumab, when added to chemotherapy, substantially reduces the risk of developing metastatic disease in the future.
  - Letrozole, an aromatase inhibitor, would further improve the cure rate for this patient.
  - The addition of trastuzumab to chemotherapy is safe, without short-term or long-term complications.
17. A 56-year-old woman with a history 4 years ago of primary node-positive breast cancer comes in with right upper quadrant pain and is found to have liver metastases from her breast cancer. Her tumor was estrogen-receptor negative and progesterone-receptor negative and HER2/neu negative (triple-negative breast cancer). Which of the following is most correct?
- Because this patient's cancer is negative for HER2, her prognosis is excellent.
  - No therapy is effective or warranted, and the patient should be placed in hospice care.
  - The addition of bevacizumab to paclitaxel improves response rate and disease-free survival but does not extend overall survival.
  - Because bevacizumab, a humanized monoclonal antibody against vascular endothelial growth factor, is not a cytotoxic chemotherapy agent, it has no significant toxicity.
18. A 64-year-old woman has a routine complete blood count showing a white blood cell count of 14,500/mm<sup>3</sup> with 75% mature-appearing lymphocytes, Hct 41%, and platelet count 180,000/mm<sup>3</sup>. She has no adenopathy or splenomegaly and feels well. Which of the following is most correct?
- The diagnosis of chronic lymphocytic leukemia (CLL) can only be made on a bone marrow aspirate and biopsy.
  - She is at increased risk for infection.
  - She is in need of urgent chemotherapy.
  - She is likely to die before her 70th birthday.
  - Splenomegaly is rare in patients such as this one.

### Answers

- C. In a woman with localized back pain and suspected metastatic breast cancer involving the spine, compression of the spinal cord should always be a major consideration. Back pain is the most common symptom of cord compression, and impending spinal cord compression is a medical emergency and an MRI should be obtained promptly. The likelihood of a good neurologic outcome is related to the absence of neurologic findings at the time of diagnosis and prompt institution of therapy. If spinal cord compression is present, emergent radiation to the involved area combined with steroids to reduce inflammation is the treatment of choice. Surgery may be considered in some cases as well. Systemic therapy, such as chemotherapy or hormonal therapy, may be indicated after radiation. Stem cell transplantation is not indicated for patients with breast cancer. (Helweg-Larsen S, Sørensen PS. Symptoms and signs in metastatic spinal cord compression: a study of progression from first symptom until diagnosis in 153 patients. *Eur J Cancer*. 1994;30A(3):396; Rades D, Huttenlocher S, Dunst J, et al. Matched pair analysis comparing surgery followed by radiotherapy and radiotherapy alone for metastatic spinal cord compression. *J Clin Oncol*. 2010;28(22):3597.)
- A. The patient has multiple myeloma, and infections are a leading cause of death for patients with myeloma. These patients are particularly at risk of infections by encapsulated organisms, but any bacterial organism is a threat. Susceptibility to infections is related to poor antigen-specific Ig production as well as neutropenia secondary to bone marrow infiltration or chemotherapy treatment. It is important to vaccinate these individuals to help reduce this risk. Viral infections have also emerged as issues with the use of novel agents. The most common bone finding in patients with myeloma is osteoporosis, not lytic bone lesions. Patients with myeloma are at risk for renal failure caused by increased serum viscosity, amyloid kidney, absorption of light chains in renal tubular cells, and hypercalcemia. Dehydration can exacerbate any of these and worsen renal failure.

- Patients with Waldenstrom macroglobulinemia frequently have lymphadenopathy and splenomegaly. IgA is variably hyperviscous, usually more than IgG. IgA tends to form either doublets or multimers, making the aggregates more viscous than single antibodies. (Blimark C, Holmberg E, Mellqvist UH, et al. Multiple myeloma and infections: a population-based study on 9253 multiple myeloma patients. *Haematologica*. 2015;100(1):107; Nucci M, Anaissie E. Infections in patients with multiple myeloma in the era of high-dose therapy and novel agents. *Clin Infect Dis*. 2009;49(8):1211.)
3. B. Risk factors for breast cancer include germline genetic mutations such as in *BRCA1* and *BRCA2*, previous biopsy with lobular carcinoma in situ, which is a “field defect” marker, and duration and degree of estrogen exposure. First-degree relatives with breast cancer substantially increase the risk for the patient, but second- and third-degree relatives add little risk, especially if the relative developed breast cancer at an older age. The Gail model has been developed to help quantify a woman’s risk of developing breast cancer. Most patients presenting with breast cancer have no identifiable risk factors. (Malone KE, Daling JR, Doody DR, et al. Prevalence and predictors of *BRCA1* and *BRCA2* mutations in a population-based study of breast cancer in white and black American women ages 35 to 64 years. *Cancer Res*. 2006;66(16):8297; Gail MH, Brinton LA, Byar DP, et al. Projecting individualized probabilities of developing breast cancer for white females who are being examined annually. *J Natl Cancer Inst*. 1989;81(24):1879.)
  4. D. The patient has metastatic disease in the brain and a lung nodule. Adenocarcinoma of the lung has now become the most common histologic type of lung cancer, and 40% to 50% of these patients will at some time in the course of their disease develop brain metastases. Prostate cancer rarely metastasizes to the brain. Pneumonia with brain abscess is rare. Colon and gastric cancers metastasize to brain far less frequently than adenocarcinoma of the lung, and usually later in the course of disease. (Mujoomdar A, Austin JH, Malhotra R, et al. Clinical predictors of metastatic disease to the brain from non-small cell lung carcinoma: primary tumor size, cell type, and lymph node metastases. *Radiology*. 2007;242(3):882.)
  5. A. Current treatment for Hodgkin lymphoma results in a high cure rate, but complications from treatment are not insignificant. Patients treated for Hodgkin lymphoma are more likely to die of other causes. Patients who receive mantle radiation (radiation to the mediastinum) have an increased risk of developing breast cancer if the radiation is delivered before they are age 30 years. The risk increases after 8 to 10 years following radiation. Treatment with ABVD and radiation does not significantly increase the risk of the patient developing acute leukemia. ABVD and radiation to the mediastinum do not cause infertility in women or men, and babies born to parents who are treated for Hodgkin lymphoma do not have an increased rate of birth defects. Both doxorubicin and mediastinal radiation are associated with an increased risk of developing heart disease, either from damage to the proximal coronary arteries from radiation or cardiomyopathy (short term and long term) from administration of doxorubicin. (Ng AK, Bernardo MP, Weller E, et al. Long-term survival and competing causes of death in patients with early-stage Hodgkin’s disease treated at age 50 or younger. *J Clin Oncol*. 2002;20(8):2101; Castellino SM, Geiger AM, Mertens AC, et al. Morbidity and mortality in long-term survivors of Hodgkin lymphoma: a report from the Childhood Cancer Survivor Study. *Blood*. 2011;117(6):1806.)
  6. B. Unfortunately, patients with stage IV metastatic nonsmall cell lung cancer are incurable. It is critical that patients be screened for mutations because some will benefit from inhibition of the EGFR with small molecules that interact with the kinase region of that receptor. The likelihood of having a response is related to the presence of mutations in the kinase portion of the receptor; those mutations are more common in women, those who never smoked, and Asians. When tumors develop resistance to kinase inhibitors, there is often an additional acquired mutation in the kinase region of the receptor preventing the inhibitor from binding and altering EGFR function (cancer is unfortunately very adaptable). Cytotoxic chemotherapy is a reasonable therapeutic choice but not the only one if her tumor has mutations in the EGFR receptor. (Lindeman NI, Cagle PT, Beasley MB, et al. Molecular testing guideline for selection of lung cancer patients for EGFR and ALK tyrosine kinase inhibitors: guideline from the College of American Pathologists, International Association for the Study of Lung Cancer, and Association for Molecular Pathology. *Arch Pathol Lab Med*. 2013;137(6):828; Lee CK, Brown C, Gralla RJ, et al. Impact of EGFR inhibitor in non-small cell lung cancer on progression-free and overall survival: a meta-analysis. *J Natl Cancer Inst*. 2013;105(9):595.)
  7. D. A 22-year-old man with an undifferentiated tumor in the supraclavicular area should be considered as having primary testicular cancer until proven otherwise, because it is highly curable with appropriate therapy. Testicular cancers are sometimes not palpable and can be detected on ultrasound in some cases. Differentiation between seminomas and nonseminomas is important. Serum tumor markers should also be measured. A radical orchiectomy is also an important part of the treatment, both to confirm the diagnosis and as a therapeutic modality because the testicle is a sanctuary site from chemotherapy. Germ cell tumors are potentially curable; therefore appropriate histologic

- evaluation and staging are critical before the initiation of treatment. (McKenney JK, Heerema-McKenney A, Rouse RV. Extragonadal germ cell tumors: a review with emphasis on pathologic features, clinical prognostic variables, and differential diagnostic considerations. *Adv Anat Pathol.* 2007;14(2):69; Bokemeyer C, Nichols CR, Droz JP, et al. Extragonadal germ cell tumors of the mediastinum and retroperitoneum: results from an international analysis. *J Clin Oncol.* 2002;20(7):1864.)
8. A. Adenocarcinoma is the most common histologic form of lung cancer. The reason for this has not clearly been identified. Cigarette filters do not reduce the risk of developing lung cancer, but they appear to change the epidemiology, making adenocarcinomas more frequent than squamous cell cancers. Asbestos and smoking are cocarcinogens, and they are additive in increasing the risk of developing lung cancer. Women appear to have a shorter latency period between smoking and the development of lung cancer than men do; they may be more sensitive to the carcinogenic effects of smoking and therefore develop lung cancer at an earlier age than men do. Lung cancer is a highly lethal disease, and, even when diagnosed at its earliest stages, almost half the patients will die of their lung cancer. (Janssen-Heijnen ML, Coebergh JW, Klinkhamer PJ, et al. Is there a common etiology for the rising incidence of and decreasing survival with adenocarcinoma of the lung? *Epidemiology.* 2001;12(2):256; Markowitz SB, Levin SM, Miller A, et al. Asbestos, asbestosis, smoking, and lung cancer. New findings from the North American insulator cohort. *Am J Respir Crit Care Med.* 2013;188(1):90.)
  9. D. The Philadelphia chromosome is now known to be a high-risk feature for patients with acute lymphoblastic leukemia. Currently, these patients should be considered for allogeneic bone marrow transplantation if an appropriate donor can be identified. The use of tyrosine kinase inhibitors plays an important role in therapy, and long-term disease control has been noted in some patients. In adults, a high blast count, T-cell phenotype, or the presence of a mediastinal mass does not convey a poor prognosis. (Hann I, Vora A, Harrison G, et al. UK Medical Research Council's Working Party on Childhood Leukaemia. Determinants of outcome after intensified therapy of childhood lymphoblastic leukaemia: results from Medical Research Council United Kingdom acute lymphoblastic leukaemia XI protocol. *Br J Haematol.* 2001;113(1):103; Moorman AV, Harrison CJ, Buck GA, et al. Adult Leukaemia Working Party, Medical Research Council/National Cancer Research Institute. Karyotype is an independent prognostic factor in adult acute lymphoblastic leukemia (ALL): analysis of cytogenetic data from patients treated on the Medical Research Council (MRC) UKALLXII/Eastern Cooperative Oncology Group (ECOG) 2993 trial. *Blood.* 2007;109(8):3189; Fielding AK, Rowe JM, Richards SM, et al. Prospective outcome data on 267 unselected adult patients with Philadelphia chromosome-positive acute lymphoblastic leukemia confirms superiority of allogeneic transplantation over chemotherapy in the pre-imatinib era: results from the International ALL Trial MRC UKALLXII/ECOG2993. *Blood.* 2009;113(19):4489.)
  10. E. It is now shown that the combination of pelvic radiation and systemic chemotherapy improves the rate of local tumor control, decreases the likelihood of developing distant metastatic disease, and improves overall survival for patients with B2 and C rectal carcinoma. (Sauer R, Becker H, Hohenberger W, et al. German Rectal Cancer Study Group. Preoperative versus postoperative chemoradiotherapy for rectal cancer. *NEngl J Med.* 2004;351(17):1731.)
  11. B. Stage III ovarian cancer is highly responsive to chemotherapy, particularly to regimens that include a platinum agent and a taxane. High response rates are attained, but almost all patients experience a relapse in their disease and very few patients are cured. Radiation therapy does not play a role in the treatment of advanced ovarian cancer. (Chan JK, Brady MF, Penson RT, et al. Weekly vs. every-3-week paclitaxel and carboplatin for ovarian cancer. *N Engl J Med.* 2016;374(8):738.)
  12. E. The presence or absence of muscle invasion in the bladder wall by transitional cell carcinomas of the bladder is the best predictive feature as to which tumors are likely to metastasize to regional nodes and distant sites. These are most often poorly differentiated tumors. Tumors that are superficial without muscle invasion are more likely to be low grade, can often be treated with local therapies, and have a low incidence of developing metastatic disease. (Babjuk M, Böhle A, Burger M, et al. EAU Guidelines on non-muscle-invasive urothelial carcinoma of the bladder: update 2016. *Eur Urol.* 2017;71(3):447.)
  13. D. Cytogenetics are the most important determinant in outcome. The height of the blast count at presentation may affect early morbidity with hyperviscosity syndrome but will not significantly influence ultimate prognosis. Likewise, sepsis at presentation will affect early but not ultimate prognosis. Acute promyelocytic leukemia has a good long-term prognosis with modern therapy including all-*trans* retinoic acid and other agents to chemotherapy. Patients whose leukemic blasts contain deletions of the long arm or all of chromosome 7 have a poor prognosis and should undergo allogeneic bone marrow transplantation if they are of appropriate age and have a suitable donor. Patients whose leukemic blasts contain t(8;21) have an excellent prognosis with standard chemotherapy without bone marrow transplantation. (Döhner H, Estey E, Grimwade D, et al. Diagnosis and management of AML in adults: 2017 ELN recommendations from an international expert panel. *Blood.* 2017;129(4):424.)

14. D. Assessing a patient for surgical resection is a critical step in the treatment of patients with lung cancer. Although the cure rate for patients with ipsilateral (N2) lymph node involvement is low, combining chemotherapy and radiation before surgical resection can result in long-term remission in a significant number of patients. Contralateral mediastinal adenopathy is a contraindication for surgical resection because these patients are almost never cured of their disease, as is the case with the presence of either a pleural effusion or supraclavicular adenopathy. Adrenal metastases are common, and an adrenal gland of 4 cm is not likely to represent a benign adrenal adenoma. Patients with metastatic disease in the adrenal gland are not curable. (Pless M, Stupp R, Ris HB, et al. Lung Cancer Project Group Induction chemoradiation in stage IIIA/N2 non-small-cell lung cancer: a phase 3 randomised trial. *Lancet*. 2015;386(9998):1049.)
15. C. Both raloxifene and tamoxifen can reduce the risk of developing breast cancers in the future. Raloxifene is a selective estrogen receptor modulator. Raloxifene is approved to increase bone density in postmenopausal women. Tamoxifen has a similar effect. Tamoxifen stimulates the endometrium and is associated with an increased risk of developing endometrial cancers, and those cancers can be life threatening. In contrast, raloxifene does not appear to stimulate the endometrium and does not appear to increase the risk of endometrial cancer. Both tamoxifen and raloxifene can increase the rates of vasomotor symptoms, including hot flashes. (Burstein HJ, Lacchetti C, Anderson H, et al. Adjuvant endocrine therapy for women with hormone receptor-positive breast cancer: American Society of Clinical Oncology clinical practice guideline update on ovarian suppression. *J Clin Oncol*. 2016;34(14):1689.)
16. C. Patients with breast cancers whose cancers overexpress HER2 have a worse prognosis. Administration of adjuvant chemotherapy will reduce the risk of recurrence and death for these patients, but the addition of trastuzumab (a humanized monoclonal antibody directed against HER2) to chemotherapy will further substantially reduce the risk of cancer recurrence. When trastuzumab is administered after doxorubicin, there is an increased risk of heart failure, and the long-term cardiac ramifications are not known. For patients with node-positive disease or node-negative tumors >2 cm, we offer the addition of pertuzumab to trastuzumab-based regimens, given evidence of improvements in disease-free survival. Aromatase inhibitors are ineffective against breast cancers negative for estrogen receptors. (Piccart-Gebhart MJ, Procter M, Leyland-Jones B, et al. Herceptin Adjuvant (HERA) Trial Study Team. Trastuzumab after adjuvant chemotherapy in HER2-positive breast cancer. *N Engl J Med*. 2005;353(16):1659.)
17. C. Patients with breast cancers negative for estrogen and progesterone receptors and for HER2 (so called triple-negative cancers) have poor prognosis, particularly when metastatic disease is present. Hormone therapy and trastuzumab have no benefit for these women because their tumors do not overexpress HER2 nor do they have estrogen receptors. The addition of bevacizumab to paclitaxel has been shown to increase response rate and duration of response but not overall survival for patients with this subset of breast cancer. Hypertension and proteinuria are the two major side effects of bevacizumab. (Dent R, Trudeau M, Pritchard KI, et al. Triple-negative breast cancer: clinical features and patterns of recurrence. *Clin Cancer Res*. 2007;13:4429.)
18. B. The patient has CLL. The diagnosis can be established by flow cytometric analysis of the peripheral blood. The circulating lymphocytes are B cells, expressing the B-cell antigen CD20, but coexpress the T-cell antigen CD5. Patients with CLL are at risk for infection with encapsulated bacteria as well as viral infections. Because she has early-stage CLL, no treatment is required. To date, early therapy does not improve outcome. Treatment is indicated when a patient has progressive and significant splenomegaly, lymphadenopathy, symptoms, or suppression of her normal blood counts. The median survival for patients with early-stage CLL, as is the case with this patient, is >15 years. (CLL Trialists' Collaborative Group. Chemotherapeutic options in chronic lymphocytic leukemia: a meta-analysis of the randomized trials. *J Natl Cancer Inst*. 1999;91(10):861.)

## Oncology Summary

CRAIG A. BUNNELL

Much progress has been made in understanding the mechanisms of cancer cell growth, identifying specific “targets” unique to the cancer cell, and optimizing cancer treatment. Outcomes have improved for both rare and common cancers.

### Selected Cancers

#### Breast Cancer

Breast cancer is the most common cancer in American women (excluding basal and squamous cell skin cancers) and the second most common cause of cancer mortality. Risk factors for breast cancer are shown in [Box 22.1](#). Mammography can detect asymptomatic early-stage breast cancers. There has been recent controversy regarding screening frequency, and expert groups differ in their recommendations ([Box 22.2](#)). Mammography does not identify approximately 10% of breast cancers; therefore biopsy is recommended for any suspicious lesion even if mammographically undetectable. Breast self-examination has not been shown to increase the rate of breast cancer diagnosis, to change the stage at diagnosis, or to reduce the risk of death from breast cancer. Clinical breast examination by a health care professional may modestly improve early detection. MRI is more sensitive than mammography but results in more false positives and therefore more biopsies of nonmalignant lesions. It also does not detect all breast cancers and notably misses some cases of ductal carcinoma in situ (DCIS). Therefore screening breast MRI may complement, but should not replace, screening mammography and is typically reserved for individuals at very high risk of breast cancer incidence, such as *BRCA1/2* mutation carriers. Regardless of how a suspicious breast mass is identified, a core biopsy has supplanted excisional biopsy as the standard diagnostic procedure.

The vast majority (>95%) of breast cancers are epithelial in origin and are classified as carcinomas. Breast carcinomas can be divided into two distinct groups: (1) in situ carcinomas, in which cancer cells are confined inside ducts or lobules and do not invade into the surrounding stroma, and (2) invasive or infiltrating carcinomas, in which cancer cells invade into the breast stroma and consequently have

the potential to metastasize. There are two major histologic types of in situ carcinomas, referred to as ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS). There are several different histologic types of invasive breast cancer, including invasive ductal carcinoma (IDC), invasive lobular carcinoma (ILC), mixed ductal/lobular carcinoma, mucinous (colloid) carcinoma, tubular carcinoma, medullary carcinoma, and papillary carcinoma. IDC is the most common histologic subtype, accounting for approximately 75% of all invasive breast cancers.

Approximately two-thirds of all invasive breast cancers are hormone receptor–positive; that is, the cancer cells express either the estrogen receptor or the progesterone receptor. Different laboratories may have different cut-off points for categorizing a cancer as “hormone receptor–positive” or “hormone receptor–negative.” Research studies have demonstrated that even cancers that have only a small percentage of cells expressing hormone receptors may respond to hormonal therapy. In 20% of invasive breast cancers, the human epidermal growth factor cell surface receptor 2 (HER2) is overexpressed. The risk of recurrence is higher for hormone receptor–negative compared with hormone receptor–positive breast cancer, and for HER2–positive compared with HER2–negative breast cancer. Invasive breast cancers that express none of these three receptors (approximately 15% of all invasive breast cancers) are referred to as “triple–negative” breast cancers

#### • BOX 22.1 Risk Factors for Breast Cancer

- Gender
- Age
- Higher weight/body mass index (for postmenopausal women)
- Personal history of breast cancer or benign breast disease
- Exposure to ionizing radiation
- Family history of breast cancer
- Race/ethnicity
- Diet
- Alcohol
- Prolonged postmenopausal hormone replacement therapy
- Longer exposure to and higher concentrations of endogenous estrogen (early menarche, nulliparity, older age at first birth, later menopause)
- Inherited breast cancer susceptibility gene; *BRCA1/2*, *p53*, etc.

and carry a poor prognosis. Inflammatory breast cancer can be of any subtype and represents a particularly aggressive, locally advanced form of breast cancer with a relatively high risk for systemic disease.

Management options are summarized in [Table 22.1](#).

## Lung Cancer

Lung cancer is a heterogeneous group of malignancies comprising small cell lung cancer (SCLC; 13%) and nonsmall cell lung cancer (NSCLC; 86%); additional rare thoracic malignancies include mesothelioma and carcinoid tumors. The single most important risk factor, smoking, accounts for approximately 85% of all lung cancers. Other associated factors include exposure to radon, asbestos, and heavy metals. Additional causative exposures include wood smoke, previous chest radiotherapy, and heavy metals such as arsenic, chromium, nickel, beryllium, and cadmium. Clinically, the respiratory symptoms of lung cancer often mimic the effects of chronic tobacco use. Many patients present with cough, worsening dyspnea, or hemoptysis, which can also be symptoms of bronchitis or pneumonia. Systemic symptoms may include weight loss, chest pain, bone pain, hoarseness, or neurologic symptoms.

Paraneoplastic syndromes are most frequently seen in patients with SCLC but can be seen in either type of lung cancer.

- Hematologic abnormalities include leukocytosis (likely from tumor secretion of granulocyte colony-stimulating factor), anemia, and thrombocytosis.

### • BOX 22.2 Mammogram Guidelines, US Preventive Services Task Force (USPSTF) 2009

1. Screening mammograms should be done every 2 years beginning at age 50 years for women at average risk of breast cancer.
2. Screening mammograms age <50 years should not be done routinely and should be based on a woman's values regarding the risks and benefits of mammography.
3. Doctors should not teach women to do breast self-examinations.
4. There is insufficient evidence that mammogram screening is effective for women age ≥75 years, so specific recommendations for this age group were not included.

USPSTF guidelines differ from those of the American Cancer Society (ACS). The ACS mammogram guidelines for women at average risk for breast cancer recommend women age 40 to 44 years have the choice to start annual mammogram screening, that women age 45 to 54 years have annual mammograms, that women age ≥55 years switch to biennial mammograms or continue yearly screening as long as they are in good health. ACS guidelines indicate that the breast self-examination is optional in breast cancer screening.

Data from <http://www.uspreventiveservicestaskforce.org/Page/Document/UpdateSummaryFinal/breast-cancer-screening>; <http://www.cancer.org/healthy/findcancerearly/cancerscreeningguidelines/american-cancer-society-guidelines-for-the-early-detection-of-cancer>.

- Syndrome of inappropriate antidiuretic hormone secretion (SIADH) can occur in up to 10% of SCLC, resulting in profound hyponatremia.
- Hypercalcemia in malignancy may result from direct bone invasion or secretion of osteoclast-activating factors and occurs most commonly in squamous cell cancers.
- Excess production of adrenocorticotropic hormone by tumor tissue can lead to Cushing syndrome: truncal obesity, hypertension, hyperglycemia, hypokalemic alkalosis, and osteoporosis.
- Pancoast syndrome is when lung tumors arising in the superior sulcus of either lung can cause damage to the brachial plexus and the sympathetic ganglia. This results in a syndrome of shoulder/arm pain, ipsilateral Horner syndrome, bone destruction, and atrophy of the hand muscles.
- Neurologic abnormalities include Eaton-Lambert syndrome (a myasthenia-like neuropathy) and antineuronal antibodies (e.g., “anti-Hu”).
- Patients present with deep vein thrombosis and/or pulmonary embolism.

Diagnostic evaluation should include a chest radiograph; a nodule on a chest x-ray or CT scan may lead to the diagnosis of lung cancer. A CT of the chest with intravenous contrast gives an overview of the extent of parenchymal disease and regional nodal involvement and can also demonstrate metastatic disease to the bones, liver, or adrenal glands. Positron emission tomography (PET)/CT scans are used frequently to evaluate the extent of regional or metastatic disease. Bronchoscopy, increasingly in combination with endobronchial ultrasound, is most useful for proximal tumors and can yield information about a primary tumor and lymph node staging. Although the diagnosis can be made from fine-needle aspiration alone, advanced molecular testing requires more tissue in the form of a core biopsy or surgical sample. Chest radiographs have repeatedly been shown to be ineffective as a means of screening for lung cancers; recent observations have suggested a role for spiral CT scans as a screening approach for high-risk individuals with a heavy smoking history.

Management options are summarized in [Table 22.2](#).

## Gastrointestinal Malignancies

The most common gastrointestinal cancers in the United States are esophageal, gastric, pancreatic, and colorectal.

### Esophageal Cancer

Esophageal cancer is diagnosed in approximately 17,000 individuals in the United States annually, leading to nearly 16,000 deaths. There are two major histologic types, squamous cell carcinoma and adenocarcinoma. Other histologic types, such as melanomas, carcinoids, lymphomas, and sarcomas, are rare.

Squamous cell carcinomas largely develop in the upper third and middle third of the esophagus. Adenocarcinomas primarily develop in the lower third of the esophagus and,

**TABLE 22.1** Management Options for Breast Cancer

Stages of Breast Cancer	Management Options
Stage 0 breast cancer (carcinoma in situ) LCIS	Consider preventative tamoxifen, raloxifene, or aromatase inhibitors (exemestane or anastrozole). Excision of breast tissue to achieve negative margins and radiation therapy is not indicated.
DCIS	Mastectomy, or lumpectomy (breast-conserving therapy) with complete removal of the tumor to achieve negative margins. Radiation therapy to the breast follows lumpectomy and reduces the risk of local recurrence. Sampling of the axillary lymph nodes is not indicated for cases of pure DCIS (i.e., no evidence of invasive cancer). Both lumpectomy followed by radiation therapy and mastectomy confer a high likelihood of survival (>98%). Endocrine therapy with tamoxifen (premenopausal or postmenopausal) or an aromatase inhibitor (postmenopausal only) is frequently recommended after lumpectomy to reduce risk of local recurrence as well as for prevention of new breast cancers.
Stage I, II, and III breast cancer (nonmetastatic)	Cure is the goal of therapy. Surgical resection includes either mastectomy or lumpectomy with axillary nodal sampling to remove the primary cancer. Radiation therapy to the breast traditionally follows lumpectomy, and radiation therapy to the chest wall following mastectomy is generally recommended in higher-risk situations (e.g., if the tumor is >5 cm or axillary lymph nodes are involved). Hormone receptor–negative breast cancers tend to recur within the first few years, whereas hormone receptor–positive breast cancers may recur ≥10 years after diagnosis. The choice of adjuvant systemic therapy depends on the risk of recurrence and the subtype of breast cancer. The higher the risk of recurrence, the greater the potential benefit of adjuvant therapy. Adjuvant endocrine therapy is specifically indicated if a tumor is hormone receptor–positive. Adjuvant chemotherapy is typically indicated for women with hormone receptor–negative cancers and selected higher-risk hormone receptor–positive cancers. Gene expression analysis, e.g., <i>Oncotype DX</i> , can be used to determine if the addition of chemotherapy to endocrine therapy would provide reduction in the risk of recurrence in hormone receptor–positive cancers. Chemotherapy for breast cancer usually involves the administration of two or three medications with minimally overlapping toxicity profiles; commonly used medications include cyclophosphamide, methotrexate, 5-fluorouracil, doxorubicin, epirubicin, paclitaxel, and docetaxel. The addition of adjuvant trastuzumab to chemotherapy is indicated for most HER2+ cancers. Pertuzumab also may be added in the neoadjuvant setting.
Stage IV breast cancer (metastatic)	Metastatic breast cancer is incurable. The primary goals of treatment include prolongation of survival and palliation of symptoms. Selection of systemic therapy is tailored for tumor subtype. Initial management of hormone receptor–positive metastatic breast cancer most commonly involves the administration of an antiestrogen hormonal medication. Hormonal treatment options can include tamoxifen, a selective aromatase inhibitor (e.g., anastrozole, letrozole, or exemestane), fulvestrant, or a gonadotropin-releasing hormone agonist for premenopausal women. CDK 4/6 inhibitors may be used in combination with endocrine therapy as well. For endocrine-refractory, hormone receptor–negative metastatic breast cancer or symptomatic metastatic disease, systemic chemotherapy is typically administered. Multiple chemotherapy medications have activity in advanced breast cancer. Anti-HER2-directed therapy, including trastuzumab, pertuzumab, T-DM1, and lapatinib, is indicated in the treatment of advanced HER2+ disease. For women who have metastatic bony deposits, the regular administration of an intravenous bisphosphonate (e.g., pamidronate or zoledronic acid) or a RANK ligand inhibitor (e.g., denosumab) helps prevent/delay the development of skeletal complications and palliates bone pain. Targeted local therapies, such as surgical excision, radiation therapy, or radiofrequency ablation, are sometimes indicated.

*DCIS*, Ductal carcinoma in situ; *HER2*, human epidermal growth factor cell surface receptor 2; *LCIS*, lobular carcinoma in situ.

particularly in cancers at the gastroesophageal junction, have markedly increased in frequency during the past several decades. The primary risk factors for squamous cell carcinomas are tobacco and alcohol exposure. Other conditions that lead to irritation of the esophageal mucosa and increase the risk of squamous cell carcinoma include achalasia, caustic injury to the esophagus, and esophageal diverticuli. Rare conditions that carry a very high risk of squamous cell carcinoma include nonepidermolytic palmoplantar keratoderma (tylosis), a rare autosomal dominant disorder characterized by hyperkeratosis of the palms and soles and thickening of the oral mucosa, and Plummer-Vinson syndrome, a

nutritional deficiency characterized by dysphagia, iron-deficiency anemia, and esophageal webs. Adenocarcinomas of the esophagus principally develop in the setting of Barrett esophagus. Risk factors associated with the development of Barrett esophagus include gastroesophageal reflux disease and obesity.

Patients with esophageal cancer commonly present with symptoms of difficulty swallowing (dysphagia) and, less frequently, with painful swallowing (odynophagia). Before diagnosis, patients often have dysphagia for solids that gradually progresses to difficulty even for liquids. Patients may also present with hematemesis, weight loss, cough,

**TABLE 22.2** Management Options for Lung Cancer

Type of Lung Cancer	Management Options
Stage I–II NSCLC	Initial treatment for stage I (small tumor without lymph node involvement) and stage II (larger and more invasive tumors or hilar lymph node involvement) consists of surgical resection. For large stage IIb tumors, and for all stage II tumors, it is estimated that patients have approximately a 5% overall survival benefit to cisplatin-based doublet adjuvant chemotherapy. For small stage I tumors there is no evidence of benefit from adjuvant chemotherapy. There is no role for adjuvant radiation therapy in completely resected NSCLC.
Stage III NSCLC	Therapy for stage III NSCLC includes a combination of chemotherapy, radiation, and sometimes surgical resection. Stage IIIB disease is generally considered surgically unresectable and is treated with concurrent chemotherapy and high-dose radiation with curative intent (“definitive” treatment). The treatment of stage IIIA disease is less standardized and often includes surgery, preoperative and/or postoperative chemotherapy, and consideration of radiotherapy.
Stage IV NSCLC	Stage IV NSCLC is incurable. Treatment generally entails the use of sequential, systemic therapies that may include chemotherapy, biologics, targeted agents, and immunotherapy. The choice of agents is determined by histology (squamous and nonsquamous) and the presence or absence of oncogenic driver mutations (e.g., EGFR, ALK, etc.). Standard first-line chemotherapy regimens consist of platinum-based doublets. In patients who have progressed on chemotherapy, anti-PD-1 checkpoint inhibitors (e.g., nivolumab, pembrolizumab) have demonstrated improved survival, longer duration of response, and fewer adverse events compared with chemotherapy.
Limited-stage SCLC	Concurrent radiotherapy and chemotherapy with cisplatin and etoposide, followed by chemotherapy alone. Following chemotherapy and radiation, prophylactic cranial irradiation.
Extensive-stage SCLC	Extensive-stage small cell lung cancer is incurable. Patients who respond to initial therapy also have a survival benefit from prophylactic cranial irradiation. Second-line therapy is more successful in patients with a disease-free interval >3 months after initial therapy (“relapsed” disease) than patients with a disease-free interval <3 months (“refractory” disease). Supportive care also plays an essential role in the management of SCLC.

*NSCLC*, Nonsmall cell lung cancer; *SCLC*, small cell lung cancer.

aspiration pneumonia, hoarseness, or symptoms related to areas of metastases.

The treatment and prognosis of esophageal cancer depend upon the stage of disease at diagnosis (Table 22.3). Squamous cell carcinomas and adenocarcinomas are radiologically indistinguishable and are approached diagnostically and therapeutically in a similar fashion. Patients who are diagnosed with esophageal cancer by upper endoscopy should undergo staging evaluation including CT of the chest, abdomen, and pelvis to assess for metastases. For patients without evidence of metastases, endoscopic ultrasound is used to evaluate the extent of invasion of the primary tumor and to assess for involvement of locoregional lymph nodes. PET/CT scans have been shown to be particularly effective in identifying spread to regional lymph nodes. The most common sites of metastases are liver, lung, lymph nodes, and bone.

### Gastric Cancer

An estimated 26,000 new cases of gastric cancer and 11,000 deaths occur in the United States annually. The vast majority of gastric tumors in the stomach are adenocarcinomas. Far less frequent histologies include lymphomas, carcinoids, leiomyosarcomas, and gastrointestinal stromal tumors. There are two subtypes of gastric

adenocarcinomas: an intestinal type with cohesive neoplastic cells forming gland-like tubular structures and a diffuse type in which individual cells infiltrate and thicken the stomach wall. Intestinal-type lesions more frequently occur in the distal stomach and are often preceded by a prolonged precancerous phase associated with *Helicobacter pylori* infection. Diffuse carcinomas are detected more often in younger patients, develop throughout the stomach, particularly the cardia, and are associated with a worse prognosis.

The most common symptoms at presentation are unexplained weight loss, abdominal pain, fatigue, nausea, anorexia, dysphagia, early satiety, and melena. Initial evaluation of symptoms suspicious for gastric cancer includes barium swallow and/or upper endoscopy. Once a diagnostic biopsy demonstrates adenocarcinoma, staging with CT is recommended. Such imaging is limited, however, in its ability to detect peritoneal metastases, which are present in up to 10% to 30% of patients who appear to have localized disease. Therefore at the time of surgery an initial exploratory laparoscopy is necessary, and detection of peritoneal disease or distant metastases should lead to either a palliative resection or bypass gastrojejunostomy.

The pathologic stage is the principal determinant of both prognosis and treatment strategy. Treatment is summarized

**TABLE 22.3** Management Options for Gastrointestinal Cancers

Gastrointestinal Cancer	Management Options
Esophageal cancer	<p>For patients with disease that does not extend beyond the muscle layer of the esophageal wall and without evidence of lymph node involvement, immediate surgery is recommended. For those with disease that extends beyond the muscle layer or with locoregional lymph node involvement, neoadjuvant therapy with chemotherapy and radiation should be considered before surgery. Chemoradiation therapy is given over 5–6 weeks with daily radiation and various combinations of chemotherapy agents. Following the completion of neoadjuvant therapy, restaging is recommended, followed by surgery approximately 6 weeks after the last dose of radiation.</p> <p>For patients with localized disease who are not surgical candidates because of concurrent medical conditions or who refuse surgery, disease is treated with chemoradiation.</p> <p>Patients with metastatic disease should be considered for palliative therapy. Chemotherapy can palliate symptoms relating to swallowing and can prolong overall survival.</p>
Gastric cancer	<p>For patients with nonmetastatic disease, the primary treatment modality is surgery. Following surgical resection, nonmetastatic patients whose disease extends beyond the muscle layer of the gastric wall or with positive lymph nodes should be considered for adjuvant chemoradiotherapy.</p> <p>For patients with metastatic disease, palliative chemotherapy is the primary treatment modality. No single regimen is considered standard. For patients with a good performance status, combination regimens that include a platinum agent are reasonable first-line choices.</p>
Pancreatic cancer	<p>For head of the pancreas lesions, a pancreaticoduodenectomy (Whipple) operation is performed with resection of part of the pancreas and duodenum, common bile duct, gallbladder, and distal stomach. For body or tail of the pancreas lesions, a distal pancreatectomy with or without splenectomy is performed. Resection of body or tail lesions is considerably less common because most such cancers are metastatic at the time of diagnosis. Following resection, adjuvant therapy with chemotherapy alone or a combination of chemotherapy and radiation is recommended.</p> <p>Combined-modality chemotherapy and radiation are typically pursued for locally advanced pancreatic cancer. Palliative chemotherapy is used for metastatic pancreatic cancer; however, benefit tends to be limited.</p>
Colorectal cancer	<p>Treatment for colorectal cancer depends on stage of disease.</p> <p>Surgery is considered the only curative therapy for colorectal cancers.</p> <p>Multiple clinical trials have demonstrated a survival benefit for adjuvant chemotherapy in stage III (lymph node–positive) colon cancer patients following surgery.</p> <p>For patients with metastatic disease, removal of the primary tumor still remains an important consideration to palliate and prevent symptoms caused by the colorectal lesion (including bleeding and obstruction).</p> <p>Chemotherapy is an important component of the treatment of patients with metastatic disease as well as many patients with surgically resected tumors. The backbone of colorectal cancer treatment for the past four decades has been the fluorinated pyrimidine, 5-fluorouracil. Newer regimens can also include oxaliplatin, irinotecan, and/or targeted biological therapy.</p>

in Table 22.3. Those patients with metastatic disease should be considered for palliative chemotherapy.

### Pancreas Cancer

Pancreas cancer carries a high risk of fatality as a result of the inability to detect such tumors at an early stage. It is the tenth most common cancer in incidence in the United States but the third most common cause of cancer-related death (after lung and colorectal cancer), and unfortunately, outcomes have not changed dramatically in several decades.

Pancreatic cancer has been associated with various hereditary syndromes. Although most commonly associated with colorectal and gynecologic cancers, hereditary nonpolyposis colorectal cancer, which results from mutations of

mismatch repair genes, also carries an increased risk of pancreatic cancer. Inherited mutations of p16 result in familial atypical multiple mole–melanoma syndrome associated with melanomas and pancreatic cancer. Other syndromes in which the risk of pancreatic cancer is increased include *BRCA2*, ataxia-telangiectasia, Peutz-Jeghers, and hereditary pancreatitis.

Tobacco is the most common modifiable risk factor associated with development of pancreatic cancer; however, obesity, certain dietary factors, and long-standing diabetes may also increase risk.

Approximately 75% of pancreatic cancers are adenocarcinomas. Other histologies include neuroendocrine tumors arising from the islets of Langerhans, lymphomas,

or metastatic disease. Adenocarcinomas most commonly arise in the head of the pancreas (65%) and less commonly are restricted to the body or tail (15%) or present diffusely throughout the pancreas (20%).

A classical presentation of pancreatic cancer is the acute onset of jaundice, occasionally unaccompanied by pain but more frequently associated with localized discomfort. Other presenting features include unexplained weight loss, pain radiating to the midback, anorexia, and nausea. Laboratory testing may show elevation of total bilirubin and other liver function tests (alkaline phosphatase more than transaminases). Occasionally, the new development of diabetes may herald the appearance of a pancreatic cancer.

Workup should include CT looking for a pancreatic mass. For patients with metastatic disease at presentation, the liver is the most common site of metastases, although distant lymph nodes, peritoneum, and lungs are frequent areas of spread. For patients who present with jaundice, endoscopic retrograde cholangiopancreatography with stent placement and cytology by brushings and/or biopsy are appropriate diagnostic-therapeutic maneuvers. Alternatively, percutaneous biopsy of the primary pancreatic mass or metastases, guided by CT or ultrasound, can be pursued.

Although a TNM (tumor, node, metastases) system that is used for solid organ tumors exists for pancreatic cancer, the more practical classification of pancreatic cancer describes three stages of disease: local, locally advanced, and metastatic. Local disease implies surgical resectability and is the only potentially curable stage of pancreatic cancer. Treatment options are listed in [Table 22.3](#).

### Colorectal Cancer

Colorectal cancer is the third most common cancer diagnosed in men, the third most common cancer diagnosed in women in the United States, and the fourth most common cancer overall. It is the second most common cause of cancer-related death in the United States, with an estimated 49,000 deaths each year.

Up to 25% of patients with colorectal cancer have a family history of the disease. Multiple hereditary syndromes carry a markedly increased risk of colorectal cancer. Familial adenomatous polyposis (FAP) results from truncating mutations in the adenomatous polyposis coli gene on chromosome 5. Afflicted individuals develop hundreds to thousands of polyps by their second decade of life and, if untreated, can develop colorectal cancer by age 40 years. It is recommended that patients with FAP pursue total colectomy by age 20 years. Variants of FAP include Gardner syndrome (in which prominent extraintestinal lesions such as desmoid tumors and sebaceous or epidermoid cysts are seen in addition to extensive polyposis) and Turcot syndrome (brain tumors, particularly medulloblastomas, in addition to colonic tumors). Hereditary nonpolyposis colon cancer, or Lynch syndrome, is characterized by the early onset of colorectal cancer, often involving the right side of the colon, and typically occurs in the absence of numerous colonic polyps. The condition is associated with germline mutations

in DNA repair genes, leading to mismatch repair defects and microsatellite instability. The presence of these DNA repair defects in colorectal tumors, interestingly, is associated with a more favorable prognosis. In addition to familial syndromes, a family or personal history of colorectal cancer increases one's risk of developing colorectal cancer. This risk is modified by number of family members affected and age at diagnosis of family members, particularly first-degree relatives. Notably, this risk is similar for individuals with a family history of adenomatous polyps, likely because such polyps may have evolved to cancer if untreated.

Patients with inflammatory bowel disease have an increased risk of colorectal cancer that can be 3- to 5-fold higher than that in the general population. The risk is associated with both ulcerative colitis and Crohn disease, particularly for patients with Crohn disease affecting the large bowel. Extent of disease involvement of the colon and rectum and duration of disease are the main determinants of the increased risk.

Screening for colorectal cancer is key to early detection and decreased mortality. The 2008 American College of Gastroenterology Guidelines for Colorectal Cancer Screening are summarized in [Box 22.3](#).

Over 98% of large intestine cancers are adenocarcinomas. Most colorectal carcinomas originate from adenomatous polyps. Progression from early adenomatous proliferations through adenomatous polyp, high-grade dysplasia, and, ultimately, invasive carcinoma occurs as a continuum.

Patients with cancer of the cecum and ascending colon may present with anemia caused by intermittent gastrointestinal bleeding. Obstruction is rare because the bowel wall is more distensible and the stool is more liquid (i.e., less formed) than in the descending colon. These cancers are often large and may be fungating or friable. Carcinomas of the transverse colon and either the hepatic or the splenic flexure, which account for about 10% of total cases, are less common than cecal neoplasms and much less common than rectosigmoid tumors. They frequently cause cramping pain, bleeding, and sometimes obstruction or perforation. Large bowel obstruction is the most common complication of colon carcinoma and may lead to proximal ulceration or perforation. Other complications include iron-deficiency anemia, hypokalemia (particularly associated with large villous rectal lesions), and intussusception in adults. Tumors of the sigmoid colon and rectal cancers usually cause changes in normal bowel habits, with tenesmus, decrease in stool caliber, secretion of mucus, and hematochezia.

Management options are summarized in [Table 22.3](#).

### Genitourinary Malignancies

#### Prostate Cancer

Prostate cancer is the most commonly diagnosed cancer in American men, representing approximately 25% of all cancers diagnosed each year, and is the second leading cause of cancer death in American men. The most relevant risk factors for prostate cancer include age and genetic factors, such as family history and ethnicity. Most prostate cancer

### • BOX 22.3 Key Elements of 2008 Colorectal Cancer Screening Guidelines

1. Colonoscopy is the preferred colorectal cancer (CRC) prevention test. Colonoscopy is recommended every 10 years beginning at age 50 years. Alternatives for patients who decline colonoscopy are flexible sigmoidoscopy or CT colonography.
2. Screening for black persons should begin at age 45 years because of the high incidence of CRC and a greater prevalence of proximal or right-sided polyps and cancerous lesions in this population.
3. CT colonography (also known as virtual colonoscopy) can be performed every 5 years as an alternative to colonoscopy every 10 years in patients who decline the traditional modality. CT colonography has a 90% sensitivity for colon polyps  $\geq 1$  cm; however, it is not considered to be equivalent to colonoscopy because of its inability to detect polyps  $\leq 5$  mm, which constitute 80% of colorectal neoplasms, and because false positives are common with CT colonography.
4. Barium enema is not recommended for CRC screening/prevention because of variability in quality of performance.
5. Fecal testing is a cancer detection test, not a cancer prevention test. Fecal immunohistochemical testing is recommended over the older guaiac-based fecal occult blood test and is the preferred cancer detection test (performed annually).
6. Screening recommendations related to family history:
  - An increased level of screening is no longer recommended for those with a history of adenomas in a first-degree relative or in patients age  $\geq 60$  years with colon cancer or advanced adenomas.
  - Single first-degree relative with CRC or advanced adenoma (adenoma  $\geq 1$  cm in size or with high dysplasia or villous elements) diagnosed at age  $\geq 60$  years: Recommended screening is the same as for those at "average risk" (colonoscopy every 10 years beginning at age 50 years).
  - Single first-degree relative with CRC or advanced adenoma diagnosed at age  $< 60$  years or two first-degree relatives with CRC or advanced adenomas: Recommended screening is colonoscopy every 5 years beginning at age 40 years or at 10 years younger than age at diagnosis of the youngest affected relative
  - Single first-degree relative with only small tubular adenoma is not considered to increase the risk for CRC, and no changes beyond average-risk screening are needed

diagnoses in the United States are made through prostate-specific antigen (PSA) screening; however, there is currently no definitive evidence that PSA screening improves mortality. Indeed, the US Preventive Services Task Force recommends against routine PSA-based screening for prostate cancer, given the potential treatment risks for PSA screen-detected prostate cancers. Nonetheless, PSA testing continues to be performed routinely in many US primary care practices. When prostate cancer is identified, PSA level, clinical stage, and pathologic results from biopsy are powerful predictors of clinical outcome.

Multiple treatment options exist for the management of low-risk localized prostate cancer, including radical

prostatectomy, external beam radiation therapy, or brachytherapy (radiation seed implants). Watchful waiting (close surveillance without treatment) is an additional and often preferable option for low-risk patients. For patients with high-risk features, adjuvant treatment, including the addition of androgen-deprivation therapy, improves outcomes.

Despite definitive local treatment, prostate cancer can recur. Patients with local recurrence may be successfully salvaged with radiation therapy. However, for those who cannot be salvaged or those with overt metastatic disease, androgen-deprivation therapy with or without chemotherapy remains the standard of care, and over 90% of men respond to therapy. Disease eventually progresses, and further palliative therapy includes subsequent antiandrogen therapy and/or transition to chemotherapy.

### Renal Cell Carcinoma

Renal cell carcinoma (RCC) accounts for approximately 3% of adult malignancies and over 90% of neoplasms arising from the kidney. RCC is characterized by a lack of early warning signs, diverse clinical manifestations, relative resistance to radiation and chemotherapy, and infrequent responses to immunotherapy agents such as interferon- $\alpha$  and interleukin-2. Although  $>50\%$  of patients with RCC are cured in early stages, the outcome for metastatic disease is poor. Immunotherapy with novel immune checkpoint blockers and molecularly targeted therapy with antiangiogenic, multiple-receptor kinase inhibitors have become the primary systemic agents for treatment of metastatic disease.

### Bladder Cancer

Bladder cancer is the fourth most common cancer in men and the twelfth in women; the higher incidence in men is likely related to higher rates of smoking and occupational exposures. Presenting symptoms include hematuria as well as urinary voiding symptoms. The primary diagnostic maneuver is cystoscopy, which not only allows visual inspection of the bladder but also identifies sites for biopsy and transurethral resection of bladder tumor. Stage and grade of disease are the most important variables in determining outcome, with invasion into muscle of the bladder wall considered higher risk and warranting aggressive treatment.

Treatment for superficial disease consists of complete transurethral resection; in the setting of higher-risk superficial disease, intravesical bacillus Calmette-Guérin is commonly used. Standard initial therapy for invasive bladder cancer is radical cystectomy with bilateral lymph node dissection, which may be accompanied by preoperative or postoperative systemic chemotherapy. Metastatic disease carries a poor prognosis and is treated with platinum-based combination chemotherapy.

### Testicular Cancer

Testicular cancers are most commonly germ cell tumors (GCT) and are classified as either seminomas or nonseminomas based on their histology. Testicular GCTs are the most common malignancy in men age 15 to 35 years but

occur rarely in the population in general. The classic presentation of testicular cancer is detection of a nodule or painless swelling of one testicle. Nearly all GCTs are potentially curable, with the likelihood of cure dependent on clinical stage. Treatment of early-stage disease can include surgery and/or chemotherapy. Advanced disease may require multimodality therapy.

### **Non-Hodgkin and Hodgkin Lymphoma**

Lymphomas are malignancies of lymphoid cells. These neoplasms originate from cells in the B- and T-lymphocyte/natural killer (NK) cell lineages and are categorized into Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). The World Health Organization recognizes five major types of HLs and at least 40 major types of NHLs. NHL represents the fifth most common cancer in the United States and is the most common hematologic malignancy.

Presenting symptoms for NHL include lymphadenopathy, constitutional symptoms, and local symptoms. Lymphadenopathy is present in more than two-thirds of patients with NHL, with the rapidity of lymph node enlargement reflecting the aggressiveness of the disease. The most clinically significant constitutional symptoms are B symptoms, defined as fever  $>38^{\circ}\text{C}$  ( $100.4^{\circ}\text{F}$ ), weight loss  $>10\%$  of body weight over a 6-month period, or drenching night sweats. B symptoms are seen in about 45% of aggressive or highly aggressive NHLs and in  $<25\%$  of indolent NHLs; when present in the setting of an indolent NHL, B symptoms tend to indicate a large burden of disease. Additional constitutional symptoms include fatigue and malaise.

Local symptoms reflect the degree to which a lymphoma impairs functioning of involved or adjacent tissues, with different NHLs displaying varying degrees of marrow, splenic, and extranodal (i.e., external to the lymphatic system) involvement. Common sites of extranodal involvement include the gastrointestinal tract, skin, and bone; rare sites include the kidneys, bladder, adrenals, heart, lungs, breast, testes, and thyroid. In addition, the central nervous system (CNS) may be infiltrated either in the form of a primary CNS lymphoma (i.e., a lymphoma that predominates in the CNS), a condition occurring particularly frequently in immunocompromised individuals such as patients with HIV/AIDS, or a secondary CNS lymphoma (i.e., a lymphoma with predominantly systemic disease that spreads into the CNS).

The workup of a suspected NHL requires a thorough history, physical examination, laboratory evaluation, imaging, and tissue sampling for pathology review.

The treatment of Hodgkin disease (HL) for most patients is combination radiation therapy and chemotherapy. In patients with advanced Hodgkin disease, involved-field radiation can be used for sites of persistent disease following chemotherapy. The treatment of NHL varies greatly depending on tumor stage, phenotype (B-, T-, or NK/null-cell), histology (i.e., whether low, intermediate, or high grade), symptoms, performance status, patient age, and comorbidities.

### **The Identification of Cancer Subsets**

The identification of subsets of cancers provides both prognostic (i.e., disease natural history) and predictive (likelihood of response to a given treatment) information highly relevant for clinical practice. Traditional pathologic analyses can discriminate cancer subgroups; for example, immunohistochemistry can identify cellular receptors such as HER2 in the setting of breast cancer, and cytogenetic analyses can detect specific chromosomal anomalies in cancers such as acute myeloid leukemia. Contemporary molecular diagnostic testing techniques have allowed the emergence of a far more specific description of DNA, RNA, or protein expression patterns in individual tumors. These “tumor fingerprints” provide an otherwise undetectable portrait of tumor behavior, growth potential, and sensitivity to treatment. Analyses can be performed on a variety of tissue sources including fresh tumor obtained at the time of biopsy, tumor cells obtained from circulating blood, or paraffin-embedded tumor tissue from prior procedures. Initial problems with the use of archival formalin-fixed paraffin-embedded tissues for DNA analyses have largely been resolved with next-generation sequencing techniques.

### **Clinical Importance of Genomic Predictors**

Evaluations for both individual gene products and multigene arrays have gained utility as predictive tools in the selection of therapy. Such assays can focus on the overexpression or mutation of a given gene that may affect protein function. The identification of such genetic changes enables more precision in the selection of targeted therapy. In addition, subgrouping cancers by their molecular portrait has emerged as a relevant tool in clinical decision making.

### **Mutation in the Epidermal Growth Factor Receptor**

The epidermal growth factor receptor (EGFR) is a member of the HER family of receptors. Multiple solid tumors overexpress EGFR, and the activation of the EGFR signaling cascade leads to cellular proliferation and subsequent tumor invasion. Both small-molecule tyrosine kinase inhibitors (administered orally) and monoclonal antibodies (administered parenterally) have been developed to target this receptor. Clinical trials in lung cancer patients treated with EGFR inhibitors demonstrate that only 15% to 20% of all patients with NSCLC respond to such therapy. The majority of those patients who responded to EGFR inhibition were found to have specific *EGFR* gene mutations, the presence of which significantly increased tumor sensitivity to EGFR-directed therapies. Treatment of NSCLC populations having EGFR mutations with EGFR inhibitor monotherapy is remarkably effective, with reported response rates of 55% and a median duration of control of metastatic disease of 9 months.

### **EML4-ALK Translocation**

The *EML4-ALK* fusion oncogene has been identified in several cancers, specifically NSCLC and less commonly anaplastic large cell lymphoma, inflammatory myofibroblastic

tumors, and neuroblastomas. The presence of the fusion protein leads to ligand-independent activation of the ALK receptor tyrosine kinase and subsequent oncogenic transformation and cellular proliferation. EML4-ALK-positive NSCLC typically occurs in younger patients without a history of tobacco exposure and classically presents as an adenocarcinoma. It is estimated that the frequency of EML4-ALK-positive NSCLC ranges from 2% to 7% of patients with NSCLC, but in selected populations of younger patients with minimal smoking history, the prevalence may be as high as 30%. Significant benefit from the use of crizotinib, an inhibitor specific for the EML4-ALK translocation, has been demonstrated, with response rates of >60% in pretreated metastatic patients and even higher with first-line therapy. Based on these data, crizotinib is recommended for first-line therapy in patients with ALK-positive NSCLC.

### Mutations in the Gene for KRAS

KRAS is a downstream target in the EGFR signaling cascade. The presence of mutations in the *KRAS* gene contributes important information for the selection of therapies in both colon and lung cancers. Approximately 30% to 40% of colon cancers have an activating *KRAS* mutation; the presence of such a mutation predicts a significantly lower likelihood of benefit from treatment with EGFR-targeting antibodies such as cetuximab and panitumumab. *KRAS* mutations occur in 10% to 30% of lung cancers and predict a diminished likelihood of response in patients treated with EGFR inhibitors.

### Microsatellite Instability

Microsatellite instability (MSI), a pathologic footprint of defective DNA mismatch repair genes, occurs in 15% to 20% of colon cancers and can be detected by either immunohistochemical or polymerase chain reaction (PCR) techniques. MSI has both prognostic and predictive value in that patients with MSI tend to experience decreased likelihood of disease recurrence but also appear to derive less benefit from 5-fluorouracil-based chemotherapy programs. The presence of MSI can thus be used to optimize treatment for this subset of colon cancers.

### Multiplex Genomic Analysis

In breast cancer the use of multigene analyses has identified distinct tumor subgroups, including luminal A and B (typically hormone receptor-positive), HER2 positive, and basal-like (typically negative for both hormone receptors and HER2 ["triple negative"]). These classifications provide independent prognostic information corresponding to differential clinical outcomes. A more favorable prognosis is observed with luminal A breast tumors, and significantly inferior outcomes are observed in the basal-like subgroup.

Commercially available techniques evaluating smaller subsets of genes provide both prognostic and predictive information. *Oncotype DX* is a reverse transcriptase-PCR assessment of a 21-gene panel performed on paraffin-fixed

tissue. The *Oncotype DX* result, called the recurrence score, provides a more precise estimate of the risk of recurrence in hormone receptor-positive patients treated with standard endocrine therapy beyond that achieved with traditional anatomic and biological features. The recurrence score can also predict potential benefit from chemotherapy and help guide the selection of patients for adjuvant treatment with chemotherapy. Scores are divided into three risk categories: low, intermediate, and high. Benefit from the addition of adjuvant cytotoxic chemotherapy to endocrine treatment appears to be limited to tumors that score in the high-risk range. The greatest benefit from the test lies in the ability to identify breast cancer patients with hormone receptor-positive disease and with low or intermediate scores for whom limited benefit is to be expected from chemotherapy and who can thus be spared exposure to the physical and economic costs of treatment. Guidelines from the National Comprehensive Cancer Network recommend the addition of *Oncotype DX* testing in the management of hormone receptor-positive breast cancer.

MammaPrint, a similar test with regulatory approval in the United States, discriminates between tumors at low and high risk of recurrence through the examination of a 70-gene profile. Its clinical use was initially limited by the requirement for fresh tissue, but the test has since been modified to allow for testing with paraffin-embedded tissue.

## Targeted Therapy

Targeted forms of treatment interact with a specific genetic site or protein that is unique to the cancer cell and on which cell survival and propagation are dependent. The development of targeted therapies has focused on identifying critical molecular sites within a cancer cell essential for tumor survival and growth, the classic "hallmarks of cancer." Creating a therapeutic strategy focusing directly on these sites may lead to cancer regression with minimal systemic toxicity. Most types of targeted therapy are either monoclonal antibodies that bind to unique protein receptors on the tumor cell surface or small molecule compounds that are typically developed for targets within the cell itself that are essential for tumor cell growth. The monoclonal antibodies are administered intravenously, whereas the small molecule compounds are typically given orally. Toxicity profiles of these agents tend to be favorable when compared with chemotherapy, although specific dermatologic, cardiovascular, and immune effects may arise. Examples of monoclonal antibodies and small molecule compounds, as well as their clinical indications, are shown in [Table 22.4](#). The list is not all-inclusive.

### Monoclonal Antibodies

Monoclonal antibodies have been developed to block ligand activation of tumor-specific cell surface proteins in patients with lymphoma (CD20, rituximab [Rituxan]), breast cancer (HER2, trastuzumab [Herceptin]), and both colorectal and head and neck cancers (EGFR receptors, cetuximab

**TABLE 22.4** Commonly Used Targeted Therapies in Clinical Oncology

Agent	Target	Disease
<b>Monoclonal Antibodies</b>		
Trastuzumab	HER2	Breast cancer, gastric cancer, esophageal cancer
Pertuzumab	HER2	Breast cancer
T-DM1	HER2	Breast cancer
Rituximab	CD-20	B-cell lymphoma
Cetuximab	EGFR	Colon cancer, head and neck cancer
Panitumumab	EGFR	Colon cancer
Bevacizumab	VEGF	Colon cancer, NSCLC, renal cell cancer, glioma
Alemtuzumab	CD-52	CLL
Ramucirumab	VEGF-2	Gastric, colon cancer, NSCLC
Nivolumab	PD-1	Classical Hodgkin lymphoma, melanoma, NSCLC, renal cell
Pembrolizumab	PD-1	Head and neck cancer, melanoma, NSCLC
Ipilimumab	CTLA4	Melanoma
Blinatumomab	CD3, CD19	B-cell ALL
<b>Small Molecule Compounds</b>		
Imatinib	BCR-abl, c-kit	CML, GIST
Dasatinib	BCR-abl, c-kit	CML
Nilotinib	BCR-abl, c-kit	CML
Erlotinib	EGFR	NSCLC
Gefitinib	EGFR	NSCLC
Sunitinib	VEGFR, PDGFR, c-kit	Renal cell cancer, GIST, PNET
Sorafenib	VEGFR, PDGFR, Raf kinase, c-kit	HCC, renal cell cancer, thyroid cancer
Lapatinib	HER2, EGFR	Breast cancer
Motesanib	VEGFR, PDGFR, c-kit	Thyroid cancer
Ibrutinib	BTK	CLL, mantle cell lymphoma
Palbociclib	CDK 4/6	Breast cancer
Bortezomib	26S Proteasome	Multiple myeloma, mantle cell lymphoma
Vemurafenib	B-RAF/MEK	Melanoma
Everolimus	mTOR	Breast cancer, RCC, PNET

*CML*, Chronic myelogenous leukemia; *CLL*, chronic lymphocytic leukemia; *EGFR*, epidermal growth factor receptor; *GIST*, gastrointestinal stromal cell tumor; *HCC*, hepatocellular carcinoma; *HER2*, human epidermal growth factor receptor 2; *NSCLC*, nonsmall cell lung cancer; *PDGFR*, platelet-derived growth factor receptor; *PNET*, progressive neuroendocrine tumors; *RCC*, renal cell carcinoma; *VEGF* or *VEGFR*, vascular endothelial growth factor receptor.

[Erbix] and panitumumab [Vectibix]). The anti-CD20 monoclonal antibody rituximab initially was proven to be effective in prolonging survival when administered with chemotherapy to patients with diffuse B-cell lymphomas, as demonstrated in Fig. 22.1, and subsequently has been shown to be beneficial in follicular lymphomas, chronic lymphocytic leukemia, and Waldenstrom macroglobulinemia. Rituximab also has an expanding role in management

of such autoimmune disorders as rheumatoid arthritis and hemolytic anemias. The use of trastuzumab, a monoclonal antibody directed against the HER2 protein on the surface of breast cancer cells, has enhanced the efficacy of chemotherapy in patients with metastatic disease whose tumors overexpress HER2 and has significantly prolonged survival when administered with chemotherapy as adjuvant therapy (Fig. 22.2). Trastuzumab therapy is associated with a

• **Fig. 22.1** Chemotherapy for B-cell lymphoma. Overall survival among patients treated with chemotherapy alone versus chemotherapy plus rituximab for B-cell lymphoma. Kaplan-Meier plot describing overall survival for 399 patients (median age 69 years) with diffuse large B-cell lymphoma randomized to standard chemotherapy alone (cyclophosphamide, doxorubicin, vincristine, prednisone [CHOP]) or with the addition of rituximab. The addition of rituximab resulted in a significant prolongation in overall survival ( $p = .007$ ). (From Coiffier B, Lepage E, Briere J, et al. CHOP chemotherapy plus rituximab compared with CHOP alone in elderly patients with diffuse large-B-cell lymphoma. *N Engl J Med*. 2002;346(4):235–242.)

• **Fig. 22.2** Trastuzumab outcomes. Survival outcomes from the combined analysis of the North American Intergroup adjuvant trastuzumab trials. Progression-free (A) and overall survival (B) were improved with the addition of trastuzumab for 3351 women evaluated in the combined analysis of National Surgical Adjuvant Breast and Bowel Project trial B-31 and the North Central Cancer Treatment Group trial 9831. (From Romond EH, Perez EA, Bryant J, et al. Trastuzumab plus adjuvant chemotherapy for operable HER2-positive breast cancer. *N Engl J Med*. 2005;353(16):1673–1684.)

rare risk of cardiotoxicity and is typically not administered concomitantly with other cardiotoxic antineoplastic compounds, such as anthracyclines. Pertuzumab and T-DM1 are two newer monoclonal antibodies also directed against the HER2 protein that have proven efficacious in the treatment of HER2-positive breast cancer. T-DM1 is an antibody-drug conjugate consisting of trastuzumab linked to the cytotoxic agent emtansine (DM1). In this case, the monoclonal antibody targets the HER2-positive cell by

binding to the HER2 protein and delivering the cytotoxic DM1 molecule directly to the cancer cell.

Bevacizumab (Avastin) is a monoclonal antibody directed against the vascular endothelial growth factor (VEGF) receptor and is thought to act in large part through an antiangiogenic mechanism, blocking the ability of tumors to elaborate new blood vessels essential for their survival. Bevacizumab has proven to be effective when administered alone in the treatment of renal cell cancer and when combined with

chemotherapy in the management of advanced colorectal and lung cancers.

An important recent advancement in the treatment of cancer has been the development of monoclonal antibody immune checkpoint inhibitors. Immune checkpoints are immune system pathways critical for modulating the immune response to minimize collateral damage to normal tissue. Some tumors are capable of coopting immune checkpoints as a mechanism for evading an immune response against the tumor antigens. Because some of these checkpoints involve ligand-receptor interactions, they can be blocked by antibodies that interfere with these interactions. Monoclonal antibodies targeting cytotoxic T-lymphocyte-associated antigen 4 (CTLA4) and the programmed cell death protein 1 (PD-1) have yielded dramatic and durable responses in many tumor types, including melanoma, NSCLC, head and neck cancers, renal cell carcinoma, and Hodgkin disease. Monoclonal antibodies targeting other immune checkpoints are in development.

### Small Molecule Compounds

One of the most dramatic examples of the impact of targeted therapy has been imatinib mesylate (Gleevec), a tyrosine kinase inhibitor that has proven to be remarkably effective through different molecular mechanisms in the management of chronic myelogenous leukemia (CML) by inhibiting the *bcr-abl* gene, gastrointestinal stromal cell tumors (GIST) by blocking *c-kit* gene function, and the hypereosinophilic syndrome through inhibition of the platelet-derived growth factor.

CML is characterized by a balanced translocation between chromosomes 9 and 22 (i.e., the Philadelphia chromosome) in which the *ABL* oncogene from chromosome 9 adheres at the “break cluster region” (*BCR*) site on chromosome 22 to create the novel *BCR-ABL* fusion gene. This *BCR-ABL* gene product uses a specific tyrosine kinase to stimulate the production of a unique “fusion” protein, which has been shown to be instrumental in the pathogenesis of CML. Imatinib mesylate precisely blocks the action of the *BCR-ABL* tyrosine kinase, thereby targeting the specific molecular cause of CML. CML usually progresses from a chronic, myeloproliferative phase to an accelerated or leukemic phase that is highly resistant to therapy within 4 years after the time of diagnosis, leading shortly thereafter to death. Allogeneic bone marrow transplantation performed early during the chronic phase had been thought to be the only curative treatment for this hematologic malignancy. The use of imatinib mesylate as the only form of treatment in close to 500 newly diagnosed patients with CML who participated in a pivotal prospective clinical trial demonstrated a remarkable 5-year survival of 90%, as demonstrated in Fig. 22.3.

• **Fig. 22.3** Imatinib outcomes in chronic myelogenous leukemia (CML). Overall survival among patients treated with imatinib as initial therapy for chronic phase of CML. Overall survival at 5 years for 553 patients treated with imatinib demonstrates an overall survival rate of 89%, improving to 95% with censoring of non-CML related deaths. (From Druker BJ, Guilhot F, O’Brien SG, et al. Five-year follow-up of patients receiving imatinib for chronic myeloid leukemia. *N Engl J Med*. 2006;355(23):2408–2417.)

Imatinib mesylate is also effective in the management of GIST, a rare cancer arising in the abdomen that is resistant to cytotoxic chemotherapy and is characterized by mutations in the *c-kit* gene. Imatinib mesylate had been shown in the laboratory to arrest the growth of GIST cells and to induce apoptosis. When given to patients with GIST, imatinib mesylate therapy results in a PET scan–documented reduction in metabolic activity in tumor tissue (as well as a marked reduction in symptoms) within days to weeks (Fig. 22.4) and substantial improvement in overall survival compared with historic controls. This survival benefit has been achieved in many patients without objective shrinkage of measurable tumor masses, suggesting that the inhibition of the *c-kit* gene does not necessarily lead to cell death but rather to a reduction in proliferative capacity, resulting in tumor quiescence and prolongation of survival.

Approximately 40% to 60% of melanomas have an activating mutation in the gene for the protein kinase B-RAF, leading to constitutive activation and stimulation of cancer cell growth. Vemurafenib, an inhibitor of B-RAF activation related to the V600E mutation, has been demonstrated to improve progression-free and overall survival in metastatic melanoma compared with standard chemotherapy in patients with a V600E B-RAF mutation.

Multiple other small molecule compounds targeting a wide range of biological targets, including EGFR, EML4-ALK, HER2, VEGFR, CDK, and many others, are in development.

• **Fig. 22.4** Imatinib outcomes in gastrointestinal stromal cell tumor (GIST). Effect of imatinib on a pelvic GIST. Serial positron emission scans obtained in a patient with a GIST tumor at baseline (A), after 1 month of imatinib (B), and after 16 months of continuous imatinib treatment (C). Images include a two-dimensional positron emission tomography (PET) image (*top*), an axial PET image at the level of the pelvic tumor (*middle*), and a CT scan image corresponding to the same level (*bottom*). ## Rheumatology

# 23

## Rheumatoid Arthritis

DERRICK J. TODD AND JONATHAN S. COBLYN

Rheumatoid arthritis (RA) is an idiopathic systemic autoimmune disorder that primarily involves the joints. It causes inflammation of the synovium (synovitis) that can lead to cartilage destruction and bone erosions. Extraarticular manifestations may also occur. The diagnosis of RA is based on a combination of clinical features, laboratory tests, and imaging studies. In recent years, great strides have been made in the pharmacologic treatment of RA, which consists primarily of immunosuppressive or immunomodulatory therapy with disease-modifying antirheumatic drugs (DMARDs). It is important to understand that RA is a heterogeneous disorder; some patients may have a severe, rapidly progressive disease with life-threatening extraarticular symptoms, whereas other patients may have indolent symptoms with little if any joint destruction over time. This point is important when making a diagnosis of RA and especially when considering treatment options.

### Epidemiology

RA is present in approximately 0.5% to 1% of the US adult population and afflicts patients of all genders, ages, and races. Women are affected three to four times more frequently than men, and peak incidence occurs at 25 to 50 years of age. Patients of northern European ancestry are at increased risk for RA, in part because the identified genetic loci associated with the disease are more common in this population. According to 1994 statistics, direct costs of RA care accounted for \$4 to \$5 billion in the United States for health care and indirect costs but approach \$20 billion annually because of lost wages and productivity.

The risk of developing RA is influenced by both genetic and environmental factors. The strongest genetic risk is conferred by the shared epitope found in close association with the class II major histocompatibility complex gene, human leukocyte antigen DR4 (specifically DRB1\*0401 and DRB1\*0404). Other gene associations have been identified, but the odds ratio for these are small. Cigarette smoking is one environmental factor clearly associated with the development of RA. Poor dental hygiene has also been associated as a risk factor for RA development, with emerging research implicating *Porphyromonas gingivalis* and other organisms of the host microbiome in the pathogenesis of RA. Obesity is

a recently recognized risk factor for incident RA. The risk of other environmental factors, such as diet, stress, and infection, is less clear.

### Pathology and Pathogenesis

The characteristic pathologic lesion in RA is proliferative synovitis in which the normally lace-like synovium is infiltrated by cells of the immune system to form a thickened pannus of inflammatory synovial tissue. The cellular infiltrate is comprised mostly of chronic inflammatory cells such as lymphocytes, macrophages, and plasma cells. Over time, pannus invades and destroys cartilage and eventually leads to bone erosions. Similar synovial proliferation can also be found in other synovial tissues, such as the lining of tendons and bursae, which explains why patients with RA can also experience inflammatory tenosynovitis and bursitis.

The molecular and cellular processes leading to autoimmunity in human RA have yet to be fully elucidated. Animal models of RA, including collagen-induced arthritis, have shed some light on the pathogenesis of synovitis. Cellular components of both innate and acquired immunity appear to contribute, as do tissue-resident synovial fibroblasts and lining cells. In years past, autoimmunity in RA was thought to be mediated by interferon- $\gamma$ -secreting Th1 T-helper cells. However, recent studies have discovered an alternative T-helper cell population that may actually drive the autoimmunity in RA. These cells, termed *Th17 cells*, secrete the proinflammatory cytokine interleukin-17 (IL-17). Additional contributions to autoimmunity may come from effector T-cell populations, B cells, tissue-resident macrophages, dendritic cells, and mast cells. These cells secrete proinflammatory cytokines (e.g., IL-1, IL-6, and tumor necrosis factor [TNF]- $\alpha$ ) and chemokines to fuel inflammation. Infiltrating cells also produce collagenases and metalloproteinases, which cause cartilage destruction and, eventually, bone erosion.

### Diagnosis

RA can lead to irreversible joint damage. It is imperative to make a timely diagnosis to initiate DMARD therapy, ideally within the first 3 months of disease onset. However,

• **BOX 23.1** American College of Rheumatology  
1987 Classification Criteria for  
Rheumatoid Arthritis

1. Morning stiffness >1-hour duration
  2. Soft-tissue swelling or fluid in three or more joints simultaneously
  3. Swelling involving wrists, MCPs, or PIPs
  4. Symmetric arthritis
  5. Rheumatoid nodules
  6. Elevated rheumatoid factor
  7. Radiographic erosion in the hand or wrist
- Must meet four of seven criteria.  
Criteria 1–4 must be present for >6 weeks.  
Criteria 2–4 must be witnessed by a physician.  
Exclude other diagnoses as deemed appropriate.

MCPs, Metacarpal phalangeal joints; PIPs, proximal interphalangeal joints.  
From Arnett FC, Edworthy SM, Bloch DA, et al. The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. *Arthritis Rheum.* 1988;31:315-324.

there is no single test or study that can be used exclusively to diagnose RA. Rather, a combination of factors needs to be considered including presenting symptoms, physical findings, laboratory data, and imaging studies. [Box 23.1](#) lists the stringent 1987 American College of Rheumatology (ACR) classification criteria for the diagnosis of RA. Patients meeting these criteria almost certainly have RA.

In 2010 new RA classification criteria were published, representing the culmination of a collaborative multinational effort between the ACR and European League Against Rheumatism ([Table 23.1](#)). These new criteria stress the presence of inflammatory arthritis and deemphasize late changes of RA (e.g., erosions and rheumatoid nodules). Thus they permit an earlier diagnosis of RA, allowing for earlier aggressive DMARD therapy in an effort to preserve joint structure and function. It should be emphasized that, strictly speaking, classification criteria are designed for the purposes of clinical research studies and not for day-to-day office practice; some patients with RA may not meet established criteria.

## Clinical Manifestations of Rheumatoid Arthritis

RA most commonly presents as a symmetric inflammatory arthritis of the small joints of the upper and lower extremities. The presentation may be of an acute polyarthritis, but it can also present as an indolent process. Patients with RA experience painful, swollen, red joints, usually with a morning stiffness that exceeds 60 minutes upon awakening and improves with physical activity. Tendons and bursae may also be involved because the lining of these structures is similar to synovial tissue. Tenosynovitis in the wrist can cause median nerve impingement and carpal tunnel syndrome (CTS), which manifests as numbness and paresthesia of the volar surface of the first through third/fourth fingers. An analogous process can occur in the ankle to cause tarsal tunnel syndrome.

**TABLE 23.1** New 2010 American College of Rheumatology/European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis

Descriptor	Score
Who should be tested? Patients with definite clinical synovitis of at least one joint not better explained by another disease process. Score-based algorithm: add scores of A–D; a score of $\geq 6/10$ is needed for classification of a patient as having definite RA.	
A. Joint involvement (use highest applicable category)	
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without large joint involvement)	2
4–10 small joints (with or without large joint involvement)	3
>10 joints (at least 1 small joint)	5
B. Serology (high-positive: $\geq 3 \times$ upper limit normal for the test)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-phase reactants	
Normal CRP and ESR	0
Abnormally elevated CRP or ESR	1
D. Duration of symptoms	
<6 weeks	0
$\geq 6$ weeks	1

ACPA, Anticitrullinated peptide antibodies; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RA, rheumatoid arthritis; RF, rheumatoid factor.

From Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League against Rheumatism collaborative initiative. *Ann Rheum Dis.* 2010;69:1580-1588.

The distribution of involved joints is useful in the differential diagnostic considerations of patients presenting with polyarthritis. RA can affect almost any joint in the body, often in a symmetric fashion but not exclusively so. Hands, wrists, and feet are most commonly involved, whereas the lumbar spine is rarely if ever affected. In the hands, RA tends to affect the proximal interphalangeal (PIP) joints, metacarpal intraphalangeal (MCP) joints, and wrists. It typically spares the distal interphalangeal (DIP) joints. Low back or DIP disease suggests a condition other than RA, such as osteoarthritis (OA) or spondyloarthritis (SpA) like psoriatic arthritis. In up to 10% of patients with RA, arthritis may manifest as a chronic, sterile, inflammatory monoarthritis. [Box 23.2](#) lists the differential diagnosis of RA. The other inflammatory disorders that need to be distinguished from RA include SpAs (e.g., psoriatic arthritis), microcrystalline disorders (e.g., gout and pseudogout), and polymyalgia rheumatica.

### • BOX 23.2 Differential Diagnosis of Rheumatoid Arthritis

Polymyalgia rheumatica  
 Other connective tissue disorders  
   Systemic lupus erythematosus  
   Sjögren syndrome  
   Mixed connective tissue disease  
   Polymyositis/dermatomyositis  
   Scleroderma  
 Spondyloarthritis disorders  
   Psoriatic arthritis  
   Reactive arthritis  
   IBD-associated arthropathy  
   Ankylosing spondylitis  
 Microcrystalline arthritis  
   Gouty arthritis  
   Pseudorheumatoid CPPD disease

   Septic bacterial arthritis  
   Viral arthritis (e.g., acute parvovirus)  
   *Mycobacterium tuberculosis* arthritis  
   Lyme arthritis  
 Osteoarthritis  
 Vasculitis  
 Sarcoid arthritis

CPPD, Calcium pyrophosphate dihydrate; IBD, inflammatory bowel disease.

Hallmarks of RA upon physical examination include the presence of erythema, warmth, and swelling of the involved joints. Chronic RA can lead to specific deformities in the hand, such as wrist fusion and the classic swan neck and boutonniere deformities that occur upon joint subluxation at the MCPs and PIPs. The symptoms of CTS can be reproduced by forced flexion of the wrist (Phalen sign) or by sharply percussing the volar wrist over the median nerve (Tinel sign). Focal posterior knee swelling, calf swelling, or a dependent ecchymosis in the ankle may be indicative of a popliteal Baker cyst (or rupture), which can occur in patients with RA and large knee effusions. Notably, patients with RA may misinterpret their disability as muscle weakness rather than joint pain, which can confound the diagnostic workup. Hoarseness and odynophagia can indicate cricoarytenoid arthritis, which can cause laryngeal obstruction in patients following extubation. Tenosynovitis of the extraocular superior oblique muscle tendon can impair eye adduction during upward gaze, a condition known as *Brown syndrome*. The cervical spine may also be involved, with particular involvement to the C1–2 articulation. This may cause basilar invagination, or C1–2 subluxation, producing, in extreme cases, myelopathic symptoms. Cervical disc disease is also commonly manifested in patients with RA.

### Laboratory Testing

No single laboratory test can be used to diagnose RA in the absence of clinical findings. Laboratory studies are used to support the diagnosis of RA in a patient with suggestive

### • BOX 23.3 Conditions Associated With an Elevated Serum Rheumatoid Factor

 Variant of normal

symptoms, to monitor RA disease activity, and to rule out other possible causes of arthritis.

Serum rheumatoid factor (RF) testing is highly useful and provides some assistance in the diagnostic workup of patients with polyarthritis because approximately 80% of patients with RA have RF detectable in the serum (termed *seropositive*). The remaining 20% of RA patients never develop detectable RF levels (termed *seronegative*), and therefore the absence of RF does not rule out the presence of RA. Routine RF analysis tests for IgM antibodies that have specificity directed against the constant (Fc) region of other antibodies. Several other medical conditions can be associated with an elevated IgM RF (Box 23.3), thereby limiting the test's specificity and utility. IgG and IgA RFs can also be measured but have even lower specificity for RA.

More recently, RA has been associated with the presence of anticitrullinated peptide antibodies (ACPAs), a subset of which are the more commonly termed *anticyclic citrullinated peptide antibodies*. Similar to RF, these ACPAs are present in the serum of 70% to 80% of patients with RA. When they are present, the specificity of ACPAs in RA approaches 95%. Importantly, ACPAs are rarely found in the conditions listed in Box 23.3. Thus a diagnosis of RA in a patient with ACPAs can be made with greater certainty. As with RF, 20% to 30% of patients with RA will never develop ACPAs, so the absence of these antibodies again does not rule out the presence of RA.

It is unclear whether RF complexes or ACPAs play a directly pathogenic role in RA. Seropositive RA patients tend to have more aggressive disease and greater numbers of extraarticular manifestations than do seronegative patients. However, serum RF and ACPA levels do not correlate well with disease activity and therefore cannot be used to monitor response to therapy. Instead, this is accomplished by measuring nonspecific markers of systemic inflammation, such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Improvement in these markers suggests an overall decrease in RA disease activity. Additional nonspecific markers of inflammation include a peripheral blood leukocytosis, thrombocytosis, anemia of chronic disease, and other elevated acute-phase proteins (e.g., ferritin,

haptoglobin, and complements). Recently, a panel of RA biomarkers has been assembled into a single assay, marketed commercially under the trade name Vectra-DA. This assay correlates with RA disease activity, but it remains unclear if the cost of the test justifies its routine clinical use above and beyond traditional markers of disease activity such as clinical assessment and ESR/CRP.

Arthrocentesis of synovial fluid is used to rule out other potential causes of arthritis such as septic arthritis or microcrystalline diseases (e.g., gout and pseudogout). Synovial fluid analysis is also an important means to differentiate inflammatory disorders from noninflammatory disorders including mechanical disorders such as OA. Rheumatoid synovial fluid is inflammatory, with white blood cell (WBC) counts typically  $>2000$  WBC/mm<sup>3</sup>. One can feel assured that the condition effusion is not inflammatory if the cell count is  $<2000$  WBC/mm<sup>3</sup> (mechanical disorders such as OA), and infection should be considered if the cell count is  $>50,000$  WBC/mm<sup>3</sup>. Neutrophils are often a dominant cell type in RA synovial fluid, but they rarely comprise  $>90\%$  of WBCs. Although rarely done, in ambiguous circumstances synovial biopsy may be carried out to confirm inflammatory features or rule out atypical crystal disease, occult infection, or malignancy in clinically appropriate situations.

## Musculoskeletal Imaging

Similar to laboratory tests, imaging studies aid in the diagnostic workup of RA and can be used to monitor disease progression. Plain film radiographs have been the staple of imaging for decades, whereas other techniques have an ever-increasing role.

The plain film radiographic changes of RA tend to follow a uniform sequence of events, with the pace of radiographic progression depending primarily on severity and duration of disease activity. The earliest radiographic findings are periarticular soft tissue swelling and periarticular osteopenia. These are followed by joint space narrowing and marginal erosions. Joint ankylosis (fusion) can occur after long-standing inflammatory damage. Interestingly, patients with seropositive RA are more likely to develop joint erosions than patients with seronegative disease. Effective DMARD therapy slows radiographic joint progression.

MRI, CT scan, ultrasound, and bone scan are all imaging techniques that can provide additional anatomic definition in patients with RA. MRI allows visualization of preradiographic erosions, bone marrow edema, soft tissue swelling, synovitis, and tenosynovitis with much greater sensitivity than plain film radiography. Gadolinium-containing contrast agents are often used to enhance MRI quality. These can be given intravascularly or intraarticularly (MR arthrogram) for definition of intraarticular structures such as ligaments and menisci. CT scan is most useful in the assessment of bony structures, especially when MRI may be contraindicated. Musculoskeletal

ultrasound with power Doppler has an emerging role in identifying bone erosions and synovitis. Bone scan is a fading technology that still has limited diagnostic utility in the patient with polyarthralgias but few objective findings of RA.

## Special Considerations

RA involvement of the cervical spine deserves special mention because of its potentially devastating consequences if unrecognized. The articulation between C1 and C2 is a synovial joint and, thus can be affected by synovitis. Patients need not have long-standing RA to have cervical spine disease. They may not complain of neck pain but may instead present with neurologic symptoms and signs to suggest a myelopathy. Paresthesias or weakness in an RA patient with brisk reflexes, clonus, positive Hoffman sign, or upgoing toes on Babinski maneuver should prompt an immediate assessment for cervical spine disease. Flexion and extension films of the cervical spine are the most useful and readily available initial imaging study. CT scan and MRI provide additional anatomic definition of the neck. Consultation with a spine surgeon is warranted for any patient with evidence of C1 to C2 instability because fusion may be required to avoid damage to the spinal cord or brainstem.

Although RA primarily afflicts the joints, extraarticular manifestations can occur. These processes can affect almost any organ or tissue in the body and are listed in [Table 23.2](#). Constitutional symptoms of fatigue and malaise occur commonly, whereas fever, anorexia, and weight loss are less frequently present. Pulmonary and hematologic complications deserve special mention. Pulmonary complications include pleural effusions whose hallmark is a strikingly low pleural fluid glucose. The effusion is often exudative, making the differentiation between RA and empyema of importance. The hematologic complications include anemia of chronic disease, thrombocytosis, and leukopenia associated with Felty syndrome or large granular lymphocyte syndrome.

Other extraarticular manifestations tend to occur in patients with clinically apparent arthritis, and a disproportionate number of patients are seropositive for RF or ACPAs. In addition, there is growing evidence that patients with RA are at increased risk of developing cardiovascular disease and lymphomas. It remains to be proven whether aggressive control of RA activity normalizes these risks.

Finally, it is worth emphasizing that patients with RA are at particular risk for septic arthritis, usually via hematogenous seeding of the joint. Contributing factors include a hypervascular synovium, the abnormal joint surface itself, any iatrogenic immunosuppression from DMARDs, and the possible presence of prosthetic joints. Septic arthritis should be strongly considered in the RA patient who presents with one joint swelling vastly out of proportion to the others. In this setting, arthrocentesis is warranted to assess for septic arthritis.

TABLE  
23.2**Extraarticular Manifestations of Rheumatoid Arthritis (Does Not Include Potential Medication Toxicities)**

Involvement	Possible Manifestations
Systemic	Constitutional symptoms Rheumatoid nodules (skin, tendons, and lungs commonly) Vasculitis (skin, kidneys, and peripheral nerves) Secondary amyloidosis (heart and kidneys)
Pulmonary	Pleural effusion Interstitial lung disease Bronchiectasis BOOP Pulmonary artery hypertension
Cardiovascular	Raynaud phenomenon Pericardial effusion Increased cardiovascular disease risk Valvular disease
Neurologic	Compressive neuropathies (carpal tunnel syndrome) Myelopathy (cervical spine disease) Mononeuritis multiplex (rheumatoid vasculitis)
Hematologic	Generalized lymphadenopathy Felty and LGL syndromes Macrophage activation syndrome Increased lymphoma risk
Cutaneous	Petechiae and purpura (rheumatoid vasculitis) Pyoderma gangrenosum
Salivary/lacrimal	Keratoconjunctivitis sicca
Ocular	Episcleritis Scleritis Scleromalacia perforans Corneal ulceration Uveitis (JIA patients)
Overlap syndromes	Systemic lupus erythematosus Sjögren syndrome Polymyositis/dermatomyositis Scleroderma Mixed connective tissue disease

*BOOP*, Bronchiolitis obliterans organizing pneumonia; *JIA*, juvenile idiopathic arthritis; *LGL*, large granular lymphocyte.

## Treatment

The last 10 to 15 years have witnessed tremendous strides in the pharmacologic treatment of RA (Table 23.3). Although corticosteroids and nonsteroidal antiinflammatory drugs (NSAIDs) continue to play important roles in symptomatic relief of RA, the advent of DMARDs has radically changed patient long-term outcomes. Traditional small-molecule DMARDs, such as methotrexate, are orally bioavailable, whereas biological DMARDs, such as antagonists of TNF- $\alpha$ , are administered parenterally. The goals of DMARD

therapy are to interrupt the inflammatory process, to reduce pain, to improve function, to slow radiographic joint destruction, and to restore a patient's overall quality of life. Most DMARDs act by suppressing or modulating the immune system to dampen synovitis. Accordingly, one potentially serious side effect of many DMARDs is the increased risk of infection by common bacterial pathogens and also opportunistic pathogens. Finally, nonpharmacologic interventions continue to be important for the treatment of RA. These include patient education, physical therapy, occupational therapy, assist devices, lifestyle modifications, and orthopedic surgery. Surgery is indicated in patients with destructive changes in a joint associated with refractory pain and functional disability.

## Traditional Non-DMARD Pharmacotherapy

Aspirin, acetaminophen, other NSAIDs, corticosteroids, and opiate analgesics have been used to treat RA for decades. These drugs, especially corticosteroids, remain effective in reducing the joint symptoms of RA. However, except for steroids, they have little if any generally accepted disease-modifying activity. Corticosteroids might be an exception to this, but they carry potentially serious adverse effects with chronic usage, especially at high doses. High-dose aspirin (3–4 g/d) or NSAID therapy is associated with a very high risk of gastrointestinal (GI) hemorrhage from peptic ulcer disease as well as worsening of any preexisting renal impairment. Cyclooxygenase (COX-2) inhibitors are presumably safer if the patient does not concomitantly use aspirin.

Relatively low doses of systemic corticosteroids (prednisone 15 mg daily or less) can rapidly control the synovitis of RA in most patients. Indeed, corticosteroids are often used to restore function acutely in patients debilitated by their RA symptoms, especially while waiting for DMARDs to take effect, which may take weeks or months. In addition, some studies have suggested that low-dose daily corticosteroids (prednisone 7.5 mg daily or less) may even have DMARD activity. However, chronic corticosteroid usage even at low doses is associated with many side effects: hypertension, diabetes mellitus, weight gain, cushingoid habitus, osteoporosis, avascular necrosis of bone, cataracts, and perhaps most importantly, worsened cardiovascular outcomes. Thus chronic daily systemic corticosteroids are an undesirable, although sometimes unavoidable, option in patients with RA. Intraarticular injections remain a suitable modality for administering corticosteroids in a patient with only one or two persistently swollen joints. Ultrasound or fluoroscopy can aid in the directed delivery of corticosteroids into joints that might otherwise be difficult to access with certainty (e.g., elbow, shoulder, and hip joints).

With modern DMARD options, opiate analgesics and other opiate receptor agonists (e.g., tramadol) should have only a limited role in the control of inflammatory RA pain. They are best reserved for discriminant use in patients who have contraindications to all other additional DMARDs,

**TABLE  
23.3**

**List of Pharmacologic Agents Used for the Treatment of Rheumatoid Arthritis**

Agent or Drug Class	Mode of Action	Common or Serious Adverse Effects
NSAIDs	Inhibit PG synthesis	Peptic ulcer disease Renal impairment Hepatotoxicity Possible cardiovascular risk
Corticosteroids <sup>a</sup>	Immunosuppressant	Immunosuppression Hypertension Diabetes mellitus Weight gain Cushingoid habitus Osteoporosis Cataracts Avascular necrosis
Methotrexate	Inhibits DHFR Increases extracellular adenosine	Nausea, diarrhea Rash, alopecia Headache Immunosuppression Hepatotoxicity Bone marrow toxicity, cytopenias Pulmonary hypersensitivity Teratogenic
Leflunomide	Inhibits DHOD	Similar to MTX but includes hypertension and weight loss and excludes pulmonary hypersensitivity
Azathioprine	Purine antagonist	Nausea, diarrhea Immunosuppression Hepatotoxicity Cytopenias, bone marrow toxicity Pancreatitis
Sulfasalazine	Incompletely understood	Nausea, diarrhea Rash Hepatotoxicity Cytopenias, bone marrow toxicity Azoospermia
Hydroxychloroquine	Incompletely understood	Retina pigmentation Myopathy and cardiomyopathy Neuropathy
Gold	Incompletely understood	Nausea, diarrhea Rash, chrysiasis Proteinuria
TNF- $\alpha$ antagonist	Inhibits TNF- $\alpha$	Immunosuppression Drug-induced lupus Demyelination? Infusion or injection site reaction
Anakinra	Soluble IL-1 RA	Immunosuppression Injection reaction
Abatacept	Blocks T-cell costimulation	Immunosuppression
Rituximab	B-cell depletion	Immunosuppression Infusion reaction Serum sickness
Tocilizumab	IL-6 receptor blocker	Immunosuppression Dyslipidemia Transaminitis Cytopenias Infusion reaction
Tofacitinib	JAK inhibitor (mostly JAK-1 and JAK-3)	Immunosuppression Dyslipidemia Transaminitis Cytopenias

<sup>a</sup>Most corticosteroid toxicities are associated with higher doses (prednisone >15 mg/dL, or equivalent), or with lower doses in patients with prolonged duration of use (>6 months). Injectable corticosteroids are rarely associated with these side effects unless a patient receives numerous injections in a short period of time. *DHFR*, Dihydrofolate reductase; *DHOD*, dihydroorotate dehydrogenase; *IL-1RA*, interleukin-1 receptor antagonist; *JAK*, Janus kinase; *MTX*, methotrexate; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PG*, prostaglandin; *TNF*, tumor necrosis factor.

have postoperative joint pain, or have end-stage bone-on-bone secondary osteoarthritis as a complication of RA. In RA patients with chronic noninflammatory joint pain, there may also be a role for pain-modulating agents such as gabapentin, pregabalin, or serotonin-norepinephrine reuptake inhibitors (e.g., duloxetine or milnacipran).

### Traditional Small-Molecule DMARDs

There are many orally available traditional small-molecule DMARDs that have been used to treat RA, often with great effectiveness. The antimetabolite drugs methotrexate, leflunomide, and, to a lesser extent, azathioprine remain effective options and an anchor for any treatment regimen. Sulfasalazine and hydroxychloroquine are less potent but relatively more safe DMARDs, making them good options for those with mild disease. Many other therapies have fallen out of favor because of ineffectiveness or excessive toxicity. These agents include gold salts, cyclophosphamide, cyclosporine, and D-penicillamine. Minocycline is rarely used as a DMARD and may take up to 1 year to be effective.

Methotrexate, the most commonly used DMARD in the treatment of RA, is a folic acid analogue that inhibits dihydrofolate reductase, the enzyme that synthesizes folic acid. At low doses, methotrexate may also raise extracellular adenosine levels, which may be the mechanism for its anti-inflammatory activity in RA. Methotrexate has been used for over 30 years to treat RA, and it remains highly effective and safe in patients who are monitored closely. Indeed, methotrexate remains at the foundation of most DMARD therapy regimens. The benefits of methotrexate cannot be overstated, and even patients on other oral DMARDs or biological agents often benefit from combination therapy with methotrexate. In fact, a recent study indicated that methotrexate usage is associated with a significant decrease in morbidity and mortality.

When used to treat RA, methotrexate is administered only once weekly, in doses up to 25 mg weekly. The once-weekly dosing markedly limits the potentially severe hepatic and bone marrow toxicities that occur with daily dosing, which should be avoided. The active metabolite is excreted primarily by the kidneys, and moderately impaired renal function is a contraindication to its use (glomerular filtration rate [GFR] <30 mL/min). Daily folic acid or once-weekly leucovorin administration (10–12 hours after the weekly methotrexate dosing) can limit the drug's hepatic and hematologic toxicity as well as the other common side effects of rash, alopecia, and GI intolerance. Methotrexate is sometimes administered by subcutaneous administration to improve bioavailability and GI tolerance of the drug.

Patients prescribed methotrexate should be monitored at least every 6 to 12 weeks for renal function, liver toxicity, and bone marrow suppression. They should also be advised to restrict alcohol consumption because of enhanced hepatotoxicity. Allergic interstitial pneumonitis

is a rare, idiosyncratic, but potentially life-threatening reaction to methotrexate that precludes a rechallenge. Pulmonary toxicity may occur at any time during therapy but tends to occur in the first 1 to 2 years. It is characterized by fever, cough, dyspnea, eosinophilia, and chest infiltrates. Symptoms are difficult to distinguish from opportunistic pneumonia, so patients often require bronchoscopy and sometimes lung biopsy for diagnosis. Finally, methotrexate is a potent teratogen and an abortifacient at high doses. Men and women both should be advised of this and use appropriate contraception.

Leflunomide inhibits dihydroorotate dehydrogenase, the enzyme responsible for the rate-limiting step in pyrimidine metabolism. It shares many features in common with methotrexate regarding efficacy and toxicity profile. It may be combined with methotrexate or used in combination with other DMARDs. Notably, leflunomide is only available orally, is administered once daily (as opposed to weekly), and folic acid supplementation is unnecessary. The most common side effects of leflunomide include anorexia, diarrhea, and weight loss. Leflunomide can cause hepatic and bone marrow toxicity and rare pulmonary toxicity and is highly teratogenic. Therefore as with methotrexate, patients should undergo regular laboratory analysis for toxicity and use contraception as appropriate. Importantly, leflunomide has a half-life of at least 2 weeks because of extensive enterohepatic recirculation of the drug. For this reason, its use in patients of childbearing age must be carefully considered, and simply discontinuing the drug for acute toxicity or pregnancy is ineffective; enteric binding therapy with cholestyramine is recommended. Finally, leflunomide can cause hypertension or significant idiopathic weight loss, correctable only by discontinuation of the drug.

Sulfasalazine and hydroxychloroquine have only modest activity in RA. They are often used in combination with other DMARDs (or each other) in patients with low disease activity or in those too frail or ill to take more effective DMARDs. Sulfasalazine is a sulfa-class agent that is administered in doses up to 3 g daily, split over the course of the day. It can cause nausea, diarrhea, and rash commonly. More serious side effects include hepatotoxicity and idiosyncratic severe pancytopenia, the latter of which requires cessation of drug. Reversible azoospermia can also occur. Hydroxychloroquine is normally well tolerated but can cause nausea or diarrhea; toxicity is dose related. Patients should not receive more than 6.5 mg/kg/d because higher doses over extended periods of time can very rarely lead to myopathy and the most serious potential adverse reaction, retinal pigmentation that can cause irreversible blindness. In patients with advanced renal disease (GFR <30 mL/min), the dose of hydroxychloroquine should be halved. It is highly advisable that all patients on hydroxychloroquine undergo screening ophthalmologic examinations to monitor for hydroxychloroquine-related maculopathy. Regular ophthalmologic examinations are prudent in these patients. Myopathy of skeletal muscle and

cardiomyopathy are very rare complications of hydroxychloroquine usage.

Emerging small-molecule DMARDs are in the therapeutic pipeline. Unlike biological agents, new small-molecule drugs have the advantage of being orally administered. Intracellular kinase inhibitors represent one of the more exciting classes of small-molecule DMARDs. These agents block intracellular signaling cascades and display remarkable efficacy and tolerability in clinical trials.

## Biological DMARDs

The advent of biological agents at the end of the 20th century has ushered in a revolution in the treatment of RA. Although methotrexate is an effective therapy for many RA patients, many more RA patients continue to experience active synovitis despite the combination of traditional small-molecule DMARD therapy. Our growing understanding of RA disease pathogenesis has led to several new biological DMARDs. Currently, 12 of these agents have been approved for use in the United States, and they fall into five categories: 7 TNF- $\alpha$  antagonists (adalimumab, certolizumab, golimumab, etanercept, infliximab, biosimilar infliximab-dyyb, and biosimilar infliximab-abda); 1 IL-1 receptor antagonist (anakinra); 1 inhibitor of T-cell costimulation (abatacept); 1 B-cell-depleting antibody (rituximab); and 2 IL-6 receptor antibodies (tocilizumab and sarilumab). Of these agents, the TNF- $\alpha$  antagonists have had the most extensive and proven record of accomplishment in the treatment of RA. All biological agents are expensive, costing approximately \$50,000 for 1 year of therapy in the United States.

All biological agents are immunosuppressive drugs that convey a significantly increased risk of bacterial infection and sepsis (up to 5% per year). Vaccination against pneumococcus is prudent. However, opportunistic infections can occur. Most importantly, patients must be assessed for latent or active infection with *Mycobacterium tuberculosis* because fatal outcomes have been associated with this pathogen in patients receiving biological drugs. Patients on any of the biological agents should not receive live vaccines because of the risk of disseminated infection. In some patients, it may be prudent to consider the zoster vaccine before administration of these agents. If this was done, treatment should be delayed for a period of 3 to 4 weeks. There appears to be an increased risk of nonmelanoma skin cancers in these patients, but there does not appear to be an increased risk of hematologic or solid-tumor cancer malignancies. Even before the emergence of biological DMARDs, patients with RA were found to have an increased risk for the development of lymphomas and some solid tumors compared with control patients without RA. A history of cancer or active malignancy will warrant special consideration before the initiation of biological therapy.

With many medications now available to treat RA, several different approaches have been advocated. One notable feature of traditional DMARDs is that these agents are often used in combination with one another, or with

a biological agent. Multiple studies have demonstrated that methotrexate in combination with a TNF- $\alpha$  antagonist outperforms either of these agents as monotherapy. Importantly, biologic DMARDs are never combined; markedly increased rates of infection have been reported without apparent benefit in patients receiving more than one biologic DMARD concurrently. Some rheumatologists advocate for a combination of traditional DMARDs as an alternative to biological agents. The Treatment of Early Aggressive Rheumatoid Arthritis trial showed that disease improved similarly in patients with early RA when comparing the triple therapy combination of methotrexate, hydroxychloroquine, and sulfasalazine versus a combination of methotrexate plus etanercept.

The TNF- $\alpha$  antagonists all inhibit the proinflammatory cytokine TNF- $\alpha$ , which is present in rheumatoid synovium. These agents all reduce signs and symptoms of RA, slow radiographic joint changes, and improve patients' physical function. A substantial number of patients treated with these agents will have significant suppression of disease activity. Combination therapy with methotrexate can synergistically amplify the effectiveness of these agents. There are subtle differences in the TNF- $\alpha$  antagonists, molecules, and their route of administration, but effectiveness is believed to be similar. Infliximab is a chimeric mouse and human anti-TNF- $\alpha$  monoclonal antibody administered by intravenous infusion. Adalimumab and golimumab are fully human anti-TNF- $\alpha$  monoclonal antibodies that are given by subcutaneous injection (in the case of adalimumab) or as either subcutaneous injection or intravenous infusion (in the case of golimumab). Etanercept is a fusion protein of soluble TNF- $\alpha$  receptor and the constant region of the immunoglobulin heavy chain. It is administered by subcutaneous injection. Certolizumab is a polyethylene glycol-conjugated (PEGylated) anti-TNF- $\alpha$  Fab fragment, administered by subcutaneous injection. Patients who do not respond to or lose response to one agent may benefit from a trial of another drug from this same class. All injectable TNF antagonists are administered at fixed doses, whereas the dosing is weight based for infusible infliximab and golimumab.

Anti-TNF- $\alpha$  antagonist agents are remarkably well tolerated. The principal toxicity is immunosuppression, as discussed previously. Infusion or injection reactions are rare and generally well tolerated. A reversible drug-induced lupus reaction has been described, as have other autoimmune phenomena such as psoriasis, dermatomyositis, and sarcoidosis. There may be a risk for unmasking a propensity for demyelinating disorders such as multiple sclerosis (MS), especially in a patient with a personal or family history of MS disorder. In addition, these therapies should be suspended in the face of an active infection or class III to IV heart failure.

Anakinra is a recombinant soluble IL-1 receptor antagonist that blocks the proinflammatory cytokine IL-1. It is of only modest efficacy in RA and is rarely used. Further, patients often develop an urticarial reaction to the daily subcutaneous injection, which decreases tolerability. Anakinra

is particularly useful in febrile adult-onset Still disease and the cryopyrin-associated diseases such as Muckle-Wells syndrome. It also appears to be highly effective in controlling the inflammation of gout and pseudogout.

Abatacept is a recombinant fusion protein of cytotoxic T-lymphocyte-associated antigen-4 and the constant region of the immunoglobulin heavy chain. It acts to impair costimulation of T cells, which is required for optimal T-cell activation. Although its time-to-onset may be longer than with other biological agents, abatacept appears to be as effective as TNF antagonists in the treatment of RA. It is administered by monthly intravenous infusion or by weekly subcutaneous injection. Abatacept is immunosuppressive but otherwise generally well tolerated.

Rituximab is a chimeric mouse and human anti-CD20 monoclonal antibody that leads to depletion of B cells. It is effective in the treatment of RA, although typically reserved for patients who are refractory to other biological therapies. In addition, rituximab is a particularly attractive option in RA patients with a history of systemic lupus erythematosus, MS, lymphoma, or other malignancy. In these conditions, TNF antagonists are often relatively contraindicated. Rituximab is administered by intravenous infusion, typically every 6 months. It is generally well tolerated. In addition to its immunosuppressive qualities, potentially severe infusion reactions, serum sickness, and late-onset cytopenias have been described.

Tocilizumab and sarilumab are anti-IL-6 receptor monoclonal antibodies. IL-6 is a proinflammatory cytokine that contributes to synovial inflammation and systemic features of RA. RA patients treated with tocilizumab demonstrate responses similar to those treated with TNF antagonists, although studies have shown that tocilizumab is as effective as monotherapy as it is in combination with methotrexate. Similar to other biological agents, IL-6 antagonists are immunosuppressive. Unlike other biological drugs, however, these agents are more associated with dyslipidemia and bowel perforation from diverticulitis, and they more commonly cause transaminitis and significant cytopenias, which may limit their use.

### Emerging Small-Molecule DMARDs

New classes of small-molecule DMARDs are being aggressively investigated and developed in the pipeline of RA therapies. Most of these new small-molecule agents are administered orally, which some patients may prefer over injectable or infusible biological options. Intracellular kinase inhibitors represent one of the more exciting classes of emerging small-molecule DMARDs. These agents block intracellular signaling cascades and display remarkable

efficacy and tolerability in clinical trials. One such agent, tofacitinib, was approved for use in the United States for the treatment of RA. Administered 5 mg twice daily or 11 mg once daily extended release, tofacitinib inhibits various Janus kinase (JAK) molecules, particularly JAK-3. Clinical trials suggest a relatively rapid onset of action of only 2 to 4 weeks, which is quicker than most other DMARDs. In a head-to-head study, tofacitinib was more effective than monotherapy with methotrexate and was as effective as adalimumab. Toxicities of tofacitinib may not yet be fully established, but adverse events from clinical trials include immunosuppression, cytopenias, transaminitis, dyslipidemia, and herpes zoster. It is suggested that tofacitinib be used only after failure of methotrexate and biological therapies.

### Summary

Rheumatoid arthritis is one of the most common chronic systemic autoimmune disorders. It is characterized by joint inflammation, cartilage destruction, and bone erosion. Patients typically present with signs and symptoms of synovitis: tender, red, swollen, warm joints with effusions and a preponderance of morning stiffness. RF assay, ACPA testing, and various imaging studies can aid in the diagnosis. ESR and CRP assist in the measurement of disease activity and response to drug therapy. Cervical symptoms, extraarticular involvement, and the possibility of concurrent septic arthritis are all special considerations.

Many treatment options exist for the patient with RA, and great strides have been made in DMARD therapies. Methotrexate and other traditional small-molecule DMARDs remain the foundation of therapy for most patients with RA. For patients not responsive or tolerant to these approaches, biological agents DMARDs are appropriate. These agents are emerging therapies that target inflammatory cytokines, B cells, or T-cell costimulation. Emerging small-molecule DMARDs impair intracellular signaling pathways to reduce RA disease activity. These agents will play an expanding role in the treatment of RA in years to come.

Implicit in the successful treatment of RA is that an early diagnosis of the disease is imperative, so that patients can have the best possible outcome. Early referral to a rheumatologist and early initiation of DMARD therapies are associated with improved outcomes symptomatically, structurally, and functionally. The last 15 years have seen a revolution in the treatment of RA with tremendous benefit to patients. Goals of therapy should now include disease-free remission. The therapeutic challenge for rheumatologists is to achieve disease remission with the potentially least toxic combination of medications possible.

## Chapter Review

### Questions

- A 58-year-old woman with long-standing RA presents to your office with 3 days of accelerating pain and swelling in her left knee. Her other joints are asymptomatic. She has had fatigue for 1 week but denies fever, chills, or night sweats. The remainder of her review is unremarkable. Her medical history is notable only for her RA and a prosthetic right hip. Her last flare of RA was 5 months ago and responded to treatment with corticosteroids. Her current medications include prednisone, 5 mg daily, methotrexate, 20 mg weekly, and etanercept, 50 mg weekly. She has a life-threatening allergy to penicillin. Examination reveals a generally well-appearing woman of average stature with an antalgic gait. Vital signs reveal a temperature 37.2°C, blood pressure 98/70 mm Hg, heart rate 110, and respiratory rate 14 breaths per minute. She has a slightly warm and markedly swollen left knee; it is only mildly tender to palpation. However, on either active or passive range of motion, severe pain is elicited with flexion greater than 30 degrees or near full extension. The remainder of her musculoskeletal examination reveals mild deformities from RA but is otherwise unremarkable. Which of the following is the most appropriate measure to do next?

  - Increase steroid dose to prednisone, 60 mg daily.
  - Initiate intravenous vancomycin and levofloxacin.
  - Perform arthrocentesis of her left knee.
  - Arrange for interventional radiology to perform arthrocentesis of her right hip.
  - Check Lyme serology and initiate doxycycline.
- An 82-year-old woman suffered a large right hemispheric stroke and has been admitted to a nursing home after a 2-week hospitalization that was otherwise uncomplicated. She had been previously healthy except for a recent diagnosis of RA made 3 months before the stroke. At the time of her stroke, her only medications were methotrexate, 17.5 mg (7 × 2.5 mg tablets) by mouth once weekly, and folic acid, 1 mg daily. When in the hospital, she had also been prescribed aspirin, 325 mg daily, atenolol, 25 mg daily, and atorvastatin, 20 mg nightly. Four weeks after being admitted to the nursing home, she developed intense nausea, vomiting, and diarrhea. Her abdominal examination is unrevealing, and she has guaiac-negative stool. She is given intravenous fluids, and laboratory testing reveals the following:

WBC:  $0.3 \times 10^3$  cells per  $\text{mm}^3$   
Hematocrit: 25.5%  
Platelet count:  $70 \times 10^3$  cells per  $\text{mm}^3$   
Mean corpuscular volume (MCV): 110 fL

Which of the following would most likely reveal the cause of her blood count abnormalities?

  - Bone marrow aspirate and biopsy
  - Serum testing for antineutrophil and antiplatelet antibodies
  - Abdominal ultrasound to measure spleen size
  - Review of daily medication administration sheets
  - Colonoscopy
- A 30-year-old woman with RA of 10 months' duration visits your office for a scheduled follow-up visit. She continues to have 2 hours of morning stiffness and multiple swollen and tender joints despite being on subcutaneous methotrexate, 25 mg weekly. She receives her methotrexate injections in your clinic and has tolerated the drug. She has had to go on disability from her job as a security guard because of persistent joint pains. Her medical history is otherwise unremarkable, and her only other medications are folic acid, 1 mg daily, and naproxen, 500 mg bid. You note that she has had a nonreactive purified protein derivative test within the past 12 months and is up to date with immunizations. Physical examination demonstrates erythema, warmth, and swelling at her wrists, knees, ankles, and all metacarpal phalangeal, and proximal interphalangeal joints. Laboratory analysis reveals ESR 90 mm/h. Which of the following is the most appropriate next measure?

  - Initiate subcutaneous etanercept, 50 mg once weekly.
  - Perform arthrocentesis of her left knee, and if no signs of septic arthritis, then inject corticosteroids.
  - Change naproxen to celecoxib, 200 mg twice daily, and see her in follow-up in 3 months.
  - Check antinuclear antibody (ANA) titer.
  - Initiate prednisone, 40 mg daily.
- A 42-year-old Hispanic man presents with 3 months of bilateral pain and swelling in his knees, elbows, wrists, and six metacarpal phalangeal joints. He has had 2 hours of morning stiffness and has been fatigued. He has been out of work in construction for 3 weeks because of symptoms. The review of systems is otherwise negative, and he has never had problems with joint pain before. Ibuprofen, 800 mg tid, has provided only minor relief. He takes no other medications and is otherwise healthy. He denies alcohol and tobacco use. Physical examination demonstrates swelling and limited range of motion of involved joints. Knee effusions are present bilaterally. Arthrocentesis of the right knee reveals 30 mL of nonbloody fluid with  $8000 \text{ WBC}/\text{mm}^3$  and 72% polymorphonuclear leukocytes. Gram stain and crystal analysis of the fluid are negative. Additional laboratory tests show WBC normal, hematocrit 35%, platelet count  $650 \times 10^3$  cells per  $\text{mm}^3$ , RF negative, ACPA negative, ANA negative, uric acid 4.5 mg/dL, and ESR 76 mm/h. Radiographic imaging demonstrates periarticular soft tissue swelling but no osteopenia, joint space narrowing, or marginal erosions. Which of the following is the most likely diagnosis?

  - Rheumatoid arthritis
  - Polyarticular gouty arthritis
  - Osteoarthritis
  - Polymyalgia rheumatica
  - Septic arthritis from *Neisseria gonorrhoeae*

5. A 48-year-old woman presents with 2 months of fever, abdominal pain, weight loss, generalized achiness, and rash on her lower extremities. She has noticed dyspnea on exertion and a 10-lb weight gain in the past 2 weeks. She is otherwise asymptomatic. She takes no medications. Medical history is notable only for a motor vehicle accident as a teen for which she received multiple blood transfusions. She does not smoke, use illicit drugs, or drink alcohol excessively. Physical examination demonstrates a thin woman in no acute distress. Vital signs are within normal limits. Oxygen saturation is 93% on room air. She has innumerable 1-mm to 2-mm nonblanching nontender erythematous lesions on her feet and calves bilaterally with pitting lower extremity edema to her thighs. Her jugular vein distension is 10 cm, and she has rales discernible at the bilateral lung bases. She has a nontender abdomen with no hepatosplenomegaly or masses. Rectal examination reveals guaiac-positive brown stool. Musculoskeletal examination is notable for periarticular tenderness but no erythema or swelling. Laboratory analysis shows the following:  
 Blood urea nitrogen 75 mg/dL, creatinine 4.1 mg/dL, electrolytes normal  
 Albumin 2.8 g/dL; total bilirubin 3.1 mg/dL, direct bilirubin 2.1 mg/dL; aspartate aminotransferase, alanine transaminase, and alkaline phosphatase normal

WBC  $7.6 \times 10^3$  cells/mm<sup>3</sup>, hematocrit 32.4%, platelets  $60 \times 10^3$  cells/mm<sup>3</sup>, international normalized ratio 1.8, partial thromboplastin time 31 s

Urinalysis: 3+protein, 20–40 red blood cells (RBC) per high-powered field with dysmorphic RBC and one RBC cast

ESR 55 mm/h, RF 280 IU/mL (normal <10), ACPA negative, ANA negative

C3 110 mg/dL (normal 90–180), C4 2 mg/dL (normal 10–40)

Blood cultures show no growth after 48 hours (three sets)

Which of the following is the most likely diagnosis?

- Rheumatoid vasculitis
- Cryoglobulinemic vasculitis
- Bacterial endocarditis
- Systemic lupus erythematosus
- Hemochromatosis

## Acute Monoarticular Arthritis

C. RYAN ANTOLINI, FLAVIA V. CASTELINO, AND ANTHONY M. REGINATO

**A**cute monoarticular arthritis represents one of the few rheumatologic emergencies that internists, emergency department (ED) physicians, and rheumatologists will encounter in their daily clinical practice. The possibility of joint infection leading to the loss of joint function is a serious potential consequence in delayed diagnosis of a septic joint. Despite advances in diagnosis and treatment, the morbidity and mortality from septic arthritis remain high; therefore timely recognition of an infected joint is imperative for a favorable outcome. The differential diagnosis of acute monoarticular arthritis is broad and includes septic arthritis, crystalline disorders, inflammatory disorders, and mechanical problems with the joint (Box 24.1).

### Evaluation of a Patient With Acute Monoarticular Arthritis

#### History and Physical Examination

Any acute inflammatory process that develops in a single joint over a few days (<2 weeks) is considered acute monoarticular arthritis. A careful history with emphasis on the chronology of symptoms may help in assessing the diagnosis of acute monoarticular arthritis. Historical features that should be sought include fever, rigors, recent sexual activity, gastrointestinal or genitourinary symptoms, recent illnesses, tick exposure, travel to an endemic area, past history of recurrent attacks, renal insufficiency, history of trauma, and a family history of gout or other arthritic conditions. Patients may note concurrent or preexisting involvement of other joints. Special attention should be paid to patients with systemic rheumatic disease such as rheumatoid arthritis (RA), spondyloarthropathy (SpA), and lupus (SLE) who present with one joint that is significantly more painful and swollen than the rest of the other affected joints and those with a prosthetic joint, as these groups represent a high risk for septic arthritis.

The physical examination should focus on determining whether the source of pain is in the true joint or periarticular soft tissues such as tendon, ligaments, or bursae. Asking the patient to point to the exact site of tenderness may be helpful. The joint should be carefully examined for

warmth, erythema, and a possible effusion. Intraarticular involvement causes restriction of active and passive range of motion. Stress pain (maximum pain at limits of joint motion) is characteristic of true arthritis. Patients with a septic or crystalline arthritis will be exquisitely tender on examination of the joint. Specific maneuvers should assist in distinguishing true inflammatory arthritis from soft-tissue periartthritis or pain syndromes such as medial epicondylitis, bicipital or rotator cuff tendinopathy, trochanteric bursitis, and prepatellar and/or anserine bursitis. Joint effusion may not be readily visible on physical examination. In the knee joint, the “bulge sign” can signal a small effusion. Musculoskeletal ultrasound may assist the identification of small effusions not detected on clinical examination and facilitate evaluation of surrounding soft tissue. The physical examination should focus not only on inspection of the involved joint but also on other joints, as well as signs of an underlying systemic disorder. Involvement of <4 joints (oligoarticular) or >4 (polyarticular) would sway the diagnosis toward crystal arthritis or seronegative or seropositive RA rather than septic arthritis or would portend a worse prognosis for a patient with polyarticular septic arthritis.

#### Diagnostic Studies

The diagnostic test for acute monoarticular arthritis is arthrocentesis of the affected joint for analysis of cell count, evaluation for the presence of crystals under compensated polarized light microscopy, and culture of the synovial fluid. Diagnostic arthrocentesis is required in most patients presenting with a monoarthritis and a suspicion of infectious arthritis. Superimposed cellulitis is a relative contraindication to arthrocentesis. The procedure can safely be performed in patients who are anticoagulated (Coumadin) by using the smallest possible needle size or under ultrasound guidance. In some instances, as little as one or two drops of synovial fluid may be aspirated in an initially presumed “dry tap,” with a priority placed in obtaining culture and crystal analysis.

Normal synovial fluid is colorless, and the gross appearance of the fluid can provide a clue to a possible noninflammatory versus inflammatory joint process as shown in Fig. 24.1. Synovial fluid that is cloudy or purulent

### • BOX 24.1 Etiology of Acute Monoarticular Arthritis

#### Common

Infectious arthritis  
 Bacteria  
   Lyme disease  
   Fungi  
   Mycobacteria  
   Viruses  
 Crystals  
   Monosodium urate  
   Calcium pyrophosphate dihydrate  
   Basic calcium phosphate  
   Calcium oxalate  
   Lipid  
 Internal derangement  
 Trauma/overuse  
 Hemarthrosis  
   Trauma  
   Anticoagulation  
   Clotting disorders  
   Fracture  
   Pigmented villonodular synovitis  
 Osteoarthritis  
 Osteomyelitis  
 Osteonecrosis

#### Less Common

Systemic rheumatic disease  
   Juvenile rheumatoid arthritis  
   Rheumatoid arthritis  
 Spondyloarthropathy  
   Reactive arthritis  
   Bowel disease–associated arthritis  
   Psoriatic arthritis  
   Ankylosing spondylitis  
 Sarcoidosis  
 Loose bodies  
 Malignancies  
   Chondrosarcoma  
   Osteoid osteoma  
   Metastatic disease

#### Rare Causes

Foreign body synovitis  
 Amyloidosis  
 Behçet syndrome  
 Familial Mediterranean fever  
 Hypertrophic pulmonary osteoarthropathy  
 Intermittent hydrarthrosis  
 Relapsing polychondritis  
 Adult-onset Still disease  
 Synovial tumors  
 Synovial metastasis

represents an inflammatory joint effusion. The presence of a bloody synovial effusion may represent a traumatic injury or fracture, anticoagulation or clotting disorder, and, less frequently, pigmented villonodular synovitis.

Analysis of the cell count of synovial fluid will give more information about an inflammatory versus noninflammatory

effusion and the likelihood of a septic joint (Box 24.2). Noninflammatory effusions have a white blood cell (WBC) count  $<2000/\text{mm}^3$ . An inflammatory synovial effusion will have a leukocyte count  $>2000$  cells/ $\text{mm}^3$ . WBC counts  $>50,000/\text{mm}^3$  are generally suggestive of a septic arthritis until proved otherwise but can be seen with a variety of inflammatory disorders (i.e., gout, pseudogout, RA, and other inflammatory arthritis). Conversely, lower cell counts can be seen in patients with septic arthritis, especially with chronic atypical infections such as *Mycobacterium* or with partially treated infections. Although the cell count is useful in determining whether or not an effusion is inflammatory, synovial fluid Gram stain and culture are required in all patients in whom septic arthritis is suspected.

#### Imaging Studies

Radiographs are of initial value, if significant trauma or focal bone pain is present, to exclude fracture, tumor, or osteomyelitis. However, they play no role in the initial distinction between acute crystal-induced or septic arthritis. Radiographs may confirm the presence of a joint effusion in joints where effusions are difficult to ascertain by physical examination (i.e., elbow, ankle, and hip). The presence of tophaceous erosions, chondrocalcinosis, and joint-space narrowing does not exclude the possibility of infection as an etiology of acute monoarthritis. Musculoskeletal ultrasound provides a simple technique not only to assess small effusions but also to perform ultrasound-guided arthrocentesis of the affected joints and is more sensitive than physical examination in detecting synovitis. CT scans should be reserved to detect effusions and needle placement for aspirations of joints that are difficult to assess, such as the hip, sacroiliac, or sternoclavicular joints. MRI is useful for diagnosing effusions in deep-seated joints such as the sacroiliac joint, hip, and shoulder, which are difficult to detect by physical examination. In addition, MRI can distinguish synovitis from ligamentous or other soft tissue abnormalities and tissue injuries.

#### Synovial Biopsy and Arthroscopy

Needle biopsy of the synovial membrane under ultrasound or biopsy obtained during arthroscopy is seldom performed as part of the initial evaluation of monoarticular arthritis. In rare instances, synovial biopsy may assist in the diagnosis of refractory monoarthritis such as that seen with atypical infectious agents (e.g., tuberculosis or fungal infections), infiltrative diseases (e.g., amyloidosis), sarcoidosis, pigmented villonodular synovitis (PVNS), or intraarticular tumors.

#### Differential Diagnosis

Acute monoarthritis can have many causes (see Box 24.1), but crystals, trauma, and infection are most common. Prompt diagnosis of joint infection is critical because of its destructive

WBC, White blood cell.

nature. An algorithm for evaluation of patients who present with acute monoarticular arthritis is outlined in Fig. 24.2. The crystal-induced arthritides are the most important forms of acute arthritis that are difficult to differentiate from acute monoarticular septic arthritis on clinical examination. Any form of chronic inflammatory joint disease such as a reactive arthritis (ReA), psoriatic arthritis (PsA), ankylosing spondylitis (AS), and arthritis associated with inflammatory bowel disease (IBD) can present with a swollen joint that simulates septic arthritis. Most patients with these conditions have extraarticular manifestations of their disease, such as recent genitourinary or gastrointestinal symptoms, conjunctivitis or uveitis, enthesopathy, or skin or mucous membrane lesions, with a predilection for lower back pain and stiffness or sacroiliac joint involvement. Another rheumatic disease that is important to differentiate from septic arthritis is RA. Although the clinical presentation of RA is a symmetric, chronic, polyarticular joint disorder, some patients may present with an acute or subacute exacerbation of one or few of their joints. One-third of the patients with RA may present with monoarticular arthritis as their initial presentation. They may present with a pseudoseptic arthritis picture, including an explosive synovitis with marked synovial fluid leukocytosis. Similarly, RA patients on biological therapy may present with monoarthritis not related to RA flares but to underlying septic arthritis, highlighting the importance of a Gram stain and culture of the synovial fluid. Other mimickers of septic arthritis include subacute bacterial endocarditis and any periarticular inflammation.

• **Fig. 24.2** Algorithm for evaluation of patients with monoarticular arthritis. AVN, Avascular necrosis; CaOx, calcium oxalate; CPP, calcium pyrophosphate dihydrate; HA, hydroxyapatite; IBD, inflammatory bowel disease; JRA, juvenile rheumatoid arthritis; MSU, monosodium urate; MSUS, musculoskeletal ultrasound; OA, osteoarthritis; PMNs, polymorphonuclear neutrophils; PsA, psoriatic arthritis; PVNS, pigmented villonodular synovitis; RA, rheumatoid arthritis; ReA, reactive arthritis; SLE, systemic lupus erythematosus; SpA, spondyloarthritis; WBCs, white blood cells.

## Septic Arthritis

Normal, diseased, and prosthetic joints are all vulnerable to bacterial infection (Box 24.3). Acute bacterial arthritis remains a medical emergency with significant morbidity and mortality even when proper antibiotic therapy is instituted; therefore timely recognition is imperative for a favorable outcome. There are two peaks of incidence that seem to be age dependent: one age <15 years and the other age >55 years. The mortality rates in adults range from 10% to >50%. More than 30% of patients will be left with some irreversible residual joint damage. As with any monoarticular arthritis, a thorough history and physical examination remain key to diagnosing septic arthritis.

## Pathogenesis

The synovium is highly vascular and contains no limiting basement membrane, promoting easy access of blood

contents to the synovial space. Most acute septic arthritis results from seeding of the joint through four possible entry routes: most commonly through hematogenous or contiguous spread of the organism, sometimes by penetrating trauma, and rarely by iatrogenic joint injection. Any infection that affects the skin, soft tissues, or mucous membranes (respiratory, gastrointestinal, or genitourinary tracts) can seed a joint through the bloodstream. Localized infections from an adjacent focus can also spread contiguously into the joint space. Direct inoculation can occur with any penetrating trauma or any procedural invasion of the joint space, such as with an arthrocentesis or arthroscopy. Once the bacteria enter the closed joint space, they can trigger an acute inflammatory response within a few hours. The synovial membrane reacts with proliferative hyperplasia and an influx of acute and chronic inflammatory cells, creating the characteristic acute purulent joint inflammation. In a few days, the inflammatory cells release various cytokines and proteases, leading to cartilage damage, inhibition of cartilage synthesis, irreversible bone loss, and joint damage.

*Escherichia coli*  
*Haemophilus influenzae*  
*Kingella kingae*  
*Klebsiella pneumoniae*  
*Pasteurella multocida*  
*Proteus mirabilis*  
*Pseudomonas aeruginosa*  
*Salmonella* species  
*Serratia marcescens*

#### Anaerobes

*Bacteroides fragilis*  
*Clostridium* species  
*Fusobacterium necrophorum*  
*Peptococcus* and *Peptostreptococcus* species  
*Spirochetes*  
*Borrelia burgdorferi*  
*Treponema pallidum*  
*Mycoplasma*  
*Mycoplasma hominis*  
*Mycoplasma pneumoniae*  
*Ureaplasma urealyticum*

### Microbiology

Septic joint effusions may be caused by bacteria, mycobacteria, or fungi. The most common etiology for joint infection is the gram-positive cocci, either staphylococci or streptococci. *Staphylococcus aureus* is the most frequent cause in joint infection, including both native and prosthetic joints, although *Staphylococcus epidermidis* occurs more commonly in prosthetic joints. Gram-negative bacilli are seen in 5% to 20% of patients and usually occur in elderly adults, those with comorbidities, or intravenous drug abusers, or both. Anaerobic organisms rarely cause septic arthritis; however, they can be seen in any penetrating trauma. *Neisseria gonorrhoeae* is the most common sexually transmitted organism causing infectious arthritis, and although it used to be a common cause for infectious arthritis in the 1970s and 1980s, the incidence has now decreased significantly.

### • BOX 24.4 Predisposing Factors in Bacterial Arthritis

#### Age

Newborns and elderly/old age

#### Local Factors

Skin infection  
Direct joint trauma  
Recent joint surgery  
Open reduction fractures  
Arthroscopy  
Preexisting joint disease: rheumatoid arthritis, crystal disease, osteoarthritis, hemophilic arthropathy  
Prosthetic joint

#### Systemic Factors

Rheumatoid arthritis  
Diabetes mellitus  
Psoriasis  
Comorbidities: cancer, diabetes, chronic renal failure, chronic liver disease  
Concomitant infection, for example, skin  
Malignancies  
Intravenous drug abuse, alcoholism  
Hemodialysis  
Hemophilia  
Immunosuppression  
Congenital: hypogammaglobulinemia, complement deficiency  
Acquired: AIDS, organ transplantation, immunosuppressant medication (steroids, biological therapies)

### Risk Factors

Experimental evidence suggests that normal joints are very resistant to infection compared with diseased or prosthetic joints. Systemic, local, and social factors are important risk factors that contribute to the risk of developing bacteremias and reduce the body's capacity to eliminate organisms from the joint (Box 24.4). Systemic disorders affect the host's response through an impaired immune system. Local factors such as damage to a specific joint from earlier trauma, recent joint surgery or arthroscopy, and the presence of a prosthetic joint are important predisposing factors for septic arthritis. Social factors include occupational exposure to animals (e.g., brucellosis), exposure to tuberculosis, mass emigration from endemic areas of the world, and factors that lead to an immunocompromised state (AIDS, intravenous drug abuse [IVDA], homelessness, therapeutic noncompliance, and emergence of drug-resistant mycobacteria). In some cases, the risk factors are compounded by medications (e.g., patients with RA or inflammatory arthritis treated with immunosuppressant, biological therapies, and steroids). Furthermore, it may also be difficult to distinguish an infectious etiology in patients receiving immunosuppressive therapy. Risk factors for increased mortality in septic arthritis include age >65 years, mental status changes at presentation, multiple joint involvement, and systemic symptoms (suggesting a higher bacterial load).

## Clinical Features

The acute onset of monoarticular pain with increasing severity, tenderness, heat, and swelling is the classical presentation for septic arthritis. Although septic arthritis is most often monoarticular, polyarticular septic arthritis occurs in 15% of cases, usually with asymmetric involvement of three or four joints. The larger joints are more commonly involved, with the knee reported in more than 60% of cases. Hip infections are common in younger children. The hip may be held in a flexed and externally rotated position, and there is extreme pain on hip motion. It is often difficult to detect an effusion of the shoulder or the hip on clinical examination, although the joint is frequently warm and tender; the presence of effusion may be confirmed by ultrasound followed by ultrasound-guided diagnostic arthrocentesis. The sacroiliac joint is involved in 10% of infections. These joints are difficult to evaluate by physical examination and may require imaging studies such as radiographs, CT scan, or MRI. Polyarticular septic arthritis is most likely to occur in patients with RA, systemic connective tissue disease, or in patients with overwhelming sepsis. Gonococcal and meningococcal infections present most commonly with migratory polyarticular arthritis. Fewer than 50% of patients with gonococcal arthritis present with a purulent joint infection of the knee or wrist. The most common extraarticular manifestations of gonococcal arthritis include fever, tenosynovitis, and dermatitis with a characteristic erythematous papular or petechial rash; however, these features are seen in the disseminated form.

## Diagnostic Workup

The key to the diagnosis of septic arthritis is the identification of bacteria in the synovial fluid by Gram stain or culture, thus making arthrocentesis the cornerstone for diagnosing septic arthritis. As previously stated, the synovial fluid is sent for cell count with differential, Gram stain,

and culture. If the WBC count is extremely high (usually  $>100,000/\text{mm}^3$ ), a presumed diagnosis of septic arthritis is made until cultures come back positive. However, cell counts can also range from  $50,000/\text{mm}^3$  to  $100,000/\text{mm}^3$  in patients with septic arthritis; therefore Gram stain and cultures are imperative. Gram stains are positive only 60% to 80% of the time. For patients in whom gonococcal arthritis is suspected, the yield of culture can be higher if plates of chocolate agar or Thayer-Martin media are inoculated with synovial fluid. If there is a specific history of tuberculosis exposure or endemic exposure to Lyme disease or fungal organisms, then the appropriate cultures need to be ordered. Other laboratory studies such as peripheral WBC count can be normal in 30% of patients, and an elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP) may be nonspecific. In children, an elevated ESR and/or CRP may be more helpful in patients with possible septic monoarthritis of the hips. Blood cultures are positive in about one-half of the patients with nongonococcal septic arthritis and should be obtained in any patient with suspected bacterial arthritis. Negative cultures may occur in those who have received recent antimicrobial therapy or those who are infected with fastidious organisms, such as *Mycoplasma* or streptococci. The coexistence of crystal-induced arthritis and bacterial infection must not be overlooked, and a wet preparation for examination under compensated polarized light microscopy is an essential test in evaluating monoarticular arthritis because of crystal deposition diseases.

## Therapy

Immediate treatment with empirical antibiotic therapy (once arthrocentesis is complete) along with removal of any purulent material from the joint space is the mainstay of therapy. A typical antibiotic regimen is based on risk factors and is shown in Table 24.1. Once culture results and

**TABLE 24.1** Empiric Antibiotic Treatments for Septic Arthritis

Risk Factors	Antibiotic Selection
No risk factors	Vancomycin 30 mg/kg per 24 h in two equally divided doses or nafcillin or oxacillin 2 g IV every 4 h
Risk for gram-negative organisms	Ceftriaxone 2 g IV every 24 h or cefotaxime 2 g IV every 8 h; if pseudomonas is a concern, then cefepime 2 g IV every 12 h
Penicillin allergy	Aztreonam 2 g every 8 h or gentamycin 3–5 mg/kg in two to three divided doses
Methicillin-resistant <i>Staphylococcus aureus</i>	Vancomycin 1 g IV every 12 h or clindamycin 600 mg IV every 8 h or linezolid 600 mg IV every 12 h or daptomycin 6 mg/kg/d
Suspected gonococcal or meningococcal infection	Ceftriaxone 2 g IV every 24 h or cefotaxime 1 g IV every 8 h plus single dose of azithromycin 1 g orally
Suspected <i>Pseudomonas aeruginosa</i>	Gentamycin (3–5 mg/kg/d in two or three divided doses) and ceftazidime; in cephalosporin-allergic patients, may use ciprofloxacin 400 mg IV every 8–12 h or 500–750 mg orally twice daily

Mathews CJ, Kingsley G, Field M, et al. Management of septic arthritis: a systematic review. *Ann Rheum Dis*. 2007;66:440-445; Goldenberg DL, Sexton DJ. Septic arthritis in adults. <https://www.uptodate.com/contents/septic-arthritis-in-adults>; 2012.

susceptibilities are available, the antibiotic therapy can then be modified; duration of therapy is usually 4 weeks or longer, and daily aspiration or lavage (arthroscopy or surgical drainage) results in removal of inflammatory products and yields a better outcome. Parenteral administration of antibiotics should be for at least 14 days followed by oral therapy (if possible) for an additional 14 days. Patients with susceptible organism sensitive to oral agents with high availability (fluoroquinolones) can be treated for a short course (4 to 7 days) of parenteral therapy followed by 14 to 21 days of oral therapy. Longer course of parenteral antibiotic therapy (3–4 weeks) may be required for difficult to treat pathogens such as *P. aeruginosa* or *Enterobacter* ssp. A longer course of therapy is warranted in the setting of bacteremia and septic arthritis associated with *S. aureus*.

### Lyme Disease

Lyme disease results from a tick-transmitted infection by the spirochete *Borrelia burgdorferi*. Patients with Lyme disease may present with an acute or chronic monoarthritis, especially of the knee. Early symptoms include erythema chronicum migrans, transient polyarthralgias with viral-like symptoms, and symptoms of aseptic meningitis. Chronic persistent synovitis develops in 20% of patients with untreated Lyme diseases. Monoarthritis occurs during the late infectious stage of Lyme disease or as an autoimmune arthritis or antibiotic-refractory arthritis with persistent joint swelling despite 2 to 3 months of oral or intravenous antibiotics in some patients.

### Viral

Viral arthritides have also been associated with acute monoarthritis. Most viral arthritides present with an acute polyarthritis, fever, and characteristic rash (parvovirus, hepatitis B and C, rubella) and are often associated with a pseudoreumatoid joint distribution. However, varicella zoster virus, cytomegalovirus, herpes simplex type 1, and HIV have been associated with monoarthritis or oligoarthritis. HIV infections may be associated with a wide variety of rheumatic disorders including reactive arthritis, psoriatic arthritis, vasculitis, and Sjögren syndrome. A subacute monoarthritis or oligoarthritis that mimics infection or gout has been described in HIV patients. HIV is an important risk factor for infectious arthritis, including atypical bacterial as well as gonococcal and mycobacterial arthritis.

### Mycobacterial and Fungal

Mycobacterial and fungal arthritides both present with an insidious onset, have an indolent course, and create diagnostic difficulties because of lack of clinical findings. Joint swelling is marked, but signs of acute joint inflammation are absent or mild.

Osteoarticular involvement occurs in 1% to 5% of individuals with tuberculosis. Osseous infection occurs during hematogenous spread, either with primary infection or after late reactivation. Tuberculous arthritis affects mainly the hips, knees, and other joints with characteristic radiographic

features including juxtaarticular osteoporosis, marginal erosions, and gradual joint space narrowing (Phemister's triad). Additional findings include soft tissue swelling, subchondral cysts, bony sclerosis, periostitis, and calcification. Synovial cultures are positive in 80% to 90% of tuberculous arthritis and culture of synovial tissue in 94%. Caseating and noncaseating granulomas are present in 90% of synovial biopsies. Atypical mycobacterial monoarthritis, especially with *Mycobacterium marinum*, *M. kansasii*, or *M. avium-intracellulare*, shows predominance of arthritis and tendinitis of the hands and wrist. *M. marinum* is acquired through exposure to fresh water, salt water, or marine life (fish tanks, swimming pools). Monoarticular involvement of the metacarpophalangeal and proximal interphalangeal joints is most frequently reported and is often only mildly painful without systemic symptoms. Patients with *M. marinum* and other atypical mycobacterial monoarthritides can test positive for purified protein derivative skin test for *M. tuberculosis*.

Fungal arthritis may present as a self-limiting acute polyarthritis in the normal host with recent exposure to fungal infection. Chronic monoarthritis is seen primarily in immunocompromised hosts. When present, associated fungal skin lesions are a clue to diagnosis. Fungal arthritis occurs by direct inoculation or hematogenous spread in IVDA, critically ill hospitalized patients with indwelling lines, immunosuppressed patients, or patients with prosthetic joints or via cutaneous inoculation by plant material, for example, with rose thorns. *Candida* infection causes a monoarthritis, whereas other fungal infections may cause an oligoarthritis in addition to monoarthritis. Other fungal etiologies such as coccidioidomycosis, sporotrichosis, blastomycosis, cryptococcosis, and histoplasmosis can cause arthritis (monoarthritis involving the knee or oligoarthritis), and their presentation is related to their geographic distribution, occupational exposure, and skin and lung involvement. Staining and culture of synovial fluid are critical for the diagnosis. Therapy for mycobacterial and fungal arthritis usually consists of appropriate pharmacologic and surgical debridement.

### Gonococcal Arthritis

The most common complication from acute gonorrhea is disseminated gonococcal infection. Gonococcal arthritis mainly affects young adults, with a 3-fold higher incidence in women. It results from dissemination of *Neisseria gonorrhoeae* in the bloodstream from primary sexual contact. In patients age <30 years, it is the most common cause of septic arthritis. Disseminated gonococcal infection can present as either an arthritis-dermatitis syndrome (more commonly) or as a localized septic arthritis. The disseminated infection is usually associated with the classic triad of dermatitis (papules, pustules with an erythematous base), tenosynovitis, and a migratory asymmetric polyarthritis. The recommended initial treatment is with 1 g/d of parenteral ceftriaxone 1 g IM/IV every 24 hours plus a single dose of azithromycin 1 g orally followed by oral cefixime or ciprofloxacin to complete a 7- to 10-day course.

## Crystal-Induced Monoarticular Arthritis

A variety of crystal disorders can lead to acute and chronic inflammatory arthritides. Calcium-containing crystals such as basic calcium phosphate (BCP), hydroxyapatite (HA), calcium pyrophosphate dihydrate (CPP), calcium oxalate (CaOx), and monosodium urate (MSU) are deposited around the joint and soft tissue, leading to bursitis,

tenosynovitis, synovitis, and acute monoarthritis. Their clinical presentations are often similar, requiring diagnostic arthrocentesis with examination of synovial fluid for crystals under compensated polarized light microscopy and sometimes the additional use of special stains for their identification (Fig. 24.3). More recently, musculoskeletal ultrasound can assist in the differentiation between MSU and CPP arthritis based on their deposition in the hyaline or articular

• **Fig. 24.3** Morphology under compensated polarized light microscopy and special stain of crystal-associated arthritis. (A) Needle-shaped monosodium urate crystal with intense negative birefringence as seen under compensated polarized light microscopy; 400 $\times$ . (B) Rectangular, rhomboid shape calcium pyrophosphate dehydrate (CPPD) crystal with weakly positive birefringence crystal when the crystal is parallel to the axis of compensator (*arrow*), adopts a blue color under compensated polarized light microscopy; 400 $\times$ . (C) CPPD crystal is rotated perpendicular to the axis of the compensator; it adopts a yellow color under compensated polarized light microscopy; 400 $\times$ . (D) Hydroxyapatite (HA) and basic calcium phosphate crystals present with amorphous features and show no birefringence under compensated polarized microscopy; 400 $\times$ . (E) Alizarin red stain of HA staining orange-red color; 400 $\times$ . (F) Bipyrnidal and small polymorphic calcium oxalate crystals (ordinary light microscopy); 400 $\times$ . (G) Intracellular-cytoplasmic spherules with a birefringent Maltese cross-like appearance. Negative birefringence: yellow when parallel to direction of the light (*arrow*) and blue when perpendicular. Positive birefringence: blue when parallel to direction of the light (*arrow*) and yellow when perpendicular. (From Anthony M. Reginato slide collection.)

cartilage. MSU crystal deposition occurs on the superficial articular cartilage layer generating a “double contour sign,” whereas CPP deposition occurs in the intraarticular or hyaline cartilage (Fig. 24.4).

## Gout

The most common crystal-induced arthritis is gout. The underlying etiology in gout is MSU crystal deposition secondary to hyperuricemia. Patients initially develop acute attacks most commonly involving the lower extremities below the knee. Over time, these attacks become more frequent and occur on a background of chronic joint pain. Eventually, patients progress toward the formation of chronic tophaceous deposits.

### Epidemiology and Risk Factors

The epidemiology of gout has changed over time. Recent evidence shows an increasing incidence and prevalence of gout over the past two decades. A recent report of medical database claims in the United States showed an increase in gout prevalence from 2.9/1000 in 1990 to 5.2/1000 in 1999. Gout occurs more frequently in men than women because of the uricosuric effect of estrogen. It is very rare for a premenopausal woman to present with an attack of gout.

The main risk factor for the development of gout is hyperuricemia. Approximately 90% of hyperuricemic patients have underexcretion of uric acid as the underlying disorder caused by renal insufficiency. Besides renal impairment, other risk factors for gout include alcohol consumption, the metabolic syndrome, hypertension, and diuretic use. In addition, the consumption of meat, seafood, and beer can increase the purine load in patients and lead to an increase in serum uric acid (sUA) levels.

### Clinical Presentations

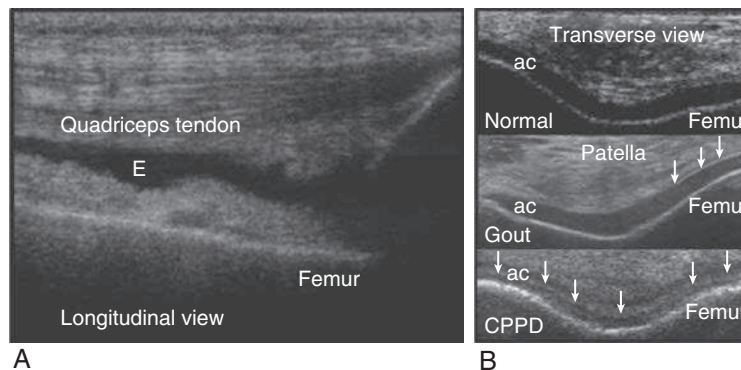

The clinical presentation of gout occurs in stages: asymptomatic hyperuricemia, acute intermittent gout, intercritical

gout, and chronic tophaceous gout. Initially, patients will have asymptomatic hyperuricemia for several years. Patients will then present with the sudden onset of an acute, painful, swollen joint. The joint will be warm, erythematous, and extremely painful to palpation or movement. Often, patients will have an acute development of pain that wakes them from sleep or is apparent when they first arise in the morning. The first acute attack will generally be monoarticular with a predilection for the big toe (podagra). Other commonly involved joints in acute attacks include the ankle, midfoot, and knee. Atypically, patients will present with the involvement of a joint in the finger, wrist, elbow, or bursa and even less frequently with spinal involvement. There may be more than one joint involved in the early-phase acute attacks, but it is uncommon to have more than three joints involved in an early presentation. Women tend to have more atypical presentations and will present more often with the involvement of gout in the hand or wrist. These acute attacks generally resolve spontaneously within 7 to 14 days. In this intermittent state, intercritical period, attacks may occur infrequently and be separated by years. Over time and with increasing hyperuricemia, these attacks become more frequent and involve more joints with longer duration of attacks.

If left untreated, patients will go on to develop chronic tophaceous gout. Patients often develop a background of chronic pain from gout with superimposed acute, painful attacks. Patients may develop polyarticular arthritis at this stage. Tophi may or may not be apparent on clinical examination and can occur anywhere on the body, in particular at areas of pressure points. Clinically apparent tophi are found most commonly on the pinnae, olecranon bursa, at sites of nodal osteoarthritis (i.e., Heberden nodes), and patellar and Achilles tendon. Tophi can lead to bony destruction and chronic bone deformities, which at times may resemble RA.

### Diagnostic Workup

The gold standard procedure for diagnosis of gout involves aspiration of the involved joint and visualization of MSU

• **Fig. 24.4** Musculoskeletal ultrasound of the knee. (A) Longitudinal view of the knee showing anechoic signal on gray scale consistent with effusion (*E*) within the suprapatellar recess. (B) Transverse view of the femoral condyles. Normal articular cartilage (*ac*) appears as an anechoic signal on gray scale. In gout, monosodium urate crystal deposited in the superficial surface of the articular or hyaline cartilage at the synovial-cartilage interphase (*arrows*) is known as the “double contour sign,” whereas in calcium pyrophosphate dihydrate deposition (*CPPD*), the calcium pyrophosphate dihydrate crystals are deposited within the middle layer of the articular cartilage. (From Anthony M. Reginato slide collection.)

crystals under compensated polarized light microscopy. In addition, patients should have evaluation of their sUA levels. The solubility of uric acid is 6.8 mg/dL, and any level above this should be considered hyperuricemia. However, an elevated uric acid alone can only help in making a presumptive and not definitive diagnosis of gout. Serum uric acid level may drop and be within normal range during an acute flare of the gout. Other helpful laboratory evaluation should include a Gram stain and culture because there can be coexistence of gout and septic arthritis and assessment of renal function. Urinary quantification of uric acid excretion is only necessary in patients who are being considered for treatment with uricosuric agents (probenecid, sulfinpyrazone, or benzbromarone).

### Treatment

The treatment of gout can be broken up into two separate management strategies: treatment of acute attacks and long-term management of hyperuricemia. For acute gouty attacks, treatment should be directed at pain relief and reduction of inflammation. First-line therapy for these attacks should be nonsteroidal antiinflammatory drug (NSAID) therapy. The classic agent prescribed has been indomethacin, but any NSAID agent should improve pain and inflammation. In patients with contraindications to NSAID therapy, other options include colchicine or prednisone. Colcrys (colchicine) is another alternative therapy that interrupts the response of neutrophils by inhibiting neutrophil chemotaxis, activating the inflammasome, and producing interleukin- $\beta$  in response to MSU crystals. The new recommendations for the treatment of gout flare consist of two tablets of Colcrys (1.2 mg) at the first sign of gout flare followed by one tablet (0.6 mg) 1 hour later for total dose of 1.8 mg/d during an acute flare followed by 0.6 mg once or twice a day for prophylaxis. The low-dose Colcrys was as effective as high-dose Colcrys, with a greater margin of tolerability and safety than the high-dose Colcrys (1.2 mg followed by 0.6 mg every hour for 6 hours, a 4.8-mg total) in treating the acute gout flares. The use of Colcrys 0.6 mg orally twice a day in conjunction with a serum uric acid-lowering agent is recommended during the first 6 months as gout prophylaxis to prevent mobilization flares while achieving the sUA target of <6.0 mg/dL with antihyperuricemic agents. Colcrys is contraindicated in patients with renal and hepatic impairment who are concurrently prescribed P-glycoprotein (P-gp) inhibitors or strong inhibitors of cytochrome P453 3A4 (CYP3A4) because life-threatening and fatal toxicity have been reported. Dose adjustment of Colcrys may be required when it is coadministered with P-gp or CYP3A4 inhibitors. The most common adverse effects of colchicine include gastrointestinal symptoms and, rarely, myelosuppression, thrombocytopenia, leukopenia, and a myopathy that is characterized by an elevated creatine kinase level and proximal muscle weakness.

The first component of the long-term management of gout is mainly lifestyle changes, especially weight loss; avoiding fructose-rich soft drinks, diets with excess purines,

such as meats and shellfish; and limiting alcohol consumption, particularly beer. Essential hypertension and diuretic use are each independently associated with hyperuricemia and gout. Given the benefits of thiazide diuretics in patients with hypertension and their low cost, we suggest switching to another antihypertensive drug to control the hypertension. Losartan has uricosuric effects and may be a good alternative agent, although in patients already taking a uric acid-lowering agent, the benefits are likely to be minimal. We recommend the use of uric acid-lowering agents in patients with a history of frequent and disabling attacks of gouty arthritis, clinical or radiographic signs of chronic gout joint disease, tophi, otherwise unexplained renal insufficiency, recurrent nephrolithiasis, or urinary uric acid excretion >1100 mg/d.

Allopurinol and febuxostat are the only readily available xanthine oxidase inhibitors. In contrast to probenecid, which is primarily indicated in patients who have impaired renal excretion of uric acid, xanthine oxidase inhibitors are effective in virtually all circumstances warranting urate-lowering therapy for gout. The starting dose of allopurinol for patients with normal renal function should be 300 mg daily. In patients with chronic renal insufficiency, a starting dose of 100 mg daily may be more appropriate in patients with weight-adjusted creatinine clearance >40 mL/min, with titration of the dose according to the antihyperuricemic effect achieved. The half-life of oxypurinol, an active metabolite of allopurinol, is prolonged in renal functional impairment, so caution is recommended during allopurinol up-titration with careful observation for adverse effects. In either setting, patients should be titrated to reach a serum uric acid target of <6 mg/dL, or even lower to <5 mg/dL, in patients with tophaceous gout. In certain individuals, doses of up to 800 mg and 900 mg daily are safe and may be required to reach the desired serum uric target. Once initiated, therapy with allopurinol should not be interrupted for any reason, to avoid precipitation of an acute attack of gout. This includes patients who have a flare of gout while on allopurinol because any adjustments to their normal allopurinol dosage can worsen a flare. Low-dose colchicine should be started 2 weeks before initiation of a serum uric acid-lowering agent (0.6 mg twice a day for patients with normal renal and hepatic function) to prevent mobilization flares. An NSAID may be used as an alternative option. We suggest that colchicine be continued for 6 months for prophylaxis after normal serum uric acid has been obtained in patients without tophi. Although the duration of prophylactic therapy is uncertain in patients with tophi, we suggest continuing colchicine until resolution of the tophi or until it becomes obvious that the tophaceous deposits will not resolve despite persistent normouricemia.

The most common adverse effects of allopurinol are minor abdominal pain, nausea, or vomiting. However, a very uncommon but potentially life-threatening reaction can occur with allopurinol. Patients should be counseled to immediately discontinue therapy if they develop a rash in response to allopurinol. Severe hypersensitivity reactions to allopurinol may involve rash, fever, acute interstitial

nephritis, and hepatitis. Fatal accounts of Stevens-Johnson syndrome have been reported and associated with human leukocyte antigen (HLA)-B\*58:01 haplotypes. For patients who are intolerant to allopurinol or develop a hypersensitivity reaction, other agents such as febuxostat or probenecid may be used. Febuxostat is a thiazole carboxylic acid derivative that, unlike allopurinol, is a nonpurine-selective inhibitor of xanthine oxidase; it is administered orally and undergoes hepatic metabolism. Febuxostat given at 40 mg/d is the recommended starting dose; if a serum uric acid level of <6.0 mg/dL is not achieved after 2 weeks, the dose is increased to 80 mg/d. Febuxostat 80 mg/d was superior to allopurinol 300 mg/d in reducing serum uric acid levels to lower than 6 mg/dL in mildly to moderately renally impaired study participants. Mobilization flares were very common, and mild transaminase elevations greater than three times the normal limit were observed in the febuxostat group. The major clinical niche for febuxostat is patients for whom uricosuric therapy is contraindicated or ineffective when they are also intolerant of or allergic to allopurinol, and/or they have mild-to-moderate chronic kidney disease.

Uricosuric agents (probenecid, sulfinpyrazone, and benzbromarone) represent another class of serum uric acid-lowering medications. They act by inhibiting the urate transporter URAT1 at the tubules, thus raising the renal excretion of urate. In patients with renal calculi, uricosuric drugs need to be used with caution. Alkalinization of urine and high urine volumes are required. Benzbromarone has been removed from the United States and some European markets because of concerns about hepatotoxicity, but it is available in some countries with restricted use. Lesinurad, a URAT1 inhibitor, was recently approved for treating hyperuricemia associated with gout in patients who have not achieved target serum uric acid levels with a xanthine oxidase inhibitor alone.

If available, uricases (rasburicase or pegloticase, its PEGylated form) provide an option for patients whose gout is actively symptomatic and refractory to or contraindicated to other urate-lowering therapies. Uricase mediates the conversion of uric acid into a more soluble molecule, allantoin. Uricase is present in most mammals but absent in humans because of mutation inactivation of the uricase gene. Pegloticase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, in whom it is associated with increased hypersensitivity reactions. Uricase is very effective in preventing and managing tumor lysis syndrome. Both forms of uricase have lowered serum uric acid levels in clinical trials, but the need for parenteral administration and development of antiuricase antibodies may limit their repetitive use in selected cases of severe gout.

### Calcium Pyrophosphate Crystal Deposition Disease (Pseudogout)

CPP crystals can lead to several findings in patients. The most common finding is the report of chondrocalcinosis on radiographs of the knee or wrist. Chondrocalcinosis

represents the calcification of articular cartilage and may be associated with the development of early osteoarthritis but is generally asymptomatic. Acute monoarticular attacks of pseudogout occur when CPP crystals are shed from the hyaline cartilage and fibrocartilage into the joint, inducing a sterile inflammatory response. CPP crystal-induced arthritis affects medium-to-large joints including knees, wrists, hips, and shoulders, although small joints can be involved. Acute CPP crystal arthritis closely resembles gout with acute onset of pain, swelling, and erythema. The diagnosis of CPP crystal-induced arthritis is established by arthrocentesis and visualization of CPP crystals, rhomboid shape with weakly positive birefringence, on compensated polarized microscopy.

CPP deposition (CPPD) disease is a common incidental finding in elderly patients. However, the discovery of calcium pyrophosphate disease in younger patients, especially those age <55 years, should prompt a workup for metabolic or genetic diseases. Diseases associated with calcium pyrophosphate disease include hemochromatosis, hyperparathyroidism, hypophosphatasia, hypomagnesemia, acromegaly, hypophosphatemic rickets (X-linked), Wilson disease, and hypomagnesemia-related kidney diseases such as Bartter syndrome and Gitelman disease. Specific laboratory tests to consider are calcium, alkaline phosphatase, magnesium, ferritin, liver function tests, and parathyroid hormone (PTH).

Guidelines for the treatment of acute CPP arthropathy follow those for gout. Often, aspiration of the joint will improve the patient's condition. Because of the high rate of reaccumulation of joint effusions during an acute attack, intraarticular corticosteroids are injected to provide relief. Corticosteroids are the preferred therapeutic agents for this condition, although colchicine may be effective. Alternative or adjuvant therapies include NSAIDs therapy. Chronic CPPD disease is difficult to manage and often refractory to medical treatment. The use of antirheumatic disease-modifying agents such as hydroxychloroquine or methotrexate has been found to be effective in reducing the frequency of flares in refractory cases.

### Basic Calcium Phosphate Deposition Disease

BCP crystal disease represents several different crystal types. The most common of these crystals are HA containing but can include crystals with octacalcium phosphate or tricalcium phosphate. These latter crystals are rarely encountered in clinical practice. HA deposition disease leads to a variety of musculoskeletal presentations including that of acute monoarticular arthritis, acute calcific periartthritis, soft tissue calcifications, and early osteoarthritis. HA may deposit in the small joints of the hands, wrists, elbows, hips, and ankles, but the shoulder joints are more commonly affected, leading to a rare destructive arthropathy called *Milwaukee shoulder syndrome*. Milwaukee shoulder generally occurs in elderly women who present with a large shoulder effusion associated with pain. Arthrocentesis of the shoulder effusion yields large volumes of synovial fluid. Basic calcium

phosphate crystals are more difficult to detect in synovial fluid than MSU or CPP crystals and may appear as amorphous material under compensated polarized light microscopy. If BCP crystals are suspected, alizarin red staining can be performed on synovial fluid to demonstrate their presence. There is no clear treatment that will reduce the burden of BCP, and acute attacks should be treated similarly to other crystalline disorders in the acute phase, with NSAIDs, analgesics, and/or intraarticular steroid injections.

### Calcium Oxalate

Oxalate is a metabolic product of glycine, serine and other amino acids, and ascorbic acid. Oxalate is readily absorbed after ingestion and almost entirely cleared by renal excretion. Secondary oxalosis complicating stage 5 chronic kidney disease, which results from inefficient removal of oxalate by hemodialysis or peritoneal dialysis, has been reported infrequently. The associated clinical manifestations are similar to CPPD or MSU deposition. Radiographic manifestations of oxalosis resemble those of CPPD, with chondrocalcinosis in the hands and knees. Therefore diagnostic arthrocentesis and examination under compensated polarized microscopy is required for proper identification of CaOx crystals. Diagnosis is made by visualization of the crystals that have characteristic bipyramidal or envelope-shaped crystals. Cell counts from arthrocentesis of effusion related to CaOx crystals are generally <2000. Treatment generally follows those of other crystal arthropathies but with avoidance of vitamin C as contained in renal multivitamins because it contributes to the developing of secondary oxalosis.

### Lipid-Laden Crystals

Rarely, crystals related to cholesterol may lead to a monoarticular presentation. Demonstration of “Maltese cross” particles that are frequently seen intracellularly in synovial fluid helps to confirm this diagnosis. However, a few sparse “Maltese cross” crystals may be commonly seen and not the cause of a monoarticular arthritis.

### Osteoarthritis

Osteoarthritis of a single joint, although usually associated with mild symptoms and a noninflammatory synovial fluid (WBC <2000 cells/mm<sup>3</sup>), can present as an acute monoarticular arthritis mimicking infection.

### Hemarthrosis

Hemarthrosis, or bleeding into the joint, is common in patients with acquired or congenital clotting abnormalities, such as those on anticoagulation therapy or with hemophilia or other clotting deficiencies. Fractures should be considered in patients with hemarthrosis and trauma, especially if synovial fluid is bloody and contains fat.

## • BOX 24.5 Bacteria Associated With Reactive Arthritis

### Genitourinary

*Chlamydia trachomatis*

*Chlamydia psittaci*

Possible: *Ureaplasma urealyticum*

### Gastrointestinal

*Shigella flexneri*

*Campylobacter jejuni*

*Campylobacter fetus*

*Salmonella typhimurium*

*Salmonella enteritis* (less common: *S. heidelberg*, *S. choleraesuis*, *S. paratyphi B*)

*Shigella sonnei*

*Yersinia pseudotuberculosis*

*Yersinia enterocolitica* 0:3 or 0:9 (less common: *Y. enterocolitica* 0:8)

*Clostridium difficile*

## Reactive Arthritis

Monoarticular arthritis in ReA is generally a diagnosis of exclusion. The pattern of involvement is often that of a large joint (knee) with lower extremity predominance. The monoarthritis is presumably reactive to an infection elsewhere in the body. Although the bacteria may have been cleared, systemic immune complex response can cause acute monoarthritis or oligoarticular aseptic synovitis and also lead to a predilection for spondylitis (vertebral inflammation) and sacroiliitis. The presence of extraarticular manifestations associated with HLA-B27 alleles, such as mild conjunctivitis or uveitis, infectious urethritis, balanitis (circinate), psoriasiform skin lesions (keratoderma blennorrhagicum), oral ulcers, sausage digit, and enthesitis may assist in the clinical diagnosis. Primary organisms associated with reactive arthritis include *Chlamydia* sp., *Salmonella*, *Clostridium difficile*, *Campylobacter*, and *Yersinia* (Box 24.5).

## Systemic Diseases

Many systemic diseases may present with an acute monoarthritis. This is true for a variety of rheumatic diseases such as the seronegative spondyloarthropathies (psoriatic arthritis, reactive arthritis, ankylosing spondylitis, and IBD), which can present with a monoarthritis of the lower extremities. Sarcoid periartthritis typically presents with pain around the ankle joints with or without erythema nodosum over the distal tibial region. Monoarthritis can be seen in early stages of RA. Myelodysplastic or leukemic disorders may cause arthralgias or acute monoarthritis. Septic monoarthritis may be the first clue to bacterial endocarditis, pneumonia, hypogammaglobulinemia, or AIDS. Serum sickness, hepatitis, and hyperlipidemias may occasionally present with an acute monoarthritis.

## Summary

Acute monoarticular arthritis is a common presenting complaint with a wide differential diagnosis. A directed history can help rule out trauma or overuse syndrome as the cause of the patient's symptoms. Clinicians should focus on excluding a septic arthritis because of the high

morbidity and mortality from this condition. The identification of crystalline arthritis is critical in the prevention of future attacks and improves long-term patient outcomes. In addition, one must be aware of monoarticular arthritis as the initial presentation of a wide array of systemic disorders.

## Chapter Review

### Questions

- A 65-year-old fireman with a history of gout presented to his primary physician with left first metatarsophalangeal (MTP) joint pain, swelling, and erythema. He was treated with oral colchicine, 0.6 mg twice daily, and prednisone, 40 mg a day for 4 days. However, the patient calls you back complaining that his left first MTP has not improved and has actually gotten worse. The most useful diagnostic test in this patient includes:

  - Radiography of the right first MTP
  - Serum uric acid level
  - Complete blood cell count with differential, ESR, and CRP
  - B and C
  - Increase prednisone to 80 mg every day
  - Diagnostic arthrocentesis
- In the patient described in Question 1, negatively birefringent needle-shaped crystals were seen under compensated polarized light microscopy of fluid obtained on aspiration of the left first MTP joint. Next, you should:

  - Increase oral colchicine to 1.2 mg twice daily.
  - Perform depot corticosteroid injection of the joint.
  - Wait for Gram stain and culture results to determine therapy.
  - Start allopurinol 300 mg orally 4 times per day.
- A 59-year-old male presents with serum uric acid level of 9.5 mg/dL. Clear-cut indications for treatment with allopurinol include:

  - A creatinine value of 3 mg/dL
  - A history of two gout flares in the past 2 years
  - Presence of a small tophi on his right ear and tophaceous radiographic changes of MTPs
  - Patient being on chronic hydrochlorothiazide
  - A 24-hour urinary excretion of >1000 mg
- An 18-year-old sexually active male is seen in the ED with right ankle joint swelling. He is afebrile. Physical examination demonstrates right ankle arthritis with an effusion. Diagnostic arthrocentesis showed an inflammatory fluid with white cell count of 35,000/mm<sup>3</sup> and 87% neutrophils on differential. Examination of synovial fluid under compensated polarized light microscopy demonstrated no crystals. He is treated with broad-spectrum antibiotics. Gonorrhea and chlamydia cultures are negative. Synovial fluid cultures after 48 hours are negative. The presumptive diagnosis is:

  - Gout
  - Avascular necrosis
  - Tuberculous arthritis
  - Gonococcal arthritis
  - ReA
- A 45-year-old male presents with acute monoarticular arthritis of the left knee. He is afebrile and symptom free. Radiographs of the left knee showed mild chondrocalcinosis. Diagnostic arthrocentesis showed an inflammatory fluid with white cell count of 25,000/mm<sup>3</sup> and 85% neutrophils on differential. Examination of synovial fluid under compensated polarized light microscopy demonstrated the presence of negative birefringent crystals consistent with CPPD. Gram stain and cultures were negative. On further examination, he is noted to have some synovitis of the second and third metacarpophalangeal joints (MCPs) with radiographs of the hands showing osteoarthritis-like changes in the second and third MCPs. Further metabolic workup should include:

  - Thyroid-stimulating hormone
  - Calcium, phosphate, and PTH
  - Adrenocorticotropic hormone
  - Iron, transferrin/iron binding capacity, ferritin, hemochromatosis gene analysis
  - Magnesium
- A 21-year-old female with a history of SLE nephritis treated with high-dose steroids and Cytoxan in the past presents with acute-onset right hip pain. She is afebrile and symptom free. Her SLE has been well controlled on plaque-nil 200 mg orally twice a day, CellCept 1000 mg orally per day, and prednisone 5 mg orally per day. Laboratory studies showed a normal ESR and CRP. Complete blood count, renal function, double-stranded DNA, and complement levels were unremarkable. Radiograph of the right hip was also unremarkable. Diagnostic arthrocentesis was performed given the concern of septic arthritis. A small amount of fluid was obtained with synovial fluid white count of 2000/mm<sup>3</sup> and subsequent negative Gram stain and cultures. The next most useful diagnostic tests in this patient should include:

  - Pulse dose steroids and monitor response
  - CT scan
  - MRI
  - Synovial biopsy

## Systemic Lupus Erythematosus and Related Disorders

BONNIE L. BERMAS

Systemic lupus erythematosus (SLE) is a multisystem disorder that preferentially affects women of child-bearing age. The etiology of SLE is not well understood, although genetics and environmental factors clearly are involved. Whether this disease is driven by T-cell, B-cell, or other immunologic malfunction is debated, but all would agree that autoantibodies such as the anti-double-stranded DNA (anti-dsDNA) contribute to the pathophysiology of this disorder. SLE can affect the skin, joints, lungs, heart, kidneys, and the hematologic and central nervous systems (CNSs). Most of the morbidity and mortality in SLE results from renal and CNS involvement, although accelerated atherosclerosis is now appreciated as a major contributor to disease burden. Furthermore, infections (especially in those who are being treated with immunosuppressive agents) can impact morbidity and mortality in lupus patients. The treatment of SLE has greatly improved over the past decade with less reliance on high-dose corticosteroids and more emphasis on treating patients with immunosuppressive and biologic agents. In the future, a better understanding of the genetics and pathophysiology of this disorder will lead to earlier disease detection and prevention as well as targeted therapy that will improve SLE outcome.

### History and Epidemiology

SLE was named for the classic rash that occurs over the bridge of the nose and face. These lesions were thought to resemble wolf-bites, leading to the name “lupus.” Although SLE can occur throughout one’s lifetime, the peak incidence is during the second to the fourth decade of life. The female-to-male ratio is 9:1, although in the older age groups, this gender skewing becomes less pronounced. This disorder is both more common and more severe in those of Asian, African-American, and Afro-Caribbean race and Hispanic ancestry. In the United States, the prevalence rates range from 164 per 100,000 among Caucasians to 406 per 100,000 amongst African Americans.

### Genetics, Hormones, and the Immune System

There is a genetic contribution to the development of SLE. Twin studies have shown a concordance rate ranging from 24% to 60% for monozygotic twins and 2% to 5% for dizygotic twins. Certain human leukocyte antigen (HLA) haplotypes (HLA DR2 and HLA DR3) predispose to SLE. Genome-wide association studies have pointed to >50 possible gene polymorphisms that may contribute to disease development. Many of these predisposing loci are centered on functional areas of the immune system. Although there is clearly a genetic susceptibility to SLE, subsequent environmental or infectious triggers are required to precipitate disease development.

The strong female predominance of this disorder suggests that hormones may be involved in SLE. Estrogen stimulates the T helper 2/humoral arm of the immune system. In mice, estradiol causes increased activation of autoreactive B cells. Use of estrogen-containing oral contraceptives and hormone replacement increases the risk of developing SLE, although these agents do not appear to exacerbate the disease in those who already carry the diagnosis.

Autoantibody production with immune complex deposition in organs and associated damage are the hallmark of this disease. However, the cause of this autoantibody production is unknown. Abnormalities in the innate immune system as manifested by poor clearance of nuclear debris mediated by toll-like receptors may play a role. Disruption of the acquired immune system vis-à-vis T and B cells may also contribute to autoantibody production. Abnormal interferon gene expression called the interferon “signature” has been found in persons with SLE and may correlate with disease activity. Other markers for this disease include low complement levels that are often found during periods of disease activation. Moreover, complement deficiencies such as C4 are found in greater frequency in patients with SLE. Thus far the precise mechanism and pathway that lead to SLE have not been worked out, and it is plausible that

<sup>a</sup>Part of the diagnostic classification.

disruption of several different pathways in the immune system may lead to the different phenotypes of SLE.

## Clinical Manifestations

### Cutaneous

Cutaneous manifestations of SLE can be subdivided into subacute and acute findings. Some of the subacute and chronic conditions such as subacute cutaneous lupus erythematosus (SCLE) and discoid lesions can be entities unto themselves or can be part of the symptoms found in SLE (Table 25.1).

### Subacute Cutaneous Lupus Erythematosus

SCLE can be seen as an isolated disorder or in conjunction with SLE. Patients with SCLE develop a rash that occurs in sun-exposed areas; mainly arms, trunk, and the neck, although the face and lower extremities can be involved to a lesser degree. There are two types of rashes found: annular, ring-like lesions and papulosquamous, psoriasiform lesions. Severe rashes can become superinfected and scalp involvement can lead to hair loss.

Biopsy of the skin lesions of SCLE reveal hyperkeratosis and a mononuclear cell infiltrate in the dermal-epidermal junction. The majority of patients with SCLE have anti-Ro (SSA) and anti-La (SSB) antibodies. Whereas  $\leq 50\%$  of these patients will also have systemic symptoms, it is rare that patients will have significant organ involvement such as renal or CNS disease.

Treatment for the skin manifestations is first focused on sun avoidance. Limiting sun exposure to nonpeak hours, wearing sun-protective clothing, and using high-SPF sunscreen are critical. Discontinuation of cigarette smoking, which increases the risk of skin flares, is important as well, and patients should be counseled accordingly. Medicines such as antimalarials can be used to prevent rashes, and topical steroids can be used for mild breakouts. In individuals who have rashes that are refractory to these therapies,

• **Fig. 25.1** Malar rash. (From American College of Rheumatology slide collection.)

systemic immunosuppression with glucocorticoids, azathioprine, or mycophenolate mofetil can be used. Thalidomide, methotrexate, and the biologic belimumab are employed for severe cases.

### Chronic Cutaneous Lupus Erythematosus

Chronic cutaneous lupus erythematosus includes discoid lupus, lupus profundus, and other skin manifestations. Discoid lesions are the most common and occur in up to 15% to 20% of patients with SLE. Similar to SCLE, these lesions occur in sun-exposed areas; however, discoid lesions more commonly occur on the scalp, face, upper arms, and ears. These lesions can cause scarring that can be disfiguring. Biopsy of discoid lesions shows follicular plugging with central atrophy. Treatment is similar to the treatment for SCLE and includes sun avoidance and sun protection, antimalarial agents, glucocorticoids, immunosuppressive agents, methotrexate, and belimumab.

Lupus profundus is a rare skin finding occurring in the absence of systemic symptoms. Lesions can destroy deep dermal layers and subcutaneous fat. As a result, scarring, sunken lesions that are often disfiguring can occur. Treatment includes antimalarials, steroids, and dapsone. In some cases, plastic surgery may be necessary to repair the lesions.

### Acute Cutaneous Lupus Erythematosus

The most common skin lesion found in acute cutaneous lupus is the malar rash. Classically, it appears as a reddish raised rash over the bridge of the nose and cheeks that spares the nasolabial folds and frequently appears after ultraviolet light or sunlight exposure (Fig. 25.1). The rash can have a burning sensation or be pruritic. It is thought to be secondary to immune deposition at the dermal epidermal junction. A malar rash can be difficult to distinguish from acne rosacea; the latter tends to have an oily texture and slight scaling. Photosensitivity is a skin rash distributed in sun-exposed areas that occurs after sun exposure. Blistering and superinfection can occur, and often patients will feel ill in conjunction with the skin rash.

## Other

Aphthous ulcers can be seen on the soft or hard palate of the mouth, in the nose, or in the vaginal area. Bullous lesions, although rare, can occur in SLE. Other skin findings include small-vessel vasculitis (palpable purpura, petechiae, splinter hemorrhages) and panniculitis. Alopecia, in particular in the temporal region, is common in SLE patients. Alternatively, patients may have patches of hair loss leading to bald spots. Urticarial lesions and urticarial vasculitis are also seen in SLE patients. Raynaud phenomenon is found in over half of lupus patients.

## Pulmonary Manifestations

The lungs are commonly involved in SLE. Pleural involvement, as manifested by pleuritis, is seen in up to 30% to 60% of patients with SLE. The most common symptom is inspiratory chest pain and associated shortness of breath. On physical examination, a rub can sometimes be heard but this finding is not always present and radiographic evaluation is often likewise negative. Thus the diagnosis of pleuritis is often a clinical one. Treatment with nonsteroidal antiinflammatory drugs (NSAIDs) and/or glucocorticoids is generally effective.

SLE patients can develop an inflammatory interstitial lung disease manifested by dyspnea and a dry nonproductive cough. On examination, dry crackles are heard and a reduced single-breath diffusing capacity of the lung can be demonstrated on pulmonary function testing. The best test for diagnosing this disorder is a high-resolution CT. Poorly controlled chronic interstitial lung disease can progress to fibrosis, causing permanent lung damage.

Pulmonary hemorrhage is a rare but devastating finding in SLE patients. Mortality from this disorder approaches 50%. Patients present with hemoptysis and dyspnea. A high percentage of these patients have associated antiphospholipid antibodies.

Shrinking lung syndrome is another rare manifestation of SLE. On radiographs, elevated diaphragms are found and patients are dyspneic. Pathology is thought to be secondary to muscle weakness of the diaphragm and intercostal muscles as well as interstitial lung disease.

## Cardiac Involvement

Pericarditis is the most common cardiac manifestation of SLE. Patients present with chest pain and shortness of breath. Hemodynamic compromise in the setting of pericardial tamponade is rare but can occur. Diagnosis is suggested with flattened T-waves on electrocardiogram but is confirmed by echocardiogram. Treatment with NSAIDs and steroids is generally effective, although occasionally pericardial drainage is necessary.

Coronary artery vasculitis and myositis are extremely rare manifestations of SLE but should be considered in patients who present with symptoms suggestive of these disorders.

Libman-Sacks endocarditis is the finding of microthrombi on the coronary valves and subsequent impairment of valvular function. The vast majority of patients who have this disorder also have antiphospholipid antibodies.

Persons with SLE have higher incidences of coronary artery disease. Whether this is the result of the disease or the treatment is unclear, but it appears to be a combination of both risk factors. Some rheumatologists believe that lupus should be considered a cardiac risk factor along the lines of diabetes mellitus and hypertension. Certainly, patients who have lupus should be counseled regarding modification of other cardiovascular disease risk factors such as hypertension, diabetes mellitus, and hypercholesterolemia. Early intervention with statins is being explored as potentially lowering the risk of accelerated atherosclerosis. Careful attention to lifestyle modifications such as maintaining a healthy weight, exercising regularly, healthy diet, and smoking cessation are important tools for cardiovascular disease prevention in SLE patients.

## Joint Symptoms

Over 90% of SLE patients will have joint symptoms at some time during the course of their disease. Arthralgias and arthritis are the most common. Some patients experience joint aching without synovitis. Others will develop an arthritis that is indistinguishable from an inflammatory arthritis such as rheumatoid arthritis. This subgroup may have the presence of a positive rheumatoid factor or anticyclic citrullinated peptide antibodies. Finally, roughly 10% of lupus patients will develop a tendinopathy that causes a particular type of deforming arthropathy called *Jaccoud arthropathy*. In this condition, tendinopathy rather than erosions cause the observed deformities.

Osteonecrosis can occur in particular in individuals who are on steroids at doses greater than the equivalent of 20 mg of prednisone a day. SLE patients who have had prior joint damage and/or are immunosuppressed are at higher risk for the development of septic arthritis.

Myositis, with a presentation similar to dermatomyositis/polymyositis-proximal muscle weakness (difficulty combing one's hair, lifting one's arms, getting out of a chair, or walking up stairs) occasionally occurs in SLE patients. Similar to the inflammatory myopathies, the muscle biopsy will demonstrate muscle inflammation. This inflammatory condition must be differentiated from drug-induced myopathies such as steroid myopathy, which likewise presents with proximal muscle weakness, and more diffuse myopathies that can be seen in those patients on statins and rarely antimalarials.

## Hematologic Disorders

Leukopenia and lymphopenia are common findings in SLE. An absolute white blood cell (WBC) count of  $<4000$  cells/mm<sup>3</sup> and an absolute lymphocyte count of 1500 cells/mm<sup>3</sup> are part of the diagnostic criteria for classification of this disorder. Thrombocytopenia (platelet count  $<100,000/\mu\text{L}$ ),

often immune mediated, is also found in systemic lupus. Anemia of chronic disease and Coombs-positive hemolytic anemia are the other hematologic disorders seen in SLE.

## Kidney Disease

Over half of persons with SLE will develop kidney involvement during the course of their disease. Clinically, patients will present with hypertension and edema, although sometimes patients are asymptomatic, and the diagnosis is suggested by the incidental finding of proteinuria or hematuria on urinalysis. The latter should prompt an evaluation by a nephrologist and consideration for a renal biopsy. Kidney disease is classified by using the World Health Organization (WHO) biopsy categories (Box 25.1, Fig. 25.2). In addition to these categories, pathology specimens are given an activity-chronicity rating that reflects the degree of inflammation occurring in the kidney. Most of the morbidity and mortality from the renal disease occurs in those who have

### • BOX 25.1 World Health Organization Classification of Renal Disease (Revised)

- Class I. Minimal change disease
- Class II. Mesangial disease
- Class III. Focal segmental glomerulonephritis
- Class IV. Diffuse proliferative glomerulonephritis
- Class V. Diffuse membranous glomerulonephritis
- Class VI. Advanced sclerosing glomerulonephritis

either focal or diffuse glomerulonephritis (classes III and IV). In addition, a high degree of chronicity in the renal biopsy portends a poor prognosis because these lesions tend to be refractory to therapy. In the past, mortality from renal disease was quite high; however, due to newer treatments this rate has dramatically diminished.

## Neurologic Disease

Nineteen neurologic syndromes have been reported to be part of neuropsychiatric lupus, although only two are listed among the classification criteria (Table 25.2). Some of these disorders, such as transverse myelitis, focal seizures, and cognitive events, are thought to be caused by focal lesions, often associated with antiphospholipid antibody-induced clotting events. Nonetheless, these findings can also occur in the absence of antiphospholipid antibodies. Global organic findings such as generalized seizures and psychosis are challenging neurologic syndromes in SLE that can be difficult to medically manage. Some neurologic findings such as depression, migraines, and certain types of cognitive difficulties are found in many disorders and can be difficult to attribute to SLE disease activity. For example, although headaches are frequently described in individuals with SLE, the actual frequency of headaches in SLE patients is not significantly higher than that found in the general population. For strict classification purposes, seizures and psychosis are the only neurologic symptoms included among the criteria for SLE.

• **Fig. 25.2** Lupus nephritis. (D) Immunofluorescence micrograph illustrating IgG localization in class V lupus nephritis (magnification,  $\times 260$ ). (Courtesy Dr. Helmut Rennke. From the JASN teaching collection.)

## Drug-Induced Systemic Lupus Erythematosus

Drug-induced SLE can occur in the setting of many medications. Isoniazid and procainamide are the most common offending agents, but many more medications can cause this entity. In most affected individuals, symptoms are limited to skin rashes, serositis, arthralgias, and fatigue whereas renal disease or CNS involvement are rare. Over 95% of these individuals will have the presence of an antihistone antibody. In most scenarios, the symptoms will resolve once the medication is removed, but occasionally, treatment with NSAIDs and low doses of steroids is needed. It is rare that more potent immunosuppressive agents are required for the management of this disorder.

## Autoantibodies

Autoantibody production is an important driver of SLE development and disease manifestations (Table 25.3). The most common, the antinuclear antibody (ANA), is found in 93% to 95% of individuals with SLE. Antinuclear

antibodies and precipitins have been found in individuals several years before the diagnosis of SLE. However, remember that low titers of these antibodies can be seen in up to 5% to 10% of the general population, in particular in those who are elderly, on certain types of medications, and/or who have other autoimmune conditions. Therefore the presence of ANA alone cannot be used to make the diagnosis of SLE. Nonetheless, the higher the titer of this antibody, the more likely it is to be a true positive and not a false positive. Other more disease-specific antibodies such as the anti-dsDNA antibody are found in 75% of individuals with SLE, and the anti-Smith (anti-Sm) antibody is found in 25% of SLE patients. Both anti-dsDNA and anti-Sm antibodies are associated with renal disease. Anti-Ro (SSA) and anti-La (SSB) antibodies are seen in individuals with SCLE as well as SLE and are the pathologic agents in neonatal lupus and congenital complete heart block. Anti-RNP antibodies are found with higher frequency in those who have mixed connective tissue disease. Antihistone antibodies are associated with drug-induced SLE, although 60% of those with SLE also have these antibodies.

## Diagnosis

Making the diagnosis of SLE can be challenging. Given the myriad of combinations of clinical manifestations with which individuals can present, it is no wonder that SLE is considered one of the great disease imitators. Although individuals may present to clinicians with symptoms suggestive of SLE, it is important to be rigorous in the diagnosis of this disorder. The diagnostic classification criteria were originally developed as a research tool; however, they are a useful guideline for evaluating patients with potential SLE. Technically, individuals require 4 out of 11 classification criteria to be diagnosed with SLE (Table 25.4). However, in individuals with a clinical presentation highly suggestive of SLE, the clinician should use his or her judgment in making the diagnosis. Given that 93% to 95% of individuals will have the presence of an ANA, and the majority of SLE patients

**TABLE 25.2 Neurologic Manifestations of Systemic Lupus Erythematosus**

Central	Peripheral

Mood disorder	
Psychosis	

**TABLE 25.3 Autoantibodies in Systemic Lupus Erythematosus and Other Collagen Vascular Disease**

ANA	SLE, progressive systemic sclerosis, Sjögren, dermatomyositis/polymyositis
Anti-dsDNA	SLE, renal disease
Anti-Sm	SLE, renal disease
Anti-RNP	SLE, MCTD
Antihistone antibody	Drug-induced SLE
Anti-Ro (SSA), Anti-La (SSB)	SLE, SCLE, Sjögren disease
Anti-SCL-70	Progressive systemic sclerosis (especially diffuse)
Anticentromere antibody	Progressive systemic sclerosis (especially limited)
Anti-Jo-1 antibody	Dermatomyositis/polymyositis (especially with lung involvement)

ANA, Antinuclear antibody; dsDNA, double-stranded DNA; MCTD, mixed connective tissue disease; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus; Sm, Smith.

**TABLE 25.4 The 1997 Revised American College of Rheumatology Criteria for the Classification of Systemic Lupus Erythematosus**

Malar rash	Fixed erythema, flat or raised, over the malar eminences, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis: convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion, <i>or</i> Pericarditis: documented by EKG or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria >0.5 g/d or >3+ if quantitative not performed or cellular casts (may be red cell, hemoglobin, granular, tubular, or mixed)
Neurologic disorder	Seizures: in the absence of offending drugs or known metabolic derangement Psychosis: in the absence of offending drugs or known metabolic derangement
Hematologic disorder	Hemolytic anemia with reticulocytosis, <i>or</i> Leukopenia: WBC count <4000/mm <sup>3</sup> on two occasions, <i>or</i> Lymphopenia: lymphocyte count <1500/mm <sup>3</sup> on two occasions, <i>or</i> Thrombocytopenia: platelet count <100,000/mm <sup>3</sup> in the absence of offending drugs
Immunologic disorder	Anti-DNA: antibody to native DNA in abnormal titer, <i>or</i> Anti-Sm: presence of antibody to Sm nuclear antigen, <i>or</i> Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies or (2) positive test for lupus anticoagulant using a standard method
Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time

EKG, Electrocardiogram; Sm, Smith; WBC, white blood cells.

who do not have an ANA will have the presence of another autoantibody, antibody-negative SLE is exceedingly rare.

Recently there has been a push to modify the existing classification system. The recommendations are to expand the criteria in the hope of ensuring that the diagnosis of SLE is not missed. New broader clinical criteria have the advantage of including neurologic symptoms and some immunologic abnormalities, but they run the risk of resulting in “overdiagnosis” of SLE. Currently the older diagnostic criteria are still considered the gold standard.

## Treatment of Systemic Lupus Erythematosus

The treatment of SLE is aimed at two goals: disease control and the prevention of long-term sequelae of this disorder. Treatment regimens are targeted to specific organ involvement. For many years only three medications, aspirin, corticosteroids, and hydroxychloroquine, were approved by the US Food and Drug Administration (FDA) for the treatment of SLE. More recently, belimumab was approved. In clinical

practice, a variety of unapproved immunosuppressive agents are also used to treat this disorder.

### Antimalarials

Hydroxychloroquine and chloroquine are the cornerstone of therapy for SLE. These medications were first used in the early 20th century to treat malaria but were found to be effective in treating inflammatory arthritis. More recently, the mechanism of action of antimalarials has been focused on interference with the expression of toll-like receptors that make up part of the innate immune system.

The major toxicity of hydroxychloroquine is retinal. This medication can cause pigment deposition in the retina and interfere with color vision first and then ultimately visual acuity. Dosing regimens that maintain a daily dose of <5 mg/kg/d minimize this risk, and current recommendations are for ophthalmologic examinations with visual field testing by an experienced ophthalmologist or optometrist at regular intervals. Chloroquine is more retinal-toxic than hydroxychloroquine. Other side effects of the antimalarials include pigment deposition in the skin leaving a grayish-blue hue

and, on very rare occasions, bone marrow suppression. These medications may also induce a hemolytic anemia in individuals with a glucose-6-phosphate dehydrogenase deficiency and can rarely cause a myopathy.

Evidence suggests that antimalarials are particularly effective in the treatment of skin disease, joint symptoms, and serositis. In addition, they may help some of the more protean systemic symptoms such as fatigue, fever, and malaise. In the long term, antimalarials may temper the development of renal and CNS manifestations. Thus many rheumatologists will advocate long-term maintenance therapy with antimalarials in lupus patients.

### Corticosteroids

Corticosteroids, especially prednisone and prednisolone, are the most common immunosuppressive agent used in systemic lupus. In low doses (<10 mg/d), these agents can be helpful for controlling joint symptoms, skin disease, and serositis. In higher doses of 0.5 mg/kg/d, they are effective in the management of severe serositis, skin disease, and CNS findings.

### Methotrexate and Leflunomide

Methotrexate is used to control joint symptoms, in particular synovitis. Methotrexate is also used to manage severe cutaneous manifestations. Leflunomide has been used for the treatment of joint symptoms as well.

### Azathioprine

Azathioprine can be used as a steroid-sparing agent in individuals who have the refractory skin disease and/or serositis. It is also used as maintenance therapy for individuals who have lupus nephritis and have received other induction immunosuppressive therapy, such as cyclophosphamide.

### Cyclosporine

Cyclosporine is less commonly used to treat renal disease (most often class V) and skin manifestations of SLE.

### Mycophenolate Mofetil

Initially used for the immunosuppression of organ transplants, mycophenolate mofetil has become an important tool for the induction and maintenance phase of managing lupus nephritis. Less toxic than cyclophosphamide, it is now often preferentially chosen to treat lupus nephritis in SLE patients, especially because this medication has no impact on fertility. Mycophenolate mofetil is also used to treat skin manifestations of SLE.

### Tacrolimus

Another immunosuppressant, tacrolimus, has also been used for the management of lupus nephritis. There is sufficient

evidence from the transplant literature to support the use of tacrolimus as well as azathioprine and cyclosporine A during pregnancy if significant immunosuppression is required for disease management.

### Cyclophosphamide

Early studies at the National Institutes of Health (NIH) showed that lupus nephritis was better treated with a regimen of cyclophosphamide and steroids than steroids alone. For the ensuing 20 years, this regimen of monthly pulse cyclophosphamide at doses of 500 mg to 1 g/m<sup>2</sup> of cyclophosphamide for 6 months, then every 3 months for a period of 2 years in combination with glucocorticoid therapy, has been the mainstay of therapy for lupus nephritis. Toxicities of cyclophosphamide include secondary carcinomas, hemorrhagic cystitis and risk for bladder cancer, and reproductive failure—an issue particularly problematic in a patient population of young women. More recently, a European group published data that 500 mg of intravenous cyclophosphamide every 2 weeks for six treatments was as effective as the original NIH protocol and had the advantage of lower toxicity. This regimen is also being used and is called the *Euro-lupus protocol*.

Cyclophosphamide is also used for the management of SLE vasculitis and severe CNS manifestations.

### Belimumab

Belimumab, a B-cell blocking therapy, has recently been shown to be effective in the management of nonnephritis manifestations of SLE. It is the first new medication in over 40 years that has been approved by the FDA for the management of SLE. Studies are under way to determine whether this medication has a role in the management of lupus nephritis.

### Other Biologics and Other Therapies

To date, none of the other biologics have demonstrated clear clinical efficacy in treating SLE. However, both rituximab (a B-cell targeted therapy) and abatacept (a cytotoxic T-lymphocyte associated protein-4 targeted therapy) have been used to treat renal disease and arthritis.

Other experimental therapy has included immunoablative therapy and autologous stem cell transplantation for severe cases of SLE. However, this therapy carries an extremely high mortality rate.

### Treatment Approaches

Milder manifestations of SLE such as skin disease, serositis, arthritis, and fatigue can be treated with NSAIDs, antimalarials, and low-dose prednisone and prednisolone. More severe symptoms warrant higher doses of corticosteroids and in some cases steroid-sparing agents. For severe arthritis, methotrexate and leflunomide are effective. Belimumab is used for musculoskeletal and cutaneous manifestations.

The drugs of choice for the induction of remission in class III and IV lupus nephritis is either mycophenolate mofetil or cyclophosphamide. Cyclosporine is used less frequently to treat lupus nephritis, most often for class V glomerulonephritis. Azathioprine and rarely tacrolimus are also used in the management of lupus nephritis. Rituximab is used to treat lupus nephritis despite clinical trials demonstrating lack of efficacy.

Other severe manifestations such as CNS involvement or vasculitis are managed with high doses of glucocorticoids, immunosuppressives, and/or cyclophosphamide.

## Conclusion

SLE is a multisystem disorder particularly impacting women of childbearing age. There is an increased disease burden in those of Asian, African-American, and Afro-Caribbean race and Hispanic ethnicity. This disorder can present with a variety of manifestations, but renal disease, CNS disease, and cardiovascular disease cause the most disease morbidity and mortality. Maintenance therapy with anti-malarials is often used, but more potent treatment with glucocorticoids, immunosuppressive agents, cytotoxic agents, and biologics can be used for their more significant findings.

## Antiphospholipid Syndrome

The antiphospholipid syndrome (APS) can be its own entity (primary APS) or can present in association with SLE and other collagen vascular diseases (secondary APS). Roughly 40% of individuals with SLE will have the presence of these antibodies, although fewer will have the full-blown antiphospholipid syndrome.

APS is defined as the presence of antibodies that react with phospholipids in conjunction with venous and arterial thrombotic events or obstetric complications. Recurrent clotting events tend to be similar to the initial event. Thus those who first present with an arterial clotting event are likely to have a subsequent arterial event, and those who initially present with a venous event are likely to have a subsequent renal event.

## Clinical Features

Venous thrombotic events such as deep vein thrombosis, superficial thrombophlebitis, renal vein thrombosis, and pulmonary emboli have all been described in this syndrome. Arterial clotting events such as myocardial infarctions, strokes, and clots involving major vessels have been reported as well. The obstetric complications include recurrent miscarriages, first trimester spontaneous pregnancy losses, fetal loss during the second or third trimesters, intrauterine growth retardation, and preeclampsia.

Raynaud phenomenon is frequently seen in patients with this syndrome. If one takes the subset of individuals

with SLE who also have Raynaud, the majority of these patients will have the presence of antiphospholipid antibodies. Migraine headaches and livedo reticularis (a lacy venous pattern most commonly seen on the legs) are also common findings. As many as 80% of individuals with hemolytic anemia and thrombocytopenia, also known as Evans syndrome, have antiphospholipid antibodies.

Rarely, widespread thrombotic events can occur that lead to multiple organ failure and a high incidence of death. This manifestation, the catastrophic antiphospholipid syndrome, is highly refractory to treatment.

## Antibodies

There are three general categories of antibodies that have been described in this disorder: false-positive Venereal Disease Research Laboratory (VDRL), anticardiolipin antibodies including the anti- $\beta$ -2 glycoprotein I, and circulating lupus anticoagulant. The false-positive VDRL antibody was the first described and was used for many years as part of the diagnostic criteria for the diagnosis of SLE. This test is of historical significance, but it has little utility in the diagnosis of this disorder and is no longer included in the diagnostic criteria. In the early 1980s, an enzyme-linked immunosorbent assay was developed to assess for the presence of cardiolipin antibodies. Currently, most laboratories will use internationally standardized sera to determine antibody levels. Although other isotype antibodies such as IgA and IgD antibodies have been reported to be associated with clinical manifestations of APS, the IgG and the IgM antibodies are most clinically relevant and are the basis of disease diagnosis. The binding of these antibodies to the phospholipid in the assay is mediated through  $\beta$ -2 glycoprotein I. Direct measurements of anti- $\beta$ -2 glycoprotein I antibodies can be used to diagnose this disorder as well.

The term *circulating anticoagulant* is a misnomer. Initially, over half a century ago, prolongation of in vitro clotting tests was described in lupus patients who were predisposed to clotting events. Many standard clotting tests such as an activated partial thromboplastin time, Russell viper venom time, and kaolin clotting time can be used as a first screen for the presence of a circulating anticoagulant. To confirm a positive screen, normal sera is added back to the assay to assess for a clotting factor deficiency. If the clotting abnormality is still present after the addition of normal sera, phospholipids are added back to assess whether the clotting prolongation normalizes. This confirms that the antibody prolonging the agent is one that reacts with a phospholipid and is thereby an antiphospholipid antibody. It is important that one uses a laboratory that does confirmatory testing and not just an initial screen.

When evaluating patients for this disorder, test for both the lupus anticoagulant and the anticardiolipin antibody because some patients will have the presence of one but not both of these antibodies.

## Diagnosis

Diagnosis of the disorder is based on the presence of either an IgG or IgM anticardiolipin antibody at >99th percentile, an anti- $\beta$ -2 glycoprotein I antibody at >99th percentile level, and/or a lupus anticoagulant on two separate occasions a minimum of 12 weeks apart. In addition to the laboratory criteria, one of the following clinical criteria must be met: either a venous or arterial thrombotic event or poor pregnancy outcome as defined by three or more first trimester spontaneous abortions, unexplained death in the second or third trimester, or one or more premature births before 34 weeks.

## Treatment

Current treatment recommendation of the nonobstetric clotting complications includes lifelong anticoagulation with warfarin. (The treatment of the obstetric complications is beyond the scope of this chapter.) The international normalized ratio should be maintained between 2.5 and 3.5 to circumvent bleeding while minimizing the risk of recurrent thrombotic events. Although the newer oral anticoagulants such as the inhibitors of activated Xa are occasionally used for the management of antiphospholipid syndrome, there have been no randomized controlled studies on these drugs to conclude their efficacy.

## Sjögren Syndrome

Sjögren syndrome is a disorder in which inflammatory damage to the lacrimal ducts and the salivary glands results in dry eyes and dry mouth. This disorder can be seen alone (primary) or in conjunction with other rheumatologic disorders, rheumatoid arthritis being the most common. The disorder is more common in women during the fourth and fifth decade of life. The pathophysiology of Sjögren syndrome is that of lymphocytic infiltrates of the lacrimal and salivary glands resulting in damage. Approximately 60% of patients may present with parotid gland or salivary gland swelling. Damage to these glands causes the decrease of tear production and salivary production and associated clinical findings. Although most of the clinical findings can be traced to the glandular damage, extraglandular involvement can also occur.

### Clinical

#### *Keratoconjunctivitis Sicca*

The damage to the lacrimal ducts causes decreased tear formation. As a result, the eyes are not as well lubricated. Usually patients will present with symptoms of dry and gritty eyes. Burning, blurriness, and photosensitivity can likewise occur. Later on, severe dryness can cause corneal epithelial damage. On examination, the eyes may appear injected and the lacrimal glands enlarged. Testing for tear formation in a designated period of time (Schirmer test) can be used to confirm poor tear formation. Rose Bengal staining with slit lamp examination is also helpful for evaluating damage to the corneal epithelium.

### *Xerostomia*

Lymphocytic infiltration of the salivary glands with resultant damage leads to decreased salivary production in Sjögren syndrome. As a result, patients will suffer from mouth dryness. In addition to mouth dryness, patients complain of difficulty swallowing food or difficulty talking for long periods of time. Over time, the poor salivary production can contribute to dental caries. Persistent dryness can also predispose to *Candida* infections in these patients. On examination, poor salivary pooling and dry mucosa are seen. In addition, poor dentition may also be present. Objective testing of salivary flow can be helpful in confirming this finding.

### *Vaginal Dryness*

Women with Sjögren syndrome can develop vaginal dryness as a result of decreased vaginal secretions. In this setting, increased urinary tract infections, local irritation, and dyspareunia can occur.

## Diagnosis of Sjögren Syndrome

The diagnosis of Sjögren syndrome is suggested by the clinical presentation of ocular and oral cavity dryness. In individuals who have ocular dryness, a Schirmer test, which measures tear formation over a designated period of time, will confirm reduced tear formation. For those with oral involvement, the best way to make a diagnosis is by salivary gland biopsy vis-à-vis a lip biopsy. Pathology reveals a CD4 T-cell predominant lymphocytic infiltrate. More than half of individuals with Sjögren syndrome will have positive anti-Ro and anti-La antibodies. Testing for these antibodies can be helpful in making the diagnosis of this disorder.

### Other Clinical Findings

Individuals with Sjögren syndrome can report systemic symptoms such as fatigue, myalgias, low-grade temperatures, and arthralgias. Dryness in the upper respiratory tract can predispose to recurrent infections and pneumonitis. Small- and medium-vessel vasculitis, as manifested by palpable purpura and skin ulcerations, have been reported in patients. Rarely, mononeuritis multiplex can occur, but peripheral neuropathies including facial nerve palsy have been reported. It is unusual for individuals with Sjögren syndrome to develop erosive arthritis without the presence of a coexisting disease such as rheumatoid arthritis. Nonetheless, close to half of patients with Sjögren will present with joint pain.

Upper gastrointestinal tract dryness can lead to difficulty in swallowing. Rarely, lymphocytic infiltration in the stomach can lead to atrophic gastritis. Glomerulonephritis and interstitial nephritis are rare manifestations of Sjögren syndrome. However, up to one-third of patients can have tubular disease including renal tubular acidosis. Non-Hodgkin lymphoma is found in about 2.5% of patients with Sjögren disease, a rate that is significantly higher than that in the rest of the population.

Treatment for the disorder is primarily directed at symptom control, because there are no approved medications for disease prevention. Avoidance of medications that may have anticholinergic effects is important. For the eyes, lubricating eye drops are used. In cases where that is insufficient, immunosuppressive eye drops containing cyclosporine may be used. If these measures do not work, then plugs for the tear ducts can be placed to maintain moisture formation. For the mouth, sucking on sugar-free candies and chewing gum can encourage saliva production. Most patients will take frequent sips of water or other liquids to keep the mouth moist as well. Cholinergic agents such as pilocarpine and cevimeline may also help by increasing tear and salivary flow; however, treatment with these agents is usually limited by side effects of flushing and sweating. Thus far, studies of B-cell depleting therapy such as rituximab have been disappointing and have not shown any lasting improvement in Sjögren syndrome.

### Progressive Systemic Sclerosis (Limited and Diffuse)

Progressive systemic sclerosis, also called scleroderma, is a relatively rare disease (1–2 individuals per 100,000) characterized by skin thickening and vascular abnormalities. This disorder is more common in women starting during their fifth to seventh decade of life. Chronic vasospasm and hypertrophy of blood vessels can cause organ damage. Fibrotic changes of the skin lead to thickening of the cutaneous tissue that are pathognomonic for this disorder. Pulmonary disease is seen in both limited and diffuse systemic sclerosis whereas renal disease is limited to the diffuse form. How the immune system mediates these changes is not well understood.

Systemic sclerosis can occur in four major forms. Limited progressive systemic sclerosis, also referred to as CREST (calcinosis, Raynaud, esophageal dysmotility, sclerodactyly, and telangiectasias), diffuse progressive systemic sclerosis, linear scleroderma, and rarely scleroderma sine scleroderma in which individuals may get the systemic symptoms of systemic sclerosis without the skin findings. The latter two presentations are beyond the scope of this chapter.

#### Limited Systemic Sclerosis (CREST)

In limited systemic sclerosis, the skin findings are limited to the hands and the face. Patients will have features of CREST syndrome. Most often, patients will have some but not all components of this disorder. Calcinosis is the deposition of calcium deposits under the skin that is more commonly found in the pediatric population. In Raynaud phenomenon, the primary lesion is vascular spasm of the vessels in the hands and the feet in response to cold or emotion. Initially, digits can have a bluish or white discoloration often with a sharp demarcation dividing involved and uninvolved regions. The digits will then turn red upon reperfusion. Esophageal dysmotility occurs when the distal

esophagus becomes fibrosed and normal peristalsis does not occur. Manifestations of this finding include reflux, heartburn, and cough. Eventually esophageal strictures and swallowing difficulties may happen. *Sclerodactyly* refers to the thickening of the skin of the digits. The fingers will appear thickened and waxy. Examination of the capillaries of the fingers shows capillary loop dilatation. Telangiectasias are small dilations of vessels that mainly occur on the face and chest. Roughly 10% of individuals with limited systemic sclerosis can develop pulmonary hypertension. Mortality within this subgroup is quite high, although the prognosis among individuals without pulmonary involvement is excellent.

#### Progressive Systemic Sclerosis

Individuals with progressive systemic sclerosis will have more widespread skin involvement that includes the arms, trunk, chest, and legs. They are more likely to have internal organ involvement including renal disease, pulmonary disease, and cardiac disease than those with limited systemic sclerosis and have a higher mortality rate.

On physical examination, skin tightening and thickening can occur over the face, arms, trunk, and lower extremities. In both limited and diffuse systemic sclerosis, narrowing of the oral aperture can occur. Individuals who have Raynaud phenomenon can have digital ulcers, and those with severe sclerodactyly can have bone reabsorption sometimes resulting in autoamputation of the digits.

Diagnosis is made by clinical findings. Laboratory testing should include an ANA, anticentromere, and anti-Scl-70 antibodies. As a general rule, the anticentromere antibodies are more likely to be positive in limited systemic sclerosis, whereas anti-Scl-70 antibodies are more likely to be positive in those with diffuse systemic sclerosis.

#### Organ Involvement Cutaneous

Initially the skin appears swollen and inflamed, and eventually thickening of the skin with fibrosis occurs. The hands, arms, chest, and abdomen are most commonly involved although the thighs, legs, and feet can be affected as well. This skin thickening can cause joint contractures and severe restriction in movement. By definition, those with limited disease have skin changes only on the face, neck, and hands up to the forearms, whereas those with diffuse disease have more extensive involvement. Pigment changes of the skin can occur as well.

#### Pulmonary Disease

Pulmonary disease is the major cause of mortality in individuals with both limited and diffuse progressive systemic sclerosis. Close to one-third of individuals with diffuse disease have involvement of the lungs, and  $\leq 10\%$  of individuals with limited disease will develop pulmonary hypertension. Patients present with shortness of breath and fatigue. On examination, dry bibasilar crackles are

seen; often elevated right-sided cardiac pressures suggestive of pulmonary hypertension can be found. Often the diagnosis needs to be made by high-resolution CT scan because a plain radiograph can underestimate disease involvement. Restrictive lung disease and interstitial fibrosis are the most common findings. Long-standing disease can lead to pulmonary hypertension.

### Renal Disease

Roughly one-half of patients with diffuse progressive systemic sclerosis will develop renal disease. Patients will present with hypertension and proteinuria but a surprisingly bland urinary sediment. Scleroderma renal crisis is a rare finding in which patients present with sudden elevated blood pressure, hemolytic anemia, and renal insufficiency. There are some suggestions that glucocorticoid therapy increases the risk of scleroderma renal crisis; thus these agents are generally avoided in these patients. The use of angiotensin-converting enzyme (ACE) inhibitors has greatly reduced the onset of scleroderma renal disease.

### Cardiac Disease

Cardiac disease secondary to pulmonary hypertension and systemic hypertension can occur in systemic sclerosis. This can lead to congestive heart failure. Pericarditis and pericardial effusions are rarer, although fibrosis of the pericardium can occur. In diffuse systemic sclerosis, myocardial fibrosis and vasospasm of the small vessels can lead to diastolic dysfunction. Rarely, fibrotic depositions in the conduction system can cause arrhythmias.

### Gastrointestinal Disease

Esophageal dysmotility occurs in many patients with progressive and limited systemic sclerosis. This can result in chronic reflux, aspiration, and esophageal strictures. Gastritis is also seen. Dysmotility in the small and large intestines can lead to bacterial overgrowth.

### Musculoskeletal Involvement

Rarely patients develop an inflammatory arthritis; however, sclerodactyly can lead to contractions and limited mobility.

### Treatment

The biggest treatment advance in progressive systemic sclerosis has been in the use of ACE inhibitors for the prevention and management of renal disease.

Unfortunately, there has been no proven therapy for the skin and other manifestations of systemic sclerosis. For many years, penicillamine was used in the hope of arresting the skin involvement, but its high toxicity and limited efficacy have decreased its use. Other studies have evaluated methotrexate, cyclosporine A, and mycophenolate mofetil for severe skin disease, but the results have been inconclusive. Several trials evaluating cyclophosphamide for

the management of pulmonary disease have demonstrated a modest improvement in symptoms. Agents such as the endothelin receptor antagonist bosentan and the phosphodiesterase type 5 inhibitor sildenafil citrate have been used to manage pulmonary hypertension and severe Raynaud phenomenon with some benefits. Calcium-channel blockers are generally used for the first-line management of Raynaud phenomenon.

### Mixed Connective Disease and Overlap Syndrome

Mixed connective disease (MCTD) is a sister disorder to SLE. Similar to SLE, this disorder is most frequently found in women of childbearing age; however, it does not have a predilection for those of African ancestry. These individuals are often initially diagnosed as having SLE because SLE and MCTD share many findings. In general, Raynaud phenomenon, myositis, and synovitis are frequently seen in patients with MCTD whereas renal disease is rare. These patients are more likely to have lung disease than lupus patients, and the lung involvement can lead to pulmonary hypertension. The chronic vasospasm of Raynaud phenomenon can lead to hand changes similar to sclerodactyly. Many of these patients have a very high-titer ANA, and the anti-RNP antibody is often positive. Treatment is similar to SLE with the use of antimalarials and nonsteroidal antiinflammatory medications. Corticosteroids can be used for more significant manifestations such as myositis or pulmonary involvement. Immunosuppression with azathioprine and methotrexate can help. Occasionally, cytotoxic therapy is used for severe lung disease and other systemic involvement.

Some individuals will present with features that are suggestive of a collagen vascular disease yet they may not neatly fit into a clear diagnostic category. For example, an individual may present with arthritis, Raynaud phenomenon, sclerodactyly, and myositis, yet not clearly fit into the category of either SLE or progressive systemic sclerosis. In these cases, the term *overlap syndrome* is used to describe the clinical presentation.

### Idiopathic Inflammatory Myopathies: Polymyositis, Dermatomyositis, and Inclusion Body Myositis

Idiopathic inflammatory myopathies such as polymyositis and dermatomyositis are rare disorders that have an increased incidence in women. There is a bimodal distribution of disease onset, with the peak incidence of these diseases being in early childhood and then again in the fourth to fifth decades of life. In polymyositis, the involvement is restricted to the muscles and occasionally the lungs, whereas in dermatomyositis the skin can be involved as well. Inclusion body myositis is rarer still, more likely occurring in middle-aged men.

## Clinical Symptoms

Individuals with polymyositis and dermatomyositis present with weakness in the proximal muscles. Activities such as combing one's hair, reaching, lifting, getting out of a chair, or walking up and down stairs become difficult. In more pronounced disease, difficulty swallowing and breathing can be problematic because individuals may have esophageal muscle weakness and respiratory muscle weakness. Some patients may present with muscle aching and pain on palpation, especially during the acute phase. On physical examination, the neck flexors, upper arms, and hip flexors in individuals with polymyositis and dermatomyositis are weak.

For those with inclusion body myositis, symptoms have a slower onset and more distal muscles are involved. Loss of muscle mass can occur before these patients present to a physician.

## Skin

Individuals with dermatomyositis have distinct skin findings. Gottron papules are reddish scaly patches that appear over the knuckles of the hands and may occur over the extensor surfaces of the elbows as well. Individuals with dermatomyositis may also have a reddish-purplish rash around the eyes and on the eyelids, referred to as a "heliotropic rash." A rash over the neck and trunk in a distribution that looks like a shawl is also found. In dermatomyositis, nail bed changes with overgrowth of the cuticle can be seen. In both polymyositis and dermatomyositis, patients may present with rough skin and cracking skin on the fingers that is referred to as "mechanic's hands."

## Pulmonary

Muscle weakness can lead to dyspnea on exertion. Pulmonary function tests will suggest poor inspiratory and expiratory effort. Interstitial lung disease occurs in  $\leq 10\%$  of all myositis patients and upwards of 50% of patients who have a positive anti-Jo-1 antibody. Presenting symptoms include dyspnea on exertion, a nonproductive cough, and hypoxemia. On examination, dry crackles are heard, and decreased diffusion capacity is found in pulmonary function tests. In addition to the aforementioned, swallowing difficulties experienced by patients can lead to chronic aspiration and resultant pulmonary disease.

## Cardiac

Rarely, patients will have involvement of the cardiac conduction system that can lead to either heart block or arrhythmias. Global cardiomyopathy is very unusual in these disorders.

## Gastrointestinal

Most of the gastrointestinal abnormalities seen in the inflammatory myopathies are caused by muscle dysfunction

along the gastrointestinal tract. Reflux, abnormal peristalsis, and delayed gastric emptying have all been described.

## Laboratory Abnormalities

In myositis, muscle enzymes such as the creatinine kinase and aldolase are often elevated. Serum aspartate aminotransferase and alanine aminotransferase can increase as well. Up to 80% of patients with immune-mediated inflammatory myopathy will have ANA. Anti-Jo-1 antibodies can be seen in patients with coexisting pulmonary disease.

## Differential Diagnosis

Other clinical presentations that can mimic those of idiopathic inflammatory muscle disease include thyroid disease, toxic metabolic syndromes, drug reactions, steroid myopathy, and some infectious diseases. Fixed errors of metabolism that lead to elevations of creatinine kinase and weakness, in particular after exercise, can also be difficult to distinguish from idiopathic inflammatory myopathies.

## Diagnosis

The diagnosis of an inflammatory muscle disease is first based on a high clinical suspicion. Laboratory testing is helpful because the majority of patients with inflammatory myopathy will have significant elevations in their muscle enzymes such as the creatinine kinase and/or aldolase levels. In addition, elevated liver function tests can be a clue that there is underlying myopathy. Electromyography (EMG) findings are characteristic in these disorders and can be helpful in the diagnostic evaluation of patients presenting with muscle weakness. There was some initial excitement for the use of MRI scanning for the diagnosis of inflammatory muscle disease; however, it has not been as helpful as initially anticipated. Nonetheless, MRI scanning does have a role in identifying areas of muscle inflammation that are likely to yield a good biopsy specimen. The gold standard for the diagnosis of inflammatory myopathy is still a muscle biopsy. In dermatomyositis, pathology reveals perivascular inflammation around the muscle fibers whereas in polymyositis, inflammation within the muscle fibers is seen. Special staining and electron microscopy are necessary to make the diagnosis of inclusion body myositis. Findings in this disorder include eosinophilic and basophilic granules in the vacuoles as well as abnormal tubular filaments of unknown significance.

## Malignancy Association

Both polymyositis and dermatomyositis are associated with a higher incidence of malignancies, dermatomyositis more so than polymyositis. In cases of coexisting inflammatory myopathy and malignancy, most lesions are diagnosed within 2 years of the initial diagnosis of muscle disease. Because of the increased risk for cancer in individuals who

present with these disorders, it is recommended that age-appropriate malignancy screenings such as mammograms, colonoscopy, prostate-specific antigen, chest radiographs, and in some cases abdominal-pelvic imaging be performed in individuals who present with these conditions.

## Treatment

The treatment of polymyositis/dermatomyositis is focused on the rapid reduction of muscle inflammation. High-dose steroids (1 mg/kg/d of prednisone equivalent) are generally given for the first 6 weeks of therapy. After that time period, and depending on the individual's response to treatment, the doses of these medications are generally tapered. Azathioprine or methotrexate can be added both to hasten disease improvement and also to facilitate the lowering of the steroid dose. In cases resistant to this approach, intravenous immunoglobulin has been used successfully. Other agents such as the tumor necrosis factor (TNF- $\alpha$ ) blockers and rituximab have yielded conflicting results as to their role in inflammatory myopathy disease management. Mycophenolate mofetil, cyclosporine A, and tacrolimus have been effective in some drug-resistant cases. Monitoring response to therapy is done by physical examination and laboratory testing. Occasionally a repeat muscle biopsy is in order. Once

the active phase of inflammation is controlled, physical rehabilitation to regain muscle strength is an important part of the treatment plan. Speech and swallowing therapy can be employed to improve swallowing. For the skin lesions of dermatomyositis, antimalarials can be helpful. The treatment options for inclusion body myositis are more limited because there has been no proven therapy for this disorder.

## Conclusion

SLE, APS, progressive systemic sclerosis, MCTD, and the inflammatory myopathies are systemic diseases that can affect multiple organ systems. These disorders can be challenging to diagnose because no single laboratory test definitively confirms the diagnosis; rather, the clinical presentation in conjunction with laboratory testing leads to classifying patients as having these disorders. Previously, diseases such as SLE and inflammatory myopathies had a grim prognosis, but now, with improved recognition and earlier initiation of therapy, the outcome is significantly better. Progressive systemic sclerosis remains challenging to manage. It is our hope that, with better understanding of the pathophysiology of these disorders and the development of newer therapies, our treatment of these disorders will continue to improve.

## Chapter Review

### Questions

1. A 23-year-old woman presents with a history of malaise, facial rash, and achiness. Appropriate workup includes:
  - A. ANA testing
  - B. Complete blood count with differential, liver function tests, creatinine and urinalysis
  - C. Anti-dsDNA antibody
  - D. All of the above
2. A 43-year-old woman presents with a deep vein thrombosis with no clear precipitant. Her medical history is notable for two first trimester miscarriages and one second trimester miscarriage. Appropriate testing includes:
  - A. Lupus anticoagulant
  - B. Anticardiolipin antibody
  - C. VDRL
  - D. A, B, and C
  - E. A and B only
3. A 57-year-old woman presents for evaluation of weakness. She is finding it difficult to comb her hair, get out of a chair, and navigate steps. She is also having shortness of breath. Initial laboratory testing includes a creatinine kinase of 2400. Which of the following tests is not appropriate?
  - A. Electromyography
  - B. MRI of the upper extremities
  - C. Mammogram, colonoscopy, pelvic/abdominal CT imaging
  - D. Muscle biopsy

### Answers

1. B
2. E
3. B

## Systemic Vasculitis

PAUL F. DELLARIPA

The vasculitides are a group of disorders that are characterized by the presence of inflammation in vessel walls, which leads to vascular occlusion and tissue necrosis. Systemic vasculitic syndromes can present clinically in protean fashion and may be caused by a variety of mechanisms involving immune dysregulation that leads to endovascular inflammation. However, these immune mechanisms are still not well understood; therefore one must rely on clinical, descriptive parameters for classification and treatment. This chapter focuses on well-recognized patterns of presentation, treatment guidelines, and emerging insights on pathogenic mechanisms, a new nomenclature, and implications for future treatment options.

Classification of systemic vasculitides (SV) has traditionally involved dividing them along the lines of vessel size (e.g., giant cell arteritis [GCA] representing large-vessel disease and hypersensitivity vasculitis representing small-vessel disease) although in reality, there is significant overlap in terms of size of vessels, and such a classification offers no information on pathogenesis or unique characteristics of different vasculitic syndromes. In this discussion, we focus on disease patterns most often associated with antineutrophil cytoplasmic autoantibody including granulomatosis with polyangiitis (GPA; formerly Wegener granulomatosis), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis, (EGPA; formerly Churg-Strauss syndrome), and other vasculitides including polyarteritis nodosa (PAN), drug-induced and cryoglobulinemic vasculitis, Takayasu arteritis (TA), GCA, and Behçet disease.

### Clinical Presentation

SV should be suspected in patients who present with systemic clinical findings or symptoms for which there is no readily identifiable source of infection or malignancy. For example, unexplained persistent fever will typically be investigated for underlying infection or lymphoma but can be a prominent feature of patients with GCA. Other signs and symptoms, such as weight loss, night sweats, rash, mononeuritis, arthritis, and malaise without identifiable etiology, can represent clinical features of an underlying vasculitis. Sometimes these findings may be embedded

within a pattern that fits into a well-described syndrome, but often they do not. Clinical syndromes that can mimic vasculitis include endocarditis, atrial myxoma, atheroembolism, and hypercoagulable states such as antiphospholipid syndrome.

### Antineutrophil Cytoplasmic Autoantibody Vasculitis

GPA, EGPA, and MPA are often considered together as a group of similar diseases because they have shared clinical features and are associated with antineutrophil cytoplasmic autoantibody vasculitis (ANCA) in most cases. The incidence among this group of rare disorders varies from 0.15 per million to 15 per million. All three can frequently present with a pauciimmune necrotizing glomerulonephritis (GN) and pulmonary involvement. ANCA is detected by indirect immunofluorescence on ethanol-fixed neutrophils and can exhibit a cytoplasmic pattern (cANCA) or a perinuclear pattern (pANCA). If the immunofluorescence test is positive, then an enzyme-linked immunosorbent assay specific for proteinase 3 (PR3) or myeloperoxidase (MPO) is performed. Most patients with GPA are PR3 positive (up to 80%) and rarely MPO positive. In MPA, up to 79%–80% of cases are MPO positive and rarely PR3 positive. In some cases, patients with GPA may be ANCA negative. Generally speaking, patients with PR3-positive ANCA-associated disease have a greater degree of multiorgan involvement, more frequent granulomatous disease, and a higher frequency of relapse. ANCA-MPO positivity may also be seen in systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), scleroderma, and inflammatory bowel disease, and in certain drug-induced vasculitic syndromes (such as with propylthiouracil and allopurinol).

### Granulomatosis With Polyangiitis (Wegener)

GPA is a systemic vasculitis characterized by granulomatous vasculitis of the upper and lower respiratory tract and segmental necrotizing GN that involves small blood vessels. Some patients with GPA have what is termed *limited GPA*, which is confined to the upper respiratory tract.

Findings often include rhinitis, epistaxis, otitis media, hearing loss, chondritis of the ears and nose, cough, dyspnea, hemoptysis, pulmonary nodules, subglottic stenosis, hematuria related to GN, progressive renal insufficiency, mononeuritis multiplex, central nervous system (CNS) vasculitis, scleritis, conjunctivitis, palpable purpura, granulomatous skin lesions, arthritis, and arthralgias.

One of the more common clinical patterns that can present in GPA is lower respiratory tract symptoms with active GN, referred to as *pulmonary renal syndrome*. In patients who present with GN and active pulmonary symptoms, especially alveolar hemorrhage, the differential diagnosis includes GPA, MPA, SLE, cryoglobulinemia, and Goodpasture disease.

Pathologically, the vessels involved in GPA include small arteries and veins. The pathology of vasculitis includes fibrinoid necrosis with inflammatory mononuclear cell infiltrates of vessel walls, focal destruction of the elastic lamina, and narrowing or obliteration of the vessel lumen. Granulomatous vasculitis may involve the lung, skin, CNS, peripheral nerves, heart, kidney, and other organs.

Most patients with GPA present with symptoms referable to the upper respiratory tract including sinusitis, nasal obstruction, rhinitis, otitis media, hearing loss, ear pain, gingival inflammation, oral and nasal ulcers, epistaxis, sore throat, laryngitis, and nasal septal deformity. Upper respiratory tract involvement may lead to damage to nasal cartilage, resulting in the saddle-nose deformity.

Lower respiratory tract involvement occurs in most patients, although it is seen less frequently as a presenting symptom; it may include cough, sputum production, dyspnea, chest pain, hemoptysis, and life-threatening pulmonary hemorrhage as noted in Fig. 26.1. GPA may also be associated with inflammation and subsequent scarring/stenosis of the subglottic region.

Radiographic findings include multiple nodular, often bilateral, cavitary infiltrates, but infiltrates with less well-defined margins occur as well (Fig. 26.2). Other less common chest radiographic abnormalities include paratracheal masses, large cavitary lesions, and massive pleural effusion. CT of the chest may reveal pulmonary lesions that are not well demonstrated on plain radiographs.

Urinalysis reveals renal involvement in approximately 80% of patients at presentation. The typical renal lesion is segmental necrotizing glomerulonephritis. Functional renal impairment may progress rapidly if appropriate therapy is not instituted promptly.

### Diagnosis

Diagnosis can be based on the clinical findings of upper and lower respiratory tract noninfectious inflammation with glomerulonephritis, and positive anti-PR3 ANCA without necessarily proceeding with a biopsy, although this is the subject of some debate. In cases with more limited involvement, or where ANCA titers are negative or show the less typical MPO specificity, tissue diagnosis may be necessary and can be sought at sites of active disease including kidney

• Fig. 26.1 A patient with granulomatosis with polyangiitis plus pulmonary nodules.

• Fig. 26.2 Patient with granulomatosis with polyangiitis and diffuse alveolar hemorrhage.

biopsy, lung biopsy, nerve, sinus, and even conjunctival biopsy.

### Treatment

Therapy with significant disease is typically based on establishment of remission with a combination of corticosteroids and rituximab or cyclophosphamide and then once

remission is achieved, usually within 6 months, step-down therapy using agents such as azathioprine, methotrexate, or mycophenolate is instituted, or if Rituxan is used instead of cyclophosphamide, then repeated doses of Rituxan may be considered. Rituximab is dosed at 375 mg/m<sup>2</sup> weekly for 4 weeks or 1 g every 2 weeks for two doses; in both cases concomitant with high dose steroids. Repeat doses of rituximab can be given in a maintenance phase if signs of recurrence occur or on a variable basis determined by disease course. Similar, if cyclophosphamide is the inducing agent, it can be given orally up to 2 mg/kg with adjustments for renal function or intravenously 500 to 1000 mg/m<sup>2</sup> monthly or 15 mg/kg every 3 weeks. Trimethoprim sulfamethoxazole may limit flares of upper respiratory symptoms and is also indicated as a prophylactic agent against pneumocystis pneumonia (PCP). Initial treatment with corticosteroids is generally given as prednisone, 1 mg/kg/d orally. In a critically ill patient with severe systemic involvement, pulse corticosteroid with intravenous methylprednisolone 1 g/d for 3 days is advocated, transitioning to prednisone 1 mg/kg/d orally or its intravenous equivalent. Cyclophosphamide can be administered as monthly intravenous boluses, every 3 weeks intravenous bolus, or as a daily oral dose. The risks associated with cyclophosphamide include hemorrhagic cystitis, opportunistic infections such as PCP and fungal infections, and the long-term, lifelong risk of bladder cancer, lymphoma, and leukemia. Rituximab carries risk for a variety of infections including an increased risk for the development of progressive multifocal leukoencephalopathy caused by infection by the JC virus. In severe cases, there may be a role for plasmapheresis, which may preserve renal function. In less severe cases or in step-down therapy to maintain remission, therapy with methotrexate, mycophenolate, azathioprine, and abatacept may be an option. The use of immunoglobulin in ANCA-associated vasculitis is uncertain and lacks support from robust prospective clinical trials.

### Microscopic Polyangiitis

MPA is a necrotizing vasculitis that involves small vessels, capillaries, and venules and presents predominantly with segmental necrotizing glomerulonephritis. The patient may have concomitant evidence of alveolar hemorrhage in about one-third of cases, which sometimes makes it difficult to distinguish between GPA and MPA, and pathologically the lesions may be indistinguishable. Neuropathy and cutaneous vasculitis may also occur with MPA, and, as noted previously, ANCA expression occurs in up to 80% of cases and nearly always specific for MPO. Treatment is similar to that for GPA.

In some patients who present with severe manifestations of the pulmonary renal syndrome, the precise diagnosis may not be apparent and may include ANCA-associated disease, lupus, and antiglomerular basement disease. In such cases where end organ failure is imminent and life threatening, therapy with high-dose steroids, cytotoxic therapy, and

plasmapheresis may be considered until a clear diagnosis is evident.

### Eosinophilic Granulomatosis With Polyangiitis (Churg-Strauss Syndrome)

EGPA is a disease characterized by the presence of eosinophilic infiltrates, granulomas in the respiratory tract, and necrotizing vasculitis in the setting of asthma and peripheral eosinophilia. The disease typically affects small-sized to medium-sized muscular arteries, most frequently of the upper respiratory tract and the lungs. Patients with EGPA present most often with a background history of asthma, in some cases lasting for many years, and then develop constitutional symptoms of weight loss followed by various forms of organ involvement including pulmonary infiltrates, mononeuritis, cardiomyopathy, cutaneous vasculitis, and gastrointestinal (GI) tract involvement. Renal involvement is less frequent than in GPA or MPA, occurring in up to 40% of patients. Clinical manifestations of disease may become evident in some patients who are treated with leukotriene inhibitors and undergo steroid taper, although it is not believed that leukotriene inhibitors are themselves causative of EGPA. ANCA to myeloperoxidase is positive in up to 40%–60% of cases and seems to be positive in those patients with mononeuritis, cutaneous vasculitis, and glomerulonephritis and frequently negative in those with cardiac involvement.

#### Treatment

Treatment in EGPA is high-dose corticosteroids. In more severe disease, use of cyclophosphamide and other immunosuppressive agents such as azathioprine or mycophenolate may be guided using the five-factor score. Novel approaches using rituximab and interleukin (IL)-5 inhibitor are in clinical trial.

### Polyarteritis Nodosa

PAN is a rare disorder that involves small-sized and medium-sized arteries. The incidence has been estimated at 9 to 77 per million. Although virtually any organ system may be involved in PAN, the GI tract, neurologic system, and the skin are most frequently affected. Patients may complain of weight loss, fatigue, fevers, and abdominal pain, and they may develop hypertension and azotemia with proteinuria as well as cardiac and CNS involvement. Glomerulonephritis and lung disease are rare. GI involvement is an important source of morbidity, which may be caused by acute GI bleeding, perforation, and mesenteric thrombosis.

The pathogenesis of PAN is unknown. Hepatitis B surface antigen is noted in a small number (<10%) of patients, suggesting a role for circulating immune complexes in some cases of PAN. Pathology shows fibrinoid necrosis and pleomorphic cellular infiltration of lymphocytes, macrophages, and polymorphonuclear leukocytes involving the entire wall of the blood vessel.

## Diagnosis

Patients with PAN often have elevated markers of inflammation such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), although antinuclear antibodies, rheumatoid factor (RF), and ANCA are not typically present. Diagnosis is made either by biopsy of specific organs affected (such as sural nerve, skin, or muscle) or identification of characteristic aneurysms of the renal, hepatic, or mesenteric vessels on mesenteric angiogram (Fig. 26.3), recalling, however, that microaneurysms can be seen in other conditions such as atrial myxoma, Ehlers-Danlos, and endocarditis.

## Treatment

Corticosteroids are the treatment for PAN, in high doses, and in severe cases intravenous methylprednisolone 500 to 1000 mg/m<sup>2</sup> monthly is reasonable. The use of a cytotoxic agent such as cyclophosphamide or other second agents is indicated in patients with moderate to severe disease, which would include renal, GI, cardiac, or neurologic involvement. Where PAN is associated with hepatitis B, judicious concomitant use of immunosuppressive therapy in addition to antiviral therapy directed against hepatitis B may be useful.

## Drug-Induced Vasculitis

Certain drugs and vaccines can cause vasculitis through a variety of mechanisms. These have often been termed *hypersensitivity vasculitides*. For example, leukocytoclastic vasculitis (*leukocytoclasia*, meaning “nuclear fragmentation”) involving small vessels might occur because of an antibiotic that results in the deposition of immune complexes within vessel walls, whereas another drug (such as propylthiouracil) may cause a systemic vasculitis that is related to the production of ANCA. In general, cases of drug-induced vasculitis can cause a self-limiting illness that resolves with discontinuation of the offending agent or can lead to multiorgan involvement. However, more severe cases can present with severe ulcerative skin lesions or renal, GI, or neurologic involvement that may require corticosteroids or, rarely, other immunosuppressive agents.

Some commonly used drugs known to result in vasculitis include hydralazine, minocycline, propylthiouracil, allopurinol, phenytoin, penicillins/cephalosporins/quinolones, vaccines (hepatitis B, influenza), and levamisole (in some cases as an additive to cocaine; Fig. 26.4).

## Cryoglobulinemic Vasculitis

Cryoglobulins are immunoglobulins that precipitate below 37°C. Type I is associated with myeloproliferative disorders; types II (mixed essential) and III (mixed polyclonal) are often associated with hepatitis C. When there is no underlying etiology it is known as *cryoglobulinemic vasculitis*, and when associated with hepatitis C it is known as *hepatitis C virus-associated cryoglobulinemic vasculitis*. Cryoglobulinemic vasculitis can lead to immune complex deposition in

• **Fig. 26.3** Patient with polyarteritis nodosa who presented with renal infarct and multiple aneurysms at branch points of mesenteric vessels (arrows).

• **Fig. 26.4** Patient with necrotizing vasculitis of the ears caused by levamisole contaminated cocaine injection resulting in high titer anti-neutrophil cytoplasmic autoantibody vasculitis in a myeloperoxidase pattern consistent with drug-induced vasculitis.

the walls of small vessels, resulting in cutaneous vasculitis, arthritis, and neuropathy, although on occasion life-threatening renal, GI, and pulmonary disease can also occur. Laboratory features include low-level C4, high RF, and elevated liver enzymes that may be indicative of hepatitis C infection. Therapy in severe cases consists of corticosteroids and sometimes other immunosuppressives such as rituximab, cyclophosphamide, or azathioprine (with concern for increased replication of hepatitis C), plasmapheresis, and consideration of treatment with antiviral therapy such as ribavirin and interferon- $\alpha$  if hepatitis C is present.

Other vasculitic syndromes in which immune complex deposition plays a significant role in pathogenesis include

vasculitis related to rheumatic disorder such as SLE or RA, infection-associated vasculitis, malignancy-associated vasculitis, and Henoch-Schönlein purpura, now known as *IgA vasculitis*.

### Giant Cell Arteritis and Takayasu Arteritis

GCA and TA are both large-vessel vasculitides that are pathologically indistinguishable, often with evidence of granulomatous disease. The incidence of GCA is most notable in Northern Europe in the range of 59 per 100,000. Incidence estimates in the United States of TA are 2.6 cases per million. Available evidence suggests that the etiologies of GCA and TA are related to cell-mediated processes and expression of various cytokines and chemokines such as IL-6, CCL-2, and IL-1B.

GCA is a large-vessel vasculitis with characteristic granulomatous and lymphocytic infiltration of arterial walls that presents in patients over the age of 50 years but more often over the age of 60 years. Symptoms of GCA include headache, scalp tenderness, visual blurriness and visual loss including blindness, jaw claudication caused by involvement of the facial artery, claudication of the upper and lower extremities, polymyalgia rheumatica, weight loss, fatigue, and fever.

Laboratory evaluation frequently reveals elevated markers of inflammation such as CRP, ESR, and alkaline phosphatase, although in about 15% of patients, the ESR may be normal. Regardless of the laboratory findings, if there is significant suspicion for the diagnosis then a temporal artery biopsy should be performed. If the patient is experiencing visual symptoms at the time of consideration of the diagnosis, high-dose corticosteroid therapy should be instituted immediately to prevent permanent visual loss; then a temporal artery biopsy should be obtained as soon as possible. Biopsy findings may persist in patients with GCA for up to several weeks on corticosteroid therapy. If the initial biopsy is negative, the contralateral temporal artery may offer a small additional yield diagnostically, although in some patients in whom both biopsies are negative it may be necessary to treat because the index of suspicion is high. In general, a negative biopsy evaluation (where both are done when the first is negative) has a negative predictive value of >91%. Ultrasound and MRA of the temporal arteries are under investigation as diagnostic tools. Large vessel involvement including the subclavian arteries can occur, and aortitis may develop concomitant with more common symptoms or later after treatment has been completed (Fig. 26.5).

Therapy with steroids involves prednisone at 1 mg/kg for at least 1 month, then a slow taper to about 20 mg/d at month 3, and then a continued taper to prevent relapse of symptoms. Therapy may last at least 2 years and many more years in some cases. Recent data support the use of IL-6 inhibition in GCA. Use of other agents such as tumor necrosis factor (TNF) inhibitors, methotrexate, and azathioprine in clinical studies has not been successful.

• **Fig. 26.5** A patient with biopsy proven giant cell arteritis with aortitis of the ascending and descending aorta (arrows).

TA is a large-vessel vasculitis that involves the aorta and branches of the aorta and affects predominantly females up to the age of 50 years. Patients will typically present with claudication of the upper or lower extremities, especially involving the subclavian arteries, although the diagnosis should be considered in any young patient with diminished pulse and constitutional symptoms. The aorta on imaging can develop aneurysms; stenosis of the large vessels and aortic valve regurgitation may occur. Constitutional symptoms such as fatigue, headache, and weight loss are often noted before claudication, and hypertension can occur as well. CNS events secondary to carotid and vertebral artery involvement and intestinal ischemia have been noted.

Diagnosis should be suspected in a young patient, particularly female, with constitutional symptoms and absent or diminished pulses or bruits on examination. Although the ESR may be elevated, it may be only modestly elevated or normal in some cases and is not always indicative of disease activity. Areas of stenosis or aneurysm can be noted with MRA, CT angiography, or conventional angiography. Treatment is high doses of corticosteroids, although some patients will not respond without addition of cytotoxic therapy. Emerging evidence suggests a role for TNF inhibitors and interventional vascular techniques such as stenting and angioplasty.

### Behçet Disease

Behçet disease is characterized by the presence of recurrent aphthous or genital stomatitis that can, in a subset of patients, also exhibit vasculitis of various-size vessels resulting in ocular involvement, intracranial hemorrhage, meningoencephalitis, and stroke. Prevalence rates are highest in the Middle and Far East. It is primarily a clinical diagnosis, and treatment can vary from colchicine and apremilast for aphthous ulcers to corticosteroids, TNF inhibition, and cytotoxic therapy in severe cases.

## Primary Central Nervous System Vasculitis

Primary CNS vasculitis is a rare entity with protean manifestations including seizure, stroke, meningoencephalitis, and cranial nerve deficits. It is important to exclude secondary causes of CNS involvement of many of the aforementioned vasculitides, such as other rheumatic diseases including SLE, antiphospholipid syndrome, Sjögren disease, sarcoidosis, infections such as tuberculosis, HIV, and Lyme disease, or a variety of drugs including cocaine, methamphetamines, and heroin. Diagnosis is suggested by cerebrospinal fluid abnormalities including elevated protein and cell counts and abnormalities on MRI. Although angiography may in some cases show classic findings of vasculitis, a biopsy of suspected areas is frequently necessary to make the diagnosis. Treatment includes high doses of corticosteroids and sometimes cytotoxic agents; however, there is a paucity of clinical trials to make definitive treatment recommendation with this rare disorder.

## Treatment Strategies in Vasculitis

Note that morbidity in vasculitides can be tied not only to end-organ effects of disease but to the treatment used to control the underlying disease. Morbidity associated with corticosteroids is well documented, including diabetes, osteoporosis, infection, poor wound healing, cataracts, hypertension, and obesity among many other side effects. Cytotoxic agents such as cyclophosphamide also have many

side effects including heightening risk of opportunistic infection such as PCP, fungal infections, and the risk of cancer and sterility. Therefore four important points regarding vasculitis treatment need to be emphasized:

1. In a patient with known vasculitis who presents with clinical deterioration, a source of infection should be pursued aggressively before, or concomitant with, escalation of immunosuppressive therapy.
2. In severe cases of vasculitis, aggressive immunosuppressive therapy such as cyclophosphamide or rituximab is used; then after remission has been achieved, less toxic agents such as MTX, azathioprine, or mycophenolate mofetil are used in a step-down approach. Dose adjustments in renal failure are important to consider with both cyclophosphamide and MTX. B-cell depleting therapy with rituximab is now an established therapy for ANCA-associated vasculitis.
3. When patients are started on immunosuppressive therapy, prophylaxis for PCP should be used, immunizations against influenza and pneumococcal pneumonia should be given, and osteoporosis prophylaxis should be offered in appropriate circumstances.
4. The role of plasmapheresis and intravenous immunoglobulin is unclear in the vasculitides and the use of plasmapheresis is the subject of an ongoing international trial. These therapies may be considered in life-threatening cases where response to standard cytotoxic therapy with steroids is insufficient, especially in the pulmonary renal syndrome.

## Chapter Review

### Questions

1. A 50-year-old male is hospitalized with hemoptysis over a period of a few days. He had a prodrome of malaise and arthralgia for several weeks. In the intensive care unit, his serum creatinine is 7.4 mg/dL, urinalysis shows 3+ protein, many red blood cells, and scattered red cell casts. He is intubated with copious bloody secretions evident from the endotracheal tube.  
Which tests should be considered as part of the diagnostic evaluation in this patient?
  - A. Anti-Sm antibodies
  - B. Anti-GBM antibodies
  - C. pANCA MPO
  - D. cANCA PR3
  - E. All of the above
2. A 45-year-old male with long-standing asthma is evaluated for new-onset fever, fatigue, skin rash, and worsening dyspnea. He had been using his albuterol inhaler more frequently and requiring more oral steroids and was recently started on a leukotriene antagonist. He complains of diffuse abdominal pain, and his chest x-ray shows bilateral patchy infiltrates; his white blood cell count is 15,000/ $\mu$ L with 25% eosinophils. His examination is notable for palpable purpura and weakness in the wrist flexors on his left.

Which of the following is the correct next step?

- A. Increase inhaled steroids.
  - B. Begin plasmapheresis.
  - C. Increase his prednisone from 10 mg to 20 mg orally per day.
  - D. Begin high-dose intravenous corticosteroids.
  - E. Perform an open lung biopsy.
3. A 70-year-old female with a history of hypertension presents with fatigue and pain in her shoulders and hips for 1 month. She notes pain in her jaw with chewing but no headaches or visual complaints. Her ESR was 18 mm/h, CRP 2.0 mg/L, and remaining laboratory evaluations are normal. The examination is notable for a blood pressure of 140/80 mm Hg, heart rate 80 beats per minute, respiratory rate 12 breaths per minute, weight 60 kg. Vision is normal, no scalp tenderness, but there is tenderness over the facial artery on the left.  
What would be the next best step in the care of this patient?
    - A. Begin prednisone, 20 mg/d.
    - B. Order a temporal artery biopsy.
    - C. Repeat ESR and follow the patient carefully.
    - D. Order a temporal artery ultrasound.
    - E. Begin prednisone, 60 mg/d.

4. The aforementioned patient does well on 60 mg per day of prednisone and a temporal artery biopsy is consistent with GCA. The patient is slowly tapered on steroids over the next 6 months and is asymptomatic on 10 mg prednisone but at that point an ESR was 32 mm/h up from 18 mm/h and a CRP was 5 mg/L, up from 3 mg/L.

What would be the next step?

- A. Increase the steroids to 60 mg/d.
- B. Perform a CT angiogram of the abdomen.

- C. Follow the patient and repeat laboratories in 1 month.
- D. Increase the steroids to 20 mg/d.

### Answers

## Common Soft Tissue Pain Syndromes

SIMON HELFGOTT

The soft tissue pain syndromes are among the most common conditions that a primary care physician encounters in daily practice. They are characterized by local or regional pain and discomfort often made worse by palpation of the adjacent soft tissue or movement of the nearby joint. In some cases, the pain may also be present at rest and especially at night. When they involve the soft tissues near a joint, they can be associated with decreased range of motion of the joint and the resultant loss of function can be significant. The diagnosis of a soft tissue pain syndrome is clinical and based on the history and physical examination of the patient. In many cases, the diagnosis is made by first excluding other causes. Imaging and laboratory testing, when indicated, may help eliminate other diagnoses such as fracture or significant arthritis damage but rarely confirm a soft tissue pain syndrome. Therefore it may not be surprising that many patients are either undiagnosed or misdiagnosed, leading to costly evaluations involving unnecessary imaging and costly therapeutics. This chapter will review some of the more common forms of soft tissue pain syndromes, their clinical presentation, the physical examination findings, and the appropriate management of these conditions.

### Classification of Disorders

Soft tissue pain can be categorized into a few major categories. Some patients may have overlap features or more than one condition simultaneously. The most common forms include tendonitis (common shoulder problems such as supraspinatus or bicipital tendonitis); bursitis (anserine, trochanteric, subacromial, olecranon); epicondylitis (medial and lateral); nerve entrapment syndromes (carpal or tarsal tunnel syndrome); regional pain syndromes, characterized by widespread pain in a region of the body such as the upper back, chest wall, or an entire extremity; and generalized pain syndromes such as chronic widespread pain syndrome, fibromyalgia, and whiplash injuries.

### Pathophysiology

The pathophysiology of these conditions is poorly understood. Because tissue biopsy is rarely if ever indicated in any

of these conditions, there are no good clinical-pathologic correlates for most of these disorders except for carpal tunnel syndrome. In this condition, the histopathology of excised soft tissue demonstrates scarring and fibrosis sometimes associated with an inflammatory infiltrate surrounding the entrapped median nerve. However, in most other disorders the findings may be minimal; for example, in some patients with recurrent shoulder pain, there may be some thinning of the tendon sheaths with sparse inflammatory cell infiltrates and occasional fibrosis.

In some patients with soft tissue pain, the origin of the discomfort lies within the bursae. Bursae are synovial lined sacs that help to facilitate tissue gliding. In general, there are two types of bursae: the subcutaneous and the deep forms. Subcutaneous bursae permit the movement of skin overlying the bursae, thus preventing stretching or tearing of the soft tissues. The deep bursae separate different tendon compartments or line the surface between tendons and bone. In general, bursae contain trace amounts of lubricating synovial fluid, which contains a high content of hyaluronic acid with few leukocytes and some mononuclear cells.

The causes of chronic widespread pain syndrome, fibromyalgia, and regional pain syndromes remain unknown. A common feature to all these conditions is that the musculoskeletal areas that are symptomatic are not the actual pain generating sites. There is mounting evidence to suggest that these disorders are caused by alterations in the central processing of pain signals either at the level of the brain or the spinal cord.

### Presentation

The onset of soft tissue pain disorders can be acute or insidious. There may be an antecedent history of excessive physical activity that may have predisposed the patient to injury. In general, patients will complain of the onset of a localized discomfort and they can usually point to an area of maximal pain. Descriptors used to describe the pain include throbbing, dull, and aching. Pain symptoms are usually described as feeling worse during periods of inactivity and rest. For example, patients will often note the pain at night, and it may awaken them from sleep or prevent them from getting to sleep; or a patient with trochanteric or subacromial

bursitis may notice the pain mostly when lying on the affected side. Similarly, nerve entrapment pain such as carpal or tarsal tunnel syndrome is often felt worse at night. Presumably, during sleep, the patient is unable to maintain a proper wrist or ankle position that would prevent irritation to the impinged nerve. These nocturnal exacerbations contrast to the situation in patients with an inflammatory arthritis such as rheumatoid arthritis (RA). In those patients, night time pain is uncommon and when present, suggests the development of a soft tissue pain disorder superimposed on their RA, a nerve entrapment syndrome, or severe destructive changes in a joint suggesting end stage arthritis in that particular joint.

## Patient Demographics and Common Presentations

Soft tissue pain syndromes can affect patients of either sex with about equal frequency and at any age (Table 27.1). The exception would be fibromyalgia, which is far more frequently seen in females. There are some specific types of soft tissue pain syndromes that can be seen in certain populations.

Patients with shoulder pain caused by supraspinatus tendonitis, subacromial bursitis, or bicipital tendonitis often present with an antecedent history of excessive use. In younger patients, this might relate to athletic activities that require repeated external rotation and abduction at the shoulder. Sports such as baseball and tennis can precipitate these episodes. In older patients, these shoulder problems can often be associated with some structural changes that have already occurred at the shoulder because of aging. For example, the presence of an osteophyte near the rotator cuff mechanism (supraspinatus, infraspinatus, and teres minor tendons) may result in a partial tear or fraying of the tendon mechanism. These patients often present with a marked limitation of mobility along with their pain. This finding contrasts with patients with bursitis or tendonitis of the shoulder where pain limits motion but passive range of motion can easily be achieved.

Medial and lateral epicondylitis are the most common causes of elbow pain. In long-standing cases, the pain can radiate distally toward the wrist and hand, mimicking other conditions such as carpal tunnel syndrome. It is often precipitated by repetitive hand squeezing and gripping maneuvers. The most common causes include excessive computer mouse use or work tools such as hammers, drills, and screwdrivers and sports that require a firm grip on the equipment such as tennis or golf.

Carpal tunnel syndrome may be associated with repetitive overuse of the hands, although the data are conflicting. Other causes include marked obesity, pregnancy, inflammatory arthritis such as RA, hypothyroidism, diabetes mellitus, and rarely amyloidosis. These systemic disorders should be considered when patients present with bilateral symptoms.

**TABLE 27.1** Clinical Features of Soft Tissue Pain Disorders

Presentation	Acute or Subacute
Location	Focal, usually asymmetric pain, though it may radiate to a wider area
Pain description	Deep aching (tendonitis, bursitis) Paresthesiae (nerve entrapment)
Time of discomfort	Often worst at night and with activities causing pressure over the area

Trochanteric bursitis is usually seen in two groups of patients. The first includes obese patients whose excess weight continually stresses the soft tissues surrounding the hip joint. The second group includes those patients who have rapidly increased their level of physical and athletic activities resulting in excessive stresses around the hip and thigh. Lack of adequate low back muscle conditioning may also contribute to added stresses imparted to the region of the trochanteric bursa, causing focal pain.

The most common soft tissue pains around the knee include pain caused by anserine and bursitis and patellofemoral dysfunction. The anserine bursa sits inferior and medial to the knee and can be distinguished from pain arising from osteoarthritis by the presence of exquisite tenderness reproduced by the palpation over the bursa. These patients are older and usually have some degree of underlying medial knee joint cartilage loss consistent with osteoarthritis. Patellofemoral dysfunction results in pain being felt over the knee when attempting to initiate activities that require knee flexion and extension.

Pain around the ankle and foot may include Achilles tendonitis as well as tendonitis affecting the extensor tendons (more often than the flexor tendons) of the foot. Tendonitis around the ankle and foot is often related to increased levels of physical activity or may be related to underlying altered foot biomechanics such as flat foot. Achilles tendonitis tends to occur in younger athletic individuals, where improper footwear may precipitate its development. A history of recent quinolone antibiotic use may predispose some patients to tendon rupture, especially the Achilles tendons.

## Specific Soft Tissue Pain Disorders

### Causes of Shoulder Pain

Shoulder pain is a common disorder, which may be caused by problems within the shoulder joints; that is, the glenohumeral, acromioclavicular, or sternoclavicular joints or from one of the periarticular structures such as the rotator cuff or bicipital tendons, the shoulder joint capsule, or the subacromial bursa (Table 27.2). Less commonly the pain is referred to the shoulder from a nerve impingement in the cervical spine, brachial plexus, or at the thoracic outlet. In some

**TABLE 27.2** Common Soft Tissue Disorders by Site

Site	Disorder
Shoulder	Rotator cuff tendonitis Bicipital tendonitis Subacromial bursitis
Elbow	Medial or lateral epicondylitis Olecranon bursitis
Wrist	De Quervain tenosynovitis Flexor tenosynovitis Dupuytren contracture Carpal tunnel syndrome
Hip/pelvis	Trochanteric bursitis Ischial bursitis Iliopsoas bursitis
Knee	Medial (no name) bursitis Anserine bursitis Prepatellar and infrapatellar bursitis Patellofemoral dysfunction
Ankle and foot	Achilles tendonitis Retrocalcaneal bursitis Plantar fasciitis Morton neuroma

cases, the pain may originate from a lesion in the diaphragm or the right upper quadrant of the abdomen such as acute cholecystitis. Pain originating from the glenohumeral joint or the rotator cuff is generally felt just a few centimeters distal to the shoulder joint margin over the deltoid muscle area. Pain that is felt above the shoulder may not be emanating from the shoulder and suggests either a cervical radiculopathy or a soft tissue injury above the shoulder with radiation of the pain toward the shoulder. Pain that is felt behind the shoulder joint is most likely caused by subscapularis tendon injuries, persistent scapular spasm, or referred pain from cervical spine disease.

Bilateral shoulder pain may be a feature of a systemic disorder such as polymyalgia rheumatica or RA. In contrast, osteoarthritis of the glenohumeral joint is very uncommon except in cases where there was antecedent shoulder joint injury or prior metabolic damage to the cartilage as seen in chondrocalcinosis.

Patients may describe a history of insidious onset of pain. Those who have an abrupt onset of pain during activity may be describing a partial tear of an affected tendon (e.g., rotator cuff tear). In those cases, patients will often present with marked inability to raise the arm.

Why does tendonitis occur so commonly in the shoulder region? This is because during shoulder abduction, the rotator cuff and long bicep tendons are subjected to impingement at the greater tuberosity of the humerus and the coracoacromial arch. With excessive or frequent repetitive overhead activities, there is tissue injury resulting in tears of the rotator cuff as well as tendonitis within the cuff mechanism. A viable rotator cuff is required for both abduction and external rotation of the shoulder as well as

stabilizing the glenohumeral joint and preventing the superior migration of the humeral head. Thus an injured or damaged rotator cuff may be unable to prevent some degree of superior migration of the humeral head, which results in further damage to the rotator cuff and to the long biceps tendon (which sits on the humeral head), which are now being squeezed by the changing architecture of the joint. With time and recurrent injury, there may be osteophyte formation over the inferior surface of the acromioclavicular joint, and this will intensify the degree of impingement of the rotator cuff and the biceps tendon. Thus the spectrum of these chronic impingement syndromes can range from episodes of mild tendonitis of the rotator cuff to the development of rotator cuff or long head of the biceps tendon tears. Because the subacromial bursa is adjacent to the rotator cuff, many of these cases are also associated with a bursitis in this location.

In some patients, there may be the onset of an exquisitely painful shoulder pain with marked difficulty with any range of motion. Patients are extremely uncomfortable and are very reluctant to comply with a physical examination of the shoulder. Radiographs of the affected shoulder demonstrate calcification within the rotator cuff tendon or subacromial bursa. These calcific deposits often disappear following resolution of the episode.

### Physical Examination: Shoulder

The physical examination of the shoulder should begin with inspection for evidence of muscle wasting or bony hypertrophy over the acromioclavicular joint. These findings suggest a long-standing problem. Shoulder fullness (suggesting effusion) is unusual and not easily visualized because a shoulder joint effusion would be found deep within the tissues and is diagnosed through imaging such as MRI or shoulder ultrasound. Shoulder range of motion and function is assessed by having the patient place their arm by their side and slowly raise it laterally to assess the range of shoulder abduction. The first 30 to 40 degrees of abduction are controlled by the deltoid muscle. Movement beyond 40 degrees is performed using the rotator cuff mechanism. In patients with rotator cuff related tendonitis or impingement syndromes, one observes a loss of motion and the onset of pain with abduction beyond 40 degrees. To confirm this finding, the patient continues this motion against the resistance of the examiner's hand, which is placed on the patient's elbow while applying downward pressure. The patient's ability to continue abduction against resistance is noted: If they complain of pain, the diagnosis of a rotator cuff–related injury (either tendonitis or tear or both) is made. A rotator cuff tear can be distinguished from tendonitis if the patient is unable to actively abduct the arm beyond 40 degrees but can passively move the arm through this arc of motion without pain. Similarly, the instillation of xylocaine into the shoulder joint will allow a patient with a tendonitis to abduct their shoulder more freely, whereas the movement noted with rotator cuff tendon tears would not change.

Patients who have a subacromial bursitis may note local tenderness on palpation of the subacromial bursa that sits at the top of the humerus just below the glenoid arch. Patients with a bicipital tendonitis often describe pain that is felt more anteriorly over the top part of the humerus corresponding to the bicep tendon insertion area. However, it should be noted that many patients have features of each of these conditions because the affected areas lie in close proximity to one another.

## Elbow Pain

The most common causes of elbow pain include medial and lateral epicondylitis. Although initially described as *tennis elbow*, lateral epicondylitis is more commonly seen with other activities such as excessive computer mouse use or repeated gripping of work tools such as screwdrivers and hammers. These activities all require repeated frequent use of the hand extensor tendons. Although it was initially considered to be a form of tendonitis with suspected inflammation at the tendon bone insertion interface, it is now considered by some to be caused by a cumulative trauma overuse disorder with repetitive mechanical overloading of the common extensor tendon particularly involving the portion derived from the extensor carpi radialis brevis tendon. In some histopathologic specimens of excised epicondylar tissue, there is evidence for fibroblastic hyperplasia and disorganized collagen bundles.

The pain is often insidious and sometimes bilateral, although usually it involves the dominant arm. The pain is generally localized to the lateral epicondyle but over time may extend both distally toward the wrist and proximally upward toward the shoulder. It is exacerbated by any squeezing activities of the hands such as holding a pen, gripping, or lifting objects. This can be confirmed by having the patient try to squeeze an object such as a cup, which will often elicit the pain. Palpation over the lateral epicondylar area usually provokes intense pain and discomfort; however, the elbow range of motion for flexion, extension and pronation, and supination are maintained. One way to distinguish either medial or lateral epicondylitis from a true elbow joint arthritis is to assess pronation and supination range of motion. In patients with elbow joint synovitis there is a reduction in these motions, whereas there is no effect on these motions with either type of epicondylitis.

Medial epicondylitis is less commonly seen than the lateral form. Although it is known as *golfer's elbow*, this condition is more commonly seen in patients who are at risk for lateral epicondylitis as well. Typically, there is an antecedent history of cumulative repetitive strain of the common flexor muscle of the forearm provoking pain and tenderness at the medial epicondylar region. The pain may radiate proximally and distally as well. The diagnosis is confirmed by noting pain over the medial epicondyle with either palpation or by the simultaneous forced full extension of the elbow and the wrist.

## Olecranon Bursitis

The olecranon bursa sits below the tip of the elbow and can become swollen and sometimes painful because of a number of conditions. These include trauma, inflammation (e.g., because of RA or gout), or sepsis. Because gouty bursitis and sepsis can both be associated with similar findings, such as increased warmth, swelling, and redness along with pain, it is generally necessary to aspirate the bursa for proper synovial fluid analysis including cell count, Gram stain, and culture of the joint fluid. Septic olecranon bursitis is usually the result of direct inoculation of bacteria via a skin abrasion and can occur in otherwise healthy individuals engaged in physical work that results in frequent trauma to the elbows. The most common pathogen is *Staphylococcus aureus*. Traumatic bursitis can occur with recurrent or incidental trauma to the elbow. Patients often present because of swelling that may be only minimally painful. The diagnosis is confirmed by joint aspiration demonstrating hemorrhagic joint fluid with few white blood cells, no bacteria, or crystals being present.

## Wrist and Hand Disorders

Perhaps the most common soft tissue disorder involving the wrist and hand is the carpal tunnel syndrome. This is caused by entrapment of the median nerve within carpal tunnel. It is characterized by painful paresthesiae and sensory loss in a median nerve distribution (generally this involves the thumb, second digit, and half of the third digit). In more advanced cases there may be loss of motor power in the median distribution in the hands as well as atrophy of the thenar muscles. There is generally a history of nocturnal pain in the median nerve distribution. Percussion of the median nerve at the flexor retinaculum just radial to the palmaris longus tendon at the distal wrist crease (Tinel sign) will produce paresthesiae in the median nerve distribution. Phalen sign is the development of paresthesiae following sustained palmar flexion of the wrist for 20 to 30 seconds. The severity of the entrapment and the need for surgical decompression can be assessed by electromyography and nerve conduction studies.

Flexor tendon entrapment syndromes of the digits can occur in patients without a history of an inflammatory arthritis or diabetes. Most cases are idiopathic, although patients with diabetes and RA may be at increased risk for this condition. Patients can present with triggering symptoms involving a digit especially following periods of inactivity such as arising in the morning. They often must use their other hand to help “unlock” the affected digit. A nodular thickening of the tendon is often present at the site of maximum tenderness that is generally in a part of the flexor tendon just proximal to the metacarpophalangeal (MCP) joint of the affected digit. The histopathology of the lesion consists of hypertrophy and fibrocartilaginous metaplasia of the ligamentous layer of the tendon sheath that results in stenosis of the tendon sheath canal and mechanical entrapment of the tendon.

De Quervain tenosynovitis is a disorder affecting the common tendon sheath of the abductor pollicis longus and extensor pollicis brevis tendons. It is characterized by pain over the radial aspect of the wrist, which is aggravated by movements of the thumb during pinching, grasping, and lifting activities. It is a tendon entrapment syndrome resulting in thickening of the extensor retinaculum that covers the first compartment of the wrist and leads to a tendon entrapment. Palpation of the affected tendon sheath recreates pain and exquisite tenderness. Using the Finkelstein test, the patient makes a fist with the fingers wrapped around the thumb and then is instructed to flex the thumb in the ulnar direction. This reproduces the pain and confirms the diagnosis.

Dupuytren contracture is caused by a nodular thickening and contracture of the palmar fascia leading to marked flexion deformities of the fingers. Most often it affects the ring finger, but it can also involve others on one or both hands. With the tendon scarring that develops, there is a gradual development of a flexion deformity of the fingers at the level of the MCP joints and an inability to fully extend the digits. The histopathology demonstrates fibrous nodules proliferating fibrosis and myofibrosis in the palmar fascia.

## Pelvis and Hip

There are three major bursae around the pelvis and hip region. These include the ischiogluteal, iliopsoas, and trochanteric bursae, with the latter affected most commonly. The trochanteric bursae are composed of three bursae with the largest and most important one clinically separating the fibers of the gluteus maximus muscle from the greater trochanter. The other two bursae lie between the greater trochanter and the gluteus medius and greater trochanter, respectively. Trochanteric bursitis presents with a deep aching pain over the lateral aspect of the upper thigh made worse by walking but also noted to be painful at night when the patient is lying on the affected side. The diagnosis is confirmed by obtaining a history of pain both at rest and activity with normal range of motion of the affected hip joint. There is focal pain with palpation over the trochanteric bursa. The pain may radiate distally but rarely beyond the knee. Risk factors include overuse activities such as excessive walking or running and improper footwear. The differential diagnosis of trochanteric bursitis includes lumbar radiculopathy involving the L1 and L2 nerve roots and the uncommon meralgia paresthetica, a syndrome characterized by entrapment of the lateral cutaneous nerve of the thigh resulting in discomfort in the same region. Unlike bursitis, these patients tend to have more dysesthesiae symptoms than pain. The iliotibial band syndrome may cause pain in the area of the trochanteric bursa, but its pain tends to be more diffuse and travels along the lateral thigh toward the knee.

The ischiogluteal bursitis presents with pain felt over ischial tuberosity. Previously known as *weavers bottom*, it is

caused by repeated leg flexion and extension in the sitting position or prolonged sitting on hard surfaces. Diagnosis is confirmed by eliciting tenderness on palpation over the ischial tuberosity with the patient lying supine and the hip and knee flexed.

The iliopsoas bursa lies over the anterior surface of the hip joint. In most cases of iliopsoas bursitis there appears to be communication between the hip joint and the bursa, and this may allow for a transfer of excess synovial fluid from one region to the other. The predisposing factors for excess synovial fluid include osteoarthritis, RA, and septic arthritis. The typical presentation consists of the onset of painful swelling in the inguinal area. When there is adjacent femoral vein or nerve compression, the resulting pain and/or swelling may involve the entire leg.

## Soft Tissue Disorders Around the Knee

There are three major bursae around the knee that can become inflamed or rarely infected, resulting in pain. These include the prepatellar, infrapatellar, and anserine bursa.

- The prepatellar bursa lies anterior to the patella and can become infected in patients who frequently kneel. Presumably there is skin breakdown resulting in bacterial infection, most commonly *S. aureus*. There is superficial swelling over the dorsum of the patella with surrounding redness and erythema. Rarely there may be systemic complaints such as fever and chills. The infrapatellar bursa lies between the upper portion of the tibial tuberosity and the prepatellar ligament. It is separated from the knee joint synovium by a fat pad. Similar to prepatellar bursitis, excessive kneeling may predispose to skin breakdown in the region and infection. In other patients there may be a noninfectious inflammatory swelling of the bursa.
- The anserine bursa lies under and adjacent to the pes anserinus, which is the insertion of the thigh adductor complex consisting of the sartorius, gracilis, and semitendinosus muscles. This region is about 5 cm below the medial aspect of the knee joint space. Pain in this area is often referred to *anserine bursitis*. Predisposing factors include underlying osteoarthritis of the medial knee compartment and excessive physical stress to the knee. Patients will often describe nocturnal pain awakening them. This can help to distinguish this condition from osteoarthritis, which is rarely painful at night except if there is end-stage osteoarthritis in the knee that would require total knee replacement. Women more commonly develop anserine bursitis perhaps in part due to having a broader pelvic area leading to greater tension caused by greater angulation of the knee adductors. Obesity is another risk factor. There is a “no name bursa” that is found over the medial joint margin of the knee. Some clinicians believe that this bursa, when inflamed, can lead to intense medial knee pain. However, medial knee pain can also be caused by osteoarthritis, trauma, and ligamentous injury.

- The iliotibial band, which connects the ilium with the lateral tibia, can become painful by repetitive flexion and extension with running. This results in iliotibial band syndrome. On examination, there is tenderness over the lateral femoral condyle approximately 2 cm above the joint line, with pain on weight bearing when the knee is flexed at about 40 degrees. As noted earlier, the pain may travel proximally as far as the trochanteric bursa.
- Patellofemoral pain syndrome was formerly known as *chondromalacia patella*. This condition refers to poorly localized anterior knee pain often made worse when the patient initiates activities such as getting up from a seated position. There is pain felt over the entire knee, and it is often made worse by forced flexion or extension of the affected knee. It is thought to result from anatomic abnormalities resulting in abnormal angulation of the patellar surface misaligning with the rest of the knee. Other theories include repetitive microtrauma to the patellar surface. This condition is more commonly seen in women but can occur in patients of either sex and at all ages. Radiographs of the knee are often unremarkable. Intensive physical therapy to enhance the strength of the medial aspect of the quadriceps mechanism is often helpful in alleviating symptoms.

## Foot Pain

The most common soft tissue disorders around the ankle and feet include Achilles tendonitis, retrocalcaneal bursitis, and plantar fasciitis. They share a common causation because these conditions are typically seen in patients who have a pes planus deformity resulting in altered foot biomechanics and excessive stress over other parts of the bone and soft tissue. The Achilles tendon can become inflamed and in rare cases can tear. Risk factors for tear also include recent use of quinolone antibiotics. Achilles tendonitis can also be the presenting manifestation of a spondyloarthropathy. Retrocalcaneal bursitis may be confused with Achilles tendonitis because the bursa lies between the tendon and a fat pad adjacent to the talus. Causes of bursitis include repetitive trauma, poor footwear, RA, and spondyloarthropathy. Plantar fascia is a common condition thought to be caused by repetitive microtrauma at the attachment site of the plantar fascia to the calcaneus resulting in injury and inflammation. There is localized pain over the heel with weight-bearing activities that worsens with the initiation of walking activities. Although the vast majority of patients with this condition do not have an underlying arthropathy, in younger individuals this might be the initial presentation of a spondyloarthropathy. A careful history and musculoskeletal examination can help identify these patients.

The *tarsal tunnel syndrome* refers to the compression of the posterior tibial nerve as it courses through the canal adjacent to the tarsal bone. It is similar to carpal tunnel

syndrome with patients presenting with sensory dysesthesiae involving the plantar aspect of the foot. Nocturnal symptoms are worse and often awaken the patient. Percussion of the flexor retinaculum reproduces the symptoms. There may be reduced vibratory sensation and decreased two-point discrimination over the plantar aspect of the foot and toes. Diagnosis can be confirmed by nerve conduction studies documenting a delay in the nerve conduction of the posterior tibial nerve across the ankle.

Morton neuroma is a condition that presents with paresthesiae or dysesthesiae in the interdigital web spaces particularly between the third and fourth interspaces. The pain is increased by weight bearing or by tight-fitting footwear. There is tenderness and a clicking sensation noted on simultaneous palpation of the web space while squeezing the patient's metatarsal bones with the other hand (Mulder sign). The diagnosis can be confirmed by injection of a local anesthetic into the interspace which should immediately, though temporarily, relieve symptoms.

## Fibromyalgia

Fibromyalgia is a disorder characterized by widespread areas of achiness and pain with an otherwise unremarkable musculoskeletal examination (Box 27.1). Laboratory tests are normal. To fulfill the clinical criteria for fibromyalgia, patients generally must demonstrate widespread soft tissue tenderness. Many of these trigger points correspond to the sensitive periarticular areas (medial and lateral epicondyles, medial knee pain, chest wall, base of cervical and lumbar spines) that are discussed earlier in this chapter. The etiology of fibromyalgia remains unclear, and there is great debate as to whether the underlying causation relates to a pain perception disorder in the spinal cord or the higher structures of the central nervous system. There is a female preponderance, and the age of onset peaks between the ages of 30 to 50 years. Other chronic pain disorders such as migraine headaches, irritable bowel syndrome, temporomandibular joint pain syndrome, and bladder dysfunctions resulting from interstitial cystitis may all be seen more frequently in patients with fibromyalgia. The hallmark features include characterizations of widespread body pain and achiness along with some component of fatigue and malaise. The physical examination should confirm the absence of objective evidence for musculoskeletal inflammation, for example, no evidence for synovitis or myositis. Laboratory testing

### • BOX 27.1 Generalized Soft Tissue Pain Syndromes

Fibromyalgia  
Whiplash injuries (post motor vehicle accident)  
Chronic regional pain syndrome  
Myofascial pain

including complete blood count (CBC); hepatic, renal, and thyroid function; C-reactive protein (CRP); erythrocyte sedimentation rate (ESR); and autoantibody production are all typically within normal limits.

## Establishing the Diagnosis of a Soft Tissue Pain Disorder

It is essential to take an accurate history and perform a thorough physical examination to rule out other causes that may mimic soft tissue pain syndromes. For example, radicular pain caused by cervical or lumbar spine nerve entrapment can mimic some of the conditions described earlier. These patients usually describe a wider area of pain and generally lack specific focal areas of tenderness on palpation. Another area of potential confusion, especially in the older patient, is the radiographic finding of osteoarthritis in adjacent joints. Sometimes these arthritic changes are ascribed as the underlying cause for the patient's pain syndrome. However, remember that soft tissue pain has some unique characteristics that help to distinguish it from pain caused by osteoarthritis. These include the finding of intense pain on palpation of the affected area along with the history of pain that is worst with rest and at night. In general, osteoarthritis pain follows a reverse pattern with the pain improving with rest and sleep and worsening with activity. Palpation of an osteoarthritic joint does not generally exacerbate the pain to the same degree as is seen in soft tissue pain disorders.

Systemic diseases that sometimes need to be considered include polymyalgia rheumatica (in patients over 50 years of age with persistent shoulder and hip girdle region discomfort), occult hypothyroidism, and, very rarely, vitamin D deficiency.

### Ancillary Studies

For most soft tissue pain disorders, laboratory investigation should be minimal. When appropriate, a CBC, ESR, and CRP might be useful. If there is a question of an underlying infectious process, an aspiration procedure should be seriously considered.

Imaging of the affected area can be helpful in some situations. For example, in patients with an acute severe pain, fracture should be ruled out especially if there is an antecedent history of trauma. If a calcific tendonitis is being considered, plain radiographs can confirm the diagnosis. In the case of periarticular knee pain, thought to be caused by bursitis, radiographs can assess the underlying cartilage loss already present and rule out other mimics such as avascular necrosis or a nondisplaced stress fracture.

### Therapy

Treatment for most soft tissue disorders (Table 27.3) begins with the education of the patient. For example, in overuse

**TABLE 27.3** Therapeutic Options

Physical therapy	Stretching Massage Electrical stimulation Ultrasound Heat/ice
Occupational therapy	Splinting Joint immobilization
Medications	Nonsteroidal antiinflammatory drugs Acetaminophen Tramadol Mild narcotic analgesics Topical lidocaine Capsaicin creams Intralesional corticosteroids

syndromes, it is necessary for the patient to understand the underlying mechanism that predisposes to the development of the pain syndrome and to be familiar with the measures to be taken to avoid these repetitive stresses in the future. Secondly, referral to physical therapy for stretching and exercise programs can be useful. Therapeutic modalities such as ultrasound provide a heat energy that can penetrate the deep soft tissues. For carpal tunnel syndrome, proper wrist splinting especially at nighttime can provide some symptom relief.

As mentioned earlier, if infection is a diagnostic concern, then an aspiration procedure should be seriously considered. Before injecting soft tissues, one must be certain that an underlying infection is not the cause of the problem. Injection of a corticosteroid preparation combined with xylocaine can provide symptomatic relief. For example, the combination of 20 to 40 mg of methylprednisolone along with 1 to 2 mL of 2% xylocaine can be injected into a bursa or near painful tendon structures to provide symptomatic relief. In general, these injections can be performed at the bedside or in the office without assistive radiology guidance. There are data to suggest that patient injections are equal to those administered with radiographic assistance.

Nonsteroidal antiinflammatory drugs can provide some modest pain relief. Other analgesics such as acetaminophen or tramadol can be useful. Narcotic analgesics should be avoided except for those circumstances requiring short-term management of severe pain. Systemic corticosteroids are not indicated for any of the soft tissue pain disorders.

For patients whose symptoms persist despite the therapeutic approaches listed previously, one should consider the possibility that there is an underlying structural causation for their pain. At this point, imaging studies may be useful. Patients describing more widespread and persistent pain may have an underlying disorder such as fibromyalgia causing the persistence of symptoms.

## Chapter Review

### Questions

1. A 72-year-old female presents with a 6-week history of abrupt onset of stiffness around her neck and shoulders. She notes pain when trying to dress herself in the morning. She also notes difficulty at night and rolls from side to side seeking a comfortable position. She describes feeling better as the day progresses and then notes pain once again developing in the early evening. Past medical history is notable for hypertension being treated with hydrochlorothiazide. On physical examination, the patient has stable vital signs. She has full range of motion in all joints tested except for some mildly decreased range of motion with external rotation in either shoulder. Motor strength is appropriate in upper and lower extremities. Laboratory data shows a hematocrit 40.1%, white blood count  $7.4 \times 10^3/\mu\text{L}$ , platelet count  $257,000/\mu\text{L}$ , thyroid-stimulating hormone 1.3 U/mL, ESR 12 mm/h.

What is the most likely diagnosis?

- A. Polymyositis
  - B. Bilateral rotator cuff tendonitis
  - C. Fibromyalgia
  - D. Polymyalgia rheumatica
  - E. Metabolic myopathy
2. A 34-year-old colleague sees you for left shoulder pain. She is a competitive tennis player and noticed some pain in her left deltoid area for the past 3 weeks. The pain is made worse by movements such as shoulder abduction or rotation. The physical examination demonstrates stable vitals. On examination of the left shoulder, there is full range of motion on abduction. Forced abduction is painful, but she can resist. Forward flexion and extension are maintained.

Which of the following is the most likely diagnosis?

- A. Supraspinatus tendonitis
- B. Full thickness rotator cuff tear

- C. Bicipital tendonitis
  - D. Calcific tendonitis
  - E. Deltoid myositis
3. A 55-year-old attorney is seeing you for left elbow pain. She developed this discomfort 2 months ago. She has trouble using her left arm for most activities and says she is beginning to drop items that she is holding. She denies trauma; she golfs occasionally. Her only medication is simvastatin 40 mg/d. She is extremely concerned because of the worsening symptoms at night. The pain awakens her from sleep and radiates along the entire forearm. An x-ray of the elbow is normal.
- Which of the following statements is correct?
- A. She should stop the simvastatin.
  - B. Check serum parathyroid hormone and iron.
  - C. Arrange for elbow MRI.
  - D. Arrange for an electromyogram.
  - E. Reassure patient, and refer to physical therapy.
4. When evaluating a patient for suspected trochanteric bursitis, which of the following statements is correct?
- A. The pain is maximally felt over the lateral aspect of the affected thigh.
  - B. It is generally a bilateral condition.
  - C. The most common cause is an underlying arthritis of the ipsilateral hip.
  - D. Pain is worse with activity but improves at night.
5. A 28-year-old patient with RA is seen by you for acute foot pain and difficulty walking. She had been in her usual state of health until a few hours earlier when she felt a searing, sharp pain in her right Achilles tendon as she was walking out of her office. She fell and had to be assisted back on her feet. She realized that she could not bear weight on her right leg. She works out regularly but denies any recent injuries. She has had RA for 7 years and currently takes the following medications: methotrexate 20 mg once per week (for the past 6 years), folate 1 mg/d, ibuprofen 400 mg twice daily as needed, etanercept 50 mg weekly (for the past 3 months), ciprofloxacin 500 mg/d (for the past 5 days, recently completed for a urinary tract infection), oral contraceptive for the past 4 years.
- Which of the following statements is correct?
- A. Stop the ibuprofen.
  - B. Stop the oral contraceptive.
  - C. Keep the patient on all her medications; avoid ciprofloxacin in the future.
  - D. Stop the methotrexate.
  - E. Stop the etanercept.

### Answers

- 1. D
- 2. A
- 3. E
- 4. A
- 5. C

The diagnosis of rheumatic disorders requires clinical evaluation, blood and imaging tests, and sometimes pathology. Laboratory testing is important in both diagnosis and monitoring of the disease. Some have also used laboratory testing to predict relapse of disease. In general, laboratory tests are most valuable when used in conjunction with clinical information.

### Acute-Phase Proteins

The acute-phase response is a major pathophysiologic phenomenon that accompanies inflammation. The acute-phase response accompanies both acute and chronic inflammatory states. It can occur in association with a wide variety of disorders, including infection, trauma, infarction, inflammatory arthritides, and various neoplasms.

Acute-phase proteins are defined as those proteins whose plasma concentrations change by at least 25% during inflammatory states. These changes largely reflect their production by hepatocytes.

Acute-phase proteins that increase include ceruloplasmin, several complement components, C-reactive protein (CRP), fibrinogen, alpha-1-antitrypsin, haptoglobin, and ferritin, whereas negative reactants include albumin, transferrin, and transthyretin.

Despite the lack of diagnostic specificity, the measurement of serum levels of acute-phase proteins is useful because it may reflect the presence and intensity of an inflammatory process. The most widely used indicators of the acute-phase protein response are the erythrocyte sedimentation rate (ESR) and CRP. The ESR depends largely on the plasma concentration of fibrinogen.

These tests may be useful both diagnostically, in helping to differentiate inflammatory from noninflammatory conditions, and prognostically. In addition, they may aid in monitoring activity of disease because they may reflect the response to therapeutic intervention and a need for closer monitoring. Serial measurements of CRP concentrations may provide prognostic information in rheumatoid arthritis (RA).

### Comparison of Erythrocyte Sedimentation Rate and C-Reactive Protein

The ESR has a number of disadvantages compared with the CRP determination:

- The ESR is only an indirect measurement of plasma acute-phase protein concentrations; it can be greatly influenced by the size, shape, and number of red cells, as well as by other plasma constituents. Therefore results may be imprecise and sometimes misleading.
- As a patient's condition worsens or improves, the ESR changes relatively slowly; the CRP concentrations change rapidly.
- ESR values steadily increase with age by approximately age in years divided by 2 and (age in years +10) divided by 2 in women; plasma CRP concentrations also increase with age. One can roughly correct the CRP for age by using the following formula: the upper limit of the normal range in mg/dL equals age in years divided by 5 for men and (age in years +30) divided by 5 in women.
- Normal values for the ESR are slightly higher among women than men.
- Slight elevations of CRP may also reflect obesity, cigarette smoking, diabetes mellitus, or other noninflammatory causes. Levels of serum CRP may also be affected by genetic factors.

### Rationale for Using Multiple Tests

Although elevations in multiple components of the acute-phase response commonly occur together, not all happen uniformly in all patients. Discordance between concentrations of different acute-phase proteins is common, perhaps because of differences in the production of specific cytokines or their modulators in different diseases. Knowing which acute-phase reactant has best correlated with an individual's disease in the past is helpful in choosing the test to follow over time.

The measurement of acute-phase reactants may be most helpful in assessing clinical activity in patients with RA, polymyalgia rheumatica (PMR), giant cell arteritis,

noninfectious aortitis, and adult-onset Still disease, and perhaps to assess the prognosis of patients with malignancy or to ascertain whether an infectious process (such as abscess, osteomyelitis, or endocarditis) has been eradicated.

Acute-phase reactants are usually of little use in distinguishing among early RA, osteoarthritis, and systemic lupus erythematosus (SLE). Elevations in both CRP and ESR are associated with radiographic progression in RA.

Although PMR and giant cell arteritis are frequently accompanied by markedly elevated levels of the ESR (often higher than 100 mm/h), these elevated levels should not be regarded as a *sine qua non* for these disorders. In addition, a few patients with PMR have normal ESRs.

In patients with these diseases, CRP and ESR have been regarded as having nearly equal value in assessing disease activity. More recently, however, reports suggest that CRP levels may be more sensitive for the detection of active disease.

SLE represents an exception to the generalization that CRP concentrations correlate with the extent and severity of inflammation in patients with rheumatic disorders. Many patients with active SLE do not have elevated CRP concentrations, although they may have marked increases in CRP concentrations during bacterial infection. This finding can be applied to the differential diagnosis of fever in patients with SLE, but one must remember that CRP concentrations may be high in some patients with active lupus serositis or chronic synovitis.

### Systemic Lupus Erythematosus

The antinuclear antibody (ANA) test is the best screening test for patients with suspected SLE, being positive in over 95% of patients but also being positive in many other rheumatic as well as nonrheumatic conditions (Table 28.1). Only about 15% of individuals with a positive ANA have SLE. Other well-recognized disorders associated with a positive ANA titer include Raynaud; chronic infectious diseases such as mononucleosis, hepatitis B, and hepatitis C; primary biliary cirrhosis; subacute bacterial endocarditis; tuberculosis; some lymphoproliferative diseases; and in up to 90% of patients taking certain drugs, especially procainamide, hydralazine, minocycline, and anti-tumor necrosis factor (TNF) biologics; however, most of these patients do not develop drug-induced lupus.

The ANA test is generally performed as an immunofluorescent (IF) assay using fixed Hep-2 cells as substrate. Many commercial laboratories also use solid-phase immunoassays for the detection of many autoantibodies but should not replace the IF Hep-2 cell test for the detection of ANA.

False-positive ANAs (i.e., ANAs in the absence of autoimmune disease) are also found in relatives of individuals with an ANA-related illness (especially SLE), normal women, and in elderly patients (usually in low titer). The presence of high concentrations of ANA (titer >1:640) should increase the suspicion that an autoimmune disorder

**TABLE 28.1 Sensitivity of the Antinuclear Antibody Test in Autoimmune and Nonrheumatic Disease**

<b>Autoimmune Disease</b>	
Systemic lupus erythematosus	95%–100%
Scleroderma	60%–80%
Mixed connective tissue disease	100%
Polymyositis/dermatomyositis	61%
Rheumatoid arthritis	52%
Rheumatoid vasculitis	30%–50%
Sjögren syndrome	40%–70%
Drug-induced lupus	100%
Discoid lupus	15%
Pauciarticular juvenile chronic arthritis	71%
<b>Nonrheumatic Disease</b>	
Hashimoto thyroiditis	46%
Graves disease	50%
Autoimmune hepatitis	100%
Primary autoimmune cholangitis	100%
Primary pulmonary hypertension	40%

is present. However, its presence alone is not diagnostic of disease. Therefore it is routine practice to test patients with a positive ANA for specific ANAs such as anti-dsDNA, Smith (Sm), ribonucleoprotein (RNP), Ro-SSA, La-SSB, Scl-70 (and other scleroderma-associated antibodies (see later), and myositis-associated antibodies (see later); their presence is more likely to facilitate making the diagnosis of a specific rheumatic disease (see later). If no initial diagnosis can be made, it is our practice to watch the patient carefully over time for the development of any ANA-associated diseases. The combination of low titers of antibody (<1:80) and no or few signs or symptoms of disease portend a much smaller likelihood of an autoimmune disease. As a result, these patients need to be reevaluated less frequently. A patient with a negative ANA and strong clinical evidence of a systemic autoimmune disorder may require specific antibody assays to accurately diagnose a rheumatic disease. ANAs produce a wide range of different staining patterns (homogeneous, diffuse, peripheral, rim, speckled, nucleolar, anticentromere, etc.). The nuclear staining pattern has been recognized to have a relatively low sensitivity and specificity for different autoimmune disorders. The pattern of dense fine speckled pattern on Hep-2 cells (because of the presence of anti-DFS70 antibodies) markedly decreases the likelihood that the positive ANA is caused by SLE. The presence of antibodies directed at specific nuclear antigens is usually more useful; these include dsDNA and the RNA-protein complexes Sm, RNP, Ro (SSA), and La (SSB).

**TABLE 28.2 Antinuclear Antibody Test Disease Associations: Sensitivity and Specificity (%) of Different Antinuclear Antibodies**

Antibody	dsDNA	ssDNA	Histone	Nucleoprotein	Sm	RNP	Ro	La
<b>Systemic Lupus Erythematosus</b>								
Sensitivity	70	80	30–80	58	25–30	45	40	15

## Antibodies to DNA

Antibodies to DNA can be primarily divided into those that react with single-stranded DNA (ssDNA) and those recognizing dsDNA.

Anti-ssDNA antibodies have been reported in SLE, RA, drug-related lupus, healthy relatives of patients with SLE, and less commonly in other rheumatic diseases (Tables 28.2 and 28.3). However, they have limited usefulness for the diagnosis of SLE or other rheumatic diseases, and because they do not correlate well with disease activity they are not useful for disease management.

Anti-dsDNA antibodies are specific (95%) although not highly sensitive (70%) for SLE, making them very useful for diagnosis when positive (see Table 28.2). They are occasionally found in other conditions, including RA, juvenile arthritis, drug-induced lupus, autoimmune hepatitis, patients taking anti-TNF biologics, and even in normal persons. Titers of anti-dsDNA antibodies may fluctuate with disease activity, especially in lupus nephritis, and are therefore useful in some patients for following the course of SLE (see Table 28.3).

The association between anti-DNA antibodies and other disease manifestations of SLE is far less clear. For example, there is no relationship between anti-dsDNA titer and disease activity of neuropsychiatric SLE.

Distinguishing active lupus manifestations from infectious complications or toxic effects of drugs and from unrelated disease is always a challenge. Anti-DNA antibodies may be helpful in some patients in making this distinction.

## Anti-Smith Antibodies and Antiribonucleoprotein Antibodies

Anti-Sm antibodies are found in only 10% to 40% of patients with SLE but infrequently in patients with other conditions; in other words, they are not sensitive but are highly specific (see Tables 28.2 and 28.3). Measurement of anti-Sm titers may be useful diagnostically, particularly at a time when anti-DNA antibodies are undetectable. Given their relatively low sensitivity, however, a negative value in no way excludes the diagnosis of SLE.

Anti-RNP antibodies are found in about 40% to 60% of patients with SLE but are not specific for SLE, being a defining feature of mixed connective tissue disease and in low titers and low frequencies in other rheumatic diseases including RA and scleroderma (see Tables 28.2 and 28.3).

The titers (levels) of anti-Sm or anti-RNP antibodies do not correlate with any clinical activity.

**TABLE 28.3 Major Clinical Associations of Specific Autoantibodies**

Antigen Specificity	Clinical Associations
dsDNA	Marker for active SLE in some, titers may fluctuate with SLE activity, correlates best with lupus nephritis
ssDNA	Nonspecific, no clinical utility
Ro/SSA	SLE, Sjögren syndrome, subacute cutaneous lupus (75%), photosensitivity, neonatal lupus
La/SSB	SLE, Sjögren syndrome, associated with Ro; low prevalence of lupus nephritis; neonatal lupus
RNP (U1-RNP)	SLE; MCTD (required for diagnosis); RA
Sm	Highly specific for SLE; not generally useful in management
Phospholipids	Thromboembolic events in some patients; thrombocytopenia, first trimester miscarriages
Histones	≤95% in some drug-related lupus; also present in <80% SLE
Ribosomal P	Low sensitivity and high specificity for SLE; possible clinical associations

*DsDNA*, Double-stranded deoxyribonucleic acid; *MCTD*, mixed connective tissue disease; *RA*, rheumatoid arthritis; *RNP*, ribonucleoprotein; *SLE*, systemic lupus erythematosus; *Sm*, Smith antibody; *ssDNA*, single-stranded deoxyribonucleic acid.

### Anti-Ro/SSA and Anti-La/SSB Antibodies

Anti-Ro/SSA antibodies are found in approximately 50% of patients with SLE (see Table 28.2). They have been associated with photosensitivity, subacute cutaneous lupus, cutaneous vasculitis (palpable purpura), interstitial lung disease, neonatal lupus, and congenital heart block (see Table 28.3).

Anti-Ro/SSA antibodies are found in approximately 75% of patients with primary Sjögren syndrome (see Table 28.2), and high titers of these antibodies are associated with a greater incidence of extraglandular features, especially purpura and vasculitis. By contrast, Ro/SSA antibodies are present in only 10% to 15% of patients with secondary Sjögren syndrome associated with RA. Therefore the presence of anti-Ro/SSA or anti-La/SSB antibodies in patients with suspected primary Sjögren syndrome strongly supports the diagnosis.

The presence of anti-Ro/SSA has also been observed in some patients with myositis, interstitial lung disease, and systemic sclerosis and in some normal individuals.

Approximately 50% of patients with SLE who have anti-Ro antibody also have anti-La antibody, a closely related RNA-protein antigen. Anti-Ro/SSA and anti-La/SSB have

also been detected in patients with photosensitive dermatitis and in 0.1% to 0.5% of healthy adults.

Levels of anti-Ro and La are not useful for disease management.

In my opinion, the indications for ordering anti-Ro/SSA and anti-La/SSB antibody tests are as follows: women with SLE who are pregnant or may become pregnant in the future; women who have a history of giving birth to a child with heart block or myocarditis; patients with a history of unexplained photosensitive skin eruptions; and patients strongly suspected of having SLE but who have a negative ANA test.

### Antinucleoprotein Antibodies

Antibodies to the DNA histone complex (nucleoprotein—sometimes also referred to as *nucleosome*) are found in patients with SLE in approximately equal, or greater, frequency as antibodies to dsDNA. They may also be found in patients with drug-induced lupus and in RA (see Table 28.2), making their diagnostic usefulness less than anti-dsDNA antibodies. The test is generally not available in the United States.

### Systemic Sclerosis (Scleroderma)

Anticentromere antibodies (ACAs) are found almost exclusively in patients with limited cutaneous systemic sclerosis, especially in those with CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia).

ACA has been observed in 57% of patients with CREST but has also been seen in patients with other conditions, including in some patients with Raynaud phenomenon alone. ACAs are typically detected by the characteristic immunofluorescent pattern on Hep-2 cells.

Approximately 15% to 20% of patients with scleroderma have antibodies to a 70-kDa protein (topoisomerase-1), subsequently named Scl-70. The usual method for detection is by enzyme-linked immunosorbent assay (ELISA). The presence of these antibodies appears to increase the risk for pulmonary fibrosis among patients with scleroderma and is quite specific for the disease.

Some patients with systemic sclerosis have antibodies to PM/Scl-75, PM/Scl-100, RNA polymerase III, NOR-90, U1 and U3 RNP, Th/To, Fibrillarin, M2, PDGFR, Nil, and so on. Some of these autoantibodies have relatively unique clinical associations.

### Polymyositis/Dermatomyositis

Quite a few autoantibodies have been associated with 1% to 40% of patients with polymyositis/dermatomyositis including Jo-1, PL-7, PL-12, EJ, OJ, KS, Ha, Zo, SRP, SMN complex, CADM140/MDA5, Mi-2, P155/140, MJ, SAE, Ku, and PM-Scl. Some have relatively unique clinical associations.

TABLE  
28.4

Rheumatoid Factor and Anticitrullinated Protein in Rheumatic and Other Diseases

	Anticitrullinated Protein		Rheumatoid Factor	
	Sensitivity	Specificity	Sensitivity	Specificity
Normal individuals	0.79

Bacterial endocarditis			25–50	
Interstitial pulmonary fibrosis			10–50	
Primary biliary cirrhosis			45–70	

*MCTD*, Mixed connective tissue disease; *RA*, rheumatoid arthritis; *SLE*, systemic lupus erythematosus.

## Antiribosomal P Protein Antibodies

Antiribosomal P protein antibodies have been detected in 10% to 20% of US patients with SLE and 40% to 50% of Asian SLE patients but rarely in other rheumatic diseases. Testing for these antibodies may be useful when the diagnosis of SLE is uncertain because of the high specificity of this antibody for SLE, albeit with low sensitivity (see Table 28.3).

Antiribosomal P protein antibodies have limited diagnostic value for central nervous system SLE and are not helpful in differentiating clinical subtypes of SLE (see Table 28.3).

## Antihistone Antibodies

Antihistone antibodies are present in more than 95% of cases of drug-induced lupus (see Tables 28.2 and 28.3), particularly those taking procainamide, hydralazine, chlorpromazine, and quinidine but not in those patients with drug-induced lupus from taking other medications (e.g., anti-TNF, minocycline, etc.). Antihistone antibodies are also seen in up to 80% of patients with idiopathic lupus (see Table 28.3); however, patients with SLE also form a variety of other autoantibodies, including those directed against DNA and small ribonucleoproteins, which autoantibodies are not found in patients with drug-induced lupus.

Note that although up to 80% of patients taking procainamide for 1 to 2 years will develop a positive ANA, most do not develop drug-induced lupus. Thus screening for antihistone antibodies in the absence of symptoms and stopping the drug if antibodies develop are not recommended.

## Rheumatoid Factors

Rheumatoid factors (RFs) are antibodies directed against the Fc portion of IgG. RF as currently measured in clinical practice is an IgM, although other immunoglobulin types, including IgG and IgA, have been described.

The presence and titers of RF are currently detected by solid phase immunoassays. Testing for RF is primarily used for the diagnosis of RA; however, RF may also be present in other rheumatic diseases and chronic infections (Table 28.4). Nonrheumatic disorders characterized by chronic antigenic stimulation (especially with circulating immune complexes or polyclonal B-lymphocyte activation) commonly induce RF production (see Table 28.4). Patients with indolent or chronic infection or chronic inflammation may also demonstrate RF positivity; examples include subacute bacterial endocarditis, hepatitis B or C virus infection, inflammatory or fibrosing pulmonary disorders including sarcoidosis, malignancy, and primary biliary cirrhosis.

RF positivity has also been detected in up to 5% of young, otherwise healthy individuals as well as in up to 25% of elderly individuals (without rheumatic diseases).

The higher the titer, the greater the likelihood that the patient has rheumatic disease. There are, however, frequent exceptions to this rule, particularly among patients with one of the chronic inflammatory disorders noted earlier. Furthermore, the use of a higher titer for diagnosis decreases the sensitivity of the test at the same time as it increases the specificity (for RA).

RF-positive patients with RA may experience more aggressive and erosive joint disease and extraarticular manifestations than those who are RF-negative. Similar findings have been observed in juvenile RA. These general observations, however, are of limited utility in an individual patient because of wide interpatient variability. In this setting, accurate prediction of the disease course is not possible from the RF alone.

### Antibodies to Citrullinated Proteins

There has been considerable interest in developing a better test for the diagnosis of RA that has greater sensitivity and specificity than the tests that detect RFs. Within the last decade, as an outgrowth of determining the molecular specificity of antFLAGgrin, antikeratin, and antiperinuclear antibodies, it was recognized that many patients with RA have antibodies to citrullinated proteins (CCPs). Proteins that are citrullinated have had an arginine replaced by citrulline, a minor amino acid. A number of peptides containing citrulline were created, and a cyclic peptide was used to develop an assay to detect antibodies thereto. This test (anti-CCP) has now been studied extensively, and it has better sensitivity and specificity than tests that detect RF for the diagnosis of RA. This is summarized in [Table 28.4](#).

In addition, antibodies to CCP are rarely found in patients with other rheumatic conditions and infectious diseases where RF is more frequently found. Anti-CCP is even found frequently before the diagnosis of RA. These observations suggest that the anti-CCP test is more useful for the diagnosis of early RA than are RF tests, and both are now part of the diagnostic algorithm for RA.

Subsequently, assays have been developed to citrullinated fibrinogen, alpha-enolase, and vimentin; tests are frequently positive in patients with RA (including in some with negative anti-CCP tests) and are infrequently positive in other conditions. Similar observations have been made in patients with RA and rheumatic diseases in respect to antibodies to carbamylated proteins.

### Antineutrophil Cytoplasmic Antibodies

Two different immunofluorescence patterns can be seen when a patient's serum is incubated with ethanol-fixed normal human neutrophils:

- Cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) stain the cytoplasm diffusely; these antibodies are almost always directed against proteinase 3 (PR3). cANCA with anti-PR3 specificity is found

**TABLE 28.5** Significance of cANCA Directed Against Proteinase 3

Disease	Frequency
Wegener granulomatosis (GPA)	90%
Microscopic polyarteritis	50%
Polyarteritis nodosa	5%–10%
Churg-Strauss angiitis (EGPA)	10%
Hypersensitivity vasculitis	Rare
Henoch-Schönlein purpura	Rare
IgA nephropathy	Rare
Postinfectious glomerulonephritis	Rare
Systemic lupus erythematosus	Rare
Controls	Very rare

cANCA, Cytoplasmic antineutrophil cytoplasmic antibodies; EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis.

**TABLE 28.6** Significance of pANCA Directed Against Myeloperoxidase

Disease	Frequency (%)
Microscopic polyarteritis	50–70
Idiopathic necrotizing glomerulonephritis	50–85
Churg-Strauss syndrome (EGPA)	70–85
Goodpasture (anti-GBM)	10–30
Wegener granulomatosis (GPA)	5–10
Polyarteritis nodosa	+
Polyangiitis overlap	+
Systemic lupus erythematosus	+
Hydralazine-induced crescentic glomerulonephritis	+

+, Reported to be present; EGPA, eosinophilic granulomatosis with polyangiitis; GBM, glomerular basement membrane; GPA, granulomatosis with polyangiitis; pANCA, perinuclear antineutrophil cytoplasmic antibodies.

primarily in patients with polyangiitis (Wegener granulomatosis; abbreviated currently as GPA), microscopic polyarteritis, and occasionally in other diseases ([Table 28.5](#)).

- Perinuclear ANCA (pANCA) are usually directed against myeloperoxidase (MPO). The pANCA fluorescence pattern represents an artifact of ethanol fixation, with ethanol and positively charged granule constituents rearranging around and on the negatively charged nuclear membrane. pANCA directed primarily against MPO has been described in patients with a variety of rheumatic autoimmune diseases ([Table 28.6](#)), whereas non-MPO pANCA have been associated with several rheumatic and nonrheumatic diseases ([Table 28.7](#)).

**TABLE 28.7** Significance of pANCA Directed Against Lactoferrin, Cathepsin G, Elastase, and Lysozyme

Disease	Frequency (%)
Giant cell arteritis	+
Rheumatoid arthritis	+
Systemic lupus erythematosus	25
Sjögren syndrome	+
Inflammatory bowel disease	+
Ulcerative colitis	+
Crohn disease	10–27
Primary sclerosing cholangitis	+
Unaffected relatives of patients with ulcerative colitis or primary sclerosing cholangitis	25–30
Chronic active hepatitis	+
Primary biliary cirrhosis	+

+, Reported to be present; pANCA, perinuclear antineutrophil cytoplasmic antibodies.

Although patients with rheumatic diseases have an increased frequency of vasculitis, data suggesting that ANCA positivity enhances the risk of vasculitis are contradictory. Nonvasculitic aspects of rheumatic disease activity, severity, and chronicity also fail to correlate consistently with ANCA status. As a result, there is little clinical utility for ANCA testing for patients in whom the presence of an ANCA-associated systemic vasculitis is not suspected on clinical grounds.

### Drug-Associated Antineutrophil Cytoplasmic Antibodies

The administration of certain drugs has been reported to induce ANCA reactivity in association with varying symptoms. These include the following: hydralazine-induced lupus with anti-MPO and anti-elastase antibodies; hydralazine-associated vasculitis and anti-MPO and antilactoferrin antibodies; minocycline-induced arthritis, fever, and livedo reticularis with anti-MPO antibodies; and propylthiouracil-induced vasculitis and positive ANCA specificities to several different target antigens including PR3, MPO, and elastase.

The role of sequential ANCA studies in patient care, primarily in patients with vasculitis, after the diagnosis is established, is still unclear. If titers of IF ANCA and anti-PR3 and MPO are sequentially followed and an increase is noted in an asymptomatic patient, surveillance should be increased to help detect a possible relapse. In this respect, we recommend monitoring all three antibodies because the anti-PR3 and anti-MPO will often be positive (and vary in titer) when the IF-ANCA test is negative.

### Antiglomerular Basement Membrane Antibody Disease

Antiglomerular basement membrane (anti-GBM) antibody disease, which has similar renal and pulmonary manifestations to GPA, may be associated with ANCA in 10% to 38% of cases.

The clinical significance of combined ANCA and anti-GBM antibodies is uncertain. Some patients have findings that are uncommon in anti-GBM antibody disease alone, suggesting that there is a concurrent systemic vasculitis. These include purpuric rash, arthralgias, granulomas in the kidney, and a more favorable renal prognosis.

### Antiphospholipid Antibodies

Antiphospholipid antibodies (APL) are antibodies directed against either phospholipids or plasma proteins bound to anionic phospholipids. Patients with these antibodies may have a variety of clinical manifestations including venous and arterial thrombosis, recurrent fetal losses, and thrombocytopenia (see Table 28.3). The diagnosis of antiphospholipid antibody syndrome (APS) is made when a patient has the combination of these clinical manifestations and persistently positive APL antibody tests 12 weeks apart.

Patients with these antibodies have either the primary APS when it occurs alone or the secondary APS when it is seen in association with SLE or other rheumatic or autoimmune disorders.

Three major types of APL have been characterized as lupus anticoagulants; anticardiolipin antibodies; and anti-beta-2-glycoprotein-I antibodies.

### Lupus Anticoagulants

Lupus anticoagulants (LA) are antibodies directed against plasma proteins bound to anionic phospholipids. The LA blocks the *in vitro* assembly of the prothrombinase complex, resulting in a prolongation of *in vitro* clotting assays such as the activated partial thromboplastin time, the dilute Russell viper venom time, the kaolin clotting time, and rarely the prothrombin time. These abnormalities are not reversed when the patient's plasma is diluted 1:1 with normal platelet-free plasma, a procedure that will correct clotting disorders caused by deficient clotting factors. The abnormal clotting test results can be largely reversed by incubation with a hexagonal-phase phospholipid, which neutralizes the inhibitor. Although these changes suggest impaired coagulation, patients with LA have a paradoxical increase in frequency of arterial and venous thrombotic events. False-positive tests for LA can occur in patients receiving heparin.

### Anticardiolipin Antibodies

Anticardiolipin antibodies (aCLs) react with phospholipids such as cardiolipin and phosphatidylserine. There is an approximately 85% concordance between the presence of

an LA and aCL. In many cases, however, the LA is a separate population of antibodies from aCLs. Therefore testing should be performed for both LA and aCL if APS is clinically suspected. LA positivity is associated with a somewhat greater risk for thrombosis than aCL.

Different immunoglobulin isotypes are associated with aCL, including IgG, IgA, and IgM. Elevated levels of IgG aCL incur a greater risk of thrombosis than do other immunoglobulin isotypes.

### Anti-Beta-2-Glycoprotein I Antibodies

Antibodies to beta-2-glycoprotein I, a phospholipid-binding inhibitor of coagulation, are found in a large percentage of patients with primary or secondary APS. Although antibodies to beta-2-glycoprotein I are commonly found in those with other antiphospholipid antibodies, they are found without anticardiolipin antibodies in approximately 11% of patients with APS. Antibodies to beta-2-glycoprotein I correlate better with symptoms of APS than do antibodies to cardiolipin alone.

Although antiphospholipid antibodies are associated with a propensity for thromboembolic phenomena and (recurrent) miscarriages, especially after 10 weeks of gestation, and with various autoimmune disorders, they are found in up to 2% to 5% of normal individuals.

### False-Positive Serologic Test for Syphilis

Some patients, especially those with SLE, have a false-positive serologic test for syphilis (STS) (e.g., Venereal Disease Research Laboratory [VDRL] test or rapid plasma reagin [RPR]). The false-positive STS should not be used to screen for APL because it has a low sensitivity and specificity for APS. The VDRL and RPR tests for syphilis have been largely replaced by specific immune tests that detect antibodies to *Treponema pallidum* (TPI).

### Associated Disorders

Antiphospholipid antibodies have been noted in increased frequency in patients with SLE; approximately 31% of patients have an LA, and 40% to 47% have an aCL. On the other hand, only 50% of patients with an LA have SLE. Antiphospholipid antibodies also occur with increased frequency (5% to 10%) in women with more than three spontaneous recurrent miscarriages.

Both LA and aCL have also been found occasionally in patients with a variety of other autoimmune and rheumatic diseases; the clinical significance of these observations is not clear.

Antiphospholipid antibodies have also been noted in patients with infections (hepatitis A, mumps, bacterial septicemia, HIV infection, syphilis, human T-lymphotropic virus 1, malaria, *Pneumocystis carinii*, infectious mononucleosis, and rubella), and after the administration of certain drugs (phenothiazines [chlorpromazine], phenytoin,

hydralazine, procainamide, quinidine, quinine, valproate, amoxicillin, propranolol, cocaine, sulfadoxine, pyrimethamine, and streptomycin). These are usually IgM aCL antibodies, which are less commonly associated with thrombotic events.

### Testing for Ankylosing Spondylitis

The only laboratory test that is relatively unique to ankylosing spondylitis is the detection of the human leukocyte antigen marker B27. It is detected in over 90% of patients with ankylosing spondylitis and in many patients with psoriatic arthritis but also in about 6% of normal individuals. Thus the test is most useful when positive in those with a high pretest probability (as in those with back pain and stiffness, and with a family history of spondylitis).

### Testing for Lyme Disease

#### Enzyme-Linked Immunosorbent Assay

The ELISA is currently the most common initial test to serologically confirm exposure to *Borrelia burgdorferi*. There are, however, false-positive results with this assay (see later); results that are positive or equivocal by ELISA should be confirmed by Western (immuno) blot analysis. False seropositivity is defined as a positive ELISA with a negative Western blot, analogous to the false-positive test for syphilis.

#### Western Blot

Western blot allows detection of antibodies to individual components of the *Borrelia* organism and is therefore much more specific than the ELISA. Antibodies have been detected against a 41-kDa flagellin; multiple outer surface proteins, of which ospA (31 kDa), ospB (34 kDa), and ospC (23 kDa) are best studied; heat shock proteins (60 and 66 kDa); and other prominent proteins, including those at 39, 75, and 83 kDa.

### Cautions to Be Used in Interpretation

There are a number of issues that must be considered when evaluating the significance of a positive or negative serologic test for the presence of antibodies to *B. burgdorferi*.

#### False Positives With ELISA

Cross-reacting antibodies by ELISA can occur in patients with other Borrelial diseases (relapsing fever), spirochetal diseases (syphilis, leptospirosis, pinta, yaws), viral illnesses, autoimmune diseases (lupus, RA), and infectious diseases (including Epstein-Barr virus, malaria, and endocarditis). Finally, it is estimated that 5% or more of the normal population may test positive for Lyme disease by the ELISA because of cross-reacting antibodies elicited by other infections or by the immune response to normal flora.

### Lack of Sensitivity in Early Disease

IgM antibodies directed against Borrelial antigens typically appear 2 to 4 weeks after erythema migrans (EM), peak at 6 to 8 weeks, and decline to low levels after 4 to 6 months. IgG appears after 6 to 8 weeks, peaks at 4 to 6 months, and often remains elevated indefinitely despite therapy and resolution of symptoms.

Because most patients with early Lyme disease will not yet have produced detectable antibodies, those with clinically definite EM need not be serologically tested. If the true nature of the skin lesion is in doubt, serologic testing may be helpful, but a negative result does not rule out disease and should not necessarily discourage treatment in settings of high clinical suspicion. Serologic testing is clearly not cost effective if treatment is to be administered independent of testing results.

In comparison to the findings in early disease, almost all untreated patients are antibody-positive in the later stages.

### Effects of Antibiotic Therapy

The administration of antibiotics in early disease may abort seroconversion, even if inadequate therapy is given. This concern does not apply in patients with long-standing Lyme disease who have recently received antibiotics; these patients should have been seropositive based on their chronic infection. The test will remain positive for some time after treatment is begun even though antibody production has ceased. However, some patients continue to make antibodies and therefore remain seropositive for long periods of time (see later).

### Interlaboratory Variation

Results of ELISA tests from different laboratories may vary because of technique; therefore it is best to compare results from the same laboratory.

### Persistence of Positivity

As mentioned earlier, high levels of IgG are commonly sustained despite adequate therapy and resolution of symptoms. For this reason, follow-up serologic testing is of no value in assessing the patient who is cured or slowly improving.

The one setting in which follow-up testing may be helpful is the patient in whom there is either worsening of Lyme disease or the appearance of new features of possible Lyme disease (as with a patient with EM who is treated and months later develops monoarthritis). In this clinical setting, if sequential immunoblots performed in the same laboratory demonstrate the appearance of new bands (i.e., reactivity with proteins not previously recognized), the clinician should consider the possibility of ongoing infection. However, the immune response does not immediately cease simply because antibiotic therapy is begun, and new reactivity on immunoblot may appear despite effective antibiotic therapy. Thus an expanding repertoire cannot be interpreted as reflecting ongoing infection unless worsening and/or evolution of the clinical signs is present.

### Usefulness of Serologic Tests

If the test is used in a clinical setting in which Lyme disease is likely, such as isolated monoarthritis or bilateral facial nerve palsy in an endemic area, a positive test is likely to confirm the clinical suspicion of Lyme disease.

In disease of long duration, such as tertiary neuroborreliosis or Lyme arthritis, seroreactivity by ELISA and immunoblot is virtually universal; however, in individuals with chronic disease suspected as being caused by Lyme, isolated IgM positivity (with negative IgG) is a false positive. Absence of seroreactivity in such a patient, unless there is a plausible explanation, should raise significant doubts about the diagnosis of Lyme disease. In other words, the negative predictive power of a test in such a patient is high. Many patients with Lyme disease or suspected Lyme disease may have infections with *Babesia* or ehrlichiosis and should be tested for them.

### Complement

Complement levels can be evaluated either by functional or antigenic assays. The most frequently used are immunoassays (antigenic assays) for C3 and C4 and the total hemolytic complement (CH50), which measures activation of the entire classical pathway.

#### CH50

The CH50 assesses the ability of the test serum to lyse sensitized sheep erythrocytes. All nine components of the classical pathway (C1 through C9) are required to give a normal CH50.

CH50 is a useful screening tool for detecting a deficiency of the classical pathway, either of a single component or of several components (as may be seen in SLE). The CH50 can also detect a homozygous deficiency of classical pathway components as indicated by a value of close to 0 U/mL. In contrast, with activation-induced reduction several components such as C4 and C3 will be decreased. In this setting, the CH50 is rarely <10 U/mL.

The CH50 assay requires appropriate collection, processing, and storage of specimens because several of the complement proteins are thermolabile. As a result, a common cause of a depressed CH50 is improper specimen handling. Serum samples should be assayed the day of collection or stored frozen at  $-70^{\circ}\text{C}$ .

#### Plasma C3 and C4 Levels

Plasma C3 and C4 levels are usually measured in solid phase immunoassays.

#### Clinical Significance

Hypocomplementemia of CH50, C3, and C4 may be present in disorders associated with excessive levels of immune

complexes, such as SLE, mixed cryoglobulinemia, certain glomerulonephritides, and certain vasculitides.

Assays of CH50, C1q, C4, and C3 may be valuable in following the course of these diseases.

- Classical pathway activation is indicated by low levels of C4 and C3 and normal levels of factor B as in lupus nephritis.
- Alternative pathway activation is indicated by decreased factor B and C3 and normal levels of C4, as in septicemia.
- Activation of the classical and alternative pathways is indicated by decreased levels of C1q, C4, C3, and factor B.
- Elevated levels of CH50, C3, C4, and factor B are common in many diseases associated with inflammation and represent an increase in hepatic synthesis as part of the acute-phase response as in RA.
- Elevated levels of split or activated complement components (especially of C4 and/or C3) may be a more sensitive way of assessing activation of the complement system.

### Inherited Complement Deficiency

A genetic deficiency of a single component is indicated by a virtually absent CH50, the fixed absence of a single component combined with normal levels of other complement components.

#### C1 Inhibitor Deficiency

A functional deficiency of C1 inhibitor (C1-Inh) produces the clinical syndrome of hereditary angioedema. In contrast to allergic angioedema, the edematous lesion lasts several days, is nonpruritic and nonerythematous, and is not associated with hives.

C1-Inh deficiency can be acquired or inherited in an autosomal dominant fashion. The acquired form is caused either by an autoantibody to C1-Inh or by excessive use (usually in the setting of malignancy).

A deficiency of functional C1-Inh prevents the proper regulation of activated C1. As a result, plasma levels of C4 and C2, the substrates of C1, are chronically reduced in most patients even between attacks and uniformly reduced during an attack.

### Uric Acid

Uric acid determination may be helpful in certain clinical settings, particularly in suspected gout or in monitoring urate-lowering therapy. Because most patients with asymptomatic hyperuricemia will never develop gout or related problems, screening patients for hyperuricemia is not recommended. Whereas finding of an elevated or high-normal uric acid has little predictive value with respect to gout, patients with low-normal uric acid levels (e.g., 5.5 mg/dL or less) rarely develop gout.

If hyperuricemia is persistent, a thorough history, physical examination, and laboratory work should be performed and directed at discovering potential causes of hyperuricemia

that may mandate treatment. As an example, hypertension, renal insufficiency, treatment with many diuretics, obesity, alcohol abuse, advancing age, lymphoproliferative and myeloproliferative disorders, polycythemia vera, vitamin B<sub>12</sub> deficiency, preeclampsia, and lead nephropathy (or lead exposure) may all lead to hyperuricemia and warrant treatment of the underlying disease.

Urinary collections for uric acid over a 24-hour period may be useful in the evaluation of nephrolithiasis, to classify a patient with gout as an overproducer or underexcreter, or if uricosuric therapy is under consideration.

Detection of an elevated serum uric acid level in individuals with podagra, especially in someone with a family history of gout and/or kidney stones, is highly suggestive of gout. The best laboratory test for confirmation of gout is to find urate crystals in synovial fluid (see Synovial Fluid Crystal Analysis), especially in a patient with an arthritis (especially podagra).

### Synovial Fluid

Synovial fluid analysis may be diagnostic in patients with bacterial infections or crystal-induced synovitis. This analysis should be performed in the febrile patient with an acute flare of established arthritis to rule out superimposed septic arthritis as well as in any patient with an undiagnosed, acute, inflammatory monoarthritis. In other situations, its main value is to permit classification into an inflammatory, noninflammatory, or hemorrhagic category and to monitor a condition (e.g., to determine whether an infection is clearing).

#### Examination of Synovial Fluid

Normal joints contain a small amount of synovial fluid with the following characteristics: highly viscous, clear, essentially acellular, protein concentration approximately one-third or less that of plasma, and glucose concentration similar to that in plasma.

If a synovial effusion is present and arthrocentesis is indicated, joint fluid should be routinely analyzed for volume, clarity, color, viscosity, cell count with differential, Gram stain, culture, and crystals. In certain clinical settings, such as partially treated septic arthritis, synovial fluid glucose and protein may have utility as well.

Noninflammatory fluids generally have fewer than 2000 white blood cells/mm<sup>3</sup>, with fewer than 75% polymorphonuclear leukocytes (Table 28.8). An unexplained inflammatory fluid, particularly in a febrile patient, should be assumed to be infected until proven otherwise.

Synovial fluid is subsequently categorized as normal, noninflammatory, inflammatory, septic, or hemorrhagic based on the clinical and laboratory analysis (see Table 28.8). The differential diagnosis of each of these specific categories is broad and not necessarily exclusive:

- Noninflammatory: The most common causes of a noninflammatory joint effusion include degenerative joint disease (osteoarthritis), trauma, mechanical derangement

**TABLE 28.8** Categories of Synovial Fluid

Measure	Normal	Noninflammatory	Inflammatory	Septic	Hemorrhagic
Volume, mL (knee)	<3.5	Often >3.5	Often >3.5	Often >3.5	Usually >3.5
Clarity	Transparent	Transparent	Translucent-opaque	Opaque bloody	
Color	Clear	Yellow	Yellow to opalescent	Yellow	Red
Viscosity	High	High	Low	Variable	Variable
WBC per mm <sup>3</sup>	<200	200–2000	2000–50,000	>50,000 <sup>a</sup>	200–2000
PMNs (%)	<25	<25	>50	>75	50–75
Culture	Negative	Negative	Negative	Often positive	Negative
Total protein (g/dL)	1–2	1–3	3–5	3–5	4–6
LDH (compared with levels in blood)	Very low	Very low	High	Variable	Similar
Glucose (mg/dL)	Nearly equal to blood	Nearly equal to blood	>25, lower than blood	<25, much lower than blood	Nearly equal to blood

LDH, Lactate dehydrogenase; PMNs, polymorphonuclear leukocytes; WBC, white blood cells.

<sup>a</sup>Lower with infections caused by partially treated or low-virulence organisms.

(ligament or cartilage injury), neuropathic arthropathy, subsiding or early inflammation, hypertrophic osteoarthropathy, and aseptic necrosis.

- **Inflammatory:** The most common causes of inflammatory effusions include RA, acute crystal-induced synovitis, and spondyloarthropathy. SLE may be associated with an inflammatory or noninflammatory effusion.
- **Septic:** Septic effusions may be caused by bacteria, mycobacteria, or fungus.
- **Hemorrhagic:** Hemorrhagic effusions may be caused by hemophilia or other hemorrhagic diathesis, calcium pyrophosphate deposition disease (pseudogout), trauma with or without fracture, mechanical derangement, neuropathic arthropathy, excessive anticoagulation, pigmented villonodular synovitis, or other neoplasm.

Infected fluid is usually purulent with a leukocyte count (most of which are neutrophils) of over 50,000 cells/mm<sup>3</sup>. However, lower cell counts may be observed among immunocompromised patients and in infections caused by mycobacteria, some *Neisseria*, and several gram-positive organisms. Chemistry studies such as the concentrations of glucose, lactate dehydrogenase (LDH), or protein have only limited value; a reduction in glucose concentration and elevation in LDH concentration are consistent with bacterial infection but are not sufficiently sensitive or specific.

### Routine Culture

The synovial fluid samples are routinely sent for culture of the common nongonococcal causes of bacterial arthritis: staphylococci followed by streptococci and gram-negative bacteria. These organisms are easily grown on routine culture media in the absence of concomitant antibiotic therapy. The diagnostic yield may be improved by inoculation of

blood culture bottles, although the efficacy of this approach is controversial.

### Gonococcal Arthritis

Gonococcal arthritis is a common cause of septic arthritis in which the organism cannot be cultured on routine culture media.

The joint aspirate should be cultured for *Neisseria gonorrhoeae* when the history is suggestive. The yield can be increased if plates of chocolate agar or Thayer-Martin medium are inoculated with synovial fluid at the bedside along with cultures from the pharynx, urethra, cervix, rectum, and skin lesions (if present). Blood cultures are often positive in patients presenting with tenosynovitis and skin lesions alone but are frequently negative if a joint effusion is present.

Cultures of synovial fluid tend to be positive in less than 50% of cases of gonococcal arthritis. Use of polymerase chain reaction techniques to detect gonococcal DNA in synovial fluid can increase the yield in culture-negative cases and permit monitoring of the response to therapy.

### When Should Cultures Be Sent for Unusual Organisms?

The history may reveal clues suggesting the possibility of an unusual cause of septic arthritis such as a history of tuberculosis exposure; a history of trauma or an animal bite; travel to or living in an area endemic with fungal infections or Lyme disease; the presence of immune suppression; or a monoarthritis that is refractory to conventional therapy.

### Synovial Fluid Crystal Analysis

Aspiration of synovial fluid from the affected joint and analysis of the fluid by polarized light microscopy permits

identification of sodium urate crystals in the great majority of instances of acute gouty arthritis. Joint aspiration is also helpful in distinguishing acute gout from pseudogout (calcium pyrophosphate crystal deposition [CPPD] disease), although occasionally both crystals may be identifiable in the synovial fluid of patients in whom these disorders coexist.

Gout crystals are needle-shaped and display strongly negative birefringence (i.e., they are yellow when parallel to the axis of the polarizer). CPPD crystals are pleomorphic, often in the shape of rhomboids with blunt ends, and are weakly positively birefringent (they appear blue when parallel to the axis of the polarizer). The clinical significance of intracellular crystals is often said to be greater than when they are extracellular, although no convincing evidence supports this suggestion.

The sensitivity of polarized microscopy in demonstrating negatively birefringent crystals in patients with acute gouty arthritis is at least 85%, and the specificity for gout is 100% if the results are unequivocal. However, gouty arthritis may occasionally coexist with another type of joint disease, such as septic arthritis or pseudogout. In some cases, needle-shaped crystals may be evident on a slide without polarized microscopy, especially when the crystals are abundant.

Even during the asymptomatic intercritical period, extracellular urate crystals are identifiable in synovial fluid from previously affected joints in virtually all untreated gouty patients, and approximately 70% of those are administered uric acid-lowering therapy. This allows late establishment of the diagnosis in the majority of patients in whom the diagnosis was not made in the acute setting.

Demonstration of urate crystals in aspirates of tophaceous deposits provides a convenient and specific means to

corroborate the diagnosis in the small proportion of gouty individuals with tophi. Because these patients are typically treated with lifelong urate-lowering therapy, identification of tophaceous gout has significant therapeutic impact.

## Immunoglobulins

Routine measurement of the major immunoglobulins (IgG, IgA, and IgM) is rarely useful in facilitating a diagnosis of a rheumatic disorder but may be useful in diagnosing an associated immunodeficiency. However, the presence of elevated serum levels of the IgG subclass IgG4, and particularly of identifying IgG4-containing plasmacytes in the lesion is useful in identifying patients with the IgG4 syndrome. This is shown in patients with autoimmune pancreatitis; sclerosing sialadenitis (formerly called *Mikulicz disease*); orbital disease (often complicated by proptosis because of lacrimal gland enlargement, involvement of extraocular muscles, or other orbital pseudotumor); and retroperitoneal fibrosis (which frequently occurs in the larger context of chronic periaortitis and can often affect the ureters, leading to hydronephrosis and renal injury).

## Acknowledgment

The editor and I gratefully acknowledge the contributions of the many authors of *UpToDate in Medicine*, whose work provided a useful framework for the development of this chapter, as well as to Dr. Robert Shmerling, with whom I have written chapters on this same subject.

## Chapter Review

### Questions

1. A 48-year-old woman presents with a 4-week history of severe fatigue, painful joints, and a rash over her face. Examination shows normal vital signs, a malar maculopapular rash, and mildly erythematous proximal interphalangeal and metacarpal joints of both hands. Initial laboratory testing reveals an erythrocyte sedimentation rate of 68 mm/h, normal electrolytes, and normal blood urea nitrogen and creatinine, liver function tests, and a low white blood cell count. Serologies are requested. Which of the following tests are most likely to help make a correct diagnosis?
  - A. An elevated ANA and anti-dsDNA
  - B. Negative anti-Sm
  - C. Detection of anti-RNP antibodies
  - D. The presence of antihistone antibodies
  - E. The presence of anti-Scl-70 antibodies
2. Which of the following statements regarding pANCA is correct?
  - A. The most common antigen associated with pANCA is PR3.
  - B. pANCA positivity is observed in over two-thirds of patients with Churg-Strauss syndrome.
  - C. A perinuclear staining pattern is frequently observed in patients with systemic lupus.
  - D. An elevated pANCA titer is observed rarely in patients with inflammatory bowel disease.
  - E. pANCA is rarely elevated in patients with microscopic polyangiitis.
3. A 49-year-old patient suspected of acute gout of his right big toe undergoes synovial fluid aspiration. Which one of the following statements is correct?
  - A. Short, rhomboidal crystals would be typical of monosodium urate monohydrate (MSU).
  - B. MSU crystals show strong negative birefringence.
  - C. The synovial fluid white blood cell count is usually  $<200/\text{mm}^3$ .
  - D. Viscosity of the synovial fluid is high.
  - E. The synovial fluid usually has a reddish discoloration.

### Answers

1. A
2. B
3. B

## Board Simulation: Rheumatic and Immunologic Disease

ELINOR A. MODY

### Questions

1. A 45-year-old woman with a 9-month history of joint pain, swelling, fatigue, and morning stiffness presents to her rheumatologist. On examination, she has swollen metacarpophalangeals (MCPs), proximal interphalangeals, wrists, knees, and ankles. She also has metatarsophalangeal (MTP) squeeze tenderness. Her rheumatoid factor and anticitrullinated proteins (anti-CCP) antibody tests are positive. Her rheumatologist starts methotrexate at escalating doses starting at 10 mg a week, up to 20 mg a week. The patient improves, with her erythrocyte sedimentation rate (ESR) dropping from 50 to 30 mm per hour, her morning stiffness improving to 30 minutes, and her joints less swollen and tender. At this point, the most appropriate action is:
  - A. Continue methotrexate at 20 mg per week.
  - B. Decrease methotrexate to 15 mg per week.
  - C. Add a second agent.
2. A 30-year-old man presents to his rheumatologist with a 4-month history of back pain and stiffness. He reports being stiff in the morning for up to 4 hours. Two years ago, he suffered anterior uveitis, treated with topical steroids. Sacroiliac radiographs show unilateral sacroiliitis. Indomethacin has helped with his back symptoms to a slight degree but has given him epigastric pain. At this point, what is the most appropriate action?
  - A. Check for human leukocyte antigen-B27.
  - B. Switch his antiinflammatory to ibuprofen.
  - C. Stop his indomethacin, and add sulfasalazine at 2 g per day.
  - D. Stop his indomethacin, and add an anti-tumor necrosis factor (anti-TNF) agent.
3. A 22-year-old woman presents to a rheumatologist with a 3-month history of a scaling, erythematous eruption across her scalp and neck; there is some evidence of scarring. Apart from mild Raynaud phenomenon, she has an otherwise negative review of systems. Her laboratories show normal complete blood count (CBC), chemistry profile, ESR, and urinalysis, but her antinuclear antibody (ANA) is positive at 1:640, with a positive Smith antibody and a minimally elevated anti-dsDNA antibody level. Biopsy of the rash reveals an interface dermatitis consistent with subcutaneous lupus erythematosus. At this point, the most appropriate action would be:
  - A. Start hydroxychloroquine.
  - B. Counsel patient on sun protection.
  - C. Consult nephrology for a renal biopsy.
  - D. A and B
  - E. All of the above
4. An 80-year-old man with chronic renal insufficiency and coronary artery disease presents with a painful, swollen, warm right ankle for 2 days. He does not recall any trauma and denies recent sexual activity. He has no significant medical history other than stated above. At this point, the most appropriate initial action would be:
  - A. Aspirate the ankle, with synovial fluid culture and crystal examination.
  - B. Obtain a radiograph of the ankle.
  - C. Obtain blood cultures.
  - D. Order blood work including CBC, uric acid level, and creatinine level.
  - E. Start allopurinol therapy.
5. A 45-year-old woman with rheumatoid arthritis has been on methotrexate for 2 years and for the past month has been on etanercept. Over the past week, she complains of a facial rash and chest pain. On examination, she has a malar rash. Her lungs are clear; however, her chest radiograph reveals a small pleural effusion. Her D-dimer level is not elevated. She has no dyspnea, just pain with a deep breath. At this point, what is the most appropriate action?
  - A. Check her ANA titers, including an anti-dsDNA level.
  - B. Start intravenous (IV) antibiotics for presumptive pneumonia.
  - C. Increase the methotrexate dose.
  - D. Stop the etanercept.

6. A 20-year-old man is referred to you by his internist for treatment of rheumatoid arthritis. On examination, he has no evidence of synovitis, just tenderness of most of his joints. His rheumatoid factor is positive, but his anti-CCP antibody titer is negative. His ESR and C-reactive protein are also within normal limits. At this point, the most appropriate action is:
  - A. Start methotrexate and folic acid.
  - B. Start an anti-TNF agent.
  - C. Suggest to the patient that he try over-the-counter antiinflammatory agents.
  - D. Obtain hepatitis serologies.
7. A 30-year-old woman with a 10-year history of Raynaud phenomenon on examination has telangiectasias, sclerodactyly distal to the wrists, and by history has significant acid reflux symptomatology. She is a smoker but quit recently. What is her most likely diagnosis?
  - A. Buerger disease
  - B. Scleroderma
  - C. CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome
  - D. Systemic lupus erythematosus (SLE)
8. The woman described in Question 7 reports recent-onset shortness of breath. She denies any recent infections. At this point, the most appropriate action is to:
  - A. Prescribe an albuterol inhaler.
  - B. Obtain a high-resolution chest CT scan.
  - C. Start nifedipine therapy.
  - D. Obtain an echocardiogram.
9. A 30-year-old man from Greece presents with painful, scarring oral ulcers and synovitis of his MCPs, wrists, and ankles. His rheumatoid factor is negative, and he has no history of colitis. What is the most likely diagnosis?
  - A. Crohn disease
  - B. Ulcerative colitis
  - C. Behçet disease
  - D. Ankylosing spondylitis
10. At this point in the case of Question 9, the most appropriate action is:
  - A. Obtain an ophthalmology consult.
  - B. Start colchicine therapy.
  - C. Start IV cyclophosphamide therapy.
  - D. Refer patient for a colonoscopy.
11. A 69-year-old woman has a 1-month history of scalp pain, low-grade fever, arthralgias, fatigue, and malaise. On examination, she has good temporal artery pulses and no evidence of scalp necrosis or tenderness. Her laboratory evaluations reveal an ESR of 99 mm per hour. At this point, the most appropriate action is:
  - A. Temporal artery biopsy
  - B. Start nonsteroidal antiinflammatory drug (NSAID) therapy.
  - C. Start methotrexate therapy.
  - D. Obtain blood cultures.
12. A 60-year-old man with a 20-year history of seropositive rheumatoid arthritis on methotrexate monotherapy presents with an open “sore” on his leg. He reports that he initially had a minor scrape in that area, which then became much larger and would not heal. On examination, he has a 5-cm diameter open, draining, very tender lesion. Cultures are negative, including wound cultures. The most likely diagnosis is:
  - A. Cellulitis
  - B. Squamous cell carcinoma
  - C. Mycosis fungoides
  - D. Pyoderma gangrenosum
13. What is the most appropriate therapy for the patient in Question 12?
  - A. Excision
  - B. IV antibiotics
  - C. Prednisone
14. A 55-year-old man with a 10-year history of plaque psoriasis and a diagnosis of osteoarthritis of his hands presents with a 2-week history of right ankle pain. On examination, the ankle is swollen, with decreased range of motion and some tenderness. Of note, he has nail pitting and onycholysis. There is no history of trauma. His past medical history is only positive for bilateral Achilles tendinitis. The most likely diagnosis is:
  - A. Psoriatic arthritis
  - B. Gout
  - C. Rheumatoid arthritis
  - D. Osteoarthritis
15. A 55-year-old woman presents with a chief complaint of bilateral hand pain for several years. She denies wrist pain, significant arm stiffness, or other joint pain. Her past medical history is significant only for mild hyperglycemia. On examination, she has no obvious synovitis but significant bilateral MCP tenderness. Radiographs of her hands reveal joint space narrowing, sclerosis, and osteophyte formation at her third MCP joints bilaterally. At this point, what is the most appropriate action?
  - A. Start methotrexate therapy.
  - B. Inject both affected joints with hydrocortisone.
  - C. Draw serum chemistries, including ferritin level.
  - D. Start NSAID therapy.
16. A 68-year-old woman presents with myalgias of a few weeks' duration. Her current medications include atorvastatin, alendronate, hydrochlorothiazide, and Premarin vaginal cream. On examination, she has no motor weakness and no synovitis, and her laboratories are normal, including a creatine phosphokinase (CPK) level. The most likely cause of this patient's myalgias is:
  - A. Polymyositis
  - B. Inclusion body myopathy
  - C. Atorvastatin
  - D. Alendronate

17. A 30-year-old man felt a “pop” at the back of his left heel while running 1 day prior. He has pain and swelling in the area and has trouble standing on his toes on that foot. The most appropriate maneuver at this point is:
- Thompson’s
  - McMurray’s
  - McBurney’s
  - Schober’s
18. A 50-year-old woman with rheumatoid arthritis on methotrexate is about to start infliximab therapy. A purified protein derivative (PPD) test is performed and is positive. The patient reports that she is an immigrant and had the Bacille Calmette-Guérin (BCG) vaccination in her youth. A chest x-ray is negative. What is the most appropriate action at this point?
- Start isoniazid (INH) therapy.
  - Start infliximab therapy.
  - Perform three sputum cultures for acid-fast bacillus.
  - Increase methotrexate dose.
19. A 26-year-old woman presents with a 2-week history of pain and swelling of her wrists, MCPs, and MTPs bilaterally, significant arm stiffness, and malaise. Her rheumatoid factor and CCP are negative. Of note, her two small children have had a recent viral infection, with fever and a rash. At this point, the most appropriate blood work to obtain is:
- ANA titer
  - Hepatitis serologies
  - Parvovirus titers
  - Epstein-Barr virus titers

### Answers

- Multiple studies have shown that combination therapy comprised of methotrexate in addition to another agent is more effective than either therapy alone. This has been shown with multiple anti-TNF drugs, leflunomide, hydroxychloroquine, and sulfasalazine. Therefore, if a patient does not fully remit on methotrexate alone, another agent should be added. (Breedveld FC, Weisman MH, Kavanaugh AF, et al. The PREMIER study: a multicenter, randomized, double-blind clinical trial of combination therapy with adalimumab plus methotrexate versus methotrexate alone or adalimumab alone in patients with early, aggressive rheumatoid arthritis who had not had previous methotrexate treatment. *Arthritis Rheum.* 2006;54(1):26–37. Landewé RB, Boers M, Verhoeven AC, et al. COBRA combination therapy in patients with early rheumatoid arthritis: long-term structural benefits of a brief intervention. *Arthritis Rheum.* 2002;46(2):347–356. Kremer J, Genovese M, Cannon GW, et al. Combination leflunomide and methotrexate (MTX) therapy for patients with active rheumatoid arthritis failing MTX monotherapy: open-label extension of a randomized, double-blind, placebo controlled trial. *J Rheumatol.*

- 2004;31(8):1521–1531. Smolen JS, Landewé R, Bijlsma J, et al. EULAR recommendations for the management of rheumatoid arthritis with synthetic and biological disease-modifying antirheumatic drugs: 2016 update. *Ann Rheum Dis.* 2017;76(6):960–977. Woodworth TG, den Broeder AA. Treating to target in established rheumatoid arthritis: challenges and opportunities in an era of novel targeted therapies and biosimilars. *Best Pract Res Clin Rheumatol.* 2015;29(4-5):543–549.)
- This patient has a spondyloarthropathy with ongoing inflammatory axial skeletal arthritis resistant to NSAID therapy. DMARD therapy, including methotrexate, has been shown not to be effective in this situation. The only class of medication proven to be effective in these patients is the anti-TNF class. However, there is some future promise for anti-IL-17 therapy to be effective in these patients. (van der Heijde D, Sieper J, Maksymowych WP, et al. 2010 update of the international ASAS recommendations for the use of anti-TNF agents in patients with axial spondyloarthritis. *Ann Rheum Dis.* 2011;70(6):905–908. Mease PJ, Genovese MC, Greenwald MW, et al. Brodalumab, an anti-IL17RA monoclonal antibody, in psoriatic arthritis. *N Engl J Med.* 2014;370(24):2295–2306. Raychaudhuri SK, Saxena A, Raychaudhuri SP. Role of IL-17 in the pathogenesis of psoriatic arthritis and axial spondyloarthritis. *Clin Rheumatol.* 2015;34(6):1019–1023. National Institute for Health and Care Excellence (UK). *Spondyloarthritis in Over 16s: Diagnosis and Management.* London: National Institute for Health and Care Excellence (UK); 2017. van der Heijde D, Ramiro S, Landewé R, et al. 2016 update of the ASAS-EULAR management recommendations for axial spondyloarthritis. *Ann Rheum Dis.* 2017;76(6):978–991.)
  - This patient has subcutaneous lupus erythematosus, and the treatment of choice is hydroxychloroquine, assuming there are no contraindications. Sun protection is extremely important, however, because sun exposure can greatly worsen subacute cutaneous lupus erythematosus and can cause other photosensitive rashes in these patients. (Ribero S, Sciascia S, Borradori L, Lipsker D. The cutaneous spectrum of lupus erythematosus. *Clin Rev Allergy Immunol.* 2017 Jul 27. [Epub ahead of print] Nutan F, Ortega-Loayza AG. Cutaneous lupus: a brief review of old and new medical therapeutic options. *J Invest Dermatol Symp Proc.* 2017;18(2):S64–S68.)
  - Although everything in this case points to an acute gouty flare, including the sudden-onset inflammatory process in a joint of the lower extremity, in the setting of renal insufficiency the only way to prove it is to see intracellular crystals in the synovial fluid. (Courtney P, Doherty M. Joint aspiration and injection and synovial fluid analysis. *Best Pract Res Clin Rheumatol.* 2013;27(2):137–169.)

5. D. This patient's symptoms, suggestive of SLE, developed after starting etanercept, an anti-TNF therapy. Given this and the fact that prior to starting etanercept the patient's diagnosis was clearly rheumatoid arthritis and not SLE, the diagnosis is most consistent with drug-induced lupus. The anti-TNF agents have been associated with drug-induced lupus. Most commonly the manifestations are mild, but nephritis has been reported. The cessation of the drug often, but not always, should lead to resolution of the process. Unfortunately, this does appear to be a class effect. (Shakoor N, Michalska M, Harris CA, Block JA. Drug-induced systemic lupus erythematosus associated with etanercept therapy. *Lancet*. 2002;359(9306):579–580. Stokes MB, Foster K, Markowitz GS, et al. Development of glomerulonephritis during anti-TNF- $\alpha$  therapy for rheumatoid arthritis. *Nephrol Dial Transplant*. 2005;20(7):1400–1406. Williams VL, Cohen PR. TNF alpha antagonist-induced lupus-like syndrome: report and review of the literature with implications for treatment with alternative TNF alpha antagonists. *Int J Dermatol*. 2011;50(5):619–625.)
6. D. Hepatitis C can cause a false-positive rheumatoid factor due to secondary mixed cryoglobulinemia. In this patient without synovitis and with a negative anti-CCP antibody titer, hepatitis C must be ruled in or out. (Misiani R, Bellavita P, Fenili D, et al. Hepatitis C virus infection in patients with essential mixed cryoglobulinemia. *Ann Intern Med*. 1992;117(7):573–577. Bizzaro N, Mazzanti G, Tonutti E, et al. Diagnostic accuracy of the anti-citrulline antibody assay for rheumatoid arthritis. *Clin Chem*. 2001;47(6):1089–1093.)
7. C. This patient has Raynaud phenomenon (R), esophageal dysmotility (E), sclerodactyly (S), and telangiectasias (T). Evidence of calcinosis (C) is not given. However, Buerger disease does not cause telangiectasias and sclerodactyly, and these symptoms do not invoke SLE. (Block JA, Sequeira W. Raynaud's phenomenon. *Lancet*. 2001;357(9273):2042–2048.)
8. D. This patient has limited scleroderma, or CREST; therefore the most likely cause of shortness of breath is pulmonary artery hypertension, evidence of which can be seen on echocardiogram. If she had a clinical picture consistent with systemic sclerosis, interstitial lung disease is the more likely cause. (Ungerer RG, Tashkin DP, Furst D, et al. Prevalence and clinical correlates of pulmonary arterial hypertension in progressive systemic sclerosis. *Am J Med*. 1983;75(1):65–74. Murata I, Kihara H, Shinohara S, Ito K. Echocardiographic evaluation of pulmonary arterial hypertension in patients with progressive systemic sclerosis and related syndromes. *Jpn Circ J*. 1992;56(10):983–991.)
9. C. Although inflammatory bowel disease cannot be completely ruled out, the absence of diarrhea in addition to the country of origin suggest that Behçet is the most likely diagnosis. (Hatemi G, Seyahi E, Fresko I, et al. One year in review 2017: Behçet's syndrome. *Clin Exp Rheumatol*. 2017 Sep 29. [Epub ahead of print])
10. B. Colchicine therapy has been shown to be effective in mild Behçet disease. However, as a significant number of patients do develop ophthalmologic disease, an ophthalmology referral should also be considered. (Kaklamani VG, Kaklamanis PG. Treatment of Behçet's disease—an update. *Semin Arthritis Rheum*. 2001;30(5):299–312. Erratum in: *Semin Arthritis Rheum*. 2001;31(1):69. Mishima S, Masuda K, Izawa Y, et al. The eighth Frederick H. Verhoeff Lecture. Presented by Saiichi Mishima, MD. Behçet's disease in Japan: ophthalmologic aspects. *Trans Am Ophthalmol Soc*. 1979;77:225–279. Dalvi SR, Yildirim R, Yazici Y. Behçet's syndrome. *Drugs*. 2012;72(17):2223–2241.)
11. A. This patient has a presentation suggestive of giant cell or temporal arteritis. The gold standard for diagnosis of this disease is still temporal artery biopsy. However, as the disease can cause “skip” lesions, a negative biopsy does not completely rule out the diagnosis. Additionally, vascular ultrasound may also be helpful diagnostically, although false negatives are not uncommon. It would not be inappropriate to start corticosteroid therapy until a temporal artery biopsy can be performed; this should be within 2 weeks of starting therapy. Performing the biopsy any further out than 2 weeks after starting corticosteroid therapy is associated with false negatives. (Breuer GS, Neshet R, Neshet G. Negative temporal artery biopsies: eventual diagnoses and features of patients with biopsy-negative giant cell arteritis compared to patients without arteritis. *Clin Exp Rheumatol*. 2008;26(6):1103–1106. Agard C, Ponge T, Hamidou M, Barrier J. Role for vascular investigations in giant cell arteritis. *Joint Bone Spine*. 2002;69(4):367–372. Weyand CM, Goronzy JJ. Clinical practice. Giant-cell arteritis and polymyalgia rheumatica. *N Engl J Med*. 2014;371(1):50–57.)
12. D. Pyoderma gangrenosum is seen in the setting of rheumatoid arthritis and is commonly a Koebner-like phenomenon. Given the open nature of the lesion and the negative cultures, infection is unlikely. Because of the short time period during which this has formed, cutaneous malignancy is unlikely. (Chua-Aguilera CJ, Möller B, Yawalkar N. Skin manifestations of rheumatoid arthritis, juvenile idiopathic arthritis, and spondyloarthritides. *Clin Rev Allergy Immunol*. 2017 Jul 27. [Epub ahead of print])
13. C. Excision is contraindicated for pyoderma gangrenosum, as this can cause worsening of the lesion. IV antibiotics are not helpful, generally. Systemic immunosuppression/treatment of the underlying condition is the treatment of choice. (Rozen SM, Nahabedian MY, Manson PN. Management strategies for pyoderma gangrenosum: case studies and review of literature. *Ann Plast Surg*. 2001;47(3):310–315.)

14. A. This patient has a history very suggestive of psoriatic arthritis given his history of Achilles tendonitis (which is a common enthesitis in this disorder), nail changes, and a 10-year history of plaque psoriasis. Gout is also possible, but a first flare would be unlikely to last for 2 weeks. Osteoarthritis does not cause an acute flare, and although rheumatoid arthritis is possible, it most commonly is a symmetric polyarthritis involving the hands and wrists. (Qureshi AA, Husni ME, Mody E. Psoriatic arthritis and psoriasis: need for a multidisciplinary approach. *Semin Cutan Med Surg.* 2005;24(1):46–51. Ritchlin CT, Colbert RA, Gladman DD. Psoriatic arthritis. *N Engl J Med.* 2017;376(10):957–970.)
15. C. Osteoarthritis of the MCPs is secondary osteoarthritis, and osteoarthritis of the third MCP is a classic presentation of hemochromatosis. (Sahinbegovic E, Dallos T, Aigner E, et al. Musculoskeletal disease burden of hereditary hemochromatosis. *Arthritis Rheum.* 2010;62(12):3792–3798.)
16. D. This is not a history consistent with polymyositis because there is no motor weakness, nor is it consistent with myositis from 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase inhibitors because the CPK is normal. Although inclusion-body myositis is possible, the most likely scenario is myalgias caused by alendronate.
17. A. This history and examination are consistent with an acute Achilles tendon rupture; the appropriate maneuver to diagnose this is the Thompson maneuver. The McMurray maneuver is used to diagnose meniscal tears in the knee, McBurney maneuver refers to a tender right upper quadrant due to acute cholecystitis, and the Schober test is one of excursion of the lumbar spine. (Thompson TC, Doherty JH. Spontaneous rupture of tendon of Achilles: a new clinical diagnostic test. *J Trauma.* 1962;2(2):126–129.)
18. A. According to Centers for Disease Control and Prevention recommendations, BCG history should be ignored when interpreting a positive PPD. Therefore because the PPD is positive, and infliximab therapy is to be started, of the choices available, starting INH therapy is the correct choice. Another appropriate choice is to perform a QuantiFERON-tb-Gold test. (Mazurek GH, Jereb J, Vernon A, et al; IGRA Expert Committee and Centers for Disease Control and Prevention. Updated guidelines for using interferon gamma release assays to detect Mycobacterium tuberculosis infection—United States, 2010. *MMWR Recomm Rep.* 2010;59(RR-5):1–25.)
19. C. Parvovirus infection in adults is often not manifested as a rash and can cause a self-limited inflammatory arthritis that can mimic rheumatoid arthritis. (Reid DM, Brown T, Reid TMS, et al. Human parvovirus-associated arthritis: a clinical and laboratory description. *Lancet.* 1985;325(8426):422–425.)

## Rheumatology Summary

DERRICK J. TODD AND JONATHAN S. COBLYN

Most rheumatic diseases can be conceptualized as either inflammatory or noninflammatory disorders. Idiopathic autoimmune diseases comprise the majority of inflammatory rheumatic disorders. Some inflammatory disorders have fibrosis as their principal manifestation. Inflammatory disorders with a better-defined origin include the microcrystalline diseases (e.g., gout and pseudogout) and the many infectious arthritides. Laboratory tests and imaging studies in rheumatology generally fall into two categories: those used to aid diagnosis and those used to monitor therapy. Most pharmacotherapy in rheumatic diseases is targeted against inflammation, pain, or both.

This chapter provides an overview summary of the many different rheumatic disorders, reviews common tests used in the diagnosis or monitoring of rheumatic diseases, and highlights the various pharmacologic agents used in the treatment of these conditions. Laboratory testing, radiologic imaging, and treatment modalities are discussed within their respective disease contexts.

### Idiopathic Autoimmune Disorders

#### Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a systemic autoimmune condition that primarily causes inflammation of synovial tissue (synovitis) with resultant inflammatory arthritis and tenosynovitis. RA classically presents as a symmetric polyarthritis of the small joints of the upper and lower extremities, although almost any joint can be involved. RA most commonly presents in patients with peak onset at ages 25 to 55 years and ratio of 2:1 women to men. However, all ages, genders, and races may be affected. The hallmark pathologic process is proliferative synovitis, which can lead to cartilage destruction, bone erosion, and deforming arthritis. Patients with RA may experience extraarticular symptoms as well, most commonly constitutional and sicca symptoms, skin nodules, interstitial lung disease (ILD), serositis (pleural and pericardial effusions), anemia, and thrombocytosis. Less common complications include vasculitis, secondary amyloidosis, ocular disease, Felty syndrome, large granular lymphocyte syndrome, and lymphomas. Please see Table 23.2 for a complete listing of extraarticular complications of RA.

The diagnosis of RA is aided by testing for serum rheumatoid factor (RF) and anti-cyclic citrullinated peptide (CCP) antibodies (ACPAs). These are present in approximately 80% of RA patients, with anti-CCP antibody ACPA testing being much more specific for RA than the serum RF. Importantly, about 20% of patients with RA never demonstrate abnormal RF or anti-CCP ACPA values. Laboratory markers of inflammation (Box 30.1) are nonspecific but often correlate with disease activity. Analysis of synovial fluid in a patient with active RA demonstrates  $>2000$  white blood cells (WBCs)/ $\text{mm}^3$ , but this finding is nonspecific and not diagnostic for RA. Arthrocentesis in this setting is used primarily to establish whether the effusion is inflammatory or not and to exclude other diagnoses (e.g., septic or microcrystalline arthritis). Plain film radiology may show soft tissue swelling, periarticular osteopenia, joint space narrowing, and marginal erosions. MRI and musculoskeletal ultrasound are playing increasingly important roles in the diagnosis of RA.

Historically, nonsteroidal antiinflammatory drugs (NSAIDs) and analgesics were mainstays of RA therapy. More recently, however, great strides have been made in the treatment of RA. These treatments focus on interrupting the inflammatory proliferative synovitis. Corticosteroids have been able to accomplish this but with many potential side effects (Box 30.2). More recent treatment strategies aim to limit corticosteroid usage and impair disease progression using disease-modifying antirheumatic drugs (DMARDs). For a list of DMARDs, their mechanisms of action, and side effect profiles, please see Table 23.3. Examples of traditional DMARDs include methotrexate, leflunomide, hydroxychloroquine, sulfasalazine, gold, and many others. The last decade has witnessed the advent of biological DMARD therapy, with drugs that antagonize the tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (adalimumab, certolizumab, etanercept, golimumab, infliximab, and biosimilar versions of infliximab), block the interleukin (IL)-6 receptor signaling (tocilizumab and sarilumab), block impaired T-cell costimulation (abatacept), or cause B-cell depletion (rituximab). Emerging therapies include the small-molecule Janus kinase inhibitor tofacitinib. Collectively, these new classes of drugs, although potent immunosuppressive

### • BOX 30.1 Common Laboratory Abnormalities Associated With Inflammation

Elevated erythrocyte sedimentation rate  
 Elevated C-reactive protein  
 Anemia of chronic disease  
 Thrombocytosis  
 Leukocytosis  
 Elevated complements  
 Elevated haptoglobin  
 Elevated ferritin

### • BOX 30.2 Side Effects of Systemic Corticosteroids

Immunosuppression  
 Insulin resistance  
 Hypertension  
 Weight gain (cushingoid appearance)  
 Bone demineralization  
 Avascular necrosis  
 Cataracts  
 Adrenal suppression  
 Steroid myopathy  
 Increased cardiovascular risk

agents, have revolutionized the treatment of RA, creating a paradigm shift in treatment goals away from palliation and toward remission.

## Polymyalgia Rheumatica

Polymyalgia rheumatica (PMR) is a systemic inflammatory disorder of individuals older than 50 years of age. It typically presents as limb-girdle aching of the shoulders and hips out of proportion to examination findings, with a preponderance of morning stiffness. Presentation is usually sudden in onset and is occasionally associated with synovitis of the small peripheral joints. Laboratory tests show evidence of systemic inflammation (see [Box 30.1](#)). Erythrocyte sedimentation rate (ESR) may be >100 mm per hour. Few other disease states are associated with such an elevated ESR, which is an uncommon finding ([Box 30.3](#)). Up to 5% to 10% of patients with PMR will evolve into an illness resembling RA. Up to 15% to 20% of patients with PMR will develop symptoms of giant cell arteritis (discussed later). Low-dose corticosteroids (typically 15–20 mg daily) are the primary initial treatment for PMR. Steroids are tapered as symptoms allow, sometimes over 1 to 2 years.

## Spondyloarthritides

The spondyloarthritides (SPAs) are a collection of disorders that include ankylosing spondylitis, psoriatic arthritis, arthropathy associated with inflammatory bowel disease (IBD arthropathy), postinfectious (reactive) arthritis, and

### • BOX 30.3 Differential Diagnosis of Diseases Associated With an Erythrocyte Sedimentation Rate >100 mm/h

#### Rheumatic Diseases

Polymyalgia rheumatica  
 Systemic vasculitis, including giant cell arteritis  
 Adult-onset Still disease  
 Unusually active rheumatic disorder (e.g., polyarticular gout, highly active rheumatoid arthritis)

#### Infectious Diseases

Endocarditis  
 Osteomyelitis  
 Septic arthritis

#### Malignant Diseases

Multiple myeloma  
 Extensively metastatic disease

undifferentiated spondyloarthropathy. Unlike RA, peripheral arthritis is typically oligoarticular, asymmetric, and most pronounced in the lower extremities. Further distinguishing features of SPAs include lumbosacral inflammation (spondylitis or sacroiliitis), enthesitis, and bone-forming lesions by radiography. Morning back stiffness in a young person should alert the clinician to the possibility of inflammatory back disease.

Ankylosing spondylitis (AS) has a >3:1 male-to-female predominance. AS primarily affects the spine and can lead to fusion (ankylosis) of the vertebrae. Women may develop AS in an atypical fashion with neck involvement before spine and sacroiliac joint involvement. Psoriatic arthritis and IBD arthropathy are associated with their respective disease entities, but spine involvement can cause “skip areas” rather than a uniform progression as one sees in AS. Arthritis may precede the skin or bowel disease in these disorders. Reactive arthritis is associated with antecedent infection by chlamydia or enteroinvasive bowel pathogens (shigella, salmonella, or yersinia). Additional extraarticular manifestations of all the SPAs may include dactylitis (sausage digit), uveitis, circinate balanitis, and scaly plantar lesions (keratoderma blennorrhagica). Rarely, these conditions are associated with proximal aortic aneurysms and pulmonary fibrosis.

Laboratory workup of the SPAs fails to reveal antinuclear antibodies (ANA), RF, or ACPAs. Although nonspecific, laboratory tests may show systemic inflammation (see [Box 30.1](#)), and synovial fluid WBC may be extremely elevated. Spinal involvement is closely associated with human leukocyte antigen (HLA)-B27. The diagnostic utility of testing HLA status is debatable, although newer criteria incorporate this test. Enthesitis, ankylosis, and sacroiliitis are hallmark radiographic findings. The treatment of the SPAs closely mirrors that of RA. Traditional DMARD therapies (including methotrexate and sulfasalazine) may only have a role in the treatment of peripheral inflammatory SPA; they are ineffective for spine disease. On the contrary,

**TABLE 30.1** Manifestations of Systemic Lupus Erythematosus

Category	Manifestations
Constitution	Fever, weight loss, fatigue, malaise
Mucocutaneous	Mucosal ulcerations, <sup>1</sup> photosensitivity, <sup>2</sup> malar rash, <sup>3</sup> discoid lupus, <sup>4</sup> SCLÉ, alopecia, lupus profundus, lupus panniculitis, erythema nodosum, vasculitic purpura, urticarial vasculitis, angioedema
Kidney	Lupus nephritis, <sup>5</sup> interstitial nephritis, renal vein thrombosis
Musculoskeletal	Nonerosive inflammatory arthritis, <sup>6</sup> arthralgias, AVN, inflammatory myopathy
Lungs	Pleural effusion, <sup>7</sup> pulmonary hemorrhage, ILD, BOOP, pneumonitis, pulmonary embolism, pulmonary hypertension, shrinking lung syndrome
Cardiovascular	Pericardial effusion, <sup>7</sup> myocarditis, Libman-Sacks endocarditis, Raynaud phenomenon, increased risk of cardiovascular disease
Nervous system	Seizures, <sup>8</sup> psychosis, <sup>8</sup> headache, cognitive or personality changes, mood disorders, meningoencephalitis, CNS vasculitis, transverse myelitis, chorea, mononeuritis multiplex
GI system	NSAID-related peptic ulcer disease, mesenteric ischemia, pancreatitis, and sterile peritonitis
CTD overlap	Erosive inflammatory arthritis, secondary Sjögren, CREST symptoms
Hematology	Leukopenia, <sup>9</sup> lymphopenia, <sup>9</sup> autoimmune hemolytic anemia, <sup>9</sup> anemia of chronic disease, thrombocytopenia, <sup>9</sup> ITP, TTP
Laboratory values	Presence of ANA, <sup>10</sup> anti-dsDNA, <sup>11</sup> anti-Smith, <sup>11</sup> anti-Ro, anti-La, anti-RNP, hypocomplementemia
APLS <sup>11</sup>	Livedo reticularis, stroke, pulmonary embolism, myocardial infarction, thrombotic microangiopathy of kidney and CNS, fetal loss
Pregnancy	Fetal loss, neonatal lupus (congenital heart block and photosensitive rash)

Superscript numbers indicate manifestations that comprise the classification criteria, with 4 of 11 indicating SLE.  
 ANA, Antinuclear antibodies; *anti-dsDNA*, anti-double-stranded DNA; *anti-RNP*, antiribonuclear protein; *anti-APLS*, antiphospholipid antibody syndrome; AVN, avascular necrosis; BOOP, bronchiolitis obliterans organizing pneumonia; CNS, central nervous system; CREST, calcinosis, Raynaud, esophageal dysmotility, sclerodactyly, telangiectasia; CTD, connective tissue disease; GI, gastrointestinal; ILD, interstitial lung disease; ITP, idiopathic thrombocytopenia purpura; NSAID, nonsteroidal antiinflammatory drug; SCLÉ, subacute cutaneous lupus erythematosus; TTP, thrombotic thrombocytopenia purpura.

TNF- $\alpha$  drug antagonists have been remarkably effective for spinal disease in the treatment of spinal manifestations of the SPAs. Newer biological agents found to be effective in the treatment of SPAs include ustekinumab, which blocks the IL-12 and IL-23 receptors, and secukinumab and ixekizumab, monoclonal antibodies directed against IL-17A. Apremilast is a small-molecule oral inhibitor of phosphodiesterase 4, and it has been shown to be effective in the treatment of psoriasis and psoriatic arthritis.

### Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease characterized primarily by constitutional symptoms, hematologic abnormalities, and immune-complex deposition in target organs. It tends to afflict women of childbearing age. Some patients with an inherited deficiency of complement are at increased risk to develop SLE. The potential manifestations of SLE are myriad (Table 30.1), and the diagnosis of SLE requires a strong clinical suspicion, laboratory or pathologic evidence of disease, and exclusion of other possible infectious, rheumatic, and neoplastic conditions. Even in patients with established SLE, new

clinical symptoms should not be attributed solely to SLE. Medication reactions and opportunistic infections occur commonly, and noninflammatory joint pain may indicate superimposed fibromyalgia or avascular necrosis (AVN) (Box 30.4).

Lupus nephritis is the principal renal manifestation of SLE and is characterized by proteinuria and hematuria with red blood cell casts. Disease severity is classified based on histologic assessment of renal biopsy. Please see Table 25.1 for the World Health Organization classification of SLE nephritis. The degree of pathologic renal involvement cannot be predicted adequately by clinical criteria alone. Despite treatment, some patients still progress to end-stage renal disease (ESRD) and require dialysis therapy or renal transplantation. Renal vein thrombosis, interstitial nephritis, and antiphospholipid syndrome (APLS) may also lead to renal dysfunction in patients with SLE.

Autoantibody formation is the hallmark immunologic signature of SLE. ANA is detectable in essentially 100% of patients with SLE, but this test lacks specificity. Many other inflammatory conditions and upward of 20% of healthy patients may have a positive ANA. Anti-double-stranded DNA (dsDNA) and anti-Smith antibody testing are much

Radiation therapy  
Decompression illness (Caisson disease)

more specific but less sensitive assays. Anti-Ro (anti-SSA), anti-La (anti-SSB), and antiribonuclear protein (anti-RNP) antibodies may also be detectable in patients with SLE. A prevailing opinion is that autoantibodies in lupus form circulating immune complexes that deposit in target tissues, recruit complement and other immunologic mediators, and cause end-organ disease.

Corticosteroids remain the mainstay of treatment in acute SLE flares. High doses (up to 1 mg/kg/d prednisone or equivalent) are often used for severe hematologic abnormalities or organ-threatening disease. Lower doses of corticosteroids or NSAIDs are often sufficient for cutaneous, musculoskeletal, and serositis manifestations. Steroid-sparing agents are used to minimize steroid-related complications. Other than corticosteroids, only hydroxychloroquine and belimumab, a B-cell suppressing anti-B cell activating factor (BAFF) monoclonal antibody, have been approved for use in SLE by the US Food and Drug Administration (FDA). Regardless, many other immunosuppressive and cytotoxic medications have been used successfully in the treatment of SLE: These drugs include hydroxychloroquine, azathioprine, mycophenolate mofetil, methotrexate, cyclosporine, cyclophosphamide, and possibly rituximab, although this agent is not FDA approved for SLE. Antimalarial agents (e.g., hydroxychloroquine) are well-tolerated drugs that play an important role in the treatment of SLE through poorly understood mechanisms. Methotrexate is particularly useful in the treatment of cutaneous, musculoskeletal, and serositis manifestations of SLE. Belimumab is effective mostly for cutaneous and musculoskeletal features of SLE. Azathioprine, mycophenolate mofetil, cyclosporine, and cyclophosphamide have proven efficacy and are often effective in the treatment of lupus nephritis. Cyclophosphamide is a cytotoxic agent reserved for the most severe manifestations of SLE (e.g., severe nephritis, pulmonary hemorrhage, severe central nervous system [CNS] disease, vasculitis). Acute complications of cyclophosphamide include hemorrhagic cystitis, bone marrow suppression, infertility, and profound immunosuppression. Lymphoma and urinary tract cancers are

potential long-term adverse events. Plasmapheresis and intravenous immunoglobulin (IVIG) may be added to immunosuppressive therapy for life-threatening SLE. Anticoagulation is used in patients with thrombotic complications.

APLS is a hypercoagulable state in which a patient suffers a clot or fetal loss in the setting of having detectable serum antiphospholipid antibodies measured on two separate tests at least 12 weeks apart. Clots may be either venous, arterial, or even microvascular in nature. Fetal loss includes any three or more first-trimester miscarriages or any fetal loss after the first trimester. Antiphospholipid antibodies include anticardiolipin antibodies (IgG or IgM), anti-beta-2-glycoprotein I antibodies, or the lupus anticoagulant, which elevates the partial thromboplastin time (PTT) or dilute Russell viper venom time and is not corrected on mixing with normal serum. Secondary APLS describes a disease that occurs in the presence of an underlying autoimmune disease, most commonly SLE, whereas no such disorder is detected in primary APLS. Catastrophic APLS is the syndrome of APLS with multiple clots, microvascular thrombosis, and organ failure. It has a mortality rate reported as 50% or greater. All forms or manifestations of APLS are treated with anticoagulation. Immunosuppression may also be used, and plasmapheresis may be added in cases of refractory APLS or catastrophic APLS.

Finally, drug-induced lupus (DIL) may occur with use of hydralazine, procainamide, isoniazid, methyldopa, quinidine, minocycline, or even anti-TNF- $\alpha$  agents. It is characterized primarily by constitutional symptoms, mucocutaneous findings, serositis, and elevated ANA. Organ-threatening disease should prompt consideration of an alternative diagnosis. Antihistone antibodies are a sensitive, but not specific, marker for DIL. Symptoms generally resolve after elimination of the offending drug.

#### Scleroderma

Scleroderma describes a family of rare but related disorders that commonly share idiopathic dermal fibrosis. Scleroderma is categorized into localized disease (various types of morphea and linear scleroderma) and systemic sclerosis (SSC). SSC is a disease characterized by both fibrosis and vasculopathy. SSC is subdivided into limited or diffuse disease based on the extent of fibrosis. In limited SSC, dermal fibrosis is restricted to the hands, feet, and face. Involvement of the proximal extremities, usually proximal to the metacarpophalangeal joints or trunk, indicates diffuse SSC. Organ fibrosis represents a major source of mortality. It occurs principally in the lungs, heart, and gastrointestinal (GI) tract. Vasculopathy accounts for pulmonary hypertension, scleroderma renal crisis, and the nearly universal Raynaud phenomenon. Patients with SSC may manifest with the CREST symptoms (*c*alcinosis cutis, *R*aynaud, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia), which have a high risk of developing pulmonary hypertension and can also occur independently of SSC. Serologic analysis of patients with SSC often have ANA positivity and more specific autoantibodies: anticentromere, anti-SCL70, and

anti-RNA polymerase III antibodies. Anticentromere antibodies are more often associated with limited SSC, CREST, and pulmonary hypertension. Anti-SCL70 antibodies are associated with diffuse SSC and cardiopulmonary fibrosis. Anti-RNA polymerase III antibodies are associated with rapidly progressive cutaneous SSC and renal crisis.

Treatment options exist for the vascular complications of SSC. Scleroderma renal crisis presents as hypertension, hematuria, and renal failure. Despite renal failure, renal crisis is treated with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, or both. Aggressive use of these drugs to lower blood pressure has changed the natural history of scleroderma renal crisis such that patients may recover from or even avoid dialysis therapy. Pulmonary hypertension and digit-threatening Raynaud disease are treated with vasodilator therapies. Dihydropyridine calcium channel blockers, alpha-receptor antagonists, and injected botulinum toxin may be effective for Raynaud phenomenon. Endothelin receptor antagonists (e.g., bosentan), phosphodiesterase inhibitors (e.g., sildenafil), and prostacyclins are also effective for Raynaud phenomenon and have markedly reduced mortality from pulmonary hypertension.

Pharmacologic treatment of fibrotic complications is sorely lacking. Immunosuppressive agents, including cyclophosphamide, have been used for pulmonary fibrosis, with only modest improvement in outcome. Additional therapy is symptom directed. High-dose proton pump inhibitors are used for gastroesophageal reflux disease and should be administered to all patients with SSC to decrease the risk of esophageal strictures. Proton pump inhibitors are used for gastroesophageal reflux disease and should be administered to all patients with SSC to decrease the risk of esophageal strictures. Proton pump inhibitors are used for gastroesophageal reflux disease and should be administered to all patients with SSC to decrease the risk of esophageal strictures. Promotility agents (e.g., metoclopramide, erythromycin) are used for GI dysmotility, and oral antibiotics are used for bowel overgrowth syndrome.

Several other syndromes may cause cutaneous or systemic fibrosis and should be considered in the differential diagnosis of SSC. Eosinophilic fasciitis causes cutaneous fibrosis and results from infiltration of eosinophils into subcutaneous fascia. Graft-versus-host disease causes cutaneous and bowel fibrosis. Gadolinium-induced fibrosis (nephrogenic systemic fibrosis) occurs in some patients with severe renal insufficiency who are exposed to gadolinium-containing contrast agents often used in MRI procedures.

## Other Connective Tissue Diseases

### Sjögren Syndrome

Sjögren syndrome (SS) may be a primary entity or may exist secondary to other connective tissue diseases (CTDs) such as SLE, RA, and SSC. Sicca describes the most predominant features of SS; dry mouth and dry eyes result from autoimmune destruction of salivary and lacrimal glands. Patients with SS often have positive ANA, anti-Ro, and anti-La antibodies, an elevated RF, and hypergammaglobulinemia. More serious complications include small-vessel vasculitis, polyarthritis, peripheral neuropathies, ILD, and lymphoma.

Lymphomas typically occur in mucosal-associated lymphoid tissue and are sometimes heralded by a monoclonal gammopathy and drop in RF titer. Treatment for SS is typically directed at symptoms with artificial saliva and tears. Vasculitis or ILD requires high-dose corticosteroids or other intensive immunosuppressive therapies such as cyclophosphamide, which may increase the long-term risk of lymphoma in these patients.

### Idiopathic Inflammatory Myopathies

The idiopathic inflammatory myopathies (IIMs) include a collection of autoimmune diseases: dermatomyositis (DM), polymyositis, malignancy-associated myositis, juvenile DM, and inclusion-body myositis (IBM). With the exclusion of IBM, these conditions present as proximal muscle weakness. Creatine kinase (CK) is typically elevated to at least 5 to 10 times the upper limit of normal, and aldolase may also be elevated. DM, malignancy-associated myositis, and juvenile DM may have cutaneous manifestations. These include a malar rash that, unlike SLE, involves the nasolabial folds, a periorbital violaceous heliotrope rash, a photosensitive shawl sign over the precordium, erythematous holster sign at the lateral thigh, Gottron papules over the dorsal knuckles, and hyperkeratotic mechanic's hands. A subset of patients with DM have only skin involvement, termed *amyopathic dermatomyositis*. ILD may occur in many of the various IIMs but is usually in patients with the anti-Jo-1 antibody. The presence of other autoantibodies has been associated with other manifestations of IIMs. Oropharyngeal involvement by any of the IIMs may be life threatening because of aspiration risk. Diagnosis is aided by MRI or electromyography and confirmed by a muscle biopsy that shows an inflammatory infiltrate. Treatment consists primarily of high-dose corticosteroids, with additional immunosuppressive agents (such as methotrexate, azathioprine, IVIG, or possibly rituximab) used in patients who are unable to taper corticosteroids. Unlike the other IIMs, IBM presents as distal muscle weakness and atrophy in elderly patients. Diagnosis is made by electron microscopy of a muscle biopsy. Treatment is generally ineffective.

### Adult-Onset Still Disease

Adult-onset Still disease (AOSD) is a systemic multisystem inflammatory disease characterized by high fever, antecedent sore throat, evanescent rash, lymphadenopathy, hepatosplenomegaly, inflammatory arthritis, elevated liver transaminases, neutrophilic leukocytosis, and markedly abnormal laboratory markers of inflammation, especially ferritin (see [Box 30.1](#)). It is a diagnosis of exclusion after ruling out RA, SLE, and infectious and malignant diseases. Treatment is similar to that of RA but may require higher doses of steroids. Notably, AOSD can respond quite dramatically to the IL-1 receptor antagonist anakinra or the anti-IL-6 receptor antibody tocilizumab.

## Mixed Connective Tissue Disease

Mixed connective tissue disease (MCTD) is an example of an overlap syndrome that manifests with various elements of several autoimmune diseases. Features may include inflammatory arthritis, sclerodactyly, Raynaud syndrome, inflammatory myositis, pulmonary hypertension, and secondary Sjögren syndrome. Serology is notable for a very high-titer positive ANA and high-titer anti-RNP antibody, but these findings still lack some specificity. Treatment is directed at the individual manifestations of MCTD.

## The Vasculitides

Collectively, the vasculitides represent a collection of diseases characterized by inflammation of blood vessels. The vasculitides are often categorized based on their involvement of large, medium, or small vessels (Table 30.2). Patient demographics and serologic analysis are additional distinguishing features. Most vasculitides are serious conditions that are organ threatening or life threatening. Fevers, constitutional symptoms, and abnormal inflammatory markers (see Box 30.1) are common features of most vasculitides. A definitive diagnosis often requires biopsy evidence of vascular inflammation. Immunosuppression with corticosteroids is a mainstay of treatment. Steroid-sparing agents (azathioprine, methotrexate, mycophenolate mofetil, rituximab) or cytotoxic agents (cyclophosphamide) are often added to limit

steroid toxicity and provide additional immunosuppression. For the most part, TNF- $\alpha$  blockers are ineffective in systemic vasculitis.

## Large-Vessel Vasculitides

### Giant Cell Arteritis

Giant cell arteritis (GCA) is the most common systemic vasculitis. Afflicted patients are exclusively >50 years old and usually of northern European ancestry. Patients typically fall into one of three types of presentations: cranial arteritis, aortitis, or fever of unknown origin (FUO). Approximately 30% of patients with GCA will have concurrent or preexisting PMR, and 15% to 20% of patients with PMR will develop GCA. Patients with PMR should therefore be questioned routinely about symptoms of cranial arteritis. Cranial symptoms or visual changes in a patient with PMR are considered a rheumatologic emergency. Symptoms of cranial arteritis include scalp tenderness, new-onset headache, jaw claudication, persistent cough, and visual changes. A dreaded complication is ophthalmic artery involvement, which can lead to irreversible blindness. GCA may present as arm claudication or cough, but aortitis itself may be asymptomatic and found on postsurgical pathology. In patients >65 years old, GCA comprises 15% to 20% of FUO cases. Inflammatory markers are typically quite elevated in GCA (see Table 30.1). Regardless of presentation, a diagnosis of

**TABLE 30.2** Categorization of the Systemic Vasculitides

Vasculitis	Hallmark Features
<b>Large-Vessel Vasculitides</b>	
Giant cell arteritis	Age >60 years, PMR symptoms
Takayasu arteritis	Pulselessness
<b>Medium-Vessel Vasculitides</b>	
Polyarteritis nodosa	Renal artery aneurysms
Kawasaki disease	Disease of childhood
<b>ANCA-Associated Small-Vessel Vasculitides</b>	
Granulomatosis with polyangiitis (Wegener granulomatosis)	cANCA, anti-PR3 (GPA)
Microscopic polyangiitis	pANCA, anti-MPO (MPA)
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)	Eosinophils
Drug-induced AAV	Offending drug
<b>Immune Complex-Mediated Small-Vessel Vasculitides</b>	
Henoch-Schönlein purpura	IgA deposition
Cryoglobulin vasculitis	HCV infection
Hypersensitivity vasculitis	Offending drug
CTD vasculitis	Associated CTD

AAV, ANCA-associated vasculitis; ANCA, antineutrophil cytoplasmic antibody; cANCA, cytoplasmic ANCA; CTD, connective tissue disease; GPA, granulomatosis with polyangiitis (formerly Wegener granulomatosis); HCV, hepatitis C virus; IgA, immunoglobulin A; MPA, microscopic polyangiitis; MPO, myeloperoxidase; pANCA, perinuclear ANCA; PMR, polymyalgia rheumatica; PR3, proteinase-3.

GCA is confirmed by histologic assessment of involved vasculature. Unilateral or sometimes bilateral temporal artery biopsy will often confirm the diagnosis in patients with cranial symptoms or FUO. The primary modality of treatment is corticosteroids (prednisone, 1 mg/kg/d) tapered over several months. Tocilizumab, the anti-IL-6 receptor antibody, has recently been shown to be an effective treatment for GCA. Methotrexate and azathioprine may be considered as steroid-sparing agents for patients unable to taper steroids in a reasonable fashion. TNF- $\alpha$  antagonists are ineffective and increase the rate of serious infection.

### Takayasu Arteritis

Takayasu arteritis is a large-vessel vasculitis that typically afflicts young women, which distinguishes it from GCA. The classic presentation is that of extremity claudication in a patient with asymmetric blood pressures, vascular bruits, or pulselessness. Proximal mesenteric or renal arteries may also be involved. Chronic arterial inflammation leads to fibrotic strictures, which account for symptoms. Tissue may be difficult to obtain, and a diagnosis may rely on imaging studies (conventional angiography, CT angiography, MR angiography, and positron emission tomography [PET] CT). ESR and C-reactive protein (CRP) may be elevated but not as reliably as in GCA. Corticosteroids are also the main treatment modality, although various biological medications may also be considered as steroid-sparing agents.

### Medium-Vessel Vasculitides

#### Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is the prototypical medium-vessel vasculitis. A subset of patients with PAN have documented infection with hepatitis B virus. Patients with PAN typically present with constitutional symptoms, purpuric skin lesions, and renal insufficiency. Additional organ involvement may include the pulmonary vasculature, intestine, gallbladder, testes, or ovaries. There is a cutaneous-limited A variant of PAN that is limited to the skin (cutaneous PAN). Serologic vasculitis workup is unremarkable. Diagnosis may be supported by renal or mesenteric angiogram showing aneurysmal disease. Biopsy of involved tissue shows necrotizing vasculitis of medium-size vessels. Treatment consists of corticosteroids, with steroid-sparing or cytotoxic agents added for more serious or refractory cases.

#### Kawasaki Disease

Kawasaki disease is a vasculitis of childhood, although cases have been reported in teenagers and young adults. It is a medium-vessel vasculitis that presents as fever >5 days, conjunctivitis, desquamative rash on the extremities, peripheral edema, and erythematous strawberry tongue in the setting of elevated ESR and CRP. Coronary artery involvement may cause life-threatening aneurysms or strictures. Although

corticosteroids are helpful in controlling symptoms, the use of aspirin and IVIG in combination has changed the natural history of this disease by markedly reducing the incidence of coronary artery complications.

### Small-Vessel Vasculitides

Vasculitides that affect the arterioles, capillaries, and venules are classified into two disease categories: those associated with antineutrophil cytoplasmic antibodies (ANCA) and those associated with immune-complex deposition. It is particularly important to exclude infectious endocarditis in the workup of a small-vessel vasculitis.

### ANCA-Associated Vasculitides

ANCA-associated vasculitides (AAVs) include granulomatous with polyangiitis (GPA, formerly Wegener granulomatosis [WG]), microscopic polyangiitis (MPA), and the eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome [CSS]), drug-induced AAV, and organ-specific AAVs (such as isolated renal AAV). AAVs cause necrotizing vasculitis of target tissues, which may include the sinuses, orbit, upper airway, alveoli, myocardium, glomeruli, CNS, peripheral nerves, GI tract, and skin. Renal involvement causes can progress to acute crescentic pauci-immune glomerulonephritis and may lead to ESRD. Life-threatening complications include pulmonary hemorrhage, myocarditis, mesenteric vasculitis, and CNS vasculitis. Lesions may be granulomatous in nature or, in the case of CSS, primarily eosinophilic. Patients may have associated arthralgias and laboratory evidence of systemic inflammation (see [Box 30.1](#)).

Serologic workup for AAV often reveals the presence of ANCA in a cytoplasmic ANCA (cANCA), perinuclear ANCA (pANCA), or nonspecific ANCA pattern. ANCA may be associated with antiproteinase-3 (anti-PR3) or anti-myeloperoxidase (anti-MPO) antibodies by enzyme-linked immunosorbent assay (ELISA). A cANCA pattern with anti-PR3 ELISA is highly specific for WG/GPA, whereas the other AAVs tend to show a pANCA pattern with anti-MPO ELISA. Nonspecific ANCA or pANCA patterns in the absence of ELISA specificity may be observed in other inflammatory conditions, including ulcerative colitis, primary sclerosing cholangitis, and drug-induced vasculitis from such agents such as minocycline, allopurinol, or propylthiouracil. Levamisole, often used as a contaminant of cocaine, can cause a drug-induced AAV often associated with dual anti-PR3 and anti-MPO antibodies. It typically presents as cutaneous lesions but can progress to glomerulonephritis and pulmonary hemorrhage. Anti-glomerular basement membrane antibodies should also be tested in patients with AAV and pulmonary-renal symptoms. Complement levels are normal or elevated in AAVs.

Immunosuppressive therapy is central to the treatment of AAVs. High-dose corticosteroids (prednisone, 1 mg/kg/d) and cyclophosphamide or rituximab are used to induce remission in any patient with organ-threatening

or life-threatening disease. Plasmapheresis may be added to those who are treatment refractory. Once remission is induced, rituximab, methotrexate, or azathioprine may be substituted for cyclophosphamide to minimize long-term toxicity of cyclophosphamide. Methotrexate has a role in the treatment of more limited AAV disease.

## Immune Complex–Mediated Small-Vessel Vasculitides

Immune complex–mediated small-vessel vasculitides may be caused by several different disease processes. These include Henoch-Schönlein purpura (HSP), cryoglobulinemic vasculitis, hypersensitivity vasculitis, and vasculitis associated with connective tissue diseases (e.g., SLE, RA, Sjögren syndrome). These conditions have in common the deposition of immune complexes in target tissues. Serum complement levels are often decreased and correlate with disease activity. HSP is an IgA-mediated small-vessel vasculitis primarily affecting the skin, kidneys, and GI tract as purpura, glomerulonephritis, and bloody diarrhea. It is usually a self-limited disorder, but severe symptoms may necessitate corticosteroid therapy. Cryoglobulinemia may cause a vasculitis characterized by glomerulonephritis, peripheral neuritis, purpura, and rarely mesenteric vasculitis. Hepatitis C virus (HCV)-associated type II (mixed) cryoglobulins are the most likely to cause vasculitis. Treatment is directed at reducing the HCV viral load. Hypersensitivity vasculitis is typically drug induced and limited to the skin as so-called leukocytoclastic vasculitis. Eliminating the offending agent is curative. CTD-associated vasculitides are discussed separately under each disease topic.

## Other Inflammatory Arthritides

### Microcrystalline Arthritis

Gout and pseudogout typically present as an exuberant inflammatory monoarthritis, although patients may have polyarticular disease. Gouty arthritis occurs because of an inflammatory reaction against crystals of monosodium urate. Pseudogout has a similar presentation, but the pathogenic crystals are calcium pyrophosphate dihydrate (CPPD). In both cases, systemic inflammation from other causes (i.e., concurrent infection) may precipitate an attack of microcrystalline arthritis. Gouty arthritis tends to affect the lower extremities, whereas pseudogout prefers the knees, wrists, and hands. Although any joint may be affected by gout or pseudogout, the shoulders, hips, and spine tend to be spared from gout.

Diagnosis of microcrystalline arthritis is confirmed by synovial fluid aspirate and observation of crystals by compensated polarized light microscopy. In the case of gout, crystals are long, needle-shaped, bright, and negatively birefringent. Customarily, this means that crystals are yellow when in the plane of the polarizing light and blue when perpendicular. On the other hand, the crystals of CPPD disease are short, rhomboid, dim, and positively birefringent

(yellow when perpendicular with the polarizer). In both gout and pseudogout, joint fluid is inflammatory, often with  $10$  to  $50 \times 10^3$  WBC/mm<sup>3</sup> fluid. Concurrent septic arthritis should be excluded by Gram stain and culture of fluid, especially if the fluid WBC is  $>100 \times 10^3$  WBC/mm<sup>3</sup>. Serum uric acid level has little role in the diagnosis of acute gouty arthritis because uric acid levels during an attack may not represent baseline levels. Chondrocalcinosis may be present on plain film of a patient with pseudogout but may be found in asymptomatic patients as well.

Acute gout or pseudogout arthritis may be managed with NSAIDs, corticosteroids, or oral colchicine. NSAIDs are effective and safe in patients without coagulopathy, renal insufficiency, or peptic ulcer disease. Corticosteroids may be administered systemically in low doses (prednisone 20 mg per day or less) or by intraarticular injection. Both are effective, although the former is more appropriate for polyarticular attacks. Oral colchicine is less effective than the others and plays a more important role in prophylaxis against gout attacks or aborting an impending attack if taken at the first sign of symptoms. It is no longer appropriate to “dose to diarrhea.” It should be dose adjusted for renal insufficiency and may cause bone marrow suppression, or liver toxicity, or even death if taken in excessive amounts. Intravenous colchicine should never be used because of its toxicity profile including cardiac arrhythmias. Hyperuricemia is a risk factor for gout. The serum uric acid may be lowered by antihyperuricemic therapies including allopurinol, febuxostat, or probenecid, lesinurad, and pegloticase. These antihyperuricemic therapies (allopurinol, febuxostat, lesinurad, probenecid, and pegloticase) are typically reserved for individuals with erosive gouty arthritis, uric acid nephropathy, uric acid nephrolithiasis, tophaceous gout, or frequent gouty attacks. They should not be initiated or adjusted during an episode of gouty arthritis. Rather, they are added several weeks after the attack, with appropriate prophylactic measures from colchicine, NSAIDs, or low-dose steroids. Allopurinol and febuxostat, both xanthine oxidase inhibitors, are excreted via the kidneys. Both agents can cause bone marrow suppression and hepatotoxicity, whereas allopurinol is associated with a severe hypersensitivity reaction that can be life threatening if not identified. Both agents potentiate the effect of azathioprine or 6-mercaptopurine, so these combinations should be used with great caution. Probenecid and lesinurad are uricosuric drugs that are generally ineffective in patients with any degree of moderate renal insufficiency (creatinine  $>2.0$  mg/dL). Pegloticase is a recombinant uricase enzyme coupled to polyethylene glycol. Although highly effective at lowering uric acid, it is associated with a very high risk of anaphylaxis during drug infusion. With any antihyperuricemic agents, the goal serum uric acid is at least  $<6$  mg/dL, or  $<5$  mg/dL if tophi are present.

### Infectious Arthritis

Infectious arthritis should top the list of concerns in any patient with an acute monoarthritis. Bacterial septic arthritis is a rheumatologic emergency. Arthrocentesis is

mandatory if septic arthritis is suspected. Risk factors are similar to those for endocarditis, including intravenous drug use, immunosuppression, breakdown of mucocutaneous barriers, and high-risk sexual activity. People with prosthetic joints and those affected by other inflammatory processes (e.g., RA) are also at risk. Although any joint may be involved, large joints are more commonly affected than small joints. Common bacterial pathogens include *Staphylococcus aureus*, *Streptococcus* species, and *Neisseria* species. In these cases, synovial fluid WBC is often very high ( $>50 \times 10^3$  WBC/mm<sup>3</sup>) with  $>95\%$  polymorphonuclear leukocytes. Synovial fluid Gram stain may show organisms, and fluid culture is diagnostic. *Neisseria* species require chocolate agar for growth. Cultures may be negative in patients who have received antecedent antibiotics. It is prudent to seek a bacterial source because septic arthritis is most commonly the result of hematogenous seeding of a joint. Septic arthritis is treated with joint aspiration, intravenous antibiotics, and often surgical arthrotomy. Infection of a prosthetic joint is particularly problematic and typically warrants removal of hardware and prolonged antibiotics.

Spirochetes, mycobacteria, fungi, and parasites may cause a more chronic septic arthritis. For example, the typical presentation of Lyme arthritis (from *Borrelia burgdorferi*) is that of a chronic monoarthritis with swelling out of proportion to pain. Lyme arthritis tends to affect the knee or other large joints. It is a manifestation of chronic Lyme disease occurring months after the offending tick bite. Diagnosis is based on clinical presentation and the presence of positive Lyme serology by ELISA and Western blot. One month of oral doxycycline is the first-line treatment for Lyme arthritis. Intravenous ceftriaxone may be used in treatment-refractory cases. A postinfectious Lyme arthritis may also develop and is treated with DMARDs such as hydroxychloroquine or methotrexate, or even biological therapies. In cases of undiagnosed chronic monoarthritis, synovial tissue biopsy is indicated to assess for mycobacteria, fungi, and parasites.

Polyarthritis is a less-common presentation of bacterial septic arthritis, although it is not unusual in the case of viral arthritis. Hepatitis B virus, HCV, human immunodeficiency virus, parvovirus B19, and rubella virus (and vaccine) are associated with a true inflammatory polyarthritis, whereas many other viruses may cause polyarthralgias without overt arthritis. Septic polyarthritis from bacterial sources may occur but is much less common. It is associated with a poor outcome because it reflects a high degree of bacteremia.

## Noninflammatory Rheumatic Disorders

### Osteoarthritis

Osteoarthritis (OA) is by far the most common cause of arthritis in the United States. It results from abnormal local mechanical forces that cause joint degeneration and cartilage injury over time. Risk factors for OA include age, obesity, family history, repetitive trauma, internal joint

derangement, and prior inflammatory arthritis (e.g., RA, SPA, septic arthritis). OA is a chronic arthritis that typically affects the knees, hips, spine, thumbs, proximal interphalangeal joints, and distal interphalangeal joints of older individuals. OA in younger individuals or OA affecting the wrists, elbows, shoulders, or ankles is uncommon. Such involvement may indicate secondary OA as a result of unrecognized internal joint derangement, inflammatory arthritis, congenital abnormality, avascular necrosis, chondrocalcinosis, hemochromatosis, or ochronosis from alkaptonuria.

Nonsurgical treatment options in OA are limited. Physical therapy, weight reduction, lifestyle changes, NSAIDs, and corticosteroid injections may be helpful interventions. Opiate analgesics should be used sparingly. Nutraceuticals such as glucosamine have no proven benefit. Prosthetic joint placement may be necessary in patients with debilitating pain that impacts function.

### Regional Musculoskeletal Disorders

Soft tissue complaints account for a substantial percentage of doctor's office visits. Unlike inflammatory arthritis, morning stiffness is short lived, and symptoms tend to be exacerbated by activity. Examination should include the involved region as well as proximal and distal structures. Processes such as tendinitis and bursitis tend to improve with ice, topical analgesics, NSAIDs, rest, or splinting. Physical or occupational therapy is an important adjunct. Corticosteroid injections usually provide only temporary relief even in refractory cases.

Common soft tissue syndromes of the proximal upper extremity include subacromial bursitis, impingement of the supraspinatus tendon, biceps tendinitis, rotator cuff tear, or cervical spine pathology. Injection of lidocaine into the shoulder should allow a patient to overcome any functional deficit if the symptoms are related to subacromial bursitis or supraspinatus tendon impingement but not rotator cuff tear. Patients with soft tissue shoulder syndromes benefit greatly from physical therapy. It is crucial not to splint the shoulder excessively or else risk adhesive capsulitis (frozen shoulder).

Common soft tissue syndromes of the distal upper extremity include lateral epicondylitis (tennis elbow), medial epicondylitis (golfer's elbow), and carpal tunnel syndrome (CTS). Despite their names, these conditions all represent overuse syndromes arising from the wrist. Epicondylitis is exacerbated by isometric resistance against the wrist. CTS presents as paresthesias in the distribution of the median nerve and is provoked by a Phalen or Tinel test. Wrist splints are an appropriate first-line treatment of these disorders. Bilateral CTS in a patient with no history of overuse may be the first sign of an inflammatory tenosynovitis as can occur in RA or other fluid-retentive disorders such as pregnancy or hypothyroidism.

Common soft tissue syndromes of the proximal lower extremity include trochanteric bursitis and iliotibial band syndrome. In trochanteric bursitis, patients complain of focal pain over the lateral trochanteric bursa that is worse

when sleeping on that side or when directly palpated. It often reflects poor back mechanics and responds to back physical therapy. Iliotibial band syndrome is an overuse syndrome that affects the lateral thigh and knee in avid runners and cyclists. NSAIDs, ice, stretching, and modification of activities may provide relief.

Common soft tissue syndromes of the distal lower extremity include anserine bursitis, tarsal tunnel syndrome, and plantar fasciitis. Patients with anserine bursitis experience pain at the medial soft tissue just distal to the knee. It likely reflects poor foot mechanics and may respond favorably to orthotics. Tarsal tunnel syndrome is analogous to CTS and results from impingement of the posterior tibial nerve. Plantar fasciitis causes plantar pain on first awakening and with excessive activity. Stretching and supportive footwear are helpful.

### Fibromyalgia

Fibromyalgia is a noninflammatory disorder in which patients experience chronic musculoskeletal myofascial pain without an identifiable musculoskeletal source. Research advances support the notion that fibromyalgia represents one of many chronic centralized dysfunctional pain amplification disorders that may arise from a low pain threshold in the brain CNS. Associated conditions include chronic lumbago, irritable bowel syndrome, seasonal affective disorder, chronic fatigue syndrome, interstitial cystitis, and noncardiac chest pain. Patients are often deconditioned, overweight, and have a coexisting mood disorder. Pain and fatigue are dominant symptoms of fibromyalgia. Physical examination may evoke exaggerated pain responses to minor pressure (trigger tender points) along the soft tissue of the upper thorax, low back, and proximal extremities. Extensive workup with laboratory and imaging studies is unrevealing and often unwarranted. Immunosuppressive agents are of no benefit, and opiate analgesics should be avoided. Neurotransmitter-directed therapy is beneficial. Pharmacotherapies are directed at neurotransmitter

signaling, and effective agents include gabapentin, pregabalin, and serotonin norepinephrine reuptake inhibitors (e.g., milnacipran and duloxetine), as well as tricyclic antidepressants. Nonpharmacologic lifestyle modifications are a critically important aspect of fibromyalgia treatment and should be recommended to most patients: physical fitness, physiotherapy, proper sleep health, diet, and weight loss. Some patients benefit from cognitive behavioral therapy, biofeedback, massage therapy, acupuncture, or correction of obstructive sleep apnea. Finally, one cannot overstate the importance of reassuring patients with fibromyalgia, who often are concerned that they have an undiagnosed malignant disorder or systemic inflammatory rheumatic condition as an explanation of their chronic myofascial pain.

### Summary

Musculoskeletal symptoms are a common cause for patients to seek medical attention. It is important for the treating physician to determine if a patient's complaints are related to an inflammatory or noninflammatory disorder. Medical history, physical examination, and some simple laboratory tests provide the best means to make this distinction. Inflammatory conditions are associated with acute or subacute symptoms, morning stiffness, and joints that are red, warm, and swollen. Inflammatory markers such as ESR and CRP are often elevated. Arthrocentesis is a safe and effective means to determine if a joint effusion is inflammatory, and it facilitates the diagnosis of microcrystalline or septic arthritis. Immunosuppressive therapy is often warranted for noninfectious, inflammatory rheumatic conditions such as connective tissue disease, vasculitis, and microcrystalline disease. Immunosuppression is generally ineffective for noninflammatory disorders, which are more responsive to NSAIDs, physical therapy, and lifestyle modifications.

# 31

## Asthma

CHRISTOPHER H. FANTA

The key clinical features of asthma are reversible airflow obstruction, persistent bronchial hyperresponsiveness (often referred to as *twitchy airways*), and a characteristic pattern of chronic airway inflammation. In 2007 the Expert Panel 3 of the National Asthma Education and Prevention Program offered the following definition of asthma: “a common chronic disorder of the airways that is complex and characterized by variable and recurring symptoms, airflow obstruction, bronchial hyperresponsiveness, and an underlying inflammation. The interaction of these features of asthma determines the clinical manifestations and severity of asthma and the response to treatment.”

### Epidemiology

The prevalence of asthma has risen dramatically in recent decades. The estimated prevalence of active asthma in the United States increased from 3.1% in 1980 to 5.5% in 1996 to approximately 8% currently. At present, around 25 million persons in the United States have asthma, including 7 million children under age 18.

The potential cause(s) of this rise in the prevalence of asthma (and other allergic diseases) remains speculative. It has occurred most strikingly in industrialized and westernized parts of the world. A seminal study that found the prevalence of asthma in the reunified Germany to be less in the former East Germany than the former West Germany weighs heavily against increasing levels of air pollution as the crucial factor. Other theories have invoked increased indoor allergen exposures, decreased exposure to endotoxin and other farm-based immunogenic stimulants, and decreasing levels of vitamin D in our increasingly indoor population.

Death caused by asthma is uncommon and has decreased in the United States in recent years to approximately 3400 deaths per year. However, morbidity remains high, and the burden of disease in terms of both morbidity and mortality is inequitably distributed across ethnic and racial groups. African-American and Hispanic minorities have two to three times the frequency of urgent care visits, hospitalizations, and deaths compared with non-Hispanic whites. This

discrepancy likely reflects both increased disease severity and poorer asthma care and tracks closely with lower socioeconomic status. For unknown reasons, asthma is more common in boys than girls before puberty and then more common in women than men in adulthood.

### Assessment and Management of Asthma

Modern management of the asthmatic patient in the ambulatory setting has come to focus on the concept of asthma control. The goal of treatment is to achieve well-controlled asthma while minimizing medication side effects and preventing as much as possible severe asthmatic attacks. In this chapter, we first define good asthma control and then outline a five-point plan describing how to achieve this goal.

### Defining Good Asthma Control

Well-controlled asthma, as defined by the Expert Panel 3 of the National Asthma Education and Prevention Program, has two aspects, or “domains.” One aspect relates to ongoing asthmatic symptoms, which can be ascertained with a few simple questions:

- Do you have symptoms of your asthma requiring treatment with your quick-relief bronchodilator more than 2 days per week?
- Do you wake with asthmatic symptoms more than twice per month?
- Does asthma interfere with your ability to exercise, limiting your usual physical activities?

Validated, easy-to-administer questionnaires, such as the Asthma Control Test and the Asthma Control Questionnaire, are available to score and track asthma symptoms relevant to asthma control.

In addition, measurement of lung function (peak flow or spirometry) should be added to reported symptoms in judging asthma control in this domain of “current impairment.” A peak expiratory flow or one-second forced expiratory volume (FEV<sub>1</sub>) within the normal range (greater than 80% of predicted normal or of measured personal best) is consistent with well-controlled asthma.

The other domain of asthma control relates to the risk of a serious asthmatic attack, based on the frequency of asthmatic attacks within the preceding year:

- Have you had more than one asthmatic attack requiring oral corticosteroids within the past year?

If the answer to any of these four questions is “yes” and/or lung function is less than 80% of baseline, then the patient’s asthma is not well controlled, and asthma care should be intensified, or “stepped up.” If the answer to these questions is uniformly “no” and lung function is within the normal range, then the goal of good asthma control has been achieved, and treatment can be continued unchanged or perhaps even reduced (“stepped down”).

This approach to the assessment of asthma (based on the concept of control rather than severity) mirrors that used in other chronic diseases such as hypertension. Treatment is adjusted to achieve certain targets or goals of care. The previously recommended model, using categories of severity to make treatment recommendations (intermittent, mild persistent, moderate persistent, and severe persistent), can still be used in patients with newly diagnosed asthma or in patients being treated only with a quick-relief bronchodilator taken as needed. However, these categories of severity have proved inadequate when used to assess patients already taking regular controller medication for their asthma.

Asthma management changes over time as asthma control varies and exposures change. This necessitates periodic patient reassessment. For example, a patient’s treatment may need to be stepped up in the winter months when his or her home is closed up and the forced hot-air heating is turned on (leading to increased exposure to dust mite antigen), or it may be possible to step down care when a new owner is found for the pet cat and the home is thoroughly cleaned of cat antigen.

## Achieving Good Asthma Control

The five steps to achieving good asthma control as discussed in this chapter are to (1) make the correct diagnosis, (2) reduce environmental inciters of asthma, (3) treat with appropriate medications, (4) help patients prepare for asthmatic attacks, and (5) consult with a specialist when needed.

## Making the Correct Diagnosis

For most adults with asthma, diagnosis simply involves review of a highly typical history dating back to childhood. Most patients with asthma are diagnosed before 7 years of age (Fig. 31.1). However, occasionally patients may be misdiagnosed in childhood, and asthma may have its onset in adulthood. Physicians are often confronted with adult patients whose symptoms raise the possibility of the new-onset asthma or who already have been given a quick-acting bronchodilator for symptoms that may or may not be caused by asthma. Obviously, the approach to the patient

• **Fig. 31.1** Age of onset of asthma. Most asthma begins in early childhood. This figure depicts the incidence of asthma among the general population in Rochester, Minnesota, in the 1980s. *Blue bars*, female; *brown bars*, male. (Modified from Yunginger JW, Reed CE, O’Connell EJ, et al. A community-based study of the epidemiology of asthma, 1964–1983. *Am Rev Respir Dis.* 1992;146:888-894.)

whose cough, shortness of breath, and wheezing are caused by chronic obstructive pulmonary disease (COPD), recurrent infectious bronchitis, or diastolic dysfunction with intermittent congestive heart failure will be different from the stepped-care approach to asthma described subsequently. In a published study of randomly selected adults who had recently (within the preceding 5 years) received a diagnosis of asthma by their community medical providers, approximately one-third were deemed not to have asthma after meticulous review of their histories and extensive additional testing.

Historical features that point to a diagnosis of asthma include the intermittent nature of symptoms, characteristic triggers, and a favorable response to appropriate therapy. The following points bear emphasis. First, the exercise-induced bronchoconstriction of asthma characteristically occurs immediately *after* a short period (e.g., 5 minutes) of exercise and is characteristically worse if the air breathed during exercise is cold. Dyspnea on exertion, such as breathlessness climbing stairs or walking up an incline, should be distinguished from the postexercise bronchoconstriction of asthma. Second, allergic triggers are unique to atopic asthma. For example, the patient who develops cough, wheezing, and chest tightness on exposure to cats almost surely has asthma. However, other triggers of asthmatic symptoms are nonspecific (e.g., exposure to smoke or strong fumes) and may be precipitants of symptoms in a variety of other respiratory diseases as well.

Third, for most patients with asthma, inhaled quick-acting bronchodilators bring rapid and effective relief of symptoms, if perhaps only temporarily, and typically a course of oral corticosteroids is dramatically successful in restoring normal breathing. Patients who report that they have tried these interventions in the past but found little benefit frequently will be found not to have asthma.

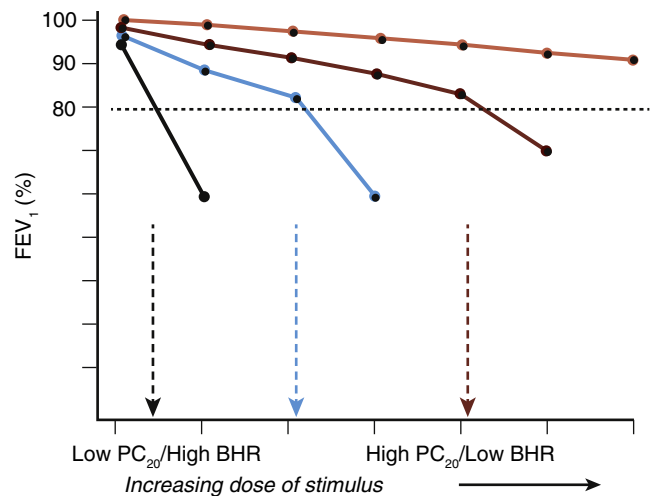

The characteristic diffuse, musical wheezing of asthma, prominent on exhalation, is familiar to most clinicians.

It is worth remembering, however, that not all wheezing sounds are caused by asthma. The single-toned, end-expiratory wheezing of COPD, repeated with little change at the end of each exhalation following deep breaths, can readily be distinguished from asthma. So, too, a unilateral or focal wheeze raises the possibility of localized endobronchial obstruction (e.g., by a bronchial neoplasm or aspirated foreign body) and is atypical of asthma. Likewise, the low-pitched wheezing of retained airway secretions, often associated with palpable vibration of the chest wall (tactile fremitus) and referred to as *rhonchi*, may indicate alternative diagnoses, such as bronchiectasis or aspiration. This physical finding is less likely to suggest a diagnosis of asthma.

If after history and physical examination the diagnosis of asthma remains in doubt, confirmation (or exclusion) of the diagnosis is established by pulmonary function testing. Asthma is defined in terms of variable airflow obstruction, observed either on measurements made at multiple points over time or in response to bronchodilator administration. Although peak flow measurements are useful for screening purposes (e.g., in assessing for workplace-induced symptoms of occupational asthma) and for monitoring established asthma, the best test for identifying and quantifying expiratory airflow obstruction is spirometry. A reduced FEV<sub>1</sub> to forced vital capacity ratio (indicative of airflow obstruction) and a reduced FEV<sub>1</sub> that increases by more than 12% (and by at least 200 mL) following bronchodilator (indicative of reversible airflow obstruction) is typical of asthma. The larger the increase in FEV<sub>1</sub> (e.g., >15%–20% increase following bronchodilator), the more likely the diagnosis of asthma and less likely the diagnosis of other obstructive lung diseases. A patient whose FEV<sub>1</sub> or peak expiratory flow (PEF) is consistently normal even when measurements are made during active respiratory symptoms probably does not have asthma.

In fully equipped pulmonary function testing laboratories, methacholine bronchoprovocation testing can be performed to evaluate for inducible bronchoconstriction in patients suspected of asthma whose lung function is repeatedly normal at the time of testing. Inhaled methacholine is administered in incremental doses, and spirometry is repeated after each dose. A fall in FEV<sub>1</sub> in response to inhaled methacholine of at least 20% from baseline is found in nearly all patients with asthma; a fall in FEV<sub>1</sub> of  $\geq 20\%$  in response to a low provocative concentration of methacholine (PC<sub>20</sub>  $\leq 8$  mg/mL) is relatively specific for asthma and uncommon in other obstructive lung diseases. Most helpful, failure to demonstrate bronchial hyperresponsiveness (FEV<sub>1</sub> does not fall to less than 80% of the baseline value even at the highest concentration of methacholine administered) excludes a diagnosis of asthma with at least 95% certainty (Fig. 31.2).

The search continues for a reliable biomarker to assist in the diagnosis of asthma. To date, measurement of the concentration of nitric oxide (NO) in the exhaled breath has proved to be the most useful indicator of asthmatic airway

• **Fig. 31.2** Bronchial hyperresponsiveness (BHR) in asthma. Lung function as the 1-second forced expiratory volume (FEV<sub>1</sub>) is expressed on the ordinate as the percentage of normal. Normal bronchial responsiveness is shown as the top line; the FEV<sub>1</sub> did not fall by >20% from baseline in response to the highest dose of the provocative agent (such as methacholine). Three examples of bronchial hyperresponsiveness are shown, consistent with three patients with asthma. They differ in the degree of their bronchial hyperresponsiveness. The patient whose FEV<sub>1</sub> falls to <20% below baseline in response to the smallest dose of provocative stimulus (line farthest to the left) has the most bronchial hyperresponsiveness, quantified by calculation of the provocative concentration of stimulus causing a 20% fall in FEV<sub>1</sub> (PC<sub>20</sub>).

inflammation. Commercially available devices can accurately record the concentration of exhaled NO in parts per billion (ppb) during a sustained exhalation at a steady expiratory flow. Among patients not taking antiinflammatory medications (particularly inhaled steroids), values of <25 ppb argue against a diagnosis of asthma, whereas values >50 ppb are suggestive of asthma even in the absence of airflow obstruction at the time of the measurement.

## Reducing Environmental Triggers of Asthma

Some of the triggers of asthma, such as exercise, cause only transient bronchoconstriction. Others, however, cause both airway smooth muscle constriction and increased airway inflammation. Examples include allergen exposure (in the sensitized atopic patient), viral respiratory tract infections, and noxious chemicals such as ozone or cigarette smoke. The resulting increase in airway inflammation is associated with heightened bronchial responsiveness that, even after a single exposure, may last for days. Therefore in the atopic patient, allergen exposure can precipitate not only an asthmatic attack but also worsened asthma in general.

In support of this hypothesis is the observation from the Cooperative Inner-City Asthma Study that among children living in poverty in inner-city communities, those with allergic sensitivities (demonstrated by positive allergy skin

tests) and intense allergic exposures in the home environment (quantified by measuring antigen levels in dust vacuumed from the children's bedrooms) had more asthmatic symptoms and need for urgent asthma care than children without the combination of allergic sensitivity and high levels of allergen exposure. In this study, the most common offending allergen was cockroach antigen, but the principle confirmed by this study applies to all the aeroallergens to which asthmatic patients may be sensitive.

Achieving good asthma control therefore begins with asking your patient about allergic (or noxious) exposures in the home or workplace, including cigarette smoking. The common allergens important in stimulating asthmatic inflammation are relatively few, leading to a short list of questions: Do you have a pet cat or dog or other furry animal (or bird)? Does your home have mold, particularly in a damp basement or bathroom? Do you have cockroaches, rats, or mice infesting your home? Does your asthma worsen when you dust or vacuum at home? Is there a large seasonal variation to your asthma, particularly with worsening in the spring (tree pollens), summer (grass pollens), or fall (weed pollens)?

With some patients, you (or they) may suspect an allergic component but be uncertain based solely on their prior experiences. In this circumstance, further testing is indicated and may include skin or blood testing for allergic sensitivities. The latter uses an immunoassay to measure the amount of circulating immunoglobulin E (IgE) to specific allergens (the assay was previously performed using a radioallergosorbent technique and is still commonly referred to as *RAST testing*). For instance, you can order measurement in the serum of the circulating IgE specific to cat dander, dog dander, dust mite, cockroach, and common molds (e.g., *Aspergillus* and *Alternaria*). Positive test results combined with a consistent history point to a role for allergic exposure in worsening asthma control.

Evidence in support of the concept that reducing environmental allergen exposures can lead to improved asthma control comes from a randomized controlled trial performed by the Inner-City Asthma Study Group. These investigators conducted this study among children with asthma living in impoverished households in several inner-city communities across the United States. In one group, an intervention team helped families reduce allergen exposure in their homes; in the other group, general encouragement to do so was offered, without equipment or educational reinforcement to help achieve those ends. Although asthma symptoms lessened in both groups, presumably as a result of their participation in a formal research study, over the first year the intervention group had significantly greater improvement (fewer days with active asthma symptoms) than the control group. The interventions were conducted and reinforced over 1 year; of interest, the greater improvement in the intervention group was sustained for the entire 2 years of follow-up observations.

The interventions to reduce allergen exposures in these homes included the following: vacuum cleaners equipped with high-efficiency particulate air (HEPA) filters; stand-alone room HEPA filters for children with pets or mold allergy; cockroach and other pest extermination; and dust-mite allergen-impermeable covers for the children's mattress and pillow. Cigarette smokers were encouraged to quit smoking or not to smoke cigarettes indoors. A reasonable supposition is that if environmental control measures can help improve asthma control in these inner-city environments among families with low socioeconomic means and limited educational resources, they will likely be at least equally effective among patients with greater opportunities for their successful implementation.

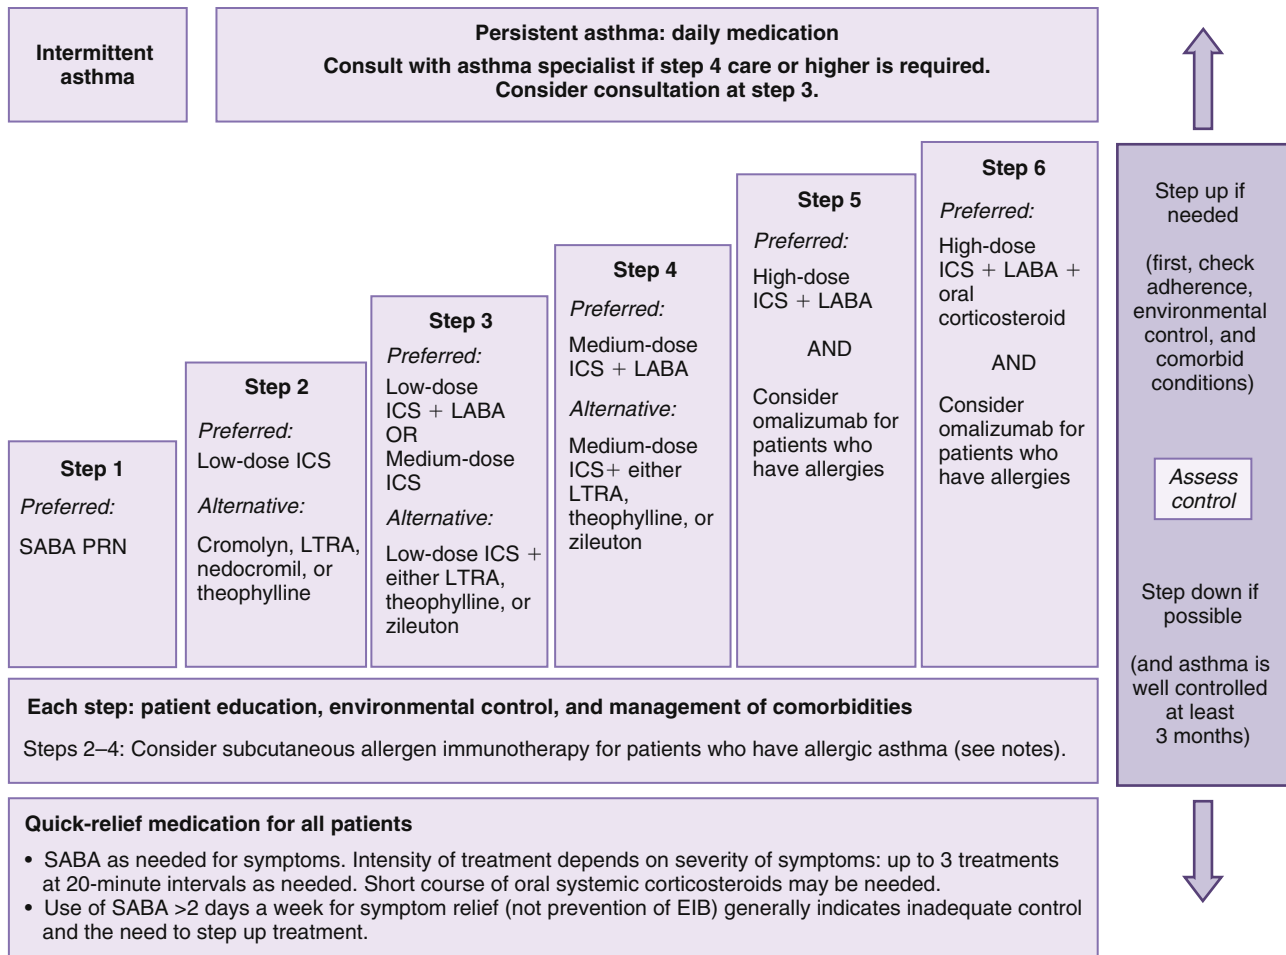

## Treating With Appropriate Medications

The medications used to treat asthma are categorized as either quick relievers or controllers. In the former category are the short-acting inhaled beta-agonist bronchodilators with a quick onset of action; in the latter category are inhaled corticosteroids, leukotriene-modifying drugs, long-acting inhaled beta-agonist and muscarinic-antagonist bronchodilators, and, most recently, the biological therapies targeting IgE or interleukin-5 (IL-5), the latter a potent chemoattractant and stimulant for eosinophils. Theophylline and inhaled chromones (e.g., cromolyn and nedocromil) have little role in modern asthma management and are not discussed in any detail in this review.

It has been an adage of asthma care for many years that the medications used to treat asthma should be individually tailored according to the severity of each patient's asthma. As discussed earlier, the Guidelines for the Diagnosis and Management of Asthma released by the Expert Panel 3 in 2007 confirm this recommendation but refocus our thinking to consider the adequacy of asthma control in adjusting medications (i.e., consider the activity of recent asthmatic symptoms, level of lung function, and the risk of a future asthmatic attack while at the same time minimizing medication side effects). These guidelines recommend that treatment be escalated along a six-step sequence until good asthma control is achieved (Fig. 31.3).

Step 1 is the recommended treatment for patients with intermittent asthma (symptoms necessitating quick-relief bronchodilator no more often than 2 days per week; nocturnal awakenings caused by asthma no more often than 2 days per month; lung function within the normal range; and no more than one attack of asthma within the past year requiring a course of oral steroids). The previously used term *mild intermittent asthma* has been modified to *intermittent asthma* to emphasize the point that even patients with intermittent asthma can suffer severe and life-endangering asthmatic attacks.

The treatment recommended at Step 1 of asthma care is an inhaled quick-acting beta-agonist bronchodilator used as needed for relief of symptoms. It is also helpful to remind (or inform) patients that they can take their quick-acting

• **Fig. 31.3** Step-care approach to achieving asthma control. This chart displays a step-care approach to achieving asthma control in children >12 years old and in adults. EIB, Exercise-induced bronchoconstriction; ICS, inhaled corticosteroid; LABA, long-acting beta agonist; LTRA, leukotriene receptor antagonist; SABA, short-acting beta agonist. (From Expert Panel 3 of the National Asthma Education and Prevention Program, [www.nhlbi.nih.gov/guidelines/asthma](http://www.nhlbi.nih.gov/guidelines/asthma).)

bronchodilator 10 to 15 minutes before physical exertion to prevent exercise-induced bronchoconstriction. The quick-acting beta-agonists of short duration of action (4–6 hours) are albuterol and levalbuterol. Levalbuterol contains a single (dextrorotatory) stereoisomer from the racemic mixture that is albuterol; at half the dose (45 µg/puff), it has the same activity and side effect profile as albuterol. Albuterol is now available in a dry-powder formulation (not used with a spacer, not requiring shaking or priming of the device before use) as well as a metered-dose inhaler.

Step 2 involves a major transition in asthma care, from intermittent to daily medication use. Patients with mild persistent asthma have asthma that is not well controlled with intermittent use of an inhaled short-acting beta-agonist bronchodilator. Within the preceding month, they have had daytime symptoms of their asthma more often than 2 days per week (but less often than daily, a feature of moderate persistent asthma); they have had nocturnal awakenings because of asthmatic symptoms more than twice per month (but fewer than five times per month); or within the past year they have had more than one attack of asthma requiring a course of oral

steroids. They have an FEV<sub>1</sub> or PEF that is still within the normal range (≥80% of predicted). It is recommended that these patients begin daily controller therapy for their asthma.

The preferred daily controller medication is an inhaled corticosteroid in low doses. Available preparations of inhaled steroids are listed in Table 31.1. Regular use of inhaled corticosteroids has been shown to improve lung function, reduce asthmatic symptoms and increase the number of symptom-free days, improve quality-of-life scores on asthma-related health questionnaires, and reduce the risk of asthmatic attacks. There are only subtle differences among the various inhaled steroids. Some are delivered from metered-dose inhalers, others from dry-powder inhalers. Some are approved for once-daily dosing, the rest are given twice daily. They vary in the particle size contained within the medication plume, potentially impacting medication delivery to small, peripheral airways; and there are some differences in intrinsic steroid potency. Budesonide has the most favorable rating in pregnancy (category B) from the US Food and Drug Administration (FDA). In general, however, efficacy and side-effect profiles are similar

**TABLE 31.1 Available Inhaled Corticosteroids**

Inhaled Steroid Preparations	µg/Puff (or Vial)
Beclomethasone MDI-HFA (Qvar)	40, 80
Budesonide DPI (Pulmicort Flexhaler)	90, 180
Budesonide solution for nebulization	250, 500, 1000
Ciclesonide MDI-HFA (Alvesco)	80, 160
Flunisolide MDI-HFA (Aerospan)	80
Fluticasone propionate MDI-HFA (Flovent)	44, 110, 220
Fluticasone propionate DPI (Flovent Diskus)	50, 100, 250
Fluticasone furoate DPI (Arnuity Ellipta)	100, 200
Mometasone MDI-HFA (Asmanex)	100, 200
Mometasone DPI (Asmanex Twisthaler)	110, 220

This table provides a list of available inhaled steroid preparations, including delivery system and dosing strengths (micrograms/puff of medication).  
*DPI*, Dry-powder inhaler; *HFA*, hydrofluoroalkane; *MDI*, metered-dose inhaler.

among the different steroid preparations. The most common side effects from low-dose inhaled steroids are oral candidiasis and dysphonia.

Recent clinical trials have tested other options for the management of mild persistent asthma. One important study found that a strategy for periodic steroid use during the time of asthmatic symptoms (10 days of high-dose inhaled steroids or 5 days of oral steroids if symptoms worsened) led to no more frequent or severe asthmatic attacks in this select patient population than daily inhaled steroids. The latter strategy (daily inhaled steroids) was associated with a better asthma control score and more symptom-free days (estimated to be on average 26 more symptom-free days per year) than those using their inhaled steroids episodically. To date, the recommendations of national and international expert panels remain daily administration of controller medication for Step 2 of asthma care.

An alternative treatment option for those reluctant to begin an inhaled steroid is a leukotriene receptor antagonist, montelukast (Singulair) or zafirlukast (Accolate). The appeal of these medications includes the convenience of their oral administration as tablets once (montelukast) or twice (zafirlukast) daily and their relative freedom from side effects (occasional mood alteration and depression have been described). Leukotriene receptor antagonists are effective in blunting exercise-induced bronchoconstriction without development of tolerance, and they help to control symptoms of allergic rhinitis. For some patients they prove highly effective in achieving asthma control, but for others they are indistinguishable from placebo. At the present time,

a therapeutic trial of 2 to 4 weeks is necessary to determine their utility. Overall, they are less effective than inhaled steroids and so are considered a second-line option for asthma that is not well controlled with an inhaled short-acting beta-agonist bronchodilator alone.

Leukotriene-modifying drugs deserve special attention in patients with asthma and aspirin sensitivity. Such patients, if they ingest aspirin or any nonsteroidal anti-inflammatory drug (any inhibitor of cyclooxygenase-1), develop symptoms of asthma within 30 to 90 minutes, often provoking a severe asthmatic attack that may be accompanied by nasal congestion and gastrointestinal upset. This subset of asthmatic patients, perhaps constituting 3% to 5% of adults with asthma, has a biochemical abnormality of arachidonic acid metabolism leading to underproduction of certain prostaglandins and overproduction of leukotrienes. Inhibition of leukotrienes with a leukotriene receptor antagonist or with the lipoxygenase inhibitor, zileuton (Zyflo), makes particular sense in this group of patients and warrants a therapeutic trial. Zileuton is available in an extended-release tablet formulation for twice-daily dosing; a small incidence of drug-induced hepatic inflammation (2% to 4%) caused by zileuton necessitates initial close monitoring of liver function when beginning therapy with this drug.

Step 3 applies to the patient whose asthma is not well controlled despite regular use of a low-dose, inhaled corticosteroid. Review of the patient's technique using the inhaled medication is always appropriate to ensure adequate delivery of medication to the airways. Use of a valved holding chamber (spacer) with metered-dose inhalers can increase deposition of medication onto the airways and minimize oropharyngeal deposition. Less oropharyngeal deposition reduces the risk of oral candidiasis (thrush) and makes less steroid medication available to be swallowed and systemically absorbed.

There is controversy surrounding the choice of treatment for patients whose asthma is inadequately controlled despite Step 2 treatment, patients with moderate persistent asthma. Two options are given equal weight in the most recent set of expert guidelines: increase the dose of inhaled steroids to moderate doses (e.g., beclomethasone, 80 µg/puff, two puffs twice daily; fluticasone, 110 µg/puff, two puffs twice daily; budesonide, 180 µg/puff, one puff twice daily; or mometasone, 220 µg/puff, one puff twice daily) or continue low-dose inhaled steroid and add an inhaled long-acting beta-agonist (LABA) bronchodilator. The LABAs, formoterol (Foradil) and salmeterol (Serevent), are available in a single inhaler combined with an inhaled steroid: combination formoterol and budesonide (Symbicort), combination formoterol and mometasone (Dulera), and combination salmeterol and fluticasone (Advair). The first two are made available as a metered-dose inhaler in two different strengths (differing in the dose of inhaled steroid); the last is made available as a dry-powder inhaler or metered-dose inhaler in three different strengths (differing in the dose of fluticasone). Newly approved for asthma is the combination

of an ultralong-acting beta-agonist (vilanterol) and inhaled steroid (fluticasone furoate) administered once daily via dry-powder inhaler (Breo), with two different strengths of the steroid component available.

In terms of optimizing asthma control, the combination of low-dose inhaled steroid plus LABA proves to be the more effective strategy of these two options. The controversy enters because of questions regarding the safety of LABAs. In a large-scale 6-month-long trial of salmeterol combined with usual therapy versus placebo plus usual therapy, more deaths and near-deaths caused by asthma occurred in the group of patients randomly assigned to receive salmeterol. The explanation for this startling finding was uncertain. The majority of patients in both treatment groups were not taking an inhaled steroid as part of their asthma therapy. It is possible that adding a LABA to other bronchodilator therapies provided temporary symptomatic relief while airway inflammation and mucus accumulation went unchecked, leading in some patients to respiratory failure and death caused by asphyxia. However, other explanations for the worse outcomes in the salmeterol-treated group were possible, including genetic differences in beta-agonist receptor response to chronic beta-agonist stimulation and inhibition of the activity of short-acting beta-agonists in a subset of patients treated with LABAs. As a result, the FDA mandated a black-box warning about the risk of death or near-death from asthma to be included in the package inserts of all products containing long-acting inhaled beta-agonists.

Recently, however, the results of large-scale randomized trials have been reported that have addressed the issue of the safety of LABAs when used in combination with an inhaled corticosteroid. These studies have found no increased risk of asthma death or respiratory failure from LABAs combined with an inhaled corticosteroid compared with an inhaled corticosteroid alone. Based on this new information, it is likely that a combination of LABA-inhaled steroids will become preferred therapy for moderate persistent asthma. A leukotriene modifier added to low-dose inhaled steroids provides greater benefit than either agent alone, but this combination is not as effective as an inhaled steroid plus a LABA and so constitutes a second-line option for Step 3 care.

For patients whose asthma remains poorly controlled despite implementation of Step 3 medications, the recommended stepwise escalation of treatment is relatively straightforward. Step 4 calls for moderate doses of an inhaled steroid plus a LABA. Examples of combination therapy are fluticasone/salmeterol by dry-powder inhaler (Advair Diskus) 250/50, one inhalation twice daily, and budesonide/formoterol by metered-dose inhaler (Symbicort) 160/4.5, two puffs twice daily, mometasone/formoterol by metered-dose inhaler (Dulera) 200/5, one puff twice daily, or fluticasone furoate/vilanterol by dry-powder inhaler (Breo) 200/25, one puff once daily. A less-effective alternative is moderate doses of inhaled steroids plus a leukotriene modifier.

Step 5, appropriate for patients with severe persistent asthma, recommends high-dose inhaled steroids plus a LABA (e.g., mometasone/formoterol by metered-dose inhaler [Dulera] 200/5, two puffs twice daily, or Advair Diskus 500/50, one inhalation twice daily), often combined with a leukotriene modifier.

Step 6 suggests the addition of systemic corticosteroids to high-dose combination therapy, using on a chronic basis the lowest possible dose of systemic steroids needed to achieve asthma control. Patients with allergic and/or eosinophilic asthma requiring Step 5 or Step 6 treatment to gain good asthma control are potential candidates for the novel biological therapies, which are discussed later when considering the subject of specialist referral.

A novel option for patients not improving on combination inhaled corticosteroid/LABA medication, and an alternative for patients intolerant of LABAs, is the use of the long-acting muscarinic antagonist bronchodilator, tiotropium (Spiriva). In randomized controlled clinical trials, addition of tiotropium to an inhaled steroid proved equally effective as the addition of a LABA to an inhaled steroid, and added benefit was observed when tiotropium was used in combination with an inhaled steroid/LABA medication. The FDA has approved tiotropium for use in asthma (always with simultaneous use of an inhaled steroid) in the new soft-mist formulation (Spiriva Respimat) at the dose of 1.25 µg/puff, two puffs once daily.

Patients whose asthma remains well controlled for at least 3 months can be considered for stepping down their treatment. Stepping-down care is particularly appropriate when changes in the home or work environment might make one suspect a lessening of asthma severity, such as when your patient quits smoking, finds another home for the pet cat, or relocates to a mold-free apartment. Medication dose reduction can save time and money and decrease unnecessary risk of side effects. This latter is particularly relevant to patients taking high-dose inhaled steroids. At high doses (more than approximately 1000 µg/day of beclomethasone or the equivalent), systemic absorption of inhaled steroids can have consequences for the skin (ecchymoses and thinning), eyes (heightened risk of cataracts and elevated intraocular pressure), and bones (accelerated loss of bone mass). We need to be attentive to the bone health of our patients taking high-dose inhaled steroids, including ensuring adequate calcium and vitamin D intake and periodically monitoring bone density by bone densitometry.

## Helping Patients Prepare for Asthmatic Attacks

Once your patient has achieved good asthma control on the minimum amount of medication necessary, the proper use of the inhaler reviewed, and allergic and irritant exposures reduced as much as possible, your work as treating clinician

is not yet done. An important aspect of the care of the asthmatic patient remains: discussion of the steps the patient should take if his or her asthma were to worsen acutely. “What if,” the discussion might begin, “your asthma were to get worse or you had a full-blown asthma attack? Do you have a plan as to what you can do at home to start getting better again?”

One of the first steps in developing such a plan (an “asthma action plan”) is ensuring that patients are able to identify deterioration of their asthma. When they experience intense wheezing, cough, and dyspnea on light exertion following an obvious allergen exposure, most patients have no difficulty recognizing a severe asthmatic attack. However, at other times, the diagnosis may be more subtle. For instance, in the context of a respiratory tract infection with low-grade fever, productive cough, chest congestion, and shortness of breath, it is easy to ascribe symptoms to a severe chest cold. Patient and clinician alike may wonder how much of this condition is caused by a respiratory infection and how much to asthma.

In this instance (and other similar examples), a peak flow meter can provide useful information. In 1 minute or less, patients can check their expiratory flow and compare it with values recorded when they were feeling well. A peak flow reduced from the usual value by 20% or more indicates an asthmatic exacerbation, and treatment of the respiratory infection alone will be insufficient; the patient needs to have his or her asthmatic attack treated as well.

When tested in randomized clinical trials, asthma action plans based on peak flow measurements have not proven superior to action plans in which interventions are guided by the severity of symptoms alone. However, like having a thermometer at home to assess the degree of temperature elevation during an infection, the information provided by use of a peak flow meter (in the hands of a reliable patient) cannot hurt, and it can be helpful to patient and physician alike. It is worth noting that on detailed investigation into the cause of asthmatic deaths, when asthmatic attacks progressed to the point of hypercapnic respiratory failure and asphyxiation, during the hours and days before death often neither patients nor their families (and sometimes, not their physicians as well) recognized the severity of the asthmatic attack. A peak flow measurement can help avoid this potentially fatal error.

A model widely used to help design an asthma action plan for your patient is based on three zones of severity: the traffic-light model. When patients feel well and have a peak flow  $\geq 80\%$  of their normal, they are said to be in their “green zone.” When they experience increased asthmatic symptoms and have a peak flow between 50% and 80% of their normal, they are in their “yellow zone.” The traffic-light analogy implies “slow down, take action, exhibit caution.” If they have intractable coughing, repeated sleep disturbance caused by asthma, and shortness of breath on light exertion, and if their peak flow is

$<50\%$  of their normal, they are in their “red zone.” The appropriate response is to stop one’s usual activities and take action to get better; this represents a severe asthmatic attack.

The specific guidelines that you offer your particular patient as to how best to respond to a mild-to-moderate asthmatic attack (yellow zone) or severe asthmatic attack (red zone) will depend on the patient’s usual medical regimen for asthma, other medications available to them at home, their experience managing prior asthmatic attacks, and your sense of their self-care capabilities. The following is offered as very broad, general advice; specific asthma action plans need to be tailored to each individual patient.

Patients may need to be reminded that in the setting of an asthmatic attack, they can take their quick-acting inhaled bronchodilator (albuterol or levalbuterol) more often than the usual “up to four times a day” recommendation for routine use. In the setting of a severe attack, they can safely repeat dosing every 20 to 30 minutes and can use four or even six puffs with each dosing. If they are not improving after the first two or three doses, they should make medical contact for further advice. Some patients may substitute nebulized bronchodilator for metered-dose inhaler use in this circumstance. The two methods of delivery provide identical benefit when the metered-dose inhaler is properly used, preferably with an attached valved holding chamber (spacer), and with sufficient dosing. However, in the context of an asthmatic attack, some patients cannot properly coordinate their metered-dose inhaler and will derive additional benefit when drug administration can be achieved with the quiet, tidal breathing of nebulized medication.

During a mild-to-moderate asthmatic attack, patients may be advised to begin an inhaled steroid in high doses. Those already using an inhaled steroid in low doses can increase their dosing 4-fold with potential added benefit.

For patients already taking high-dose inhaled steroids or not improving despite increasing their usual dose of inhaled steroids, or having a severe asthmatic attack (red zone), often oral steroids are needed. Practitioners tend to delay administration of oral steroids because of concern regarding potential serious side effects, but it is the oral steroids that most effectively reverse severe asthmatic attacks and have the greatest likelihood of preventing deterioration, hospitalization, and risk of death. Oral steroids are a routine part of the care of asthma attacks provided in hospital-based emergency rooms, and patients can be advised when to initiate therapy at home. Patients who have experienced previous severe asthmatic attacks may be given a supply of prednisone or methylprednisolone to have available at home and advised to begin 40 to 60 mg in the event of an asthmatic crisis and then call their physician.

Finally, as part of the discussion about asthma action plans, it is worth reminding your patient that self-initiation

of care at home is not meant to substitute for treatment by health care professionals. The bottom line in all asthma action plans should be to get help. If you as the patient are uncertain as to what to do, if your asthma is not improving with the measures that you have begun, or if you are frightened and feel in danger, seek medical help by phone, by medical visit, by emergency room care, or by calling 911, as necessary.

## Consulting With a Specialist

The Expert Panel 3 of the National Asthma Education and Prevention Program has offered the following indications for referral to an asthma specialist, typically either an allergist or a pulmonologist: uncertainty as to the diagnosis; additional testing being needed for assessment of asthma or complicating medical conditions; patients not achieving and maintaining good asthma control and patients requiring Step 4 or higher care; patients who have had a life-threatening asthmatic attack, have required more than two courses of oral corticosteroids in the past year, or who have had an asthmatic attack necessitating hospitalization for their asthma; patients being considered for specialized treatments, such as allergen immunotherapy or biologics; and/or patients requiring extra time spent for education around issues of medication adherence and side effects or allergen avoidance strategies.

Besides more time and expertise focused on this one medical problem, the consultant can offer a systematic approach to the patient with difficult-to-control asthma. Without going into depth about this approach, its elements are elucidated here. They include (1) evaluating in detail for inciters of asthma that may be causing the patient's asthma to be severe; (2) exploring comorbid conditions (e.g., gastroesophageal reflux, rhinosinusitis, aspirin sensitivity, and allergic bronchopulmonary aspergillosis) that may be aggravating or complicating the patient's asthma; (3) emphasizing the importance of medication understanding and adherence and exploring the barriers to compliance; and (4) ensuring that the diagnosis of asthma is correct and not being mimicked by other conditions (e.g., vocal cord dysfunction, tracheomalacia, COPD, bronchiolitis, or bronchiectasis).

Therapies that might be considered by the specialist treating asthma resistant to conventional medications include monoclonal antibodies targeting IgE or IL-5, bronchial thermoplasty, and aspirin desensitization followed by maintenance therapy in the patient with aspirin-sensitive asthma. The monoclonal antibody omalizumab (Xolair) was approved for use in the United States in 2003 for the treatment of severe allergic asthma. It is administered by subcutaneous injection every 2 or 4 weeks (depending on dose). The dose is adjusted according to body weight and level of total serum IgE. Treatment with omalizumab significantly reduces all circulating free IgE antibody regardless of the allergen to which it has been formed. Because the routine assay for IgE measures both free IgE and IgE bound

to omalizumab, it cannot be used to monitor IgE levels once therapy with omalizumab has been begun.

The most consistent beneficial effect of omalizumab has been a reduction in the number and severity of asthmatic attacks. Patients may also be able to reduce their steroid medications, use their quick-relief bronchodilator less frequently, and achieve stable-to-improved lung function. Anaphylactic reactions to omalizumab have been observed with a frequency of approximately 1:1000, some delayed for hours after the injection, leading to the recommendations that patients be observed in the medical office for 2 hours after the first three injections and carry with them prefilled epinephrine-containing autoinjector syringes for a day or two after receiving their injections. Mepolizumab (Nucala) and reslizumab (Cinqair) are monoclonal antibodies targeting IL-5 and therefore indicated in patients with severe eosinophilic asthma (severe asthma with  $>300$  eosinophils/ $\mu\text{L}$  of blood). The former is administered in a fixed dose by subcutaneous injection once monthly, the latter by weight-based dosing as an intravenous infusion once monthly. In patients with asthma selected for peripheral blood eosinophilia and symptomatic despite standard therapy, anti-IL-5 monoclonal antibody had the following beneficial effects: improved lung function, reduced frequency of exacerbations, and steroid dose reduction without worsening of lung function. These medications have been well tolerated, with potential increased risk of hypersensitivity reactions and herpes zoster reported. The availability of targeted monoclonal antibodies for severe, refractory asthma heralds an era of personalized or targeted medicine in asthma, with useful biological markers (such as serum total IgE and peripheral blood eosinophil count) helping to identify patients most likely to benefit from specific therapies.

Specialized centers offer oral aspirin challenges and oral desensitization procedures for patients with aspirin-sensitive asthma. In most instances, patients with sensitivity to aspirin and other nonsteroidal antiinflammatory drugs can then tolerate daily aspirin. Remarkably, continued daily ingestion of aspirin, typically at doses of 650 mg twice daily, can then lead to improved asthma control in many patients, as well as improved nasal symptoms and delayed regrowth of nasal polyps, a common accompaniment of aspirin-sensitive asthma (*Samter's triad* or *triad asthma* refers to the combination of asthma, aspirin intolerance, and nasal polyposis. *Aspirin-exacerbated respiratory disease* is the currently preferred term used to describe this combination of upper and lower respiratory manifestations). However, if aspirin ingestion is stopped for more than approximately 3 to 4 days, asthmatic reactions to cyclooxygenase-1 inhibitors recur, and aspirin desensitization must be reinitiated if aspirin maintenance therapy is to be continued.

Bronchial thermoplasty involves application of thermal energy to the bronchial walls using a specially designed catheter passed into the airways via fiberoptic bronchoscopy. The goal is to reduce the potential for bronchoconstriction of the asthmatic airways. Typically, to treat all accessible bronchi, patients undergo three

bronchoscopies spaced approximately 3 weeks apart. In the year following bronchial thermoplasty, patients achieve improved asthma quality of life; they also experience fewer asthmatic attacks. However, as one might predict, bronchoscopies performed in patients with severe asthma entail considerable morbidity, and useful biological indicators of which patients are most likely to benefit have not yet been identified.

## Summary

In the vast majority of patients, good asthma control can be achieved—with a minimum of side effects—using currently available therapies in a step-care approach.

Achieving asthma control typically involves confirming the correct diagnosis, helping patients avoid allergic and irritant stimuli that exacerbate their asthma, periodically monitoring and readjusting therapy, and patient education in asthma comanagement skills. Patients should be equipped with an asthma action plan to help them initiate appropriate actions to counteract an asthmatic attack. Specialist consultation can help achieve these goals in difficult-to-manage patients. Novel therapies for refractory asthma include anti-IgE monoclonal antibody, omalizumab, the anti-IL-5 monoclonal antibodies, mepolizumab and reslizumab, bronchial thermoplasty, and in aspirin-sensitive patients, aspirin desensitization and maintenance therapy.

## Chapter Review

### Questions

- A 22-year-old woman without prior history of asthma complains of intermittent cough and chest tightness over the past 6 months. About 1 year ago she moved home to live with her parents, who own two cats. You suspect possible asthma. To evaluate her for asthma, you would order which of the following diagnostic tests:
  - Measurement of serum IgE
  - Allergy skin tests
  - Blood tests for specific IgE to common aeroallergens
  - Spirometry prebronchodilator and postbronchodilator administration
  - Chest radiograph
- Which of the following is not applicable to the assessment of a patient's asthma control?
  - Peak flow
  - Forced expiratory volume in 1 second (FEV<sub>1</sub>)
  - Frequency of use of quick-acting bronchodilator for relief of symptoms
  - Frequency of nighttime awakenings caused by asthma
  - Blood eosinophilia
- Persons with atopic asthma are susceptible to making allergic reactions to a variety of allergens. If a patient with atopic asthma experiences worsening asthma control, common inciters of allergic inflammation that may be contributing to worsened symptoms include all of the following except:
  - Dust mites
  - Cockroaches
  - Mice
  - Peanuts
  - Aspergillus
- Over the last few weeks, a 30-year-old man with asthma reports needing to use his albuterol inhaler five or six times per week because of recurrent chest tightness and shortness of breath. He finds that he is no longer able to jog 2 to 3 miles comfortably and so has given up his daily exercise routine. He is taking the leukotriene receptor antagonist montelukast (Singulair) once daily and rarely misses a dose. His peak flow is 480 L/min, 80% of his usual. The recommended next step in his care would be:
  - Add combination inhaled corticosteroid and long-acting inhaled beta-agonist bronchodilator (e.g., fluticasone-salmeterol [Advair 250/50] by dry-powder inhaler, 1 inhalation twice daily).
  - Double the dose of montelukast (take 10 mg twice daily).
  - Change from the leukotriene receptor antagonist montelukast to the lipoxygenase inhibitor zileuton (Zyflo), 600 mg two tablets twice daily
  - Begin an inhaled steroid such as budesonide (Pulmicort Flexhaler 180), one inhalation twice daily.
  - Review inhalational technique with his albuterol metered-dose inhaler, have him restrict his outdoor physical activity for 1 week, and continue montelukast at the present dose.
- Anti-IgE monoclonal antibody omalizumab (Xolair) is a novel therapy for the treatment of asthma. You would consider referral for this therapy in a patient who has which of the following characteristics:
  - Patients with features of both asthma and COPD
  - Patients with aspirin-sensitive asthma
  - Poorly controlled asthma despite Step 4 care
  - Asthma and nasal polyposis
  - Asthma with high peripheral blood eosinophil count

## Pleural Diseases

SCOTT L. SCHISSEL

The pleural space is lined by the parietal and visceral pleurae. The parietal pleura covers the inner surface of the thoracic cavity, including the mediastinum, diaphragm, and ribs. The visceral pleura covers all lung surfaces, including the interlobar fissures. The right and left pleural spaces are separated by the mediastinum. The pleural space contains a relatively small amount of fluid, approximately 10 mL on each side (approximately 0.13 mL/kg of body weight). The pleural space plays an important role in respiration by coupling the movement of the chest wall with that of the lungs by the presence of a relative vacuum in the pleural space, which keeps the visceral and parietal pleurae in close proximity, and the small volume of pleural fluid serves as a lubricant to facilitate movement of the pleural surfaces against each other in the course of respirations. The small volume of fluid is maintained through the balance of hydrostatic and oncotic pressure and lymphatic drainage, a disturbance of which may lead to pathology. A pleural effusion is defined as an abnormal amount of pleural fluid accumulation in the pleural space and is the result of an imbalance between excessive pleural fluid formation and pleural fluid absorption.

### Pleural Effusion

A pleural effusion is a common clinical problem; the incidence of pleural effusions is estimated at 1 million per year in the United States. There are two types of pleural effusions: a transudative effusion, which is caused by an increase in hydrostatic pressure within the pleural capillaries or a decrease in colloid osmotic pressure in the circulatory system, and an exudative effusion, which is caused by an increase in capillary permeability resulting from an inflammatory or destructive process such as may be seen in infections and malignancies (Table 32.1).

Diseases causing an increase in vascular volume and sodium retention, such as congestive heart failure (CHF), cirrhosis, and chronic kidney disease, are the most common causes of transudative effusion, whereas movement of fluid into the pleural space from other anatomic compartments, such as urine, ascites, or cerebrospinal fluid, are much less common causes of transudative effusions.

Exudative effusions are most commonly from infection (e.g., pneumonia), malignancies, pulmonary emboli, or autoimmune disease, such as rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE). Causes of pleural effusions may also be classified by systemic versus local thoracic etiologies (Table 32.2).

### Clinical Features of Pleural Effusions

The symptoms of a pleural effusion include dyspnea, pleural pain, and dry cough. On examination, patients may have tachypnea, decreased movement of the chest wall, diminished tactile fremitus, dullness to percussion, diminished transmission of breath sounds (vocal resonance), and the presence of a friction rub. These features are usually evident when >500 mL of fluid has accumulated in the pleural cavity. Above the effusion, where the lung is compressed, there may be bronchial breath sounds and egophony (“E-to-A change”). With a large effusion (>1000 mL), there may be tracheal deviation and mediastinal shift away from the effusion.

Clinical features frequently provide clues to the diagnosis. Patients with a malignant pleural effusion usually present with dyspnea, a nonproductive cough, and evidence of anorexia and weight loss, whereas patients with an infectious etiology may present with fever, chest pain, and a productive cough. Systemic inflammatory causes of a pleural effusion are accompanied by joint pains, myalgia, rash, or evidence of abnormalities in other organ systems (for example, a pleural effusion from SLE may be accompanied by a rash, arthralgias, mouth ulcers, and evidence of nephritis). Displacement of the trachea and mediastinum toward the side of the effusion is an important clue to obstruction of a lobar bronchus by an endobronchial lesion, which can be caused by malignancy or, less commonly, a nonmalignant cause such as a foreign body.

### Diagnostic Evaluation of a Pleural Effusion

Identifying the cause of a pleural effusion (or effusions) requires a comprehensive clinical evaluation, a detailed review of radiographic studies, and usually an analysis of the pleural fluid.

**TABLE 32.1** Causes of Pleural Effusion

	Transudate	Exudate
Common	Congestive heart failure Cirrhosis (including hepatic hydrothorax) Atelectasis (which may be caused by malignancy or pulmonary embolism) Hypoalbuminemia Nephrotic syndrome	Malignancy Parapneumonic effusions Primary empyema
Less common	Hypothyroidism Nephrotic syndrome Mitral stenosis Pulmonary embolism	Pulmonary infarction Viral pleuritis Autoimmune diseases (rheumatoid arthritis, lupus, sarcoidosis) Benign asbestos effusion Pancreatitis Postmyocardial infarction syndrome Tuberculosis Trauma Postcardiac injury syndrome Esophageal perforation Radiation pleuritis
Rare	Constrictive pericarditis Urinorhax Superior vena cava obstruction Ovarian hyperstimulation Meigs syndrome (ascites and pleural effusion caused by a benign ovarian tumor)	Yellow nail syndrome Drugs (e.g., amiodarone, nitrofurantoin, phenytoin, methotrexate) Fungal infections

**TABLE 32.2** Systemic and Local Causes of Pleural Effusion

Systemic Causes of Pleural Effusion	Local Causes of Pleural Effusion
Transudative/noninflammatory: heart failure, renal failure, liver failure Exudative/inflammatory: malignancy, connective tissue disorders	Empyema: pus in pleural space resulting from infection Hemothorax: blood in pleural space resulting from chest wall injuries, complications of surgery, etc. Chylothorax: chyle accumulation in pleural space caused by disruption of the thoracic duct

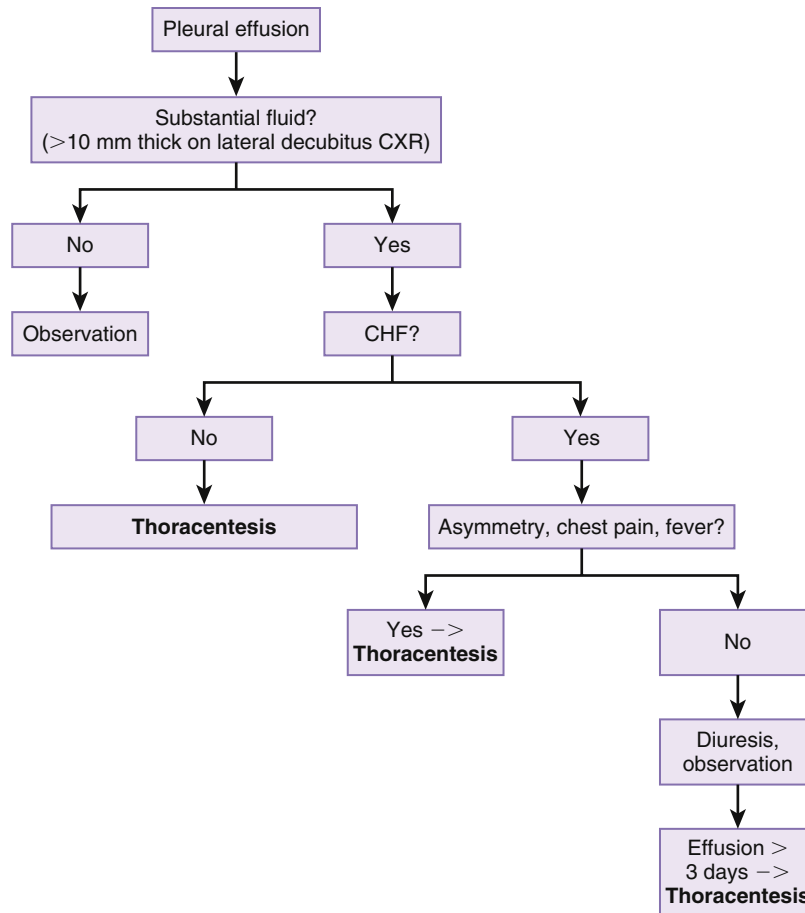

## Chest Imaging

Pleural effusion is often confirmed by chest x-ray (CXR). Effusions >175 to 300 mL are apparent as blunting of the costophrenic angle on upright posteroanterior CXR. A lateral decubitus CXR (with the patient lying on his/her side) is more sensitive and can detect a 50-mL effusion. On supine CXR (usually in the intensive care setting) moderate-to-large pleural effusions appear as a homogeneous increase in density throughout the lower lung fields. An elevation of the hemidiaphragm, lateral displacement of the dome of the diaphragm, or increased distance between the apparent left hemidiaphragm and the gastric air bubble suggests subpulmonic effusions. Layering of an effusion on lateral decubitus films defines a freely flowing effusion and, if the layering fluid

is  $\geq 1$  cm thick, indicates an effusion of >200 mL that is amenable to thoracentesis. Failure of an effusion to layer on lateral decubitus films indicates loculated pleural fluid or some other etiology causing the increased pleural density. Other chest imaging modalities, such as ultrasound and CT, can identify pleural fibrosis and loculations, associated pneumonia or lung abscess, lung tumors, and associated mediastinal lymphadenopathy, all of which may help identify the underlying cause of a pleural effusion (see [Table 32.4](#)).

## Pleural Aspiration/Thoracentesis

A pleural aspiration or diagnostic thoracentesis consists of placing a small needle through the chest wall using local anesthetic and aspirating from the fluid pocket to collect some fluid for analysis. Relative contraindications to a diagnostic thoracentesis include a small volume of fluid (<1 cm thickness on a lateral decubitus film), pleural effusions that are likely caused by CHF or volume overload and rapidly resolve with heart failure therapy ([Fig. 32.1](#)), bleeding diathesis or systemic anticoagulation, and cutaneous disease over the proposed puncture site. Mechanical ventilation with positive end-expiratory pressure does not increase the risk of pneumothorax after thoracentesis, but it increases the likelihood of severe complications (tension pneumothorax or persistent bronchopleural fistula) if the lung is punctured. Therapeutic thoracentesis to remove larger amounts of pleural fluid requires insertion of an intercostal small-bore catheter and is often performed at the same time as

• **Fig. 32.1** Indications for performing an initial thoracentesis. CHF, Congestive heart failure; CXR, chest x-ray.

a diagnostic thoracentesis for several possible indications, including alleviation of dyspnea and to prevent ongoing inflammation and fibrosis in parapneumonic effusions. Oxygen saturation should be monitored during and after thoracentesis because arterial oxygen tension paradoxically might worsen after pleural fluid drainage caused by shifts in perfusion and ventilation in the expanding lung. The onset of chest or shoulder pain during the removal of fluid typically indicates lung reinflation with apposition of inflamed pleural surfaces but is an indication to stop the procedure.

Complications from thoracentesis include pain at the puncture site, cutaneous or internal bleeding, pneumothorax, empyema, and spleen/liver puncture. Pneumothorax may complicate as many as 12% to 30% of thoracenteses in some series but requires treatment with a chest tube in <5% of cases. The frequency of complications from thoracentesis is lower when a more experienced clinician performs the procedure and when performed with ultrasound guidance. Postprocedure expiratory chest radiographs to exclude pneumothorax are not needed in asymptomatic patients after uncomplicated procedures (single needle pass without aspiration of air). However, postprocedure inspiratory chest radiographs are recommended to establish a new baseline for patients likely to have recurrent symptomatic effusions. Symptomatic reexpansion pulmonary edema complicates only 0.5% of therapeutic

thoracenteses and was believed to be caused by removing large volumes, >1.5 liters, of pleural fluid from the chest. However, reexpansion pulmonary edema after thoracentesis did not correlate with the volume of fluid removed, the change in pleural pressures during the procedure, or with patient symptoms in a more recent large series of patients undergoing a therapeutic thoracentesis. Therefore there are no strong data to support limiting a thoracentesis to 1.5 liters, and considering removing larger volumes of a free-flowing pleural effusion is reasonable in individual cases, especially if there are no other risk factors for pulmonary edema (e.g., preprocedure vascular volume overload or decompensated CHF).

### Pleural Fluid Analysis

The gross appearance and even odor of pleural fluid can sometimes be very informative; for example, frankly purulent-appearing or putrid smelling pleural fluid indicates a likely empyema, whereas a milky, opalescent fluid suggests a chylothorax or pseudochylothorax. Grossly bloody fluid may result from trauma, malignancy, postpericardiotomy syndrome, and asbestos-related effusion.

An initial chemical analysis is critical in distinguishing a pleural transudate from an exudate. Exudates have a protein level of >3 g/dL and transudates a protein level of <3 g/dL.

However, if the patient’s serum protein level is abnormal or the pleural protein level is close to the 3 g/dL cutoff point, using the criteria by Light is recommended. This requires measurement of serum and pleural fluid total protein and lactate dehydrogenase (LDH) levels. Light’s criteria are used for differentiating a transudate from an exudate. The fluid is considered an exudate if any of the following apply:

- Ratio of pleural fluid to serum total protein >0.5
- Ratio of pleural fluid to serum LDH >0.6
- Pleural fluid LDH greater than two-thirds of the upper limits of normal serum value

Light’s criteria identify nearly all exudates correctly (i.e., very sensitive at detecting exudates), but they misclassify approximately 20% of transudates as exudates (i.e., not specific), usually in patients on long-term diuretic therapy for CHF because of the concentration of protein and LDH within the pleural space. Using the criterion of serum minus pleural fluid albumin concentration of  $\leq 1.2$  g/dL to classify exudates is more specific than Light’s criteria and often is helpful at identifying a “true transudate” when a pleural effusion was classified as a false exudate by Light’s criteria (Table 32.3, sensitivity and specificity of these criteria).

The pleural fluid, usually only when exudative, can be tested for other chemical markers, cellular analysis, cytologic examination, and microbiologic cultures to help identify its underlying etiology:

- Differential cell counts on the pleural fluid: Pleural lymphocytosis is common in malignancy and tuberculosis. An eosinophilic pleural effusion is defined as the presence of 10% or more eosinophils in the pleural fluid.

The presence of pleural fluid eosinophilia is disappointingly nonspecific and may be found in parapneumonic effusions, tuberculosis, drug-induced pleurisy, benign asbestos pleural effusions, Churg Strauss syndrome, pulmonary infarction, parasitic disease, and malignancy. Air or blood in the pleural space can also elicit an eosinophilic response.

- Cytology: Consideration of a malignant etiology for pleural effusion should prompt cytologic evaluation. Cytology alone has an approximate sensitivity of 60%. If there is clinical suspicion of a malignancy, and if the first pleural fluid cytology specimen is negative, then it should be repeated a second time. Both cell blocks and fluid smears should be prepared for examination and, if the fluid has clotted, it needs to be fixed and sectioned as a histologic section. Immunocytochemistry, as an adjunct to cell morphology, is becoming increasingly helpful in distinguishing benign from malignant mesothelial cells and mesothelioma from adenocarcinoma. Epithelial membrane antigen is widely used to confirm a cytologic diagnosis of epithelial malignancy. When malignant cells are identified, the glandular markers for CEA, B72.3, and Leu-M1 together with calretinin and cytokeratin 5/6 will often help to distinguish adenocarcinoma from mesothelioma.
- Pleural fluid amylase: Amylase may be elevated in esophageal rupture (Boerhaave syndrome), pancreatitis, or pancreatic cancer. Absolute amylase levels and isoenzymes can be used to differentiate esophageal rupture (salivary isoenzymes) from a pancreatic source, these different disorders, as reviewed in Table 32.4.
- Pleural fluid glucose: The glucose is characteristically decreased with malignancy, SLE, esophageal rupture, tuberculosis, empyema, and rheumatoid pleuritic (the lowest glucose concentrations are found in rheumatoid effusions and empyema).
- Pleural fluid pH: The pH of the normal pleural fluid is approximately 7.64 because of active transport of bicarbonate into the pleural space. Typically, the pH is <7.2 with an empyema and indicates the need for drainage. Urinothorax is the only transudative effusion that can present with a low pleural fluid pH and a physiologically normal serum pH.
- Pleural fluid Gram staining and culture: The pleural space is normally sterile. The finding of bacteria on Gram

**TABLE 32.3 Sensitivity and Specificity for Detecting Exudative Pleural Effusions Using Light’s Criteria and the Serum: Pleural Fluid Albumin Difference**

Test	Sensitivity	Specificity
PF:serum protein >0.5	98%	83%
PF:serum LDH >0.6	86%	84%
PF LDH >2/3 nl serum	90%	82%
Serum-PF albumin <1.2	87%	92%

LDH, Lactate dehydrogenase; PF, pleural fluid.

**TABLE 32.4 Pleural Fluid Amylase as a Diagnostic Marker**

Test	Acute Pancreatitis	Chronic Pancreatitis	Esophageal Rupture	Malignancy
PF amylase level (IU/L)	500–10,000	>50,000–100,000	~500	200–600 (rarely up to 10,000)
PF ISOamylase	Pancreatic	Pancreatic	Salivary	Salivary
PF:serum amylase	10:1	>20:1	3–5:1	3–5:1

PF, Pleural fluid.

stain or culture raises concern for empyema. The yield of mycobacteria on culture of pleural fluid in patients with tuberculous pleurisy is low (approximately 30%). If there is suspicion of tuberculosis, additional analysis can include measurement of pleural fluid adenosine deaminase and interferon- $\gamma$  (markers for tuberculous pleurisy) and polymerase chain reaction (PCR) for tuberculous DNA (see later).

If pleural fluid analysis does not reveal the cause of a pleural effusion, additional investigation may be required, including sampling of pleural tissue (thoroscopic biopsy), as reviewed in [Table 32.5](#).

## Characteristics and Management of Common Transudative and Exudative Pleural Effusions

### Transudative Effusions

#### Congestive Heart Failure

CHF is the most common cause for a transudative pleural effusion. Over 80% of effusions from CHF are bilateral. Other causes of bilateral pleural effusions are shown in [Box 32.1](#). The most likely mechanism is pulmonary venous hypertension. Patients present with clinical features of CHF. The chest radiograph shows cardiomegaly and bilateral effusions of relatively equal size with evidence of vascular congestion. Treatment is directed at the underlying heart failure. Removal of a modest amount of fluid, 500 to 1000 mL, should be considered in patients who are refractory to medical therapy or are dyspneic because of large effusions. If therapeutic thoracentesis relieves the dyspnea but the effusion cannot be controlled with medical therapy, chemical pleurodesis with doxycycline or talc is a therapeutic consideration.

#### Hepatic Hydrothorax

Pleural effusions develop in approximately 6% of patients with hepatic cirrhosis. Although most of these effusions are caused by hepatic hydrothorax, undiagnosed pleural effusions in patients with cirrhosis should be sampled to exclude infection, including spontaneous bacterial pleuritis (akin to spontaneous bacterial peritonitis) and other causes of pleural exudates, including malignancy. These pleural effusions from hepatic hydrothorax are usually unilateral and right-sided but may occur on the left (16%) or be bilateral (16%). They may vary in size from small to massive. Large effusions may cause significant dyspnea. Therapy is directed at reducing the ascites with diuretics and sodium restriction. Therapeutic thoracentesis will bring only temporary relief because the ascitic fluid rapidly reaccumulates in the pleural cavity. Insertion of a chest tube for continuous pleural drainage involves risk and can result in severe hypovolemia and hypoalbuminemia. If medical management is not successful, placement of a transjugular intrahepatic portal systemic shunt or chemical pleurodesis may be attempted, but insertion of a chest tube

**TABLE 32.5 Key Facts on Additional Pleural Imaging Tests and Procedures**

Type of Imaging/Procedure	Key Fact
Ultrasound	Major indication is in differentiating solid lesions (e.g., tumor or thickened pleura) from fluid and in detecting abnormalities that are subpulmonic (under the lung) or subphrenic (below the diaphragm) Superior to CT scan for detection of fibrinous septations Guide thoracentesis in small or loculated pleural effusions to enhance safety
CT scan	Indications include distinguishing empyema from lung abscess, in detecting pleural masses (e.g., mesothelioma, plaques), in detecting lung parenchymal abnormalities “hidden” by an effusion, differentiating benign and malignant pleural thickening, and in outlining loculated fluid collections (loculated effusions on CT scans tend to have a lenticular shape with smooth margins and relatively homogeneous attenuation) Should routinely use contrast enhancement unless contraindicated
Pleural biopsy	Indications for needle biopsy of the pleura include tuberculous pleuritis and malignancy of the pleura; for tuberculosis, consider pleural biopsy when tuberculous pleuritis is suspected and the pleural fluid adenosine deaminase or interferon- $\gamma$ levels are not definitive; for malignancy, consider pleural biopsy when malignancy is suspected but cytologic study of the pleural fluid is negative and thoracoscopy is not readily available
Thoracoscopy	Indications include pleural effusions of unknown cause, particularly if mesothelioma, lung cancer, or tuberculosis is suspected; it can also be done to introduce sclerosing agents

 Malignancy

involves risk. Tube thoracostomy may drain both the pleural fluid and the ascites, resulting in severe hypovolemia.

### Peritoneal Dialysis

Pleural effusions are observed in approximately 2% of continuous ambulatory peritoneal dialysis (CAPD) patients. Large, symptomatic effusions can develop within hours of initiating peritoneal dialysis. The dialysate moves from the peritoneal to the pleural cavity across the diaphragm in a manner analogous to the movement of ascitic fluid in the patient with cirrhosis. If this problem is going to occur, it usually develops in the first month after dialysis is initiated. However, it may be a year or more before the effusion develops in some patients. Most effusions are right-sided, but left-sided or bilateral effusions do occur. Patients with dialysis-related effusions generally complain of dyspnea, but approximately 25% of the effusions cause no symptoms and are discovered on routine radiographs. Therapy comprises stopping the dialysis and draining the peritoneal fluid. The patient should be switched to hemodialysis. If this is not feasible, chemical pleurodesis should be performed before reinstituting CAPD. Small-volume peritoneal dialysis in the semierect position may be attempted while pleurodesis is being performed. The diaphragmatic defect may have to be repaired surgically if pleurodesis is unsuccessful.

### Urinothorax

A urinothorax is a rare cause of a transudative effusion. The pleural effusion is caused by the retroperitoneal leakage of urine entering the pleural space via diaphragmatic lymphatics. It generally develops in association with obstructive uropathy but has been reported in patients with trauma, malignancy, kidney biopsy, and renal transplantation. Patients generally present with complaints related to the urinary tract obstruction. The pleural effusion is suspected because of dyspnea, or it may be asymptomatic and recognized on a routine chest radiograph. The pleural effusion is invariably ipsilateral to the urinary obstruction. Thoracentesis yields fluid that looks and smells like urine. The fluid has the characteristics of a transudate, but the pH may be high or low depending on urine pH; in fact, a urinothorax is the only cause of an acidic transudative effusion with a normal serum pH. The pleural fluid creatinine is always higher than the serum creatinine in a urinothorax. Relief of the urinary obstruction results in prompt resolution of the associated effusion.

### Nephrotic Syndrome

Pleural effusions are frequently present in patients with nephrotic syndrome. In one study, radiographic evidence of effusions was found in 21% of 52 children with nephrosis. Hypoalbuminemia leads to a decrease in the plasma oncotic pressure, whereas salt retention produces hypervolemia and increased hydrostatic pressures, thereby favoring the development of transudative effusions. The effusions are bilateral and are frequently infrapulmonary. They are often associated with the presence of peripheral edema. Thoracentesis should

be performed whenever an effusion is recognized in a patient with nephrotic syndrome, to confirm that the fluid is a transudate. If an exudate is found, thromboembolism is the most likely cause. These patients suffer from a hypercoagulable state, and venous thrombosis in the legs and at other sites is common. Treatment is directed at the underlying nephropathy. Therapeutic thoracentesis is indicated if there is severe dyspnea. Failure to medically control symptomatic effusions is an indication for chemical pleurodesis.

### Exudative Effusions

#### Parapneumonic Pleural Effusions and Empyema

Pleural effusions are present in 30% to 40% of patients with bacterial pneumonia, but the majority are “simple,” meaning they are small, free-flowing effusions, and fully resolve on antibiotic therapy alone. A minority, however, are complicated by persistent bacterial invasion into the pleural space and can evolve into empyema, defined by visible bacteria on pleural fluid Gram stains or the presence of frank pus on pleural aspiration. Complex pleural effusions and empyema are associated with a 20% mortality rate and with other chronic thoracic complications, including secondary lung abscess, bronchopleural fistulas, empyema necessitans (bronchopleural-cutaneous fistula), and pleural fibrosis and lung entrapment. Because definitive pleural space drainage in addition to antibiotic therapy can prevent these complications, proper classification of pleural space infections is critical. Table 32.6 summarizes the pleural space anatomic and fluid characteristics that place patients at high risk for complications without definitive pleural drainage.

Parapneumonic pleural effusions at moderate or high risk for complications (see Table 32.6) and frank empyemas require definitive drainage of the pleural space. Although moderate-sized free-flowing effusions can be drained by therapeutic thoracentesis or even serial thoracenteses, most larger effusions and complicated parapneumonic effusions require drainage by tube thoracostomy. Traditionally, large-bore chest tubes (20–36 F) have been used to drain thick pleural fluid and to break up minor loculations in empyemas. However, such tubes are not always tolerated by patients and are difficult to specifically direct into the pleural space. Thus small-bore tubes (7–14 F) inserted under radiographic guidance can provide adequate pleural drainage, even when empyema is present. In addition, for pleural effusions that do not adequately drain 24 to 48 hours after chest tube placement, instilling recombinant tissue plasminogen activator (tPA) and DNase short term into the pleural space via the chest tube(s) can promote pleural fibrinolysis and pleural drainage and decrease the subsequent need for surgical intervention. Despite these advances in tube thoracostomy and management of pleural space infections, surgical intervention is still needed in up to 30% of complex pleural space infections, including pleuroscopy and thoracotomy with lung decortication. Appropriate antibiotic therapy is a critical adjunct to pleural space drainage and should target the common community-acquired pathogens (*Streptococcus pneumoniae*,

**TABLE 32.6 Anatomic and Pleural Fluid Findings That Necessitate Pleural Space Drainage to Prevent Complications of Parapneumonic Pleural Effusions**

Pleural Anatomy	Fluid Microbiology	Fluid pH	Risk of Poor Outcome	Drain?

*Streptococcus milleri*, staphylococci, anaerobes, *Haemophilus influenzae*) or hospital-acquired pathogens (methicillin-resistant *Staphylococcus aureus*, *Enterobacter*, *Enterococci*, anaerobes) that infect the pleural space; antibiotic treatment is required until the pleural space remains drained without a chest tube and the signs and symptoms of infection have resolved, which can be up to several weeks.

### Tuberculosis

Pleural effusions occur in approximately 10% of patients with tuberculosis (TB). Potential mechanisms for the exudative effusion are direct extension of TB infection into the pleural space and rupture of a subpleural caseous focus into the pleural space, resulting in an immunologic hypersensitivity reaction and subsequent accumulation of fluid. The clinical presentation is one of fever, chest pain, and weight loss. Initial evaluation should include a tuberculin skin test and diagnostic thoracentesis. The pleural fluid is rich in lymphocytes, often with <5% mesothelial cells. Pleural fluid acid-fast bacilli staining is <10% sensitive, and pleural fluid cultures for *Mycobacterium tuberculosis* (MTB) are positive in <30% of cases. PCR detection of MTB in pleural fluid is surprisingly insensitive, detecting MTB in only 30% to 50% of cases when the pleural fluid cultures are negative for MTB. Closed pleural biopsy is still the most sensitive test, detecting MTB in up to 95% of cases.

### Chylothorax

A chylothorax occurs when there is damage to the thoracic duct (e.g., surgery, malignancy, or trauma) (Table 32.7). The most common malignant cause is lymphoma. The pleural effusion is most commonly right sided because the duct is in the right hemithorax, although a left-sided effusion may occur if the damage is at the level of the aorta. A true chylothorax has a milky gross appearance of the fluid (although this can be misleading because a tuberculous or rheumatoid pleural effusion can have a similar appearance, termed *pseudochylothorax*); it has a high fat content (>400 mg/dL of mostly triglyceride), and chylomicrons can be seen. A pleural fluid triglyceride level >110 mg/dL is highly suggestive of a chylothorax, whereas a pleural triglyceride

**TABLE 32.7 Causes of Chylothorax and Pseudochylothorax**

Chylothorax	Pseudochylothorax
Neoplasm: lymphoma, metastatic carcinoma	Tuberculosis
Trauma: operative, penetrating injuries	Rheumatoid arthritis
Miscellaneous: tuberculosis, sarcoidosis, lymphangi-oleiomyomatosis, fibrosing mediastinitis, cirrhosis, obstruction of central veins, amyloidosis, filariasis	Inadequately treated empyema
	A chronic exudative effusion from almost any cause

level <50 mg/dL virtually excludes the diagnosis of chylothorax. Treatment strategies include treating the underlying cause (e.g., radiation of lymphomatous obstruction or surgical repair of a ruptured thoracic duct) and therapeutic thoracentesis for symptomatic effusions. In addition, because flow in the thoracic duct is also highly dependent on fat intake, manipulation of the diet can also be used to reduce flow. Consequently, switching to a low-fat diet with medium-chain triglycerides and parenteral nutrition has been used successfully. Concomitant medical therapy with somatostatin or octreotide can successfully decrease chylothorax formation in inoperable cases.

### Malignancy

A malignant pleural effusion is diagnosed when exfoliated malignant cells are found in pleural fluid or when malignant cells are seen in pleural tissue obtained by percutaneous pleural biopsy, thoracoscopy, or thoracotomy. Carcinoma of any organ can metastasize to the pleura. Carcinoma of the lung is the most common (see Table 32.7). Lung cancer can cause a pleural effusion either directly by metastasizing to the pleura or indirectly by causing atelectasis, pneumonia, or lymphatic obstruction. Clinical features include the underlying tumor and the effects of the effusion (e.g., a large effusion may cause dyspnea). Evaluation should include a CXR (carcinoma of the lung usually results in an effusion ipsilateral to

**TABLE 32.8 Benefits of an Indwelling Pleural Catheter Versus Pleurodesis for Malignant Pleural Effusions**

Costs	PD	IC
Invasive	+++	+

Spontaneous pleurodesis	—	58%

IC, Indwelling pleural catheter; PD, pleurodesis.

the primary location of the tumor, and effusions are usually moderate to large). Notably, the presence of bilateral effusions in the absence of cardiomegaly is a clue suggesting a malignancy rather than CHF. Diagnostic thoracentesis may yield a serous, serosanguinous, or grossly bloody-appearing fluid that is an exudate rather than a transudate. Demonstrating the presence of malignant cells in pleural fluid or pleural tissue is diagnostic. Cytology is a more sensitive test for the diagnosis than percutaneous pleural biopsy because pleural metastases tend to be focal and may be missed on biopsy. If a patient's symptoms are markedly alleviated after a large volume thoracentesis, then a malignant pleural effusion should be more definitively drained. Although chemical pleurodesis is one treatment option, placement of an indwelling pleural catheter is much better tolerated than pleurodesis, is highly effective (Table 32.8), and has become the treatment of choice for malignant effusions.

### Autoimmune Diseases

Both SLE and RA are important causes of exudative pleural effusions. Effusions in SLE are small to moderate in size, whereas effusions with RA tend to be large and can become complicated by pleural fibrosis, fluid loculations, and even the formation of bronchopleural fistulas that can cause chronic pleural space infections. Pleural fluid analysis is usually helpful in establishing the diagnosis of an RA- or SLE-related pleural effusion and can help exclude alternative diagnoses (e.g., infection and malignancy). For the diagnosis of an SLE effusion, measurement of pleural fluid antinuclear antibody levels (ANA) is recommended; an ANA titer >1:160 or a pleural-to-serum ANA ratio >1 indicates lupus pleuritis. With regard to RA effusions, measurement of rheumatoid factor (RF) in the pleural effusion is not helpful, because an elevated RF is nonspecific and can be associated with pleural effusions from pneumonia, TB, and malignancy. Uncomplicated, free-flowing pleural effusions in RA and SLE can often be successfully managed with drainage via a thoracentesis followed by treatment with nonsteroidal antiinflammatory drugs (e.g., indomethacin) or moderate dose oral corticosteroids (e.g., prednisone at 10–20 mg each day) until the fluid resolves, followed by a

**TABLE 32.9 Pleural Fluid Hematocrit and Various Pleural Disorders**

Fluid Hematocrit	Cause
<1%	Not significant
1%–20% (hemorrhagic process)	Cancer>>pulmonary embolism>trauma>empyema
20%–50%	Hemorrhagic process vs. hemothorax
>50% circulating hematocrit	Hemothorax

rapid taper. More complex effusions may require surgical intervention with pleuroscopy or decortication.

### Asbestosis

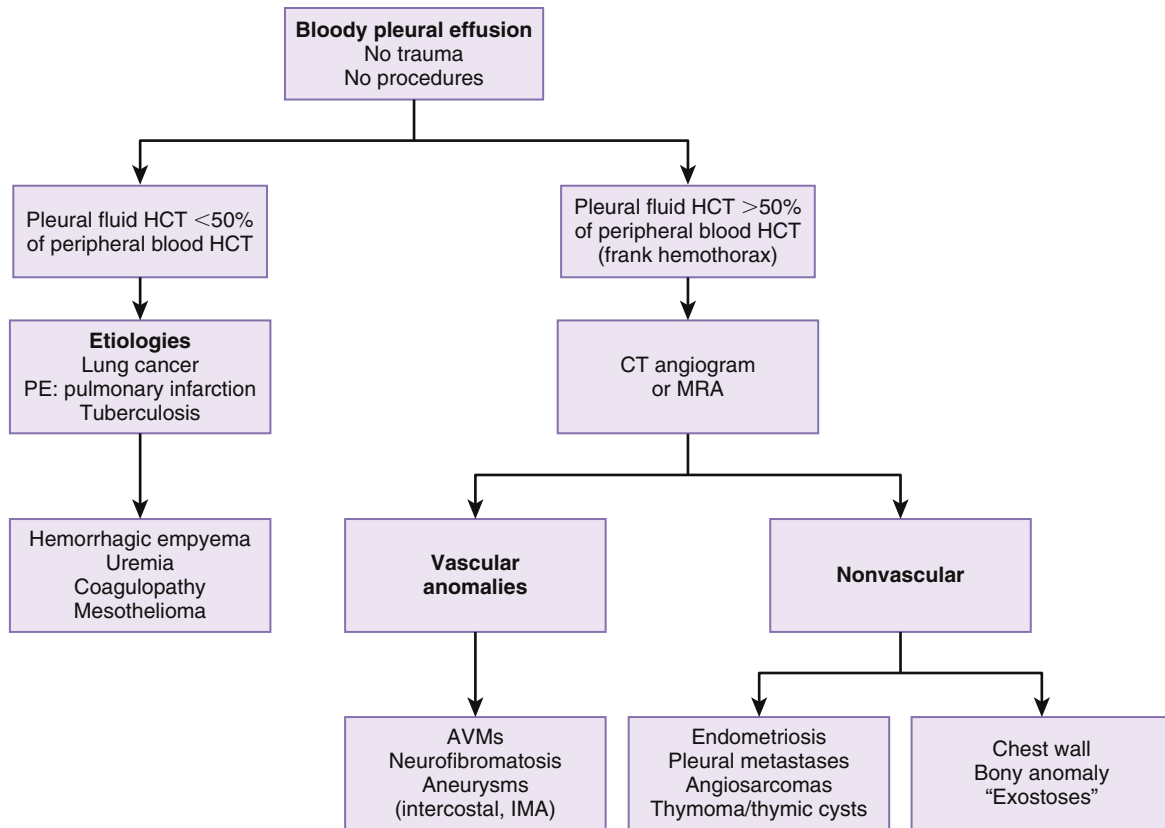

Asbestos exposure may result in a benign asbestos effusion. Benign asbestos effusions are usually observed 10 to 15 years following asbestos exposure and commonly are associated with symptoms such as pleurisy, fever, and dyspnea. They usually resolve spontaneously after 3 to 4 months. On diagnostic thoracentesis, the pleural fluid is bloody in gross appearance and exudative. These effusions are usually not associated with the subsequent development of mesothelioma.

### Hemothorax

Grossly bloody pleural effusions can result from hemorrhagic pleural processes, such as pleural infection and malignancy, or from parietal or visceral pleural vascular injury and frank hemothorax. A pleural fluid hematocrit >50% of the circulating blood hematocrit defines frank pleural hemorrhage. However, pleural hemorrhage in a variety of disorders is often on a spectrum, yielding a modestly bloody pleural exudate or bona fide hemothorax, as reviewed in Table 32.9. Both open and closed chest trauma, especially in patients on anticoagulation, must be excluded when evaluating a bloody pleural effusion. Spontaneous pleural bleeding and hemothorax, however, are not uncommon and can be caused by infectious, inflammatory, and malignant pleural diseases or as a result of thoracic vascular anomalies or very vascular pleural neoplasms; Fig. 32.2 contains an algorithm to approach the diagnosis of bloody pleural effusions. In addition to treating the underlying process causing pleural hemorrhage, all blood should, in general, be evacuated from the pleural space to prevent secondary infection and organization into a fibrothorax.

### Pleural Tumors

Most pleural neoplasms are metastatic in origin. Primary tumors of the pleura can be categorized as diffuse or localized. Diffuse malignant mesothelioma is more common, related to asbestos exposure, and associated with a poor prognosis. A definitive diagnosis of malignant mesothelioma can be difficult to obtain, even after pleural fluid analysis and focal pleural biopsy. Identifying reliable mesothelioma tumor markers, therefore, is important to help select patients for

• **Fig. 32.2** A diagnostic algorithm for bloody pleural effusions. *AVMs*, Arteriovenous malformations; *HCT*, hematocrit; *IMA*, inferior mesenteric artery; *MRA*, MR angiogram; *PE*, pulmonary embolism.

more aggressive diagnostic testing, including pleuroscopy. Prior mesothelioma tumor markers, including mesothelin-related protein and osteopontin, lacked sensitivity; however, elevated serum and pleural fluid levels of fibulin-3, an extracellular glycoprotein, are 95% sensitive and specific for detecting malignant mesothelioma and can be useful in the evaluation of patients with suspected mesothelioma.

Localized mesothelioma is now referred to as localized (or solitary) fibrous tumor of the pleura (LFTP). It is a rare neoplasm of controversial histogenesis and unrelated to asbestos exposure. LFTPs exist in benign and malignant forms with

the ratio of benign to malignant LFTPs 7:1. Most LFTPs cause local thoracic symptoms (cough, dyspnea, or chest pain) but can have systemic manifestations, including digital clubbing (hypertrophic osteoarthropathy) and even refractory hypoglycemia from tumor secretion of insulin-like growth factor II. Only rarely is the localized fibrous tumor invasive or does it cause local recurrence after resection. The diagnosis of LFTP is important because the tumor is potentially resectable for cure despite its typically large size on presentation. In many cases, resection can be repeatedly used to treat recurrence, although sometimes with increasing difficulty.

## Chapter Review

### Questions

1. A 42-year-old man presents with gradually worsening dyspnea for the past 9 months. His medical history is remarkable for long-standing RA. He also admits to sustaining a road traffic accident approximately 1 year previously. On examination, there is dullness to percussion of the right base. His CXR shows a right-sided effusion. A diagnostic thoracentesis is performed and reveals cloudy fluid with a pleural protein level of 3.5 g/dL and pleural triglyceride level of 240 mg/dL.

The most likely diagnosis is which of the following?

- A. RA as the cause of his effusion
- B. A chylothorax resulting from his road traffic accident
- C. A malignant pleural effusion

D. Subclinical CHF

E. Langerhans cell granulomatosis (histiocytosis X)

- 2–5. Match the following pleural fluid results with the appropriate diagnoses:

Pleural/Serum Protein Ratio	Pleural/Serum LDH Ratio	pH	Glucose, mg/dL
2. 0.6	2.2	7.3	75
3. 0.2	0.4	6.9	94
4. 0.3	0.4	7.3	90
5. 0.7	5.0	7.2	25

- A. Urinothorax
- B. Uncomplicated parapneumonic effusion
- C. CHF
- D. RA

6. A 72-year-old man presents with 4 days of cough, sputum, and dyspnea. Examination reveals his temperature is 100.6°F and there are absent breath sounds with dullness to percussion at the right lung base. His white blood cell count is 15,000 with 80% polymorphonuclear leukocytes and 10% band forms. His CXRs revealed a moderate sized, free-flowing right pleural effusion. A diagnostic right-sided thoracentesis removed 50 cc of serosanguinous pleural fluid with the following characteristics: protein 3 mg/dL (serum 4), LDH 800 U/mL (serum 300), pH 7.18, Gram stain and initial bacterial cultures are negative. What is the next step in managing this effusion?
- Antibiotic therapy and close observation, including daily CXRs
  - Thoracentesis to drain the right pleural space and repeat the procedure as necessary for recurrent effusion
  - Chest tube drainage
  - Chest tube drainage and fibrinolytic therapy to the right pleural space
  - B or C
7. A 67-year-old man presents with cough and dyspnea for 2 months. Examination reveals poor chest

excursion on the right with severely diminished breath sounds. CXR demonstrates complete opacification of the right hemithorax with the trachea shifted toward the right. Chest ultrasound demonstrated a small right pleural effusion. Pleural fluid protein was 3.9 mg/dL (serum 7.9), pleural fluid LDH 200 U/mL (serum 275), and pleural fluid pH 7.48; pleural fluid cultures and cytology were unrevealing. What is the next best management step?

- Perform a large volume thoracentesis.
- Place an indwelling pleural catheter.
- Thoracoscopy and pleural biopsy
- Perform a bronchoscopy.
- B and D

### Answers

## Evaluation of the Dyspneic Patient in Primary Care

BRADLEY M. WERTHEIM AND BARBARA A. COCKRILL

**D**yspnea is a complex and pervasive symptom, with origins in biology, psychology, social interactions, and the environment. Dyspnea is “a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity.” Its clinical significance ranges from the benign to the “critical threat to homeostasis.” Acute, subacute, and chronic dyspnea each possesses a distinct differential diagnosis spanning nearly every organ system. Chronic unexplained dyspnea can be a particularly vexing problem in the ambulatory setting and is associated with considerable diagnostic resource use and burden to patients.

### Epidemiology

Dyspnea is common in nearly every clinical context. According to one survey of 1556 tertiary care inpatients, 49% endorsed at least some degree of dyspnea, and 18% reported “extremely severe” dyspnea at least half or more of the time. In a landmark study of over 1,000,000 Americans in the ambulatory population, up to one-quarter of individuals reported shortness of breath. In a whole-of-population study of 5476 rural and metropolitan community dwellers (10,600 approached), 8.9% of respondents reported being limited by exertional dyspnea, and approximately 1% of those age  $\geq 65$  years reported feeling too breathless to leave the house.

Dyspnea predicts mortality and adverse outcomes. In chronic obstructive pulmonary disease (COPD), dyspnea, as measured by the modified Medical Research Council (MMRC) breathlessness scale (Box 33.1), is independently associated with hospitalization and mortality. It is a more reliable predictor of 5-year survival than forced expiratory volume in 1 second ( $FEV_1$ ). In a longitudinal study of 3436 persons age  $>65$  years, the MMRC score demonstrated a dose-response relationship with 13-year all-cause mortality. Dyspnea also informs prognosis in those with or at risk for cardiovascular disease. In 17,991 individuals screened for coronary artery disease (CAD) with myocardial perfusion single-photon emission CT, the presence or absence

of dyspnea predicted cardiac and all-cause mortality better than angina, even in those patients with known CAD. In congestive heart failure (CHF) with reduced left ventricular ejection fraction (CHFrEF), dyspnea is more closely associated with mortality than orthopnea and fatigue.

The economic and social burden of dyspnea is substantial, but precise estimates are lacking. Of the 10 most common principal diagnoses in US hospitals, five (pneumonia, septicemia, CHF, cardiac dysrhythmias, and COPD/bronchiectasis) are commonly associated with shortness of breath. The medical cost of COPD alone in the United States is estimated at 36 billion dollars annually. A European Union report valued the economic toll of respiratory disease among member countries to exceed 380 billion Euros each year (nearly 426 billion US dollars).

### Mechanism

Many factors contribute to dyspnea, not just blood oxygen or carbon dioxide ( $CO_2$ ) levels. Attempts to unify a common neurophysiologic mechanism for the symptom of dyspnea have been unsuccessful, because of the diversity of stimuli, modulators, and neural pathways involved. As outlined in reviews by Schwartzstein and Parshall, the sensation has been experimentally demonstrated to include an “urge to breathe” (also known as “air hunger”) and a “sense of excessive effort.” Afferent contributors include chemoreceptors in the medulla; carotid and aortic bodies; pulmonary stretch receptors; C-fibers in the pulmonary parenchyma, vasculature, and airway; corollary discharge from the medulla, motor cortex, and limbic structures; upper airway “flow” receptors; trigeminal nerve receptors in the skin; mechanoreceptors in skeletal muscle, airways, vasculature, and chest wall; and metaboreceptors in respiratory pump muscles. Information from these sources is integrated in the cerebral cortex, limbic system, and respiratory control center located in the medulla and pons. Indeed, both positron emission tomography and functional MRI demonstrate that dyspnea activates corticolimbic structures.

### • BOX 33.1 Modified Medical Research Council Breathlessness Scale

- 0 = Not troubled by breathlessness except with strenuous exercise
- 1 = Troubled by shortness of breath when hurrying on level ground or walking up a slight hill
- 2 = Walks slower than people of the same age on level ground because of breathlessness or has to stop for breath when walking at own pace on level ground
- 3 = Stops for breath after walking about 100 yards or after a few minutes on level ground
- 4 = Too breathless to leave the house or breathless when dressing or undressing

Modified from Mahler DA, Wells CK. Evaluation of clinical methods for rating dyspnea. *Chest*. 1988;93(3):580–586.

Hypoxia, acidosis, exercise, and hypercapnia can experimentally induce the “urge to breathe/air hunger” component of dyspnea, likely via an increase in brainstem ventilatory drive.

“Excessive effort” can be provoked with external resistive or elastic loads or by pharmacologically weakening or fatiguing the muscles of respiration. Applying these observations, dyspnea in the setting of lung disease can be viewed as an imbalance of “supply” and “demand.” The diseased lung with abnormal mechanical properties is unable to satiate the ventilatory requirements of a heightened respiratory drive. Put simply, when the amount of effort to breathe is not matched by an appropriate amount of ventilation, patients will sense dyspnea. However, because dyspnea may arise in the setting of normal gas exchange and normal pulmonary mechanics, other factors must be involved.

Dyspnea is also influenced by psychosocial factors. It is a common symptom of panic disorder, and experimental data demonstrate that it can be modulated by mood, previous experience, surprise, and context.

## Dyspnea and Exercise Physiology

A mechanistic understanding of exercise physiology is important in the clinical evaluation of unexplained dyspnea. The mammalian response to exercise can be viewed as Wasserman’s three interlocked gears: cellular respiration, the circulatory system, and pulmonary respiration. During sustained exercise, adenosine triphosphate regeneration in the muscles is chiefly performed by aerobic metabolism, which consumes oxygen and produces CO<sub>2</sub>. The large increase in oxygen consumption ( $\dot{V}O_2$ ) and CO<sub>2</sub> production ( $\dot{V}CO_2$ ) by the exercising muscle necessitates parallel increases in blood flow and ventilation. To facilitate gas transport in the blood, cardiac output increases via sequential increases in stroke volume and heart rate while peripheral circulatory responses include enhanced extraction of oxygen from hemoglobin and dilation and recruitment of skeletal muscle capillary beds. The pulmonary circulation accommodates the increase in blood flow through recruitment of

pulmonary capillary beds leading to a drop in pulmonary vascular resistance with exercise. Although the increased cardiac output shortens the average red blood cell (RBC) transit time through the pulmonary circulation, the increased pulmonary capillary blood volume ensures sufficient RBC contact with the alveoli to facilitate gas exchange. In response to CO<sub>2</sub> production, lactic acidosis, and perhaps cues from exercising skeletal muscle, the central nervous system triggers an increase in alveolar ventilation to maintain a physiologic arterial pH. This is achieved by a sequential rise in tidal volume and respiratory rate to minimize the work and oxygen cost of breathing, in a manner analogous to the sequential rise in cardiac stroke volume and heart rate. Put very simply, exertion requires that the heart move more blood and the lungs move more air.

Exertional dyspnea can be explained by a difficulty in effective achievement of one or more of these processes. As such,  $\dot{V}O_2$  at peak exercise (the maximum amount of oxygen a patient uses at the point at which exertion is symptom-limited) serves as an integrative barometer of cardiorespiratory function. In healthy persons, peak  $\dot{V}O_2$  is determined by the limits of the cardiovascular system, as the ability to increase cardiac output plateaus. In normal individuals, the pulmonary capacity to increase minute ventilation has not peaked. Thus in healthy persons, there is still unused pulmonary capacity even at peak exercise.

## Pathophysiology of Disorders Associated With Exertional Dyspnea

### Pulmonary Causes of Dyspnea

Rather than memorizing specific causes of dyspnea (Box 33.2), etiologies can be approached “mechanistically.” As discussed earlier, the normal respiratory response to exertion requires an increase in minute ventilation, which is accomplished by increasing both respiratory rate (air moves faster in and out of the lung) and tidal volume (larger breaths are taken). As a framework, pulmonary disorders that make either of these actions more difficult can result in dyspnea: obstructive diseases make airflow more difficult, and restrictive diseases make increases in tidal volume more difficult. In addition, disorders of ventilatory control may contribute to the sensation of dyspnea.

Upper or central airway obstruction may produce dyspnea when an anatomic abnormality leads to airflow limitation. The defect may localize to any region between the oropharynx and bronchi, and it may manifest during inspiration, expiration, or both. Lesions may include malignancy, benign neoplasms, disorders of the larynx, goiter, tracheobronchomalacia, infiltrative disorders of the airway, airway stenosis or web, infection, lymphadenopathy, vascular lesions, granulation tissue, hematoma, and foreign body. Paradoxical vocal fold motion (PVFM) is a particular type of intermittent upper airway obstruction and refers to episodic unintentional adduction of the true vocal cords. Diagnosis of PVFM is often difficult, delayed, and associated with extensive antecedent testing.

#### Other

Anemia  
Acidosis  
Thyrototoxicosis  
Fever

Obstructive pulmonary diseases are common and are defined by the American Thoracic Society (ATS) as having an FEV<sub>1</sub>-to-forced vital capacity ratio (FEV<sub>1</sub>/FVC) below the fifth percentile of the predicted value for a given patient, which is usually around 0.7 (the lower limit of normal decreases with age). Obstructive lung diseases include asthma, COPD, bronchitis, and other less common disorders. These conditions are characterized by increased airway resistance, and thus increased effort is required to move air in and out of the lungs. A less obvious but extremely important cause of dyspnea in patients with a severe asthma attack or more advanced COPD is decreased respiratory system compliance caused by hyperinflation of the lungs. In these patients, because of severe obstruction of airflow on exhalation, the lungs do not empty to the normal residual volume, and patients are breathing at higher lung volumes. The sensation can be experienced by normal individuals upon taking a deep breath and then trying to breathe without exhaling fully. Hyperinflation, which may be present at rest or develop with exertion, can lead to intolerable dyspnea

at even low levels of exercise in the absence of significant arterial desaturation. It places the muscles of respiration at a mechanical disadvantage and increases the work and oxygen cost of ventilation. Ventilation-perfusion mismatch leads to gas exchange abnormalities, including a greater burden of “wasted” or dead space ventilation and alveolar hypoxia. The ensuing hypercapnia, hypoxemia, and acidosis further stimulate respiratory drive and enhance the perception of dyspnea. Exertional hypoxemia can be observed in COPD, but it is typically modest in the absence of pulmonary hypertension (PH).

In contrast with other diseases in this category, the obstructive deficit in asthma reverses with bronchodilator administration. Clinical overlap can be seen in some persons with COPD, who also have an asthma-like response to a bronchodilator. Exercise-induced bronchoconstriction, seen in some asthmatics, peaks after (not during) exertion after the withdrawal of bronchodilatory sympathetic tone upon exercise completion. Exertional hypoxemia is not seen in the ambulatory asthmatic population and should prompt concern for other etiologies of dyspnea.

Restrictive pulmonary diseases, defined by the ATS as those with a total lung capacity (TLC) below the fifth percentile of the predicted value for a given patient, encompass a heterogeneous group of diffuse parenchymal lung diseases, neuromuscular conditions, and disorders of the chest wall. The common theme of these disorders is an abnormal decrease in lung volumes. Restrictive diseases can be characterized by a decrease in respiratory system compliance (“a stiffer” lung and/or chest wall) leading to an increase in the work of breathing and a breathing pattern consisting of rapid, shallow breaths or by a decrease in inspiratory muscle (usually diaphragmatic) strength causing smaller lung. The most obvious connection between restrictive diseases and dyspnea is the increased effort required to expand the lungs. However, diffuse parenchymal lung diseases associated with pulmonary fibrosis are also characterized by abnormalities in gas exchange owing to ventilation-perfusion mismatch and oxygen diffusion limitation consequent to destruction of the alveolar-capillary interface. This parenchymal destruction may be associated with stimulation of afferent mechanical, irritant, and/or vascular receptors that stimulate central ventilatory drive and enhance the perception of dyspnea. Exertional hypoxemia is common because RBC transit time quickens across a pruned pulmonary vascular bed and can be profound in advanced disease. Diffuse parenchymal lung disease can also be complicated by PH.

Disorders of respiratory control are not associated with mechanical issues affecting ventilation. One relatively common condition includes idiopathic hyperventilation, although the cause of this syndrome is unknown. In other instances, hyperventilation may be appropriate, as in those with chronic metabolic acidosis. Hyperventilation is also commonly associated with panic disorder as well as endogenous and pharmacologically dosed progesterone. The P2Y<sub>12</sub>-receptor antagonist ticagrelor has also been shown to cause dyspnea in dose-dependent fashion and has also been

associated with Cheyne-Stokes respiration and an increased chemoreceptor sensitivity to hypercapnia.

## Cardiovascular Causes of Dyspnea

Analogous to the respiratory response, the cardiac response to exertion requires an increase in cardiac output accomplished by increasing heart rate and stroke volume. Again, as a framework for thinking about dyspnea, cardiac conditions that impair either of these actions can result in dyspnea.

CAD and myocardial ischemia must be considered in all patients presenting with dyspnea on exertion. In the patient with known risk factors or a “good story” for exertional angina, it is advised to assess for myocardial ischemia before performing other evaluations. Myocardial ischemia may manifest as exertional dyspnea owing to aberrant left ventricular systolic or diastolic function or as an independent symptom with unclear pathophysiologic roots. Symptomatic CAD may manifest as a reduced  $\dot{V}O_2$ , often caused by a limited increase in stroke volume relative to heart rate. It may be subtle and difficult to distinguish from deconditioning on formal cardiopulmonary exercise testing in the absence of electrocardiogram (EKG) changes. Exertional hypoxemia is not typically seen in CAD.

CHF arises in the setting of reduced (CHFrEF) or preserved (CHFpEF) left ventricular ejection fraction, cardiomyopathy, or valvar heart disease. At rest, the cardiac output may be reduced or normal. However, with exertion, the diseased heart is unable to sufficiently augment cardiac output owing to a reduction in stroke volume from impaired left ventricular systolic or diastolic function. It has long been appreciated that peak  $\dot{V}O_2$  strongly predicts mortality in patients with CHF, and consequently, it is used to risk stratify patients for advanced therapies including orthotopic heart transplantation. In heart failure, mechanisms of dyspnea include a high ventilatory requirement relative to the rate of  $CO_2$  production (caused by decrease perfusion of the lung and/or concomitant pulmonary vascular disease), early onset of metabolic acidosis, stimulation of pulmonary vascular afferent C-fibers (formerly J-receptors), exercise-induced changes in pulmonary vascular pressures, and changes in the structure and function of skeletal muscle. Oscillatory breathing, also known as Cheyne-Stokes respiration, is seen in a subpopulation of these patients, both at rest and exercise. Arterial hypoxemia is not typically seen in the absence of PH, pulmonary edema, or concomitant pulmonary disease.

CHF may also arise in the setting of elevated cardiac output, as can be seen in hyperthyroidism, liver disease, arteriovenous shunts (including hereditary hemorrhagic telangiectasia, hemodialysis fistula, Paget disease), thiamine deficiency, anemia, and morbid obesity.

Disorders of heart rate and/or rhythm can impair the heart rate response to exercise and thus cardiac output. In the author’s experience, chronotropic incompetence (i.e., lack of appropriate increase in heart rate) caused by

medication or conduction system disease is a commonly overlooked cause of dyspnea. Exercise-induced arrhythmias, especially rapid atrial fibrillation, may also present with dyspnea on exertion.

Congenital heart disease can be overlooked in the adult population. Although complex lesions are more likely to present in childhood, some conditions such as bicuspid aortic valve, atrial septal defect, and partial anomalous pulmonary venous connection are often diagnosed in adulthood. Lesions associated with long-standing left-to-right shunt may present with Eisenmenger syndrome in adulthood, which manifests as hypoxemia, cyanosis, and sequelae of PH.

Disorders of the pericardium, including pericarditis and pericardial effusion, can present insidiously with dyspnea, fatigue, and edema. Chronic inflammation may lead to constrictive pericarditis, which hinders diastolic ventricular filling and cardiac output.

An unusual but increasingly recognized cause of dyspnea on exertion is preload limitation to cardiac output and may be seen in the setting of impaired venous return such as central venous obstruction and dysautonomia.

Deconditioning, a common contributor to dyspnea, is challenging to diagnose with certainty. It is putatively characterized by a reduced or low normal peak  $\dot{V}O_2$ , reduced stroke volume, increased heart rate relative to  $\dot{V}O_2$ , impaired skeletal muscle oxygen use, and early onset of lactic acidosis. In practice, it is challenging to distinguish from early cardiovascular disease. It remains a diagnosis of exclusion.

## Pulmonary Vascular Disease

PH encompasses a category of diseases with disparate etiologies, pathophysiology, and treatments, unified under a common hemodynamic definition of a mean pulmonary pressure  $>25$  mm Hg during pulmonary arterial catheterization. PH shares common features of both parenchymal lung disease and heart failure. Exertional dyspnea is a hallmark of PH, and the mechanism varies depending on whether the condition arises in the setting of idiopathic pulmonary arterial hypertension, left heart disease, parenchymal lung disease, chronic hypoxemia, chronic thromboembolic PH, or unknown/multifactorial mechanisms. Typical gas exchange derangements include an increase in ventilation relative to  $CO_2$  production (similar to CHF) and arterial hypoxemia arising in the setting of ventilation-perfusion mismatch (similar to parenchymal lung disease). Over time, PH may progress to right ventricular failure.

Pulmonary embolism (PE) is an important cause of dyspnea and should be always kept in mind. Although PE is more likely to present with acute dyspnea, a subset of patients will present with a more indolent onset of exertional dyspnea in the setting of subacute PE or chronic thromboembolic PH.

Pulmonary arteriovenous malformations (AVMs) are seen in hereditary hemorrhagic telangiectasia, the hepatopulmonary syndrome, and congenital heart disease and may

manifest with hypoxemia and dyspnea if the degree of right-to-left shunt is sufficient.

## Disorders of Peripheral Oxygen Transport and Use

Anemia reduces the oxygen-carrying capacity of the blood. Exertional dyspnea is common in this setting and may arise because of early onset of lactic acidosis with exercise. Resting hypoxemia is not seen with anemia in the absence of other disorders affecting gas exchange. Cardiac output is typically preserved or increased.

Impaired tissue oxygen use may arise in conditions with aberrant oxidative metabolism or microcirculatory dysregulation leading to an imbalance of oxygen supply with demand in exercising skeletal muscle. Mitochondrial myopathy is a rare but well-described cause of exertional dyspnea, owing to impaired oxygen extraction and early onset of anaerobic metabolism. Impaired peripheral oxygen extraction has also been described in subpopulations of patients with CHFpEF and orthotopic heart transplantation. It has also been reported in deconditioning.

## Multifactorial Causes of Dyspnea

Obesity is associated with increased prevalence and severity of exertional dyspnea. Reported physiologic derangements include decreased respiratory system compliance, modest reduction in functional residual capacity and FEV<sub>1</sub> (although TLC, the ATS standard for determining restriction, remains within normal limits), increased airway resistance, reduced respiratory muscle strength, and increased work of breathing. However, the effector of dyspnea in this setting remains controversial. Although ventilation-perfusion mismatch in morbid obesity is associated with a modest reduction in arterial oxygen tension, it is rarely sufficient to cause resting hypoxemia.

Pregnancy can be associated with exertional dyspnea in up to 75% of women by the 30th week of gestation, although it is not usually severe enough to constrain daily activities or peak  $\dot{V}O_2$ . Pregnancy is associated with resting and exertional hyperventilation via an increase in tidal volume. Patients typically breathe with “deeper breaths” but a normal respiratory rate. These changes are likely caused by the stimulatory effects of progesterone and estrogen on the respiratory control center as well as increased chemoreceptor sensitivity to CO<sub>2</sub>. Although the phenomenon is incompletely understood, it is hypothesized that the physiologic breathlessness of pregnancy may be caused by a greater awareness of this increased central ventilatory drive. Notably, pregnancy does not constrain the maternal ventilatory apparatus, despite progressive uterine growth. In fact, hormonally induced ligamentous relaxation of the chest leads to a change in shape of the thorax and preservation of TLC. Systemic hypoxemia is never normal in pregnancy and warrants evaluation.

Thyroid disorders may present with dyspnea and a spectrum of cardiopulmonary pathology. Clinical hypothyroidism is associated with decreased ventilatory drive, whereas hyperthyroidism is associated with increased respiratory drive. Respiratory muscle weakness and PH may be seen in either condition.

## Diagnostic Evaluation

### History

A thorough history remains the cornerstone of the dyspnea evaluation. The differential diagnosis can be narrowed using the chronology of symptoms: for the purposes of this review, we will focus on chronic symptoms defined as dyspnea lasting more than one month. Acute etiologies will not be discussed. In addition to exploring the patient's current symptoms, a history of prior conditions including a history of respiratory complications in childhood, atopy, hospitalizations for dyspnea, respiratory infections, inhaler or diuretic use, cardiac or thoracic surgeries, and relevant conditions in family members as well as a general review of any recent changes in the medical history or prescribed medications should be elicited.

It is important to challenge the patient to precisely describe his or her symptoms and exclude comorbid symptoms like pain and fatigue as a barrier to exertion. As patients may slowly curtail their lifestyle in response to their dyspnea, it is important to assess their functional capacity. A patient may deny exertional dyspnea, but the clinician may uncover that she is sedentary for the majority of the day. Important questions include “What is the most strenuous activity for your breathing that you undertake during the course of your day?” and “When was the last time you could perform this activity without limitation by shortness of breath?” Dyspnea that is intermittent raises the prospect of bronchospasm, hyperventilation, or pulmonary edema, whereas persistent dyspnea suggests a more chronic pathology. It can be helpful to ask the patient to quantify his or her functional capacity by asking him or her to estimate how many flights of stairs he or she can climb or how many feet he or she can walk before having to stop on account of his or her breathing. Dyspnea with activities of daily living such as dressing, toileting, and eating suggests advanced cardiac or pulmonary disease.

Exacerbating and alleviating factors refine the differential diagnosis. The supine position aggravates dyspnea in the setting of diaphragm weakness (usually occurs immediately after lying supine) and orthopnea in the setting of congestive heart disease (usually worsens over minutes). Platypnea (breathing improves when supine) and orthodeoxia (oxygen saturation improves when supine) may arise in the setting of pulmonary AVM, the hepatopulmonary syndrome, atrial septal defect with right-to-left shunt, and pericardial pathology. “Trepopnea” describes dyspnea precipitated in either the left or right lateral decubitus position, a phenomenon occurring when an abnormality lateralizes to one

lung or when the positional change unmasks an intraatrial right-to-left shunt. For the reasons explored earlier, exertion is a common exacerbating factor for patients with dyspnea; however, in exercise-induced bronchoconstriction, symptoms are absent to mild during activity, peak 10 to 15 minutes after stopping, are worse in cold weather, and are ameliorated by a gradual warm-up to exercise, pretreatment with bronchodilator, and interventions to warm and humidify inspired air.

A detailed exposure history is essential in the setting of suspected pulmonary disease. A smoking history should review past and current exposure to tobacco smoke, biomass fuels and other sources of combustion (for example, burn pit exposure in combat veterans), and illicit drug use. A diagnosis of COPD is unlikely in the absence of significant exposure to these sources, although exceptions exist in the setting of alpha-1-antitrypsin deficiency, chronic mycobacterial infection, and fixed airway obstruction that may arise as a consequence of long-standing, poorly controlled asthma. Precipitants of hypersensitivity pneumonitis are numerous and may include organic and inorganic antigens from animals, bacteria, fungi, protozoa, grains, textiles, wood, plant matter, and chemicals. Asbestos, beryllium, silica, coal dust, talc, cobalt, and other hard metals may cause occupational lung disease. Certain occupational exposures may manifest as a temporal relationship with symptoms. A travel and infectious disease history may also be helpful in the diagnosis of *Mycobacterium tuberculosis*, endemic fungal and parasitic infections of the lung, and HIV.

Certain associated symptoms may be useful in narrowing the etiology of the dyspnea. Chest pain associated with dyspnea on exertion should prompt consideration of CAD. Common precipitants of worsening asthma control include upper respiratory infection, gastroesophageal reflux disease (GERD), and rhinosinusitis. GERD may exacerbate laryngeal disorders and is also believed to accelerate the course of certain diffuse parenchymal lung diseases and the bronchiolitis obliterans syndrome seen after lung transplantation. Nonproductive cough may be a manifestation of diffuse parenchymal lung disease, asthma, and aspiration pneumonitis, whereas sputum production may be seen in COPD, chronic suppurative infections of the lung, malignancy, and bronchiectasis. Causes of central airway obstruction may also be associated with cough. Chest pain may be associated with CAD, CHF, and pulmonary vascular disease. Exertional light-headedness and syncope may be seen in the setting of advanced PH. Associated hemoptysis may suggest bronchiectasis, pulmonary vascular disease, or CHF (especially mitral stenosis).

The language used by the patient to describe his or her symptoms has been correlated to pathophysiology. A sensation of chest “tightness” has been associated with bronchospasm. Hypoxemia and hypercapnia, conditions that stimulate central respiratory control structures, can be associated with sensations of “air hunger” or a “need

or urge to breathe.” Disorders of increased airway resistance, decreased compliance of the respiratory system, and neuromuscular weakness are more likely to present with a sensation of “effort” or “work” associated with breathing.

## Physical Examination

The first step in the physical examination is to observe the patient walking. If patients are “roomed” before the encounter, we strongly encourage the clinician to accompany the patient outside the examination room and observe the patient walking or climbing stairs at some point during the visit. Observation may reveal accessory muscle use, pursed-lip breathing, and increased anteroposterior thoracic diameter in COPD. Deformities of the thorax, kyphoscoliosis, and thoracotomy scars may suggest evidence of restriction. Respiratory paradox (the diaphragm moves up instead of down during inspiration) is associated with diaphragmatic muscle weakness. Dilated venous collaterals may herald the presence of the superior vena cava syndrome. Digital clubbing may be seen in diffuse parenchymal lung disease, cyanotic congenital heart disease, the hepatopulmonary syndrome, bronchiectasis, pulmonary neoplasm, and chronic pulmonary infections; it is unusual for patients with COPD alone to present with clubbing. Percussion of the chest may reveal evidence of pleural effusion, pneumothorax, cardiomegaly, and decreased diaphragmatic excursion and can estimate lung volume. Central airway obstruction may present with monophonic wheezing or stridor. In patients with obstructive physiology, a forced expiratory maneuver may accentuate wheezes that were otherwise unappreciated during tidal breathing. Bronchiectasis may present with inspiratory “squawking.” Basilar inspiratory crackles suggest CHF, whereas crackles that are diffuse or over the upper lung zones alone favor a disease of the pulmonary parenchyma rather than CHF.

A detailed cardiovascular examination may demonstrate Cheyne-Stokes respirations, murmurs suggesting undiagnosed valvular disease,  $S_3$  or  $S_4$  gallop, elevated jugular venous pulse, hepatojugular reflux, displaced point of maximal impulse, peripheral edema, hepatomegaly, or ascites in those patients with heart failure. PH may present with a right ventricular heave, pulmonary artery tap, accentuated pulmonic component of the second heart sound, right-sided gallop, murmur of tricuspid regurgitation, or engorged jugular veins with prominent atrial or ventricular waves.

In addition to a focused assessment of the chest, a general medical examination may reveal useful clues. Palpable purpura may reflect underlying vasculitis, whereas stigmata of connective tissue disease may heighten suspicion for diffuse parenchymal lung disease or pulmonary arterial hypertension. Manifestations of cirrhosis should prompt investigation for orthodeoxia and platypnea. Ptosis, fasciculations, or bulbar weakness necessitate further neurologic evaluation.

Ambulatory oximetry is perhaps the most efficient bedside diagnostic maneuver in the chronically dyspneic patient. When personally performed by the clinician, this accomplishes the goal of observing the patient during effort and affords insight into functional status, the presence of nondyspnea limits to exercise (back or leg pain, gait instability, orthostasis), affective contributors, pattern of breathing, chronotropic response to exercise, and the presence and/or tempo of arterial desaturation.

## Diagnostic Testing

For many patients, a thorough history and physical examination will point the clinician toward the most likely cause, and a therapeutic trial without further formal testing may suffice. For example, an otherwise healthy patient with a history consistent with exercise-induced asthma can be treated with albuterol. If the dyspnea resolves, no further testing would be needed. The history should guide the clinician, and in most instances a focused, cost-effective approach can be accomplished (Fig. 33.1).

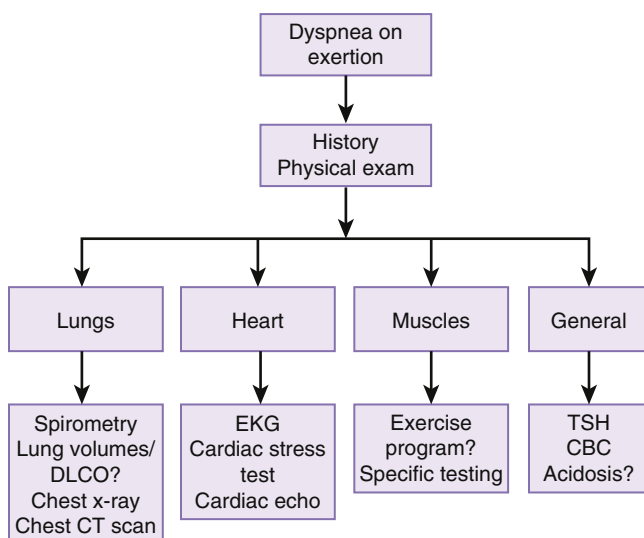

For patients in whom the diagnosis is uncertain after an initial evaluation, a basic metabolic profile and complete blood count are reasonable initial laboratory investigations. Elevated serum bicarbonate may indicate a chronic respiratory acidosis, which can be confirmed by arterial blood gas analysis. Occult hypoxemia may produce an erythrocytosis. CHF or PH commonly present with elevated B-type natriuretic peptide (BNP or NT-proBNP). The EKG may inform the presence of CAD, disorders of rate or rhythm, pulmonary hyperinflation or pericardial effusion (low precordial voltage), pulmonary vascular disease (right atrial dilation, right ventricular hypertrophy, the “S1Q3T3” pattern, right axis deviation, precordial ST deviation or T-wave

inversions), and an underlying substrate for CHFpEF (left ventricular hypertrophy, left atrial enlargement).

Pulmonary function testing can start with simple spirometry for patients suspected of having airway obstruction. A bronchodilator challenge should be administered in those with possible asthma. Measurement of lung volumes and the single-breath diffusing capacity for carbon monoxide ( $D_{LCO}$ ) are indicated in more complex patients or when restrictive or pulmonary vascular diseases are suspected. Respiratory muscle strength may be interrogated with maximum static inspiratory and expiratory pressure assessment, although these studies require excellent cooperation and motivation; alternatively, a decrease in vital capacity going from the upright to the supine position implicates severe diaphragm weakness. A reduction in  $D_{LCO}$  suggests a compromise in the alveolar surface area for gas exchange and can be seen in diffuse parenchymal lung disease, pulmonary vascular disease, anemia, emphysema, surgical resection of the lung, or extrapulmonary causes of restriction. An isolated or “out-of-proportion” deficit in  $D_{LCO}$  is a hallmark of pulmonary vascular disorders.

Transthoracic Doppler echocardiography is the principal screening tool for structural heart disease. Its breadth of physiologic information, lack of ionizing radiation, and ease of assessment make it an attractive modality in the evaluation of chronic dyspnea. Echocardiography will identify valvar heart disease and abnormal ventricular function. In addition, an agitated saline study may unmask an occult intracardiac or intrapulmonary right-to-left shunt. An elevated right ventricular systolic pressure (RVSP), right ventricular and atrial dilation, right ventricular hypertrophy, and intraventricular septal flattening should raise concern for PH. However, echocardiographic suggestion of PH warrants invasive confirmation, owing to the poor correlation between invasive and noninvasive measurements of pulmonary artery pressure. Furthermore, as Doppler RVSP measurement may underestimate the true value, a normal RVSP should not completely reassure the clinician when the concern for pulmonary vascular disease is high.

A chest x-ray is the appropriate first radiographic study of the chest. Cardiomegaly, CHF, and hyperinflation and hypoinflation of the lungs can be seen. CT of the chest may be needed to further evaluate abnormalities seen on x-ray and is the principal tool to assess for diffuse parenchymal lung diseases. In some instances, CT imaging may obviate the need for a surgical lung biopsy. In addition to the parenchyma, a standard chest CT without intravenous contrast offers a limited, but occasionally fruitful, assessment of coronary calcification and cardiac, pericardial, vascular (better delineated with intravenous contrast), and mediastinal morphology. Dedicated inspiratory and expiratory protocols can assess for tracheobronchomalacia or air trapping. Although CT angiography has become the gold-standard method of interrogating for acute PE, ventilation/perfusion scintigraphy is still regarded as a more sensitive test for chronic thromboembolic PH.

• **Fig. 33.1** A simplified approach to the primary care evaluation of chronic dyspnea. *CBC*, Complete blood count; *DLCO*, diffusing capacity for carbon monoxide; *Echo*, echocardiogram; *EKG*, electrocardiogram; *TSH*, thyroid-stimulating hormone.

A problem with evaluating a patient for dyspnea on exertion is that most of the testing occurs with the patient at rest. Cardiopulmonary exercise testing (CPET) provides an integrative assessment of the pulmonary, cardiovascular, and metabolic response to exercise, usually by cycle ergometer or treadmill. CPET may be used when the aforementioned investigations do not satisfactorily explain a patient's dyspnea. Its utility also extends to perioperative risk assessment, quantification of functional impairment, and evaluation for heart and lung transplantation. Through assessment of peak  $\dot{V}O_2$ ,  $\dot{V}CO_2$ , ventilatory parameters, anaerobic threshold, arterial oxygen saturation, and EKG tracing, a standard CPET can reliably identify pulmonary disease as the limitation to exertion, in circumstances when cardiac reserve outweighs that of the lungs. CPET may also implicate CAD, CHF, chronotropic incompetence, exercise-induced arrhythmias, pulmonary vascular disease, or peripheral oxygen use factors, such as mitochondrial myopathy, as the most likely etiology of dyspnea.

In our institution and others, invasive CPET is available to further assess complex patients where diagnostic uncertainty persists. In this test, a CPET is performed with pulmonary artery (Swan-Ganz) and radial artery catheters in place. Standard metabolic monitors, including oxygen uptake and  $CO_2$  production, in addition to data from the pulmonary arterial and radial artery catheters are used to definitively quantify cardiac output and filling pressures, pulmonary vascular resistance, and peripheral oxygen extraction.

## Therapy

Etiology is the most important determinant of dyspnea therapy, which further emphasizes the importance of an accurate diagnosis. Treatment of all of the disorders discussed earlier is beyond the scope of this chapter. However, in addition to addressing the underlying disease, rehabilitation is an important adjunct to managing dyspnea related to pulmonary and cardiac pathologies. Rehabilitation is designed to address the physiologic and psychologic aspects of disease, through a tailored program of exercise training and patient education.

Pulmonary rehabilitation has been most carefully studied in COPD, where its effects include improved quality of life and exercise capacity and decreased dyspnea. Contrary to a commonly held belief, symptomatic individuals with more modest obstructive deficits still derive benefit. In those recently discharged after an acute exacerbation of COPD, early implementation of rehabilitation may decrease the rate of rehospitalization. The impact of rehabilitation on mortality remains inconclusive in observational studies and requires further study. The merits of rehabilitation are most evident in those with COPD but have also been appreciated in diffuse parenchymal lung diseases, pulmonary arterial hypertension, bronchiectasis, cystic fibrosis, asthma, and lung cancer.

The salutary benefits of structured rehabilitation extend to cardiovascular disease, where there are more conclusive and nuanced data to guide its use. In a metaanalysis of 63 randomized-controlled trials of exercised-based cardiac rehabilitation, compared with no rehabilitation, structured rehabilitation was associated with reduced cardiovascular mortality and hospitalization in those with recent myocardial infarction, revascularization, angina, or angiographically proven CAD. In CHF<sub>r</sub>EF, aerobic training increases  $\dot{V}O_2$  peak and left ventricular EF, improves quality of life, and decreases hospitalization. There are conflicting data on the impact on all-cause mortality, but the data clearly attest to the safety of rehabilitation in this population. Exercise-training increases  $\dot{V}O_2$  peak and quality of life in CHF<sub>p</sub>EF, but the benefits appear more modest compared with CHF<sub>r</sub>EF.

Regardless of participation in a formal rehabilitation program, it is our practice to encourage all patients with chronic dyspnea to exercise after acutely life-threatening conditions have been addressed. An "exercise prescription" can be created, based on the patient's underlying disease, comorbidities, and functional status.

Dyspnea that arises in the setting of intractable pulmonary or cardiac disease can be challenging to manage in the ambulatory patient. Opioids are the principal means of pharmacologically modulating dyspnea through a decrease in respiratory drive and a modulation of central dyspnea perception. Opioids are a core aspect of palliative therapy in those with terminal disease, although some clinicians advocate using them at an earlier stage of illness to address refractory dyspnea.

In select patients, oxygen supplementation may offer symptomatic relief of dyspnea, but there are insufficient data to justify this practice for most nonhypoxemic patients. In addition to relieving hypoxemia, oxygen delivery by nasal cannula may attenuate dyspnea via activation of "flow" receptors in the nasopharynx, independent of arterial oxygen tension. Use of a fan to blow cool air at the face has also been shown to improve experimentally induced dyspnea, perhaps by activation of trigeminal nerve afferent pathways.

## Summary

Dyspnea on exertion is a common problem in primary care and may be the manifestation of life-threatening and much less serious diseases. The differential is very broad, and a mechanistic approach based on a basic understanding of exercise physiology can help the clinician evaluate the patient in an efficient and cost-effective manner. A thorough history and physical examination are often all that is needed for the clinician to make a preliminary diagnosis and, after considering dangerous conditions such as CAD, begin a therapeutic trial. Further targeted testing may be required, and in the patient with unexplained dyspnea an invasive CPET can elucidate the cause.

## Chapter Review

### Questions

- A 42-year-old woman presents with a complaint of shortness of breath. She has gained 40 lbs since her mid-20s. She recently started an exercise program and notices that she is feeling more dyspneic and is coughing during and after she jogs. She has no other symptoms. Her body mass index (BMI) is 31, but vital signs and the remainder of a detailed cardiac and pulmonary physical examination are within normal limits.

Which of the following is true?

  - Rest and exercise spirometry is indicated to assess for exercise-induced asthma.
  - A trial of albuterol before exercise can serve as both a diagnostic and therapeutic trial.
  - A 40-lb weight gain and BMI of 31 are sufficient to explain her dyspnea, and no further evaluation is needed.
  - At age 42 years, even if she has risk factors for coronary disease, further testing for myocardial ischemia is not indicated.
  - In the absence of pleuritic chest pain or abrupt onset of dyspnea, PE does not warrant further evaluation.
- A 68-year-old heavy smoker presents to his primary care physician in a follow-up after a recent hospitalization for an acute myocardial infarction (MI) and percutaneous angioplasty and coronary artery stenting. The left ventricular EF was low-normal at discharge as assessed by transthoracic echocardiography. New medications since the MI include aspirin, atorvastatin, metoprolol, ticagrelor, and sublingual nitroglycerin in addition to his pre-MI medication enalapril. Since discharge, the patient has noticed new symptoms of dyspnea on exertion.

Which of the following is true?

  - Participation in a cardiac rehabilitation is unlikely to help his dyspnea and is not indicated in this setting.
  - Since he underwent revascularization, ongoing cardiac ischemia should not be considered further at this point.
  - Prescription of inhaled albuterol is an appropriate first step both as a diagnostic and therapeutic trial.
  - Chronotropic incompetence caused by metoprolol is a likely diagnosis and should be discontinued.
  - Ticagrelor may be associated with dyspnea likely caused by an increase in chemosensitivity.
- A healthy 20-year-old college student has not been exercising regularly. She had been on the cross country running team in high school. However, since starting college 2 years ago, she has not been running “because of stress.” She is on no medications and has no known medical problems. She decides to “get back in shape” but notices that running is much more difficult, and she is more dyspneic than she remembers being when she ran before. She has no other symptoms.

Which of the following is true?

  - Given these symptoms, she should be evaluated for thyroid disease before starting an exercise program.
  - The normal response to exercise includes an increase in cardiac output through an increase in heart rate and stroke volume.
  - Prescription of inhaled albuterol is an appropriate first step both as a diagnostic and therapeutic trial.
  - Her shortness of breath is abnormal and merits further evaluation.
  - Anxiety is the most likely cause, and she should be encouraged to continue exercising.

## Chronic Obstructive Pulmonary Disease

TILAK K. VERMA AND AJAY K. SINGH

Virtually every health care practitioner who provides care to adults will encounter individuals with chronic obstructive pulmonary disease (COPD). Current estimates of the prevalence of the condition vary based upon the method of ascertainment; most surveys show that ~6% of adults report a doctor's diagnosis of COPD but that ~25% have airflow obstruction when assessed by spirometry. COPD is common, morbid, mortal, and expensive: estimates are that >20 million US adults and ~14% of adults ages 40 to 79 have COPD and that it is responsible for >120,000 deaths annually with a cost to the US economy of >\$38 billion. This chapter will describe the definition of COPD, presenting clinical symptomatology and evaluation, natural history, differential diagnosis, current concepts of pathogenesis, therapeutic options, and the evaluation of a patient with known or suspected COPD considering surgery.

### Definition of Chronic Obstructive Pulmonary Disease

The definition of COPD has undergone an evolution; originally presented as an umbrella term to encompass emphysema, chronic bronchitis, and chronic asthma, it has most recently been defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) as “a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases.” In contrast, the definition of emphysema is based on anatomic features (enlargement of the airspaces distal to the terminal bronchiole) and that of chronic bronchitis is based on symptoms (daily cough and phlegm for 3 months for 2 or more consecutive years). Neither actually requires the presence of airflow obstruction.

### Pathogenesis

There are compelling epidemiologic data relating inhalational exposure to tobacco smoke to the development of

COPD. Exposure to tobacco smoke results in an inflammatory reaction in the lung in virtually everyone who smokes. As discussed below, however, the precise mechanisms by which tobacco smoke exposure results in COPD remain to be defined. Exposure to biomass fuels is also a risk factor in the development of COPD because they cause inflammation.

Observational human studies in the 1960s that identified the association of alpha-1-antitrypsin deficiency with emphysema and work on animal models of disease led to the formulation of the protease-antiprotease hypothesis, which proposes that emphysema results from an imbalance of proteases and antiproteases in the lung. In the case of alpha-1-antitrypsin, it is believed that the deficiency of this inhibitor allows unrestricted activity of neutrophil elastase, leading to alveolar destruction. It is not yet clear which proteases and antiproteases are involved in the pathogenesis of emphysema in smokers with normal alpha-1-antitrypsin levels. There is experimental evidence supporting potential participation of elastases of several different classes, including macrophage metalloelastase, in the pathogenesis of emphysema. Inhibition of these enzymes or modulation of the protease-antiprotease balance by targeting relevant regulatory pathways is a potential target of new therapeutic agents.

In addition to the protease-antiprotease hypothesis, there is also evidence supporting the potential roles of oxidative stress, inflammatory cytokines, suppressed angiogenesis, and apoptosis in the pathogenesis of COPD. Also unanswered is the question of whether COPD is a disease of defective repair rather than excessive destruction.

Genetic risk factors have focused on a hereditary deficiency of alpha-1 antitrypsin. There are also data to support the hypothesis that genetic factors may underlie the relative predisposition to or protection from the development of COPD as a result of exposure to cigarette smoke. Work to date has not convincingly identified a “COPD gene” other than alpha-1-antitrypsin, and current concepts of complex genetic traits suggest that there are likely a number of genes, each of which has a relatively small effect size.

## Classification of Chronic Obstructive Pulmonary Disease

A number of classification schema have been proposed for COPD. They share the common property of characterizing severity by the degree of airflow obstruction present on spirometry. The presence of a reduction in the ratio of forced expiratory volume in 1 second ( $FEV_1$ ) to forced vital capacity (FVC) establishes the presence of obstruction; the degree of reduction in the  $FEV_1$  is used to determine severity. Currently, the most widely used schema is the GOLD system, presented in Table 34.1. Another classification tool proposed by GOLD in 2011 combines symptomatic assessment with spirometric classification and/or risk of exacerbations. The ABCD assessment tool, however, had limitations as it did not perform better in predicting outcomes or mortality.

As the definition of COPD indicates, there are clinically significant manifestations of the disease that are not accurately measured by indices of airflow obstruction. A number of classification systems have been developed in an attempt to better capture the total impact of the disease. The most widely used of these is the BODE (Body mass index, airflow

Obstruction, Dyspnea, and Exercise) Index, developed by Celli and colleagues, that incorporates body mass index, airflow obstruction, symptoms of dyspnea, and exercise tolerance in a scoring system that has been demonstrated to better predict mortality than using airflow obstruction alone. The BODE Index is presented in Table 34.2.

The BODE Index more accurately correlates with prognosis than systems that use spirometry alone to classify patients. Recently, GOLD has proposed a multidimensional system incorporating airflow obstruction, symptoms, and exacerbation frequency. Currently there are not enough published prospective data to establish whether it has improved performance over the GOLD classification based on spirometry alone.

## Clinical Presentation

The majority of persons diagnosed with COPD initially present for medical evaluation in one of two ways: with gradually progressive symptoms that include dyspnea on exertion or with an acute illness characterized by an abrupt increase in cough, sputum, and dyspnea (COPD exacerbation). In the latter scenario, questioning usually reveals antecedent gradual increase in exertional dyspnea and/or chronic cough.

## Demographics and Symptoms

The typical patient presents between age 50 and 70 years and frequently has a history of significant cigarette use. As mentioned above, the most frequently cited symptom is dyspnea on exertion, which has usually been gradually increasing for months to years. Given the age and demographic characteristics of patients with COPD, the increase in dyspnea is often attributed to aging, deconditioning, weight gain, or concomitant comorbid medical conditions, including cardiovascular disease, osteoporosis, metabolic syndrome, depression and anxiety, and lung cancer. Cough,

Modified from Celli R, Cote CG, Marin JM, et al. The body-mass index, airflow obstruction, dyspnea, and exercise capacity index in chronic obstructive pulmonary disease. *N Engl J Med*. 2004;350:1005–1012.

particularly morning cough with sputum production, is common and frequently accepted by patients as “a normal smoker’s cough.”

In addition to chronic symptoms, patients may also report episodic exacerbations in symptoms with a syndrome of increased cough, increase and/or change in characteristics of sputum production, and increased dyspnea. Exacerbations are defined by GOLD as “acute worsening of respiratory symptoms that result in additional therapy.” The best predictor of an exacerbation is a history of a previous one. This may be accompanied by fever, myalgias, and other symptoms suggesting viral infection. Not infrequently, patients will report a repeated seasonal occurrence of such events, stating “every winter I get a cold and it settles in my chest” or similar descriptions.

### Physical Examination

In patients with mild or moderate disease, the history of symptoms in the appropriate exposure setting is the key to pursuing evaluation, as the physical examination is frequently normal. As airflow obstruction becomes more severe, the physical examination may reveal a prolonged expiratory phase of the respiratory cycle, inspiratory basilar rhonchi or crackles, and expiratory polyphonic wheezing. Supportive signs on the physical examination may include stigmata of cigarette smoking, including dental changes, skin thinning and wrinkling, and nicotine staining of fingers. Clubbing is not seen in COPD, and its presence should prompt evaluation for other causes, most frequently lung cancer.

In patients with severe or very severe COPD, there may be skeletal muscle wasting, the use of accessory muscles of respiration at rest with patients seeking positions that allow them to brace the shoulder girdle to provide mechanical advantage for these muscles. These positions include the classic “tripod” position while seated and using the handles on a shopping cart or wheelchair while ambulating. Examination of the chest reveals markedly prolonged expiratory phase, symmetrically diminished breath sounds, and medial and inferior displacement of the cardiac point of maximal impulse to the subxiphoid position. It is unusual for patients to present with signs of overt right heart failure (“cor pulmonale”) or physical findings of severe pulmonary hypertension.

### Differential Diagnosis

The differential diagnosis of a middle-aged person presenting with dyspnea on exertion is broad. It includes COPD, asthma, interstitial lung disease, anemia, congestive heart failure, coronary artery disease, and deconditioning. Given the nonspecificity of the presenting symptoms and physical examination, the ability to diagnose COPD depends on obtaining spirometry as part of the initial evaluation of the patient. The presence of airflow obstruction as manifest by a reduction in the  $FEV_1/FVC$  that does not normalize after the administration of an inhaled bronchodilator strongly supports the diagnosis (Fig. 34.1). The importance of

ordering spirometry is underlined by the fact that National Health and Nutrition Examination Survey 3 (NHANES 3) survey data suggest that at least 50% of patients with airflow obstruction have not been diagnosed with COPD and are not receiving any therapy.

### Pulmonary Function Testing

All patients with COPD have, by definition, incompletely reversible airflow obstruction on pulmonary function testing. Measurements of lung volumes will reveal increases in functional residual capacity (FRC), the ratio of residual volume to total lung capacity (RV/TLC), and TLC, all indicative of hyperinflation that is in proportion to the degree of airflow obstruction.

Measurement of the diffusing capacity for carbon monoxide (DLCO) may show a reduction. The magnitude of this reduction is in proportion to the amount of emphysematous destruction of the lungs in an individual patient.

### Arterial Blood Gases and Assessment of Oxygenation

As discussed later, the data demonstrate that patients with COPD and chronic resting hypoxemia, defined as partial pressure of oxygen ( $P_{O_2}$ ) <55 mm Hg or oxygen saturation ( $SaO_2$ ) <88%, benefit from supplemental oxygen therapy.

• **Fig. 34.1** Spirogram and flow-volume loop in airflow obstruction compared with normal, showing reduced expiratory flow rates and “coving” of flow-volume loop. FEF, Forced expiratory flow; FEV, forced expiratory volume; FVC, forced vital capacity; PEFR, peak expiratory flow rate; PIFR, peak inspiratory flow rate.

It is appropriate to assess oxygenation with either an arterial blood gas measurement or oximetry in patients with moderate or greater disease or those presenting with an increase in symptomatology. Measurement of arterial blood gases provides information not only about oxygenation but also acid–base status and partial pressure of carbon dioxide ( $\text{PaCO}_2$ ). Knowledge of the latter two parameters is important in the assessment of acute respiratory failure.

### Thoracic Imaging

Imaging of the chest can be performed with conventional chest radiography, CT, and/or MRI.

Chest x-rays (CXR) are frequently normal in patients with mild or moderate disease. Signs of hyperinflation with increase in anterior–posterior dimension and/or flattening of the diaphragms are nonspecific but are consistent with the presence of COPD (Fig. 34.2). Some smokers may manifest a nonspecific increase in interstitial markings (“dirty lungs”). In patients with more advanced disease, the images may demonstrate increased lucency of the lung fields consistent with the tissue destruction of emphysema, a diminishment in visualized vascularity, and medial and inferior

• **Fig. 34.2** Posterior-anterior (A) and lateral (B) chest x-rays in patient with chronic obstructive pulmonary disease showing increased A-P dimension, flattened diaphragms, and increased retrosternal airspace. (Courtesy Dr. George Washko, Brigham and Women’s Hospital.)

• **Fig. 34.3** Posterior-anterior (A) and lateral (B) chest x-rays in patient with severe chronic obstructive pulmonary disease showing hyperlucency, flattened diaphragms, and inferomedial rotation of cardiac silhouette. (Courtesy Dr. George Washko, Brigham and Women’s Hospital.)

displacement of the cardiac silhouette (Fig. 34.3). Focal areas of hyperlucency are suggestive of bullous disease. In patients presenting with acute respiratory decompensation, the x-ray should be carefully reviewed for evidence of congestive heart failure, pneumonia, or pneumothorax. The latter can be difficult to distinguish from severe bullous changes in some individuals with marked underlying emphysema.

Chest CT scanning may be normal in mild disease. It is the current test of choice for assessing the presence of emphysema. It is much more sensitive than plain chest radiography for demonstrating emphysematous changes. Qualitatively, these changes can be described as consistent with centriacinar, panlobular, or paraseptal emphysema. In addition, the distribution of the changes can be described: upper-lobe predominant, diffuse, lower-lobe predominant. The latter is suggestive of underlying alpha-1-antitrypsin deficiency. More recently, tools are being developed to provide a more precise quantitation of emphysema on CT scanning. Although still largely a research tool, these approaches have been used to evaluate patients considering surgical therapy for COPD. The CT scan is also the test of choice to evaluate for the presence of bronchiectasis. The presence of enlarged airways (greater in diameter than the associated blood vessel), nontapering airways, or airways visible within 1 to 2 cm of the pleural surface are findings of bronchiectasis; airway thickening may also be seen involving these structures.

Chest CT scanning with intravenous contrast is frequently used to evaluate patients with suspected pulmonary embolism and may be ordered in a patient with COPD presenting with chest pain or acute respiratory decompensation.

In addition to demonstrating emphysema, chest CTs performed in patients with significant smoking history and COPD frequently demonstrate pulmonary nodules (10%–30% depending on the definition used), a minority of which represent malignancy (Fig. 34.4). If such a nodule is detected, further evaluation is required. Published guidelines use the size of the nodule and the underlying risk factors of the patient to recommend evaluation and monitoring strategies.

The issue of whether to use chest CT scans to screen asymptomatic middle-aged smokers for the presence of lung cancer was the subject of a large government-funded multicenter trial in the United States (National Lung Screening Trial). This study demonstrated a 20% reduction in lung cancer mortality in individuals between age 55 and 74 years with 30 or more pack-years of cigarette smoking. It is likely that this study and others will result in a more widespread institution of lung cancer screening programs using low-dose CT scans.

The current role of CT scanning in the assessment of a patient with known or suspected COPD is in evolution. Agreed-upon indications include the evaluation of patients considering surgical therapy for COPD such as bullectomy, lung volume reduction surgery (LVRS), or lung transplantation; evaluation of large airways in patients in whom a focal anatomic abnormality is in the differential diagnosis; establishing the presence and extent of emphysema in individuals with alpha-1-antitrypsin deficiency; and (with contrast)

• **Fig. 34.4** (A–B) Chest computed tomography showing emphysematous destruction of lung parenchyma and nodule in posterior aspect of left lung. (Courtesy Dr. George Washko, Brigham and Women's Hospital.)

to evaluate possible pulmonary embolism in a patient with underlying COPD and acute decompensation.

MRI scanning of the chest has its greatest utility in visualizing the mediastinum, trachea, and proximal large airways. The nature of the lung parenchyma, with its large air content, limits the applicability of MRI in imaging the lung parenchyma. Although current research in the field includes the development of functional imaging techniques in COPD, there is currently little role for chest MRI scanning in the evaluation and management of patients with COPD.

### Blood Tests

There are no specific blood tests establishing the presence or absence of COPD. Traditionally, it has been recommended to obtain an alpha-1-antitrypsin (A1AT, also known as alpha-1-antiprotease) level in patients with a strong family history of COPD, patients presenting at a young age (<45–50 years), patients with basilar predominant emphysema, and patients with unexplained bronchiectasis and/or liver disease. More recent guidelines have recommended checking a level in every patient diagnosed with COPD. Those with a low A1AT level should be evaluated for replacement therapy and counseled concerning the genetics of A1AT deficiency. In patients with unexplained bronchiectasis, evaluation of IgG subclass deficiency (IgG2, IgG4), IgA deficiency, cystic fibrosis, and immotile cilia syndrome should be considered.

### Summary of Diagnosis of Chronic Obstructive Pulmonary Disease

Middle-aged or older patients complaining of unexplained or worsening dyspnea should be evaluated for COPD; this is particularly true of those individuals with a significant cigarette smoking history. For patients with mild-to-moderate disease, the physical examination may be relatively normal. Establishing the diagnosis requires consideration of COPD in the differential diagnosis and obtaining spirometry before and after bronchodilator use. Spirometry alone is usually enough to establish the diagnosis; lung volumes

and diffusing capacity provide additional information concerning degree of hyperinflation and emphysema and may be useful in situations where there is concern about the presence of an additional disease process (interstitial lung disease, weakness, neurologic disease), as part of preoperative evaluation for chest surgery, or in patients being considered for therapy specific for emphysema.

### Controversies Concerning Screening for Chronic Obstructive Pulmonary Disease

Given that COPD has a strong association with cigarette smoking and that >20% of lifelong smokers will develop clinically significant COPD, there is a school of thought that advocates performing spirometry on all middle-aged smokers regardless of the presence of symptoms. The logic is that identification of early airflow obstruction, before the onset of symptoms, will provide an opportunity for early intervention. The only intervention determined to influence the natural history of early COPD is smoking cessation. The available data are relatively limited, but those available do not establish that the knowledge of early signs of COPD results in a higher smoking cessation rate than smoking cessation interventions irrespective of spirometry results. The opposing school of thought reasons that (1) all smokers should be counseled to quit and provided appropriate cessation therapy regardless of the results of spirometry and (2) the majority of smokers with normal lung function may be inappropriately reassured that they are not at risk for smoking-related disease(s). As a result, screening for COPD is not in widespread practice.

### Therapy for Chronic Obstructive Pulmonary Disease

#### Goals of Therapy

Treatment of any chronic disease has the goals of improving current symptoms, eliminating the disease or reducing the rate of progression, and reducing mortality. These combine to produce an improvement in health-related quality of life. In addition, the most desirable goal of therapy is to

**TABLE 34.3 Pharmacotherapy for Smoking Cessation**

Medication	Trade Name	Form	Side Effects
Nicotine		Lozenge Gum Nasal spray Transdermal patch	Nausea, insomnia (transdermal)
Bupropion	Zyban Wellbutrin	Pill	May exacerbate seizures
Varenicline	Chantix	Pill	Nausea, neuropsychiatric symptoms

prevent the development of disease in the first place. COPD is somewhat unique in medicine because the strategy to prevent development of disease in the majority of patients is very clear: prevent people from starting to smoke cigarettes.

### Disease Prevention

As noted earlier, there is compelling evidence implicating cigarette smoking as the major risk factor for the development of COPD. There are data suggesting that there is (are) genetic predisposition(s) to develop COPD, and COPD is frequently cited as an example of gene-environment interactions. Although the majority of patients with COPD are cigarette smokers (>80%–90% in most series), the majority of smokers do not develop COPD.

Given that cigarette smoking is a risk factor for disease development, it is logical to assume that smoking cessation will have a favorable impact on disease course. This hypothesis is supported by data from the Lung Health Study, which demonstrate that individuals with early airflow obstruction who are able to cease smoking experience an improvement in the rate of decline of lung function back to normal rates for age and reduced mortality in 15-year follow-up.

Clearly, the most desirable approach is to prevent individuals from starting smoking. Public health campaigns have succeeded in reducing the proportion of US adults who smoke, but the prevalence of smoking in the US adult population is still approximately 20%. For such individuals who express a desire to quit, the current recommendations are to consider pharmacotherapy to aid in smoking cessation, based on reports that the chances of success are significantly improved with such therapy. Options for therapy are presented in [Table 34.3](#).

### Therapy of Chronic Stable Disease

A variety of pharmacologic and nonpharmacologic therapies are available for COPD. Pharmacologic therapy includes medications intended to produce bronchodilation, anti-inflammatory medications, mucolytics, antioxidants, and protease inhibitors. Although there is some controversy about their efficacy (discussed later), the majority of available data

suggest that pharmacotherapy does not alter the rate of decline in lung function or mortality. Thus they are best viewed as intended to improve current symptoms.

Other available therapies include supplemental oxygen, surgical therapy, and pulmonary rehabilitation. Of these, supplemental oxygen and LVRS have been demonstrated to reduce mortality in appropriately selected patients.

The algorithm published by the Global Initiative on Chronic Obstructive Lung Disease recommends a stepwise escalation of therapy with worsening airflow obstruction. These recommendations are summarized in [Fig. 34.5](#).

### Vaccines

#### Influenza Vaccine

Available data support the use of the annual poly(tri)-valent influenza vaccine in patients with COPD based on a reduction of serious exacerbations/hospitalizations related to influenza. It is recommended in the GOLD guidelines.

#### Pneumococcal Vaccine

The currently available polysaccharide vaccine is intended to stimulate antibody protection against the 23 most common serotypes of *Streptococcus pneumoniae* associated with human disease, including the six serotypes most commonly associated with invasive human infection. Pneumococcal vaccinations PCV13 and PPSV23 are recommended for all patients >65 years. Despite the fact that pneumococcus is one of the three bacterial species associated with COPD exacerbations, there are very little available data addressing the efficacy of this vaccine in the COPD population. Nevertheless, many physicians recommend it to their patients with COPD on the premise that it has an excellent safety profile, and it theoretically may reduce the risk of infection.

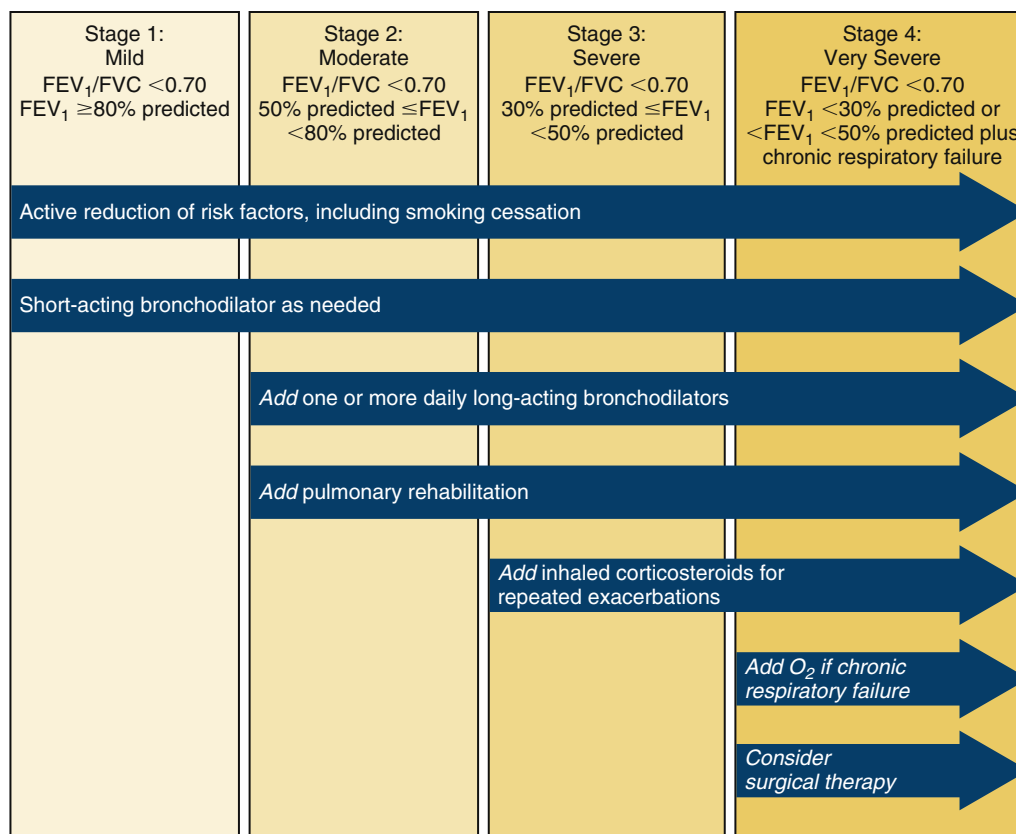

### Pharmacotherapy

#### Short-Acting Beta Agonists

Examples of short-acting beta agonists (SABAs) include albuterol (also known as salbutamol), levalbuterol, pirbuterol, and fenoterol. As the name suggests, they have relatively rapid onset of action and last 4 to 6 hours. They are appropriate therapy for patients with intermittent symptoms or acute symptoms despite long-acting therapy. Side effects include tachycardia and tremor. The inhaled route of delivery is preferred, as side effects are more common with parenteral administration (usually oral, rarely subcutaneously).

#### Long-Acting Beta Agonists

Long-acting beta agonists (LABAs) are available in inhaled form, via dry powder inhalers or nebulized solutions, and either alone or in combination with a corticosteroid. Examples include salmeterol and formoterol. The side-effect profile is similar to that of SABAs, although less pronounced. The rate of onset of action is longer than that of short-acting medications, and the duration of action is 8 to 12 hours. They are indicated for patients with daily symptoms. Available data suggest that they provide modest improvements in FEV<sub>1</sub> and health-related quality of life (HRQOL). They

• **Fig. 34.5** GOLD (Global Initiative for Chronic Obstructive Lung Disease) recommendations for chronic obstructive pulmonary disease therapy. FEV, Forced expiratory volume; FVC, forced vital capacity; O<sub>2</sub>, oxygen. (Figure prepared by Ms. Jimette Gilmartin.)

have also been reported to reduce the risk of COPD exacerbation by 20% to 25%. The magnitude of benefit is similar to that seen with inhaled anticholinergic medications; a combination of a LABA and anticholinergic produces more bronchodilation than either medication alone. Currently, there are no available data to suggest that use of LABAs is disease modifying in terms of affecting the rate of decline in FEV<sub>1</sub> over time or in reducing mortality.

#### Short-Acting Inhaled Anticholinergics

Short-acting inhaled anticholinergics (SAMAs), such as ipratropium bromide, can be used in the same manner as SABAs: episodically for patients with intermittent symptoms. They may be used alone or in a combination with a SABA. The latter, inhaled albuterol/ipratropium, offers more bronchodilation than either agent alone. The choice of whether to use a short-acting beta agonist or anticholinergic therapy as initial intermittent therapy for patients with COPD is a matter of patient and physician preference; the magnitudes of benefit and costs are similar. Anticholinergics are less likely to produce tachycardia and tremor, although some patients do report dry mouth.

#### Long-Acting Anticholinergics

Tiotropium is an inhaled anticholinergic medication with a recommended dosing schedule of once daily. It produces improvement in maximal expiratory flow rates and

HRQOL of a magnitude similar to LABAs. As with ipratropium, the side-effect profile is related to anticholinergic properties, the most common being dry mouth. Tiotropium does not affect the rate of decline in FEV<sub>1</sub>, nor has it been shown to affect mortality.

#### Inhaled Corticosteroids

The role of inhaled corticosteroids (ICS) in patients with COPD is incompletely defined. Examples include fluticasone, budesonide, and triamcinolone. Studies to date involving different ICS preparations and somewhat different patient populations have consistently demonstrated that ICS do not affect the rate of decline in FEV<sub>1</sub> when used regularly for 3 years. Also, regular treatment with ICS alone has shown inconclusive benefit on mortality. There are good data demonstrating that inhalation of a combination of LABA and ICS produces more symptomatic benefit than an inhaled LABA alone, suggesting symptomatic benefit. There are also convincing data that ICS reduce exacerbation risk but also increase the risk of bacterial pneumonia. Studies to date, involving different ICS preparations and somewhat different patient populations, have consistently demonstrated that ICS do not affect the rate of decline in FEV<sub>1</sub> when used regularly for 3 years. An unresolved controversy is the impact of ICS on COPD mortality; several retrospective analysis and observational studies suggest that ICS may reduce mortality in COPD, but in the Towards a

Revolution in COPD Health (TORCH) prospective study, the reduction in mortality in patients receiving LABA/ICS did not reach statistical significance.

The addition of a long-acting muscarinic agonist (LAMA) to treatment with LABA and ICS (triple therapy) improves lung function and patient-reported outcomes and reduces exacerbations.

### Oral and Parenteral Corticosteroids

Oral and parenteral steroids have a role in the treatment of an acute exacerbation but, given the morbidity of long-term corticosteroid use and the absence of convincing evidence of benefit, they are not recommended for use in patients with stable COPD.

### Aminophylline/Theophylline/Methylxanthines

Once a mainstay of COPD therapy, this class of medications has fallen into relative disfavor because of a high incidence of side effects, which include nausea, tremor, tachycardia, supraventricular arrhythmias, and seizures (rarely). They are available in either oral or intravenous preparations. They are mild bronchodilators and also may improve diaphragmatic contractility and respiratory drive. Their use as nocturnal therapy has largely been supplanted by LABAs.

More recently, it has been suggested that low-dose theophylline may restore glucocorticoid responsiveness in COPD patients because of their interaction with histone deacetylase. The clinical relevance of this observation awaits appropriately designed clinical trials.

### Combination Bronchodilator Therapy

Various combinations of bronchodilators are available in one device and include SABA and SAMA and LABA and LAMA. SABA and SAMA combinations improve symptoms and FEV<sub>1</sub> in comparison to either agent alone. Several combinations of LABA and LAMA are available and improve lung function greater than LABA used alone, with a larger improvement in FEV<sub>1</sub> and also reduced exacerbations, and had more frequent improvements in quality of life and were associated with a lower risk of pneumonia.

### Antioxidants/Mucolytics

Given the putative role of oxidative stress in the pathogenesis of COPD, as well as the incidence of mucous hypersecretion in some patients, multiple studies have investigated the utility of *N*-acetylcysteine and other antioxidants. Although several smaller studies suggested benefit, the large Bronchitis Randomized on NAS Cost-Utility Study trial failed to demonstrate any favorable impact on rate of decline in lung function or exacerbation rate. Thus they are not recommended for use in COPD.

### Alpha-1-Antiprotease Replacement Therapy

For patients with established alpha-1-antiprotease deficiency and evidence of lung disease (bronchiectasis, emphysema, and/or airflow obstruction), regular intravenous infusions of alpha-1-antiprotease protein are recommended.

This recommendation is based upon pathophysiologic principles and observational registry data suggesting a slower rate of decline in FEV<sub>1</sub> in patients on replacement therapy. Therapy is associated with inconvenience in the form of intravenous infusions every 1 to 4 weeks and with considerable expense. There is no role for replacement therapy in patients with COPD and normal alpha-1-antiprotease levels. Although there is controversy as to whether or not patients heterozygous for a deficient alpha-1-antiprotease allele are at increased risk for the development of COPD, there are no data to support the use of replacement therapy in such patients who do develop COPD.

### Oxygen Therapy

The use of supplemental oxygen in appropriately selected patients is one of the few interventions that have been shown to improve mortality in patients with COPD. The Medical Research Council Trial and the Nocturnal Oxygen Therapy Trial demonstrated that supplemental oxygen dramatically reduces mortality in patients with resting hypoxemia (defined as partial arterial pressure of oxygen (PaO<sub>2</sub>) <55 mm Hg or 59 mm Hg with dependent edema, hematocrit >55% or P pulmonale on electrocardiogram [EKG]) and that continuous therapy provided more benefit than nocturnal therapy. In current practice, resting oximetry is often substituted for measurement of arterial blood gases; a resting SaO<sub>2</sub> of 88% or less is used as the threshold for therapy.

The role of supplemental oxygen in patients with COPD and nocturnal hypoxemia and/or exertional hypoxemia is less clear. For the latter, there is evidence that dyspnea may improve, as well as exercise tolerance. In neither group has it been demonstrated that there is a mortality benefit from preventing episodic hypoxemia.

The role of oxygen therapy in patients with moderate resting hypoxemia is undefined and is currently the subject of a large multicenter trial.

### Pulmonary Rehabilitation

The name is a misnomer because it has been widely interpreted as suggesting an improvement in lung function as the result of an exercise program. It is more appropriately termed "rehabilitation of patients with lung disease." Most programs include two broad areas of intervention: education centered on strategies to minimize dynamic hyperinflation and to improve medication compliance and delivery and physical conditioning primarily focused on improving cardiovascular conditioning. The latter emphasis is the result of studies demonstrating that deconditioning is a limiting factor for exertion in many patients with COPD, even accounting for their reduced ventilatory limit to exercise. In addition, some programs include strengthening specific target muscle groups including the muscles of inspiration. Whether inspiratory muscle training results in clinically important patient improvement remains unclear.

It is clear, however, that pulmonary rehabilitation results in substantial improvements in symptoms and HRQOL. The magnitude of these improvements is as large or larger than that reported for any available pharmacologic therapy. Although a mortality benefit has not been clearly demonstrated, short-term studies do demonstrate a reduction in health care resource use. The benefits of pulmonary rehabilitation wane with time if patients do not continue maintenance activities after completing the typical 6- to 8-week program.

In the GOLD guidelines, rehabilitation is recommended for patients with moderate or greater COPD. In common practice, it has often been reserved for patients with very severe disease and/or recurrent hospitalization. Of the available therapies for patients with symptomatic COPD, it is the most underused.

### Newer Therapeutic Strategies

**Phosphodiesterase-4 (PDE4) Inhibitors.** PDE4 inhibitors (roflumilast) reduce inflammation by inhibiting breakdown of cyclic AMP. Roflumilast is a once-daily medication that is approved to reduce the risk of COPD exacerbations in patients with a history of frequent COPD exacerbations. Its use is generally limited to patients with continued exacerbations despite maximal use of inhaled treatments. Adverse effects include nausea, diarrhea, poor appetite, weight loss, and insomnia. The possibility of increased adverse psychiatric reactions requires caution in patients with a history of depression.

**Antibiotics.** Previously it was thought that continuous use of antibiotics had no effect on exacerbation frequency, and use of antibiotics in the winter months over a period of 5 years yielded no benefit. Recent studies show that regular use of antibiotics (azithromycin) may reduce exacerbation rates. Adverse effects include higher incidence of bacterial resistance and hearing loss. There are no efficacy or safety data beyond 1 year of treatment.

**Biologics.** Mepolizumab, a monoclonal antibody against interleukin-5, is used in severe eosinophilic asthma and has been studied in COPD associated with an eosinophilic phenotype. In patients with blood eosinophil counts >150 cells/mL and with a history of exacerbations despite triple therapy, mepolizumab slightly reduced exacerbation rates compared with placebo. However, further studies are needed to investigate this strategy.

**Palliative Care.** COPD patients can continue to have significant dyspnea despite maximal therapy, and this can lead to anxiety, panic, and depression. Palliative care in these situations can play an important role, with focus on quality of life and on decisions on end-of-life care.

### Surgical Therapy for Chronic Obstructive Pulmonary Disease

There are three types of surgical intervention used in selected patients with COPD to improve symptoms. These are bullectomy, LVRS, and lung transplantation. In years past, a variety of other operative procedures for COPD have been

tried and subsequently abandoned, including tracheotomy, glomectomy, and visceral denervation.

**Bullectomy** refers to the resection of a large dominant bulla(e) that prevents expansion of surrounding more functional lung tissue. Factors that have been identified suggesting bullectomy will achieve substantial physiologic benefit include size >60% of the hemithorax and the presence of adjacent "compressed normal" lung tissue. Patients with these characteristics are quite rare but do experience dramatic improvement in measured lung function and symptoms as a result of the procedure.

LVRS is based on a physiologic rationale similar to that used for bullectomy: resection of poorly functional lung tissue will improve elastic recoil, "reset" the resting volume of the respiratory system to a lower and more physiologic level, and result in improved symptoms and higher expiratory flow rates. First proposed in the early 1950s by Otto Brantigan, it was reintroduced in the 1990s. The National Emphysema Treatment Trial demonstrated that in patients with upper-lobe predominant emphysema, as determined by review of chest CT scans, LVRS produced improvements in exercise performance and symptoms as compared with maximal medical therapy. In patients with upper-lobe predominant emphysema and dramatically impaired exercise capacity, there was also a substantial mortality benefit of almost 50% during the observation period. The trial also demonstrated, however, that there is significant morbidity and mortality associated with LVRS, including a ~5% mortality rate in the postoperative period. Current efforts in the area focus on the development of an endobronchial approach to lung volume reduction; several clinical trials are currently under way attempting to determine whether the same results may be achieved via a bronchoscopic approach that would presumably eliminate some of the morbidity associated with the surgical procedure. Candidates for LVRS are patients with COPD that produces limiting symptoms despite appropriate pharmacotherapy and pulmonary rehabilitation, who have upper-lobe predominant emphysema on CT scan, and do not have pleural scarring, prior chest surgery, significant pulmonary hypertension, or other contraindications to the procedure. Such patients should be referred, if they so desire, to a center with expertise in providing the procedure.

Lung transplantation is the third surgical option for selected patients with COPD. COPD is the most common diagnosis for which patients receive a lung transplant. Common practice has evolved to performing primarily bilateral transplantation in this population, based upon data suggesting improved long-term outcomes compared with single lung transplantation. Patients with COPD do well compared with other patients after lung transplant, with 1-year and 5-year survival rates of 86% and 47%, respectively. Candidates for lung transplantation are patients with very severe airflow obstruction and disabling symptoms despite maximal medical therapy and pulmonary rehabilitation, who are reasonably healthy other than having advanced COPD, and have the capabilities and willingness to comply with a lifelong complex regimen of immunosuppressive and prophylactic medications. Most experts agree that in patients evaluated for transplant who have the characteristics

suggesting a high likelihood of benefit from LVRS (as outlined previously), LVRS should be offered first because of lower morbidity. Prior LVRS is not a contraindication to lung transplantation. Current concepts are that lung transplantation is a quality of life intervention for patients with COPD, and whether or not the intervention results in improvement in mortality remains controversial.

### Summary of the Approach to Individuals With Stable Chronic Obstructive Pulmonary Disease

- Spirometry should be obtained in individuals with exposure (smoke or occupational) with symptoms of dyspnea and considered in nonexposed individuals with unexplained cough or dyspnea.
- All smokers with COPD should be actively encouraged to quit smoking and, if willing to attempt to quit, offered pharmacotherapy.
- COPD patients should receive pneumococcal and influenza vaccines.
- In the absence of proof of disease modification, pharmacotherapy is indicated to improve symptoms. When possible, inhaled pharmacotherapy is preferred to parenteral therapy. SABAs and/or anticholinergics can be used in patients with intermittent symptoms; LABAs and/or anticholinergics can be used in patients with frequent symptoms. Combining both classes of medications produces more benefit than either alone. The role of inhaled corticosteroids remains to be completely defined, but they may improve symptoms and reduce exacerbations and should be considered in those with persistent symptoms despite long-acting bronchodilators and/or with frequent exacerbations. The use of chronic parenteral corticosteroids for the treatment of COPD is not recommended.
- Patients reporting symptoms and/or limitation while on a long-acting agent should be considered for pulmonary rehabilitation.
- Patients with resting hypoxemia when clinically stable should be prescribed supplemental oxygen.
- Surgical therapy should be considered in patients with disabling symptoms and very severe airflow obstruction despite use of maximal medical therapy and completion of a pulmonary rehabilitation program.

### Chronic Obstructive Pulmonary Disease Exacerbations

In addition to chronic symptoms in COPD, with associated exercise limitation and impact on HRQOL, many patients with COPD experience an episodic acute or subacute increase in symptomatology. These events, characterized by an increase in dyspnea and/or cough with an increase and/or change in character of phlegm, are often termed an *acute exacerbation* and are often abbreviated as AECB (acute exacerbation of chronic bronchitis) or AECOPD (acute exacerbation of COPD).

Exacerbations are important for several reasons. Clinically, they are important because they are independent determinants of HRQOL and may be associated with an accelerated rate of decline. Hospitalized patients have a mortality of up to 11%. One-year mortality after hospitalization for AECOPD has been reported to range from 22% to 43%. Economically, they are important because they are responsible for 50% to 70% of COPD-associated health care expenditures in the United States (estimated at \$21 billion/year).

### Definition

There is no universally agreed upon definition, but the vast majority of those in current use incorporate major criteria of (1) increase in cough, (2) increase in dyspnea, and (3) increase in volume of phlegm and/or increasing purulence of phlegm. Minor criteria include fever, myalgias, and/or fatigue. For clinical studies, the definition often requires that the constellation of symptoms results in a change in treatment for the patient.

### Etiology

As one might expect from the presenting criteria, infectious etiologies are important and are responsible for the majority of exacerbations. There are strong data implicating viruses in the etiology of 30% to 50% of exacerbations, the most common being rhinovirus. Other viral etiologies include corona virus, influenza A and B, parainfluenza, adenovirus, and respiratory syncytial virus. Bacterial infection plays a role in up to 50% of exacerbations, with *Haemophilus influenzae*, *Moraxella catarrhalis*, and *S. pneumoniae* being the three most commonly implicated species. Exposure to other irritants, such as ambient air pollution, is associated with increasing exacerbation rates. In 25% to 30% of cases, however, no etiology is identified.

### Prevention

The inhaled agents prescribed for the treatment of chronic symptoms have all been reported to reduce the risk of having a COPD exacerbation. For any individual agent, the magnitude of this risk reduction is ~20% to 25%. Combining more than one agent has been reported to reduce risk by up to 30%. Note that there is a bimodal distribution of exacerbation frequency in patients with COPD: a significant proportion of patients with COPD have none or very infrequent exacerbations. At the present time, the best identifier for patients at risk of COPD exacerbation is a prior history of COPD exacerbations. For such patients, consideration can be given to providing pharmacotherapy to reduce the risk. It should be noted that regimens containing inhaled corticosteroids, although clearly demonstrating a lower risk of exacerbation, have been reported to have an increased risk of pneumonia.

In addition to these options, a recent randomized trial demonstrated that the use of daily azithromycin in subjects

at high risk for exacerbations (based on a history of exacerbation in the previous year or requiring continuous supplemental oxygen) resulted in a reduction in exacerbations during a 12-month observation period.

### Assessment of the Patient With Exacerbation

The assessment of the patient presenting with symptoms of exacerbation has four goals: attempting to characterize the baseline severity of COPD and any comorbid conditions, ruling out other conditions that may produce similar symptoms, characterization of the severity of the exacerbation, and ascertainment of the etiology of the AECOPD.

Given these goals, the evaluation of the patient should include a history focused on determining baseline functional status and medication use, basis of the diagnosis of COPD and, if known, severity, comorbid condition, recent ill contacts, current symptoms, past history of exacerbations, smoking history (current, ex, never), and risk factors for conditions producing similar symptoms (congestive heart failure, pulmonary embolism, pneumothorax). The physical examination should include assessment of mental status, respiratory rate, presence or absence of paradoxical breathing pattern, use of accessory muscles of respiration, cyanosis, and chest examination (breath sounds, prolonged expiration, focal findings or asymmetry). An objective assessment of oxygenation should be conducted. For patients with mild or moderate underlying COPD who are not tachypneic or in overt respiratory distress, this can be accomplished by use of pulse oximetry. For patients with abnormal mental status, severe underlying disease, tachypnea, or use of accessory muscles of respiration, an arterial blood gas (ABG) should be performed. In addition to assessment of oxygenation, the ABG will provide pH and PaCO<sub>2</sub>; these parameters are important in the treatment algorithm for patients.

The CXR has been reported to be abnormal in up to 25% of patients being evaluated for an acute exacerbation, with the majority of findings being either pneumonia or congestive heart failure. The decision as to whether or not to obtain a CXR depends on the patient's baseline status and degree of distress at presentation. Many patients, for instance, will be treated with antibiotics (discussed later) regardless of the presence or absence of a focal opacity on CXR, suggesting that in patients who are not in respiratory distress and in whom the likelihood of congestive heart failure is small, the CXR can be omitted from the evaluation. In patients in whom congestive heart failure is more likely or in whom the history or examination suggests another etiology such as pneumothorax, the CXR may provide important information.

The decision concerning venue of treatment is complex, and no hard and fast guidelines exist. Patients with mild symptoms and mild-to-moderate underlying disease may be safely treated as outpatients. Patients with significant respiratory distress, hypercarbia and acute respiratory acidosis, multiple comorbid conditions, severe underlying disease, and/or poor social and family support structures are appropriate candidates for admission and inpatient therapy.

### Treatment

The treatments for acute exacerbations include bronchodilators, antiinflammatory medications, antibiotics, and supportive therapies. The latter may include supplemental oxygen therapy and noninvasive or conventional mechanical ventilatory support.

#### Antibiotics

Most studies report that the use of antibiotics results in a faster clearing of symptoms than no antimicrobial therapy; this is particularly true in patients with two or more of the "major" exacerbation criteria. Antimicrobial therapy should be chosen with consideration of the most common pathogens, *H. influenzae*, *M. catarrhalis*, and pneumococcus along with the local antibiotic resistance patterns within these species. Many recommend the use of fluoroquinolones, extended spectrum macrolides or amoxicillin/clavulanic acid, although studies using less expensive medications such as tetracyclines or trimethoprim/sulfamethoxazole have also shown benefit. The utility of sputum cultures in guiding decision making concerning antibiotics is questionable because many patients are chronically colonized with one or more of the species that are also associated with exacerbations.

#### Corticosteroids

Parenteral corticosteroids have been demonstrated to reduce returns to the emergency department in patients treated as outpatients in that setting and to shorten hospital length of stay in patients admitted for AECOPD. Although the optimal dose, route, and duration of therapy are unclear, a reasonable synthesis of the literature is that there is probably little difference between enteral and parenteral routes in patients able to take oral medications. The initial dose should be the equivalent of 40 mg or more of prednisone, and 2 weeks of tapering therapy is as effective and less morbid than an 8-week taper.

#### Bronchodilators

Current guidelines recommend the use of beta agonists and anticholinergic inhaled agents during an exacerbation, with initial preference for short-acting agents delivered frequently, transitioning to longer-acting agents as patients improve. In patients capable of demonstrating good technique with metered-dose inhaler (MDI) devices, studies have shown use of MDIs is as effective and less costly than the use of nebulizer therapy. Many institutions have instituted pathways that transition patients from nebulizer therapy to MDI devices shortly after hospital admission.

The use of aminophylline or other xanthines has not been demonstrated to provide additional benefit over bronchodilators alone in the treatment of AECOPD.

#### Supportive Therapies

Many patients demonstrate hypoxemia when presenting with AECOPD. Supplemental oxygen should be provided and titrated to achieve a resting saturation of

≥90%. This is true even in patients with hypercarbia. Although it is true that supplemental oxygen may alter ventilation/perfusion relationships and result in a modest rise in  $\text{PaCO}_2$ , it does not alter minute ventilation and should not be withheld because of concerns about suppressing respiratory drive.

In addition to pharmacotherapy, patients with acute respiratory failure in the context of COPD exacerbation may benefit from mechanical ventilatory support. A series of recent studies have demonstrated that patients with AECOPD and respiratory decompensation manifested by tachypnea, signs of respiratory muscle fatigue, respiratory acidosis, and hypercarbia benefit from the institution of noninvasive positive-pressure ventilation (NIPPV). In such

patients, institution of NIPPV has been demonstrated to reduce the need for endotracheal intubation and mechanical ventilation, intensive care unit and hospital lengths of stay, and mortality. For patients unable to tolerate NIPPV or for whom NIPPV is ineffective at correcting acidosis/hypercarbia, endotracheal intubation and mechanical ventilation are indicated.

## Acknowledgments

The authors thank Dr. John J. Reilly for authoring a prior version of this chapter. The views and opinions expressed in this chapter are those of the authors and do not reflect the official policy or position of Tufts Health Plan.

## Chapter Review

### Questions

1. A 72-year-old white male presents to his physician's office with a 9-month history of wheezing, dyspnea on exertion, and daily sputum production. He is a 60-pack-year smoker. Examination shows markedly decreased breath sounds with mild wheezing at the end of expiration. Spirometry is consistent with a diagnosis of COPD. Which of the following interventions will be most effective for improving this patient's long-term survival?
  - A. Inhaled ipratropium
  - B. Long-term oral corticosteroids
  - C. Inhaled corticosteroids
  - D. Smoking cessation
2. A 66-year-old patient with COPD has repeated exacerbations (at least two episodes each year for the past 3 years) and has an  $\text{FEV}_1$  45% predicted. She is currently being treated with salmeterol, two puffs twice per day, and albuterol, two puffs every 6 hours as needed. Which one of the following should be added to her treatment regimen?
  - A. Inhaled corticosteroid
  - B. Home oxygen therapy
  - C. Prophylactic antibiotic therapy
  - D. Long-term low-dose oral corticosteroid
  - E. Long-term theophylline therapy

3. A 68-year-old man with a 40-pack-year tobacco history presents with recent onset of pain in both knees and shins. Physical examination shows clubbing, gynecomastia, tenderness of both shins, and mild expiratory slowing of lung sounds. What is the most likely diagnosis?
  - A. Rheumatoid arthritis with pulmonary involvement
  - B. Idiopathic pulmonary fibrosis
  - C. Cryptogenic organizing pneumonia
  - D. Hypertrophic pulmonary osteoarthropathy
  - E. Acromegaly

### Answers

1. D
2. A

## Venous Thromboembolic Diseases

ARIC PARNES AND JEAN M. CONNORS

**V**enous thromboembolism (VTE) is common and complex and can be deadly. It can occur in any vein, although it is most common in the deep veins of the legs (deep vein thrombosis [DVT]) and lungs (pulmonary embolus [PE]). VTE has many causes; however, in up to half of cases the cause cannot be elucidated. Fortunately, many treatment options exist, although management of this disease is often complicated.

Because every physician will at some point encounter VTE, knowing the basics is essential. This chapter reviews the pathophysiology of VTE, including its risk factors and long-term consequences, diagnostic algorithms that integrate clinical findings, laboratory testing and imaging, and the role of risk stratification. Finally, practical recommendations for VTE treatment and prevention are provided.

### Pathophysiology

#### Clinical Risk Factors

Determining a patient's risk factors for VTE (Box 35.1) is critical because they determine the risk of recurrence, use of prevention, treatment duration, and, at times, affect the risk of VTE in family members. Patients are categorized as provoked, when a cause is found, or unprovoked, when no cause is found. Unprovoked patients have a higher risk of recurrence, whereas provoked patients essentially return to normal if the provoking factor is removed. In 20% to 50% of cases, no identifiable cause can be determined. The factors that carry the highest risk include antiphospholipid syndrome, antithrombin III deficiency, and certain cancers such as pancreatic and central nervous system cancers.

Advanced age, cancer, obesity, personal or family history of VTE, recent surgery, trauma, immobilization, and long-distance travel are well-recognized clinical risk factors. Recent hospitalization has been implicated in the development of VTE among outpatients. Common medical conditions including acute infectious illness, chronic obstructive pulmonary disease, chronic kidney disease, and heart failure increase the risk of VTE. Atherosclerotic cardiovascular disease and its associated risk factors, including obesity, smoking, diabetes, hypertension, and dyslipidemia, also increase the risk of VTE. Chronically indwelling central venous

catheters or devices such as pacemakers or implantable cardiac defibrillators are associated with an increased incidence of upper extremity DVT.

VTE is an important women's health concern. Pregnancy is a well-recognized risk factor for VTE. In addition, the combination of oral contraceptive pills (odds ratio [OR], 1.1–4.8) and hormone replacement therapy has been associated with an elevated risk of VTE. The increased estrogen state is primarily responsible for the increased VTE risk, although those that contain the progestin agent drospirenone have been associated with increased risk as well. Along the same lines, tamoxifen, an antiestrogen hormonal therapy used in hormone-receptor positive breast cancer, also poses an increased risk (OR, 1.5–3.5).

#### • BOX 35.1 Major Risk Factors for Venous Thromboembolism

#### Clinical Risk Factors

- Advancing age
- Cancer
- Personal or family history of venous thromboembolism
- Recent surgery, trauma, hospitalization, or immobilization
- Acute infectious illness
- Chronic obstructive pulmonary disease
- Chronic kidney disease including nephrotic syndrome
- Atherosclerotic cardiovascular disease and its associated risk factors (including obesity, smoking, diabetes, hypertension, dyslipidemia, diet)
- Heart failure
- Inflammatory bowel disease
- Pacemaker or implantable cardiac defibrillator leads and indwelling venous catheters
- Long-distance air travel
- Pregnancy, oral contraceptive pills, or hormone replacement therapy
- Tamoxifen, lenalidomide, thalidomide, other chemotherapy

#### Thrombophilias

- Factor V Leiden
- Prothrombin gene mutation G20210A
- Antiphospholipid syndrome
- Antithrombin deficiency
- Protein C deficiency
- Protein S deficiency

Other medications carry a risk of VTE. Chemotherapy increases risk beyond that of the malignancy. Immunomodulatory agents, including lenalidomide and thalidomide, carry a particularly high risk when combined with steroids or multiagent chemotherapy. The antiangiogenesis treatment bevacizumab, an antivascular endothelial growth factor antibody, also likely increases clotting.

A history of VTE at a young age, multiple family members with VTE, idiopathic or recurrent VTE, or recurrent spontaneous abortions should raise suspicion for inherited or acquired thrombophilia. Laboratory evaluation for hypercoagulable states should focus on the common thrombophilias such as factor V Leiden mutation resulting in activated protein C resistance, prothrombin gene mutation G20210A and antiphospholipid syndrome with anticardiolipin antibodies, beta-2 glycoprotein-1, and lupus anticoagulant. Deficiencies of antithrombin III, protein C, and protein S are less common, and testing for these disorders may be inaccurate in the setting of an acute thrombosis or anticoagulation.

Controversy exists over the utility and cost effectiveness of hypercoagulable testing. These tests should be ordered only if they will change management. They should not be ordered when there are strong provoking factors. Although malignancy is a risk factor for thromboembolic disease, extensive testing for occult malignancy when a patient has an unprovoked VTE has been demonstrated to be low yield.

### Pathophysiology of Deep Vein Thrombosis

DVT most often results from a combination of stasis, hypercoagulability, and endothelial injury as first postulated by Virchow in 1856. Recently recognized is the pivotal role that inflammation plays in promotion of VTE. Infection, blood transfusion, and other inflammatory states activate platelets that release procoagulant microparticles or form neutrophil extracellular traps that participate in the development of thrombosis.

Although the deep veins of the lower extremity are the most common location for DVT, thrombosis may also form in the veins of the upper extremities and pelvis or, less commonly, the splanchnic and cerebral veins. Damage from DVTs may lead to dysfunction of the valves of the deep venous system and, ultimately, the postthrombotic syndrome. Chronic lower extremity edema and calf discomfort characterize the postthrombotic syndrome and are associated with reduction in quality of life and impaired functional status that can last for months or years. Postthrombotic syndrome is also associated with an increased risk of recurrent VTE.

### Pathophysiology of Pulmonary Embolism

Most pulmonary emboli originate from thrombus in the deep pelvic or lower extremity veins. Thrombi embolize through the inferior vena cava (IVC) and right heart and lodge in the pulmonary arteries, where they cause gas

exchange abnormalities by ventilation-perfusion mismatch and right-to-left shunting. Arterial hypoxemia and an increased alveolar-arterial gradient are typical.

Direct physical obstruction of the pulmonary arterial tree and release of potent pulmonary arterial vasoconstrictors cause an acute increase in pulmonary vascular resistance and right ventricular (RV) afterload. This may lead to RV dilatation and ultimately acute RV failure. PE patients with acute RV failure may rapidly decompensate into cardiogenic shock and cardiac arrest. Up to 4% of patients who survive acute PE may develop disabling chronic thromboembolic pulmonary hypertension.

## Diagnosis

### Deep Vein Thrombosis

#### Clinical Findings

Patients with lower extremity DVT will often note a cramping or pulling sensation of the calf that may be exacerbated by ambulation. Physical findings of warmth, edema, tenderness, a palpable cord, or prominent venous collaterals may be present. Importantly, some patients do not demonstrate any abnormalities on physical examination.

Massive DVT describes thrombus that extends into the pelvic (iliofemoral) veins. Sometimes massive DVT causes arterial insufficiency, known as phlegmasia cerulea dolens, an emergency necessitating urgent direct intervention such as thrombolysis or thrombectomy. Proximal DVT involves the common femoral, superficial femoral (a misnomer because it is actually a deep vein), deep femoral, or popliteal veins. Isolated calf DVT involves the venous system distal to the popliteal vein. Upper extremity DVT affects the subclavian, internal jugular, axillary, and brachial veins. The basilic vein is superficial, not deep.

Late findings include chronic pain and edema, a syndrome referred to as postthrombotic syndrome.

#### Laboratory Evaluation

A nonspecific marker of fibrinolysis, D-dimer is increased in VTE as well as in many other systemic illnesses. D-dimer levels can be elevated because of other conditions such as acute myocardial infarction, pneumonia, malignancy, surgery, second-semester or third-trimester pregnancy, and increasing age. However, D-dimer testing can produce false-negative results in the setting of a small thrombus such as an isolated calf DVT.

#### Imaging

Duplex venous ultrasonography is the initial imaging test of choice in the evaluation of suspected lower and upper extremity DVT (Fig. 35.1). Noncompressibility of a vein is diagnostic of DVT. Alternative imaging modalities for assessment of patients with suspected DVT, including CT, MR, and contrast venography, may be warranted when ultrasonography is inadequate, such as when acute-on-chronic thrombosis is suspected. In addition, anatomic limitations

• **Fig. 35.1** Venous ultrasound demonstrating a dilated, noncompressible right common femoral vein (*RT CFV*) with absence of venous flow consistent with deep vein thrombosis. *A*, Artery; *V*, vein.

**TABLE 35.1** Venous Thromboembolism Severity

Severity	Defining Features
Massive DVT	Extending into pelvic (iliofemoral) veins
Phlegmasia cerulea dolens	DVT causing arterial insufficiency
Submassive PE	RV failure but normal blood pressure
Massive PE	Hypotension and cardiogenic shock

*DVT*, Deep vein thrombosis; *PE*, pulmonary embolism; *RV*, right ventricular.

may hinder ultrasonographic evaluation of the pelvic veins and upper extremity veins proximal to the clavicle.

## Pulmonary Embolism

### Clinical Findings

Dyspnea is the most frequently reported symptom in patients with acute PE. Whereas pleuritic pain, cough, or hemoptysis may indicate a smaller peripherally located PE, severe dyspnea, cyanosis, or syncope suggests a massive PE. Tachypnea is the most common physical finding. Patients without underlying cardiopulmonary disease may appear anxious but well compensated even with anatomically large PE. Hypotension and cardiogenic shock define massive PE whereas patients with submassive PE have preserved systolic blood pressure but exhibit signs of RV failure (Table 35.1), including tachycardia, jugular venous distension, tricuspid regurgitation, or an accentuated sound of pulmonic valve closure. These patients have an increased risk of adverse events and early mortality. Acute PE patients with normal blood pressure and no evidence of RV dysfunction generally have a benign hospital course when treated with standard therapeutic anticoagulation alone, and appropriate patients can be treated without hospital admission.

**TABLE 35.2** Wells and Simplified Wells Criteria

Variable	Wells: Points	Simplified Wells: Points
Clinical symptoms and signs of DVT	3	1
Alternative diagnosis less likely than PE	3	1
Heart rate >100 beats/min	1.5	1
Recent immobilization or surgery	1.5	1
Previous VTE	1.5	1
Hemoptysis	1	1
Malignancy undergoing treatment or palliation within 6 months	1	1
PE unlikely	≤4	≤2

*DVT*, Deep vein thrombosis; *PE*, pulmonary embolism; *VTE*, venous thromboembolism.

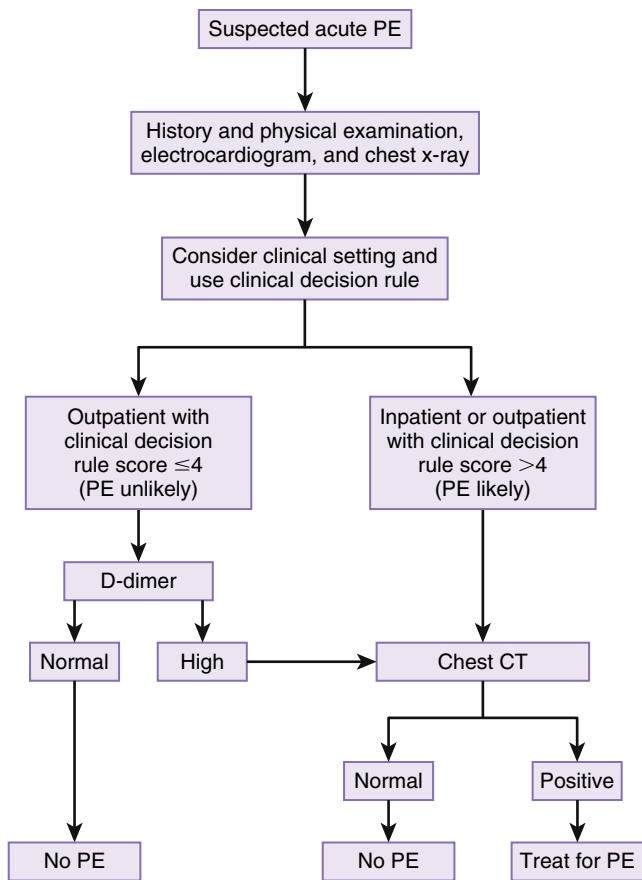

From Wells PS, Anderson DR, Rodger M, et al. Excluding pulmonary embolism at the bedside without diagnostic imaging: management of patients with suspected pulmonary embolism presenting to the emergency department by using a simple clinical model and d-dimer. *Ann Intern Med.* 2001;135:98–107; Gibson NS, Sohne M, Kruij MJ, et al. Further validation and simplification of the Wells clinical decision rule in pulmonary embolism. *Thromb Haemost.* 2008;99:229–234.

### Clinical Decision Rule

Simplified clinical decision rules assist clinicians in synthesizing important elements of the history and physical examination into an overall assessment of probability a patient has a PE. The Christopher study used a generally accepted clinical decision rule known as the Wells criteria, which assigns points for specific symptoms, signs, and medical history as outlined in Table 35.2. Patients were categorized as “PE unlikely” for scores ≤4 and “PE likely” for scores >4. Patients who were classified as “PE unlikely” underwent D-dimer testing and were referred to chest CT only if the result was positive, whereas patients in the “PE likely” category proceeded directly to chest CT. PE was excluded in patients categorized as “PE unlikely” with negative D-dimer results and in patients with negative chest CT scans. PE within three months was rare in the PE-unlikely group with a negative D-dimer at a 0.5% incidence versus 1.3% in those with a negative CT scan (Fig. 35.2). A simplified Wells criteria is listed in Table 35.2. Similar clinical decision rules exist for DVT assessment as well.

### Laboratory Evaluation

Because of the high negative predictive value of a normal result, D-dimer can be used to exclude PE in patients with low scores on clinical decision rules in outpatients without the need for further costly and potentially harmful testing.

• **Fig. 35.2** An integrated approach to diagnosis of acute pulmonary embolism (PE).

Inpatients should proceed directly to imaging as the initial test for PE because most are already at high risk and frequently have an elevated D-dimer caused by comorbid illness.

### Electrocardiogram

In PE, the electrocardiogram (EKG) may detect RV strain, which includes a right bundle branch block, T-wave inversions across the precordium, and the classic, but uncommon, S wave in lead I, Q wave in lead III, and T-wave inversion in lead III (S1Q3T3). The most common EKG finding is sinus tachycardia.

### Imaging

The chest x-ray (CXR) constitutes an important part of the evaluation of patients with suspected PE because it may suggest alternate diagnoses such as pneumonia. A normal or near-normal CXR in a patient with dyspnea or hypoxemia suggests PE. However, the majority of patients with PE will have some radiographic abnormality such as cardiomegaly or pleural effusion.

Contrast-enhanced chest CT angiography has emerged as the dominant diagnostic imaging modality for the evaluation of suspected PE (Fig. 35.3). The improved resolution of multidetector CT scanners has markedly reduced the frequency of nondiagnostic studies, resulting in a sensitivity of 98% while maintaining a high specificity of 94%. In the

• **Fig. 35.3** Contrast-enhanced CT demonstrating bilateral segmental pulmonary emboli (arrows).

Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) trial, chest CT was found to be accurate for the exclusion of the vast majority of patients suspected of PE. Further diagnostic testing should be considered if clinical suspicion and chest CT results are discordant.

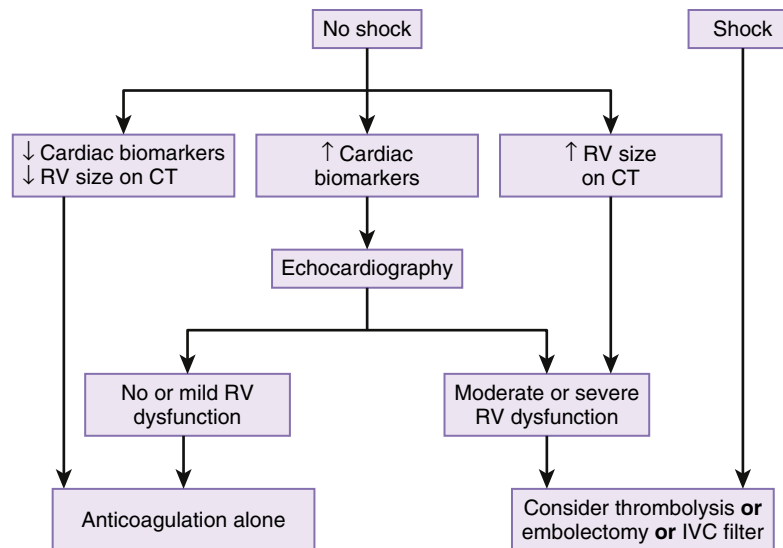

Alternative imaging modalities used in the evaluation of patients with suspected PE include ventilation-perfusion nuclear lung scan, MR angiography, and invasive contrast pulmonary angiography. Ventilation-perfusion lung scanning is most often used for patients with renal impairment, allergies to intravenous contrast, or pregnancy but has a high percentage (28%–46%) of nondiagnostic results. Although it avoids the risks of contrast and ionizing radiation, MR angiography is not as sensitive as chest CT for detection of PE but has demonstrated promise for the imaging of DVT. Invasive diagnostic pulmonary angiography is reserved for the rare circumstance when other noninvasive imaging studies are inconclusive and a high clinical suspicion for PE persists.

Transthoracic echocardiography is insensitive for the diagnosis of PE, even though it plays a critical role in the risk stratification of patients with proven acute PE. Transthoracic echocardiography is superb for the detection of RV dysfunction caused by RV pressure overload. RV dilatation and hypokinesis, paradoxical interventricular septal motion toward the left ventricle, tricuspid regurgitation, and pulmonary hypertension are characteristic echocardiographic findings of acute PE. Echocardiography is warranted in acute PE patients with clinical evidence of RV failure, elevated cardiac biomarkers, or unexpected clinical deterioration.

### Risk Stratification for Pulmonary Embolism

A subset of normotensive patients with acute PE will abruptly deteriorate and suffer systemic arterial hypotension, cardiogenic shock, or cardiac arrest despite standard therapeutic anticoagulation. Risk stratification to identify these patients before they decompensate has become an essential step in the management of acute PE (Fig. 35.4).

The history and physical examination can provide important clinical clues for risk stratification of acute PE patients. Heart failure, chronic lung disease, cancer, systolic blood

• **Fig. 35.4** Algorithm for risk stratification of patients with acute pulmonary embolism. *IVC*, Inferior vena cava; *RV*, right ventricular.

**TABLE 35.3** Pulmonary Embolism Severity Index (PESI)

Variable	Points	Class	Total Points
Age	Age (in points)	I: Very low risk	<66
Male	+10	II: Low risk	66–85
Cancer (previous or active)	+30	III: Intermediate risk	86–105
Congestive heart failure	+10	IV: High risk	106–125
Chronic lung disease	+10	V: Very high risk	>125
Heart rate $\geq 110$	+20		
Systolic blood pressure <100 mm Hg	+30		
Respiratory rate $\geq 30$	+20		
Temperature <36°C	+20		
Altered mental status	+60		
Arterial O <sub>2</sub> <90% (with or without supplemental O <sub>2</sub> )	+20		

From Aujesky D, Obrosky DS, Stone RA, et al. Derivation and validation of a prognostic model for pulmonary embolism. *Am J Respir Crit Care Med.* 2005;172:1041–1046.

pressure <100 mm Hg, age >70 years, and heart rate >100 beats per minute have been demonstrated to be significant predictors of increased mortality.

Elevation in cardiac troponin and brain-type natriuretic peptide correlate with the presence of RV dysfunction, an independent predictor of early mortality in acute PE patients. Normal levels of cardiac biomarkers identify a low-risk subset of acute PE patients. Conversely, patients with acute PE and elevated cardiac biomarkers should undergo echocardiography to confirm the presence of RV dysfunction.

RV enlargement on chest CT is a predictor of increased 30-day mortality in patients with acute PE. Detection of RV enlargement by chest CT is a particularly convenient tool for risk stratification because it uses data acquired from the initial diagnostic scan.

Echocardiography remains the imaging study of choice for risk stratification of acute PE patients. Normotensive patients with acute PE and RV dysfunction on echocardiography demonstrate an increased risk of early mortality. RV enlargement predicts more than doubling of hospital mortality for PE patients.

The Pulmonary Embolism Severity Index (PESI) scores patients by various features such as age, cancer history, and hypoxemia (Table 35.3) and ranks them by severity grade, which correlates with mortality. Metaanalysis of the PESI and other clinical prediction rules for prognostic scoring has shown a low mortality in the low-risk classes (2.2%; 95% confidence interval [CI], 1.2–3.4) and may be more sensitive for prognostic determination than echocardiography or other biomarkers. Others have proposed that these low-risk patients may be suitable for outpatient management.

**TABLE 35.4** Options for Anticoagulation

Agent	Advantages	Disadvantages
Intravenous unfractionated heparin, start 80 U/kg IV × 1, then 18 U/kg/h, adjust for PTT	Can be easily discontinued and rapidly reversed Preferred in patients undergoing thrombolysis, surgery, or catheter-assisted embolectomy Can be used in severe renal insufficiency	Requires continuous infusion Associated with HIT
Low-molecular-weight heparin, enoxaparin 1 mg/kg SC q12h (or 1.5 mg/kg SC daily)	Longer half-life Consistent bioavailability More predictable dose response Does not require dose adjustment or laboratory monitoring under usual circumstances Lower risk of HIT Preferred in patients with active cancer	Renally cleared Patients with renal impairment, massive obesity, and pregnancy will have altered pharmacodynamics
Fondaparinux, 5 mg SC daily if weight is <50 kg, 7.5 mg SC daily if weight is 50–100 kg, 10 mg SC daily if weight is >100 kg	Longer half-life Consistent bioavailability More predictable dose response Does not require dose adjustment or laboratory monitoring Does not cause HIT	Renally cleared Longer half-life is problematic if bleeding occurs No laboratory test to monitor level of anticoagulation
Warfarin, start at 2–5 mg po daily and adjust as needed to keep INR therapeutic Direct oral anticoagulants: apixaban, start 10 mg po bid × 7 days, then 5 mg bid Dabigatran, 150 mg po bid (must start after at least 5 days of parenteral anticoagulation) Edoxaban, 30 mg po daily if weight <60 kg, 60 mg po daily if weight >60 kg (must start after at least 5 days of parenteral anticoagulation) Rivaroxaban, start 15 mg po bid × 21 days, then 20 mg daily with food	Oral Inexpensive Oral Consistent bioavailability More predictable dose response Does not require monitoring or dose adjustments	Many drug interactions Requires regular monitoring and dose adjustments Partially renally cleared Twice a day dosing for apixaban and dabigatran Renally cleared No laboratory test available to monitor level of anticoagulation No currently available reversal agent except for dabigatran

*bid*, Twice daily; *HIT*, heparin-induced thrombocytopenia; *INR*, international normalized ratio; *IV*, intravenous; *po*, orally; *PTT*, partial thromboplastin time; *q*, every; *SC*, subcutaneously.

## Management

### Anticoagulation Strategies

Patients with acute VTE should be immediately anticoagulated whenever possible. For decades, the only choices for anticoagulation included vitamin K antagonists (VKA) and heparin. The 1990s saw the advent of low-molecular-weight heparins (LMWHs) and, for patients with heparin-induced thrombocytopenia (HIT) syndrome, direct thrombin inhibitors, but in recent years, a number of new options have emerged. The new oral agents are referred to as direct oral anticoagulants (DOACs) because they directly target specific clotting factors. Currently the US Food and Drug Administration (FDA)-approved agents include the direct thrombin inhibitor, dabigatran, and the factor Xa inhibitors, apixaban, edoxaban, and rivaroxaban. Fondaparinux, a parenteral agent that binds to antithrombin similar to the heparins, is a recombinant molecule not derived from animal or human sources. All anticoagulants except the VKAs have rapid onset of action and can be used for immediate anticoagulation in treating acute VTE. In fact, warfarin

should never be used to initiate anticoagulation without a bridge from a rapid-onset anticoagulant because of its procoagulant effects in the first 24 hours as levels of the natural anticoagulants protein C and protein S (both vitamin K dependent) drop rapidly because of the short 6-hour half-life of each. The bridging agent should be overlapped with a VKA in patients with acute VTE for 5 days to allow decline in the levels of prothrombin, which has a 72-hour half-life. Dosing for all the anticoagulants can be found in [Table 35.4](#).

Intravenous unfractionated heparin is administered according to weight-based protocols as a bolus followed by a continuous infusion titrated to a target activated partial thromboplastin time (aPTT) of 2 to 3 times the upper limit of normal (approximately 60 to 80 seconds). Because it can be discontinued and reversed rapidly, unfractionated heparin is preferred in patients undergoing thrombolysis, surgery, or at increased risk of bleeding.

LMWH and fondaparinux have longer half-lives, more consistent bioavailability, and predictable dose responses compared with unfractionated heparin. They are administered

subcutaneously according to weight and do not require dose adjustment or routine laboratory monitoring in patients with normal weight and renal function. Whereas unfractionated heparin is largely eliminated by the liver, LMWH and fondaparinux are cleared by the kidney. Patients with impaired renal function, massive obesity, or pregnancy will have altered pharmacokinetics. In these patients and in the setting of unanticipated bleeding or recurrent thromboembolism, therapeutic levels can be confirmed with antifactor Xa activity. LMWH as monotherapy without transition to oral anticoagulation is preferred in cancer patients with VTE (risk reduction for recurrent VTE with LMWH compared with VKA = 0.6; 95% CI, 0.45–0.79;  $P < .001$ ) based on the landmark CLOT trial published in 2003. A more recent study found no statistically significant difference in risk of recurrent VTE with VKA compared with warfarin, although differences in patient populations between the two studies might be responsible for the discrepant results. Data for the use of DOACs in cancer populations are lacking; trials are ongoing.

Warfarin has been the mainstay of outpatient anticoagulation for VTE for decades. The goal international normalized ratio (INR) is 2 to 3 for the majority of VTE patients and 2.5 to 3.5 for patients with mechanical heart valves. Nomograms are available to assist clinicians with warfarin initiation ([www.WarfarinDosing.org](http://www.WarfarinDosing.org)). Although pharmacogenomic studies focusing on cytochrome P450 2C9 and the gene-encoding vitamin K epoxide reductase complex 1 have helped to explain the wide variation in warfarin dosing requirements, knowledge of polymorphisms in these genes has not demonstrated significant clinical utility or cost effectiveness.

Management of warfarin can be challenging because of many drug–food, drug–alcohol, and drug–drug interactions. Commonly implicated warfarin potentiators (inhibiting P450 metabolism, increasing INR) include acetaminophen, quinolone antibiotics, selective serotonin release inhibitors, and amiodarone, whereas common inhibitors (inducing P450 metabolism, decreasing INR) include rifampin, spironolactone, thiazide diuretics, and anticonvulsants. Home INR monitors can improve control of oral anticoagulation and lead to fewer bleeding and clotting complications.

DOACs do not require routine monitoring or dose adjustment. They have been shown to be both safe and effective in the treatment of acute VTE. They have different degrees of renal clearance and dosing recommendations based on renal function. Concomitant medications that are strong inducers or inhibitors of p-glycoprotein transporter and CYP3A4 will also affect DOAC concentrations; package insert should be reviewed for drug contraindications and dose adjustments.

In a randomized, double-blind, noninferiority trial of 2539 patients with acute VTE who were initially given at least 5 days of parenteral anticoagulation therapy, dabigatran was compared with dose-adjusted warfarin. The primary outcome was the 6-month incidence of recurrent

symptomatic, objectively confirmed VTE and VTE-related death. Recurrent VTE was observed in 2.4% of the patients randomized to dabigatran (noninferior) compared with 2.1% of those randomized to warfarin. Major bleeding occurred in 1.6% of patients assigned to dabigatran and 1.9% of those assigned to warfarin (hazard ratio [HR] with dabigatran, 0.82; 95% CI, 0.45–1.48).

A randomized noninferiority study compared the oral anti-Xa agent rivaroxaban with enoxaparin followed by a VKA in 3449 patients with acute, symptomatic DVT. Rivaroxaban demonstrated noninferior efficacy with respect to the primary outcome of recurrent VTE (36 events [2.1%] vs. 51 events [3.0%]; HR, 0.68; 95% CI, 0.44–1.04;  $P < .001$ ). The rate of major bleeding or clinically relevant non-major bleeding was similar in both groups.

A subsequent randomized noninferiority trial of 4832 patients who had acute symptomatic PE with or without DVT compared rivaroxaban with enoxaparin followed by a dose-adjusted VKA. Rivaroxaban was noninferior to standard therapy for the primary efficacy outcome of symptomatic recurrent VTE (2.1% vs. 1.8%; HR, 1.12; 95% CI, 0.75–1.68). Major bleeding was less frequent in the rivaroxaban group (1.1% vs. 2.2%, HR, 0.49; 95% CI, 0.31–0.79;  $P = .003$ ).

In the AMPLIFY trial, oral monotherapy with the factor Xa inhibitor apixaban was shown to be noninferior to enoxaparin as a bridge to warfarin for prevention of recurrent symptomatic VTE or death related to VTE. Like rivaroxaban, apixaban was associated with significantly fewer bleeding events than warfarin. In HOKUSAI-VTE, the factor Xa inhibitor edoxaban following 5 days of parenteral anticoagulation was noninferior to parenteral anticoagulation as a bridge to warfarin for prevention of recurrent symptomatic VTE. Edoxaban also resulted in significantly fewer bleeding events than warfarin. Major bleeding and other clinically relevant bleeding occurred in 8.5% of the edoxaban patients and 10.3% of the warfarin patients (HR, 0.81; 95% CI, 0.71–0.94;  $P = .004$ ).

Concern has been raised regarding the lack of effective reversal agents for the DOACs, although in practice, bleeding events have been found to be lower with DOACs compared with VKA. Despite these outcomes, a large effort is being made to develop reversing agents. The first success was with idarucizumab, a humanized monoclonal antibody that neutralizes the anticoagulant effect of dabigatran. To date, this is the only FDA-approved reversing agent for a DOAC. Andexanet, a recombinant factor Xa decoy protein that binds all Xa inhibitors, reversed the effects of apixaban and rivaroxaban in healthy volunteers and stopped major bleeds in patients in an ongoing real-world study but has yet to be approved for commercial use. Further antidote strategies can be found in [Table 35.5](#).

### Duration of Anticoagulation

The optimal duration of anticoagulation depends on the individual patient's risk for recurrent VTE weighed against

**TABLE 35.5** Reversing/Antidote Strategies

Anticoagulant	Reversing Agents
Warfarin	Vitamin K, fresh frozen plasma, 4-factor prothrombin complex concentrate
Heparin, enoxaparin, dalteparin, fondaparinux	Protamine: 100% reversal of UFH 70%–80% reversal of LMWH No effect on fondaparinux
Dabigatran	Idarucizumab
Apixaban, edoxaban, rivaroxaban	No ideal agent

*LMWH*, Low-molecular-weight heparin; *UFH*, unfractionated heparin.

the risk of bleeding. Thromboembolic events can be divided into provoked and unprovoked clots. Unprovoked clots have a higher risk of recurrence (30% over 5 years and 40% by 10 years). VTE caused by transient risk factors are associated with a significantly lower risk of recurrence (3% over 5 years). Risk of recurrence persists after completion of standard anticoagulation in patients with idiopathic or unprovoked VTE. Several studies, including randomized controlled trials of warfarin, dabigatran, rivaroxaban, and apixaban, have validated the safety and efficacy of indefinite duration anticoagulation for patients with idiopathic VTE, although the risk of recurrent VTE versus the risk of bleeding should be considered for the individual patient. For patients with provoked events, a 3-month duration is usually sufficient, although individual patient risk factors should be assessed.

### Use of Aspirin

Aspirin may also play a role in the prevention of recurrence in patients with unprovoked VTE. In a multicenter, investigator-initiated double-blind study (WARFASA), patients with an initial unprovoked VTE who had completed 6 to 18 months of oral anticoagulant treatment were randomly assigned to aspirin 100 mg daily or placebo for 2 years. VTE recurred in 28 of the 205 patients who received aspirin versus 43 of the 197 patients who received placebo (6.6% vs. 11.2% per year; HR, 0.58; 95% CI, 0.36–0.93). A second multicenter, double-blind study compared aspirin 100 mg daily with placebo for 2 years in 822 patients with unprovoked VTE and did not show a difference in recurrent VTE. However, a composite of the rate of VTE, myocardial infarction, stroke, major bleeding, or death from any cause was reduced by 33% in the aspirin group (HR, 0.67; 95% CI, 0.49–0.91;  $P = .01$ ).

### Primary Therapy

#### Thrombolysis

Thrombolysis, also known as fibrinolysis, for DVT should be catheter directed and is most often used to treat upper

extremity or iliofemoral DVT in young, otherwise healthy patients. This approach is usually combined with mechanical disruption of thrombus (“pharmacomechanical therapy”). Thrombolytic therapy for PE is reserved for patients with either massive or submassive acute PE. Thrombolysis is generally accepted as a lifesaving intervention in patients with massive PE, but for submassive PE, it remains controversial.

The European-based Pulmonary Embolism International Thrombolysis Trial (PEITHO) is the largest randomized controlled trial of systemic thrombolysis in submassive PE to date, enrolling 1006 patients. The study evaluated the impact of the thrombolytic agent tenecteplase followed by heparin versus heparin alone on the primary outcome of all-cause mortality or hemodynamic collapse within 7 days of randomization. Thrombolysis with tenecteplase was associated with a significant reduction in the frequency of the primary outcome (2.6% vs. 5.6%,  $P = .015$ ) with the majority of the benefit caused by a reduction in hemodynamic collapse within 7 days of randomization (1.6% vs. 5%,  $P = .002$ ). However, the benefit of thrombolysis came at the cost of increased major bleeding (6.3% vs. 1.5%,  $P < .001$ ). More than 2% of the tenecteplase-treated patients suffered intracranial hemorrhage.

In the Moderate Pulmonary Embolism Treated with Thrombolysis (MOPETT) trial, 121 hemodynamically stable patients with acute symptomatic and anatomically large PE were randomized to either half-dose thrombolysis with t-PA and concomitant anticoagulation versus standard anticoagulation with enoxaparin or heparin. The frequency of pulmonary hypertension was lower in patients who received thrombolytic therapy than in the standard anticoagulation group (16% vs. 57%,  $P < .001$ ). No in-hospital bleeding events were reported in either treatment group. Mean length of hospital stay was decreased in patients assigned to the thrombolytic arm compared with standard anticoagulation (2.2 days vs. 4.9 days,  $P < .001$ ). An earlier trial randomized 118 patients with massive or submassive PE to t-PA 50 mg over 2 hours or 100 mg over 2 hours and demonstrated similar efficacy but fewer bleeding events with the half-dose regimen.

#### Catheter-Assisted and Surgical Interventions

Surgical interventions are considered in patients with massive or severely symptomatic DVT and massive or submassive PE in whom thrombolysis has failed or is contraindicated. At medical centers with experience in these techniques, surgical thrombectomy for DVT and embolectomy for PE are safe and effective alternatives.

In recent years, catheter-assisted techniques have grown in popularity. These may be used for treatment of DVT or PE when systemic thrombolysis and surgical intervention are contraindicated. Catheter-assisted embolectomy is an emerging technique for the treatment of massive and submassive PE. Catheter-assisted

techniques combining low-dose “local” thrombolysis and thrombus fragmentation or aspiration (“pharmacomechanical therapy”) offer the greatest success rate. A combination of catheter-directed thrombolysis with high-frequency, low-intensity ultrasound (EkoSonic Endovascular System, EKOS Corporation, Bothell, WA) has been developed to augment clot resolution. These procedures have multiple potential benefits including the use of lower-dose thrombolytics thus resulting in fewer bleeding complications and faster and more effective lysis of clot thus leading to decreased hospital length-of-stay and quicker resolution of symptoms, possibly even preventing postthrombotic syndrome. In a metaanalysis of 35 studies, the overall clinical success rate for catheter-directed therapy was 86.5% with a relatively low rate of minor (7.9%) and major (2.4%) procedural complications.

### **Inferior Vena Cava Filters**

IVC filter insertion is considered for VTE patients in whom anticoagulation is absolutely contraindicated, those who experience recurrent PE despite adequate anticoagulation, massive or submassive PE patients with contraindications to thrombolysis or embolectomy, and those undergoing surgical embolectomy. Although effective in the short-term prevention of PE, IVC filters have been shown to increase the long-term incidence of DVT. In addition, IVC filters can migrate, fracture, and penetrate vessel walls. For these reasons, the filter should be removed as soon as it is safe to do so.

### **Heparin-Induced Thrombocytopenia**

HIT is caused by heparin-dependent IgG antibodies directed against heparin-platelet factor 4 complexes and may result in limb-threatening and life-threatening arterial and, more commonly, venous thromboembolic complications. Although the risk is lower with LMWH, both unfractionated heparin and LMWH can result in HIT. A decline in platelet count of >50% from baseline or a new thromboembolic event while administering any heparin product, including heparin flushes, should raise concern for HIT and prompt the discontinuation of all heparin-containing products if the risk is significant. Pretest risk assessment can be made using the 4-T scoring system where points are awarded for the percent from baseline decrease in platelet count, the timing of the fall in relation to heparin exposure, thrombosis, and whether or not other causes of thrombocytopenia could have contributed. The full scoring system is outlined in [Table 35.2](#). A total score >3 should prompt immediate cessation of all heparin products, the start of argatroban, bivalirudin, or fondaparinux, and urgent testing by means of antiplatelet factor 4 (anti-PF4) heparin antibodies. The negative predictive value of a low 4-T score in combination with a negative PF4 is 99.8%. The sensitivity and specificity for the anti-PF4 antibody are high, and therefore additional

testing beyond this is typically unnecessary. However, when suspicion is high despite a negative anti-PF4 antibody test, a serotonin release assay can provide further information.

When HIT is suspected, an intravenous direct thrombin inhibitor, such as argatroban, bivalirudin, or fondaparinux should be administered to prevent arterial and venous thromboembolism. Argatroban is hepatically cleared and should be used cautiously in patients with impaired liver function. Bivalirudin and fondaparinux require downward dose adjustment for renal impairment. Argatroban and bivalirudin have extremely short half-lives (39–51 and 25 minutes, respectively) compared with fondaparinux (17–21 hours) and are preferred in patients at high risk of bleeding, such as those with recent surgery.

### **Prevention**

Progress has been made to prevent VTE in hospitalized medical and surgical patients. Evidence-based guidelines have been developed by many societies and are more routinely followed now than a decade ago. Hospital rates of postoperative VTE in particular are now followed as quality indicators.

### **Options for Prophylaxis**

Pharmacologic agents for the prevention of VTE include subcutaneously administered unfractionated heparin, LMWH, warfarin, fondaparinux, dabigatran, apixaban, and rivaroxaban. Mechanical prophylaxis, including graduated compression stockings and pneumatic compression devices, is an alternative in patients who cannot receive prophylactic dose anticoagulation.

### **Duration of Prophylaxis**

Numerous studies have validated extended duration prophylaxis for up to 4 to 6 weeks in highly selected patients at risk, such as those who have undergone extensive orthopedic or oncologic surgery. Caprini and others have attempted to risk stratify surgical patients to find those at high risk for VTE and who might benefit from extended prophylaxis. Randomized controlled trials of extended-duration VTE prophylaxis after hospital discharge of medical service patients, however, have not demonstrated a net clinical benefit.

### **Recommendations**

Despite the significant progress made to reduce in-hospital and postoperative VTE, many questions remain unanswered. Prophylactic regimens should consider the patient population as well as the individual patient’s risk factors for VTE.

## Chapter Review

### Questions

- All of the following are risk factors for venous thromboembolism, except:
  - Chronic obstructive pulmonary disease
  - Atherosclerotic cardiovascular disease
  - Shoveling heavy snow
  - Chronic kidney disease
  - Heart failure
- A 48-year-old woman with a history of hypertension and hyperlipidemia presents to the emergency department (ED) with sudden-onset right-sided pleuritic pain and dyspnea while gardening. She has no other medical conditions and takes a thiazide diuretic and statin daily. She does not smoke. On physical examination, she has a heart rate of 90 beats per minute, blood pressure of 160/90 mm Hg, respiratory rate of 20 breaths per minute, and oxygen saturation of 97% on room air. Cardiac examination reveals a regular rate and rhythm with no murmurs, rubs, or gallops. Her lungs are clear to auscultation. Her lower extremities are symmetric without edema. An EKG and CXR are unremarkable. What is the most appropriate next step to evaluate for acute PE?
  - Contrast-enhanced chest CT
  - D-dimer testing
  - Lower extremity duplex ultrasonography
  - Ventilation-perfusion lung scanning
- Which of the following does not identify acute PE patients at high risk for adverse outcomes?
  - RV dysfunction on echocardiography
  - RV enlargement on chest CT
  - Elevated cardiac troponin levels
  - Age >70 years
  - Systolic blood pressure >170 mm Hg
- All of the following statements regarding the management of VTE are true except:
  - Thrombolysis may be considered for patients with massive or submassive PE and is associated with a negligible risk of bleeding.
  - Surgical embolectomy at tertiary medical centers skilled in this procedure is a safe and effective alternative for the treatment of acute PE patients with contraindications to thrombolysis.
  - IVC filter insertion reduces the short-term risk of PE but may increase the long-term risk of DVT.
  - Appropriate agents for the immediate anticoagulation of VTE patients include intravenous unfractionated heparin, LMWH, and fondaparinux.
  - Indefinite duration anticoagulation has been shown to reduce the risk of recurrence in patients with idiopathic VTE.
- A 71-year-old man with a history of coronary artery disease, heart failure with a left ventricular ejection fraction of 30%, and diabetes mellitus is admitted to the telemetry floor with decompensated heart failure. Which of the following admission orders is not appropriate for VTE prophylaxis?
  - Unfractionated heparin, 5000 units subcutaneously 3 times a day
  - Enoxaparin, 40 mg subcutaneously daily
  - Dalteparin, 5000 units subcutaneously daily
  - Aspirin, 81 mg orally daily
  - Intermittent pneumatic compression devices

## Sleep Apnea

DOUGLAS B. KIRSCH AND LAWRENCE J. EPSTEIN

More has been learned about sleep in the last 60 years than in the preceding 6000 years, to paraphrase one sleep researcher, and sleep apnea is an area in which knowledge growth has been particularly exponential. In the last several decades, sleep specialists have explored methods of studying sleep, subdividing it into stages based on the sleep-related changes in the electroencephalogram (EEG), eye movements, and muscle tone. Additional measurements of airflow, respiratory effort, limb muscle movements, electrocardiogram (EKG), and oxygen saturation allow a full characterization of the changes and problems that occur during sleep. The process of studying physiologic parameters during sleep, polysomnography, has allowed sleep specialists to better understand the nocturnal rhythms of sleep and identify disruptors, one of the most common being obstructive sleep apnea (OSA). This chapter covers the epidemiology, pathophysiology, evaluation, and treatment of this common chronic disorder and its significant long-term effects on patients' well-being and health.

### Definition of Obstructive Sleep Apnea

The term *apnea* means no airflow. Apneas are subdivided into types, including obstructive apneas, meaning that there is ongoing effort in the muscles of respiration (thorax and abdomen) with no airflow caused by blockage of the airway; central apneas, in which the airway is open but there is neither effort nor airflow (the apnea is mediated by the central nervous system [CNS]); and mixed apneas, during which the event begins as a central apnea and then becomes obstructive. OSA is caused by collapse of the upper airway, preventing or inhibiting airflow and causing disruption of sleep. Obstructive apneas are caused by total collapse of the airway and are defined as periods of complete stoppage of breathing for 10 seconds or more. Partial collapse of the airway results in a hypopnea, which is a reduction in airflow lasting at least 10 seconds in association with a decrease in oxyhemoglobin saturation or an arousal from sleep. Mild collapse can increase resistance in the airway, and the increased work necessary to overcome the resistance can cause arousals from sleep, called *respiratory event-related arousals* (RERAs). The severity of OSA is often expressed as the apnea-hypopnea index (AHI); this index is determined by adding the number

of apneas to the number of hypopneas and dividing by the hours of sleep during the study. Although the AHI is used quite frequently as a primary measure of apnea severity, the minimum oxygen saturation, arousal index (arousals per hour of sleep), and sleep architecture breakdown may also be useful in evaluating the severity of sleep apnea. The respiratory disturbance index (RDI), which is the numbers of apneas + hypopneas + RERAs per hour of sleep, is often used interchangeably with the AHI. Although polysomnography is the gold standard for evaluation, historically some variability existed when attempting to compare different sleep laboratories because of different criteria for defining hypopneas (which in some laboratories were scored with 3% desaturations vs. 4% desaturations, 25% vs. 50% airflow decreases, and thermistor vs. nasal pressure transducers). New scoring rules have standardized the definition of hypopnea as a >30% decrease in airflow for >10 seconds associated with either a 3% desaturation or arousal from sleep. The diagnostic criteria for OSA in an adult is an AHI  $\geq 15$  events per hour with or without symptoms or an AHI between 5 and 15 events per hour and patient complaints of unintended sleep episodes, daytime sleepiness, unrefreshing sleep or insomnia, waking up gasping or choking, or the bed partner reporting witnessed apneas. The criteria are different in young children, where often a lower AHI is accepted as clinically significant.

### Epidemiology

Several studies have been performed to estimate the prevalence of OSA in the US and world populations. Based on available population-based studies, the prevalence of OSA including sleepiness as a symptom is 3% to 7% for adult men and 2% to 5% for adult women in the general population. The prevalence of OSA is higher in the overweight population, older individuals, and possibly in some non-Caucasian racial groups (Asians, African Americans, and Hispanics). Other factors that increase the risk for OSA include craniofacial anatomy (small mandibular body length), family history of OSA, smoking and alcohol use, and some medical conditions (Box 36.1).

Little information is available from a standpoint of disease progression. Weight change can clearly play a role; subjects

with a 10% increase in weight had a 32% increase in their AHI compared with subjects with stable weight. However, in one study, even in the absence of weight change, 20% of men and 10% of women developed sleep apnea over a 5-year observational period.

## Pathophysiology

What happens during an apnea? As the patient falls asleep his or her airway collapses, with tongue and soft palate pressed against the back of the pharyngeal space. Airflow ceases because of airway blockage. Worsening hypoxemia and hypercapnia stimulate repetitive efforts to breathe (thoracic and abdominal effort). Increasing effort causes marked reductions in intrathoracic pressure, which increases pulmonary artery pressure, venous return, and cardiac afterload. The hypoxemia stimulates peripheral artery chemoreceptors, triggering the response of peripheral vasoconstriction and increased arterial blood pressure. Increased respiratory efforts from hypoxemia and hypercarbia trigger a CNS arousal, awakening the person from sleep and causing the airway to open. The arousal causes a further increase in sympathetic stimulation that elevates blood pressure. With the airway open, a period of hyperpnea ensues to correct the blood gas derangements. The reoxygenation that then occurs may increase oxidative stress, leading to increasing inflammation and mitochondrial dysfunction. Once the blood gases return to normal values the person is able to fall asleep, allowing the airway to collapse and starting the cycle of events again. This sequence happens repetitively during the night, hundreds of times a night in severe cases.

Multiple factors contribute to the collapse of the airway and production of obstruction. These include upper airway anatomy, the functioning of upper airway musculature during sleep, stability of the respiratory control and arousal systems, and the effect of lung volume on the previous factors.

## Upper Airway Anatomy

The airway, composed of muscles and soft tissue but without bony support, contains a collapsible portion from the hard palate to the larynx. It has three primary functions: speech,

breathing, and swallowing. Patients with OSA have a smaller airway lumen than those without. This may be caused by an increase in the lateral pharyngeal wall, increased tongue volume, adenotonsillar hypertrophy, or increase in the size of the parapharyngeal fat pads. The most common location of airway collapse is the retropalatal region; other areas of collapse may include the hypopharynx and retroglottal region.

## Upper Airway Muscle Control

During wakefulness, patients with OSA are able to maintain airway patency, even with a compromised airway, because of increased pharyngeal muscle tone. However, as they fall asleep, airway dilator muscle activity diminishes significantly compared with waking, allowing the airway to collapse.

## Collapsibility

The airway of OSA patients tends to be more collapsible, demonstrated by measurement of the closing pressure,  $P_{crit}$ . This value is the pharyngeal pressure at which the airway collapses, determined by the relationships among the soft tissue extramural pressure, pharyngeal wall compliance, and upper airway muscle activity.  $P_{crit}$  is higher in those patients with OSA, meaning that the airway will collapse at a less negative pressure than a patient who does not have OSA. Conversely, a normal airway requires application of a more negative pressure to cause collapse than an airway of a patient with OSA.

## Arousal Threshold

Restoration of airflow following airway collapse occurs after increasing ventilatory drive triggers an arousal from sleep and activation of airway dilator muscles. Patients with OSA tend to have an impaired arousal response to airway occlusion compared with control subjects, requiring more negative pressures to trigger a respiratory-related arousal from sleep. Continuous positive airway pressure (CPAP) therapy decreases the arousal threshold in patients with severe OSA but not to the level of controls. However, about one-third of OSA patients have a low respiratory arousal threshold and awaken before ventilatory drive can build. This subset may benefit from medications increasing arousal threshold and reducing sleep fragmentation.

## Feedback Loops

Ventilation is controlled by feedback loops. Increases in carbon dioxide and decreases in oxygen stimulate increased breathing, which reverses the blood gas changes, causing ventilation to decrease. Changes in the sensitivity or output of the system can promote unstable, irregular, or cyclical breathing patterns. Apneas tend to occur more frequently during unstable breathing and in a cyclical pattern.

## Lung Volume

Changes in lung volume modify upper airway mechanics; as lung volume decreases during sleep, upper airway resistance increases. Conversely, as end-expiratory lung volume increases, airway collapsibility decreases, improving sleep-disordered breathing in OSA. The underlying mechanisms of this action have not been well described.

## Clinical Evaluation of Obstructive Sleep Apnea

Although diagnosis of OSA is generally not based solely on a patient's symptoms and signs, the history and physical examination continue to play a significant role in the evaluation of the patient. In many cases, particularly in patients with low AHIs, the symptom history may be the primary tool in determining the course of action.

Snoring, the most common reported symptom of OSA, occurs because of narrowing of the upper airway; the noise results from the vibration of the surrounding tissue by turbulent airflow through this constricted space. The rate of habitual snoring in the population is 25% in men and 15% in women; however, this rate increases with age. Given the epidemiologic rates of OSA listed earlier, snoring does not have positive predictive value for OSA, but it is quite sensitive because 95% of patients who have OSA also snore. Witnessed apneas, a common cause of referral to a sleep center, are more specific for OSA although they may be observed in 6% of the normal population. Other nocturnal symptoms may include gasping arousals, choking, insomnia, frequent urination, and nocturnal sweating.

Daytime symptoms may also aid in the identification of patients with OSA. Excessive daytime sleepiness (EDS) is commonly reported by patients with OSA. Although OSA may be one of the most common medical causes of EDS, sleepiness by itself is not highly specific for OSA and may be caused by a variety of other disorders. In addition, many patients with OSA do not recognize their level of sleepiness or may report alternate symptoms such as fatigue or lack of energy. Other described daytime symptoms may include memory impairment, morning headaches, and depression.

Physical examination of the patient with OSA may be helpful in assessing pretest risk level for OSA (Box 36.2). As body mass index (BMI) rises, risk for OSA increases. Although high blood pressure is a common symptom in adults, it may be seen at a higher rate in patients with OSA. The majority of the assessment time should be spent on evaluation of the upper airway. The nasal examination should explore for reduced nasal airflow caused by either congestion or structural abnormalities. The oropharynx is inspected for evidence of airway narrowing. The Mallampati airway classification score, an assessment of airway crowding, has shown to be predictive of OSA likelihood. Other features that may predispose to OSA include a high-arching soft palate, large tongue, soft palate redundancy, increased

### • BOX 36.2 Physical Risk Factors

- Obesity
- Neck circumference (>17 inches in men, >16 inches in women)
- Small, hypoplastic, and/or retroposed maxilla and mandible
- Narrow posterior airway space
- Inferiorly positioned hyoid bone
- High and narrow hard palate
- Abnormal dental overjet
- Macroglossia
- Tonsillar enlargement
- Nasal obstruction

uvula size, abnormal molar occlusion, and retrognathia or micrognathia. Further evaluation of the upper airway may include use of cephalometry, fiberoptic laryngoscopy, and CT or MRI of the upper airway. The complete examination should include palpation of the neck, a cardiorespiratory evaluation, and a neurologic evaluation.

Subjective measures of daytime sleepiness have often been used to aid in the assessment of patients with sleep disorders. One of the most frequently used measures is the Epworth Sleepiness Scale (ESS), an 8-question scale with scores ranging from 0 (not sleepy) to 24 (very sleepy; Table 36.1). This scale assesses a patient's chronic level of sleepiness in different situations, from lying down to napping to driving a car. A score >10 suggests excessive sleepiness, and higher values on this scale (particularly those >15) may be suggestive of a sleep disorder. The ESS is neither specific for OSA nor a replacement for objective testing.

The polysomnogram is the gold standard for objective testing for OSA, evaluating electroencephalography, electroculography, respiratory parameters, oxyhemoglobin

saturation, cardiac rhythms, and muscle activity during sleep (Fig. 36.1). In general, the diagnostic test will last at least 6 hours, although some sleep centers have opted to perform split-night studies to minimize health care cost, in which the first half of the study is devoted to diagnosis and the second half is a positive-pressure treatment trial (Fig. 36.2). A technologist places all the appropriate probes and wires on the patient at the beginning of the night and observes that patient throughout the night, ensuring that the patient is medically stable and that the recorded data are accurate. The advantages of the polysomnogram are the assessment of sleep stage and the effect of stage on

• **Fig. 36.1** Monitoring obstructive apnea. This is a slide of a 37-year-old man demonstrating an obstructive apnea (30-second epoch). Note the continuous thoracic and abdominal effort with absent nasal airflow, increasing respiratory effort, the dropping oxygen saturation with a slight delay, and the electroencephalogram (EEG) arousal (identified). The top six leads are EEG (right and left frontal, central, and occipital), followed by two eye leads (right and left), two chin leads, electrocardiogram, two leg leads (right and left), snore channel, oronasal thermistor, nasal pressure transducer, effort bands (thorax and abdomen), oxygen saturation, continuous positive airway pressure level, and body position.

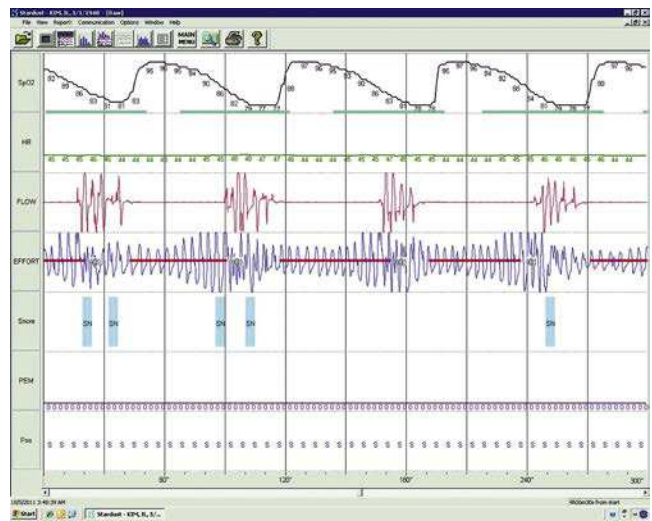

• **Fig. 36.2** A split-night study. This is an overnight hypnogram for a split-night study; the first half of the night is diagnostic, the second half is a continuous positive airway pressure titration study. From the top down, the horizontal images are oxygen saturation, heart rate, respiratory events (central apneas, obstructive apneas, mixed apneas, and hypopneas), sleep architecture (wake to deep sleep moving downward), positive airway pressure (PAP), snoring, arousals, leg movements, and sleep position. Obstructive events (red, black, and pink) are eliminated as the PAP is increased. Notice the improvement in the sleep architecture (fragmented in the first half, fewer arousals in the second half), elimination of obstructive apneas and hypopneas, and reduction in oxygen desaturations after introduction of positive airway pressure around 2 AM.

sleep-disordered breathing, observer report and video for evaluation of patient behavior, scoring of EEG-based arousals from sleep, and ability to intervene to assure high-quality data and provide patient assistance.

In-home monitors have been developed for the diagnosis of OSA. These portable monitors (referred to as *home sleep apnea tests*, *home sleep tests*, and *out of center sleep tests* [OCSTs]) measure only a subset of the parameters of a typical polysomnogram (e.g., airflow, respiratory effort, heart rate, and snoring). In-home testing is most likely to be successful for patients who have a high likelihood of moderate-to-severe OSA in the absence of comorbid medical conditions such as lung disease, congestive heart failure, neuromuscular conditions, or other suspected sleep disorders. An example image of a home sleep test is observed in Fig. 36.3. These home sleep tests have been increasingly used to limit health care costs because they are less expensive than an in-laboratory test. A significant limitation for most portable monitors is the lack of EEG leads; absence of brain wave measurement generally limits accurate sleep staging and identification of cortical arousals. Although generally accurate for diagnosing OSA in patients with moderate-to-severe OSA, they underestimate severity compared with in-laboratory polysomnography. Because of this, in cases where a home sleep test is normal in the setting of patients with high likelihood of OSA, a follow-up in-laboratory study is indicated. Single-channel monitors such as oximeters may assess the efficacy of treatment of OSA; however, oximetry may poorly identify cases of OSA, especially mild apnea.

The diagnostic criteria for OSA are given in Box 36.3. The primary value used by clinicians to assess severity of OSA is the AHI. OSA severity is defined as mild for AHI

• **Fig. 36.3** This is a 5-minute epoch of a home sleep test demonstrating obstructive sleep apnea. The top of the image demonstrates a fluctuating oxygen level associated with each respiratory event. Next is the heart rate signal showing slowing with each event. The flow signal shows intermittent nasal airflow despite increasing ventilatory effort in the effort channel, consistent with airway closure. Snoring occurs during the times of airflow. The last two channels are for patient event signaling (none seen) and body position (s = supine).

≥5 and <15, moderate for AHI ≥15 and <30, and severe for AHI ≥30. However, sleep laboratories may use different criteria for scoring events and for defining apnea severity.

## Consequences of Obstructive Sleep Apnea

The long-term medical effects of OSA are the result of the physiologic derangements that accompany the repetitive obstructive respiratory events (Box 36.4). These are discussed in the following paragraphs.

### Hypertension

Hypertension is one of the most common medical conditions associated with OSA. Obstructive sleep-disordered breathing causes acute peripheral vasoconstriction and increased blood pressure during sleep. Typically, sleep is associated with decreased blood pressure compared with wakefulness (reduced 10%–15%). This dip in blood pressure occurs to a lesser degree, or not at all, in many patients with OSA. The Wisconsin Sleep Cohort, looking at 709 subjects, demonstrated prospectively that the severity of OSA at baseline is associated with the presence of hypertension 4 years later. Compared with a reference AHI of 0, the odds ratios (95% confidence interval in parentheses) were

#### • BOX 36.3 Diagnostic Criteria From the International Classification of Sleep Disorders, Third Edition

- A. The presence of one or more of the following:
  1. The patient complains of sleepiness, nonrestorative sleep, fatigue, or insomnia symptoms.
  2. The patient wakes with breath holding, gasping, or choking.
  3. The bed partner or other observer reports habitual snoring, breathing interruptions, or both during the patient's sleep.
  4. The patient has been diagnosed with hypertension, a mood disorder, cognitive dysfunction, coronary artery disease, stroke, congestive heart failure, atrial fibrillation, or type 2 diabetes mellitus.
- B. PSG or OCST demonstrates:
  1. Five or more predominantly obstructive respiratory events (obstructive and mixed apneas, hypopneas, or RERAs per hour of sleep during PSG or per hour of monitoring OCST)

OR
- C. PSG or OCST demonstrates:
  1. Fifteen or more predominantly obstructive respiratory events (i.e., apneas, hypopneas, or RERAs) per hour of sleep during a PSG or per hour of monitoring (OCST)
  2. Evidence of respiratory effort during all or a portion of each respiratory event

(A and B) or C satisfy the criteria.

OCST, Out of center sleep testing; PSG, polysomnography; RERAs, respiratory event-related arousals.

From the American Academy of Sleep Medicine (AASM). *Diagnostic Criteria From the International Classification of Sleep Disorders*, 3rd ed. Darien, IL: 2014; AASM.

2.03 (1.29–3.17) for an AHI between 5 and 14.9 events per hour and 2.89 (1.46–5.64) for an AHI ≥15 events per hour. In a large study of nurses aged 40 to 65 years, there was a higher incidence of hypertension in those women who reported snoring. Multiple studies have also demonstrated that treatment of OSA with CPAP therapy will lower blood pressure in hypertensive patients, even in those patients who are considered refractory (poor control of blood pressure with use of three or more medications).

### Cardiovascular Morbidity and Mortality

The large multicenter Sleep Heart Health Study found that as OSA worsened, so did the prevalence of coronary heart disease. Another large prospective study demonstrated that over a mean observation period of 10 years, patients with severe OSA had a 3-fold higher risk of cardiovascular events than healthy controls. Prospective studies of patients from a sleep clinic evaluated 60 men with OSA and 122 men without sleep-disordered breathing and found that the OSA population had a higher incidence of cardiovascular disease (37%) than the controls (7%). Even snoring appears to be potentially associated with an increased risk of cardiovascular disease. The Nurses' Health Study discovered that occasional snorers had a 1.46 times age-adjusted relative risk of cardiovascular disease when compared with nonsnorers; frequent snorers have a 2.02 times increased risk. However, this study did not differentiate between those with OSA and nonapneic snorers.

OSA has been linked to arrhythmias in several studies. The Sleep Heart Health Study demonstrated that patients with an RDI >39 events per hour had a higher rate of atrial fibrillation, nonsustained ventricular tachycardia, and ectopic ventricular beats than those subjects with an RDI <5 events per hour. Among patients who had been electrically cardioverted for atrial fibrillation, the patients with untreated OSA had a recurrence rate twice that of patients treated with CPAP. Nocturnal hypoxemia from OSA has also been associated with the incidence of atrial fibrillation.

A few studies suggest that treatment of OSA may improve cardiovascular disease, although the data are quite limited. One study compared patients who did not tolerate CPAP with those who were treated over a mean follow-up time

of 7.5 years. Deaths from cardiovascular disease were more common in the untreated group compared with the treatment group (14.8% vs. 1.9%).

### Cerebrovascular Disease

Similar to cardiovascular disease, an association of OSA and stroke has been observed in multiple studies. Subjects studied after a first stroke or transient ischemic attack (TIA) have a reported prevalence of sleep-disordered breathing of 63% to 70%. One longitudinal study found that an AHI >20 events per hour was a risk factor for stroke. In another 3-year study of more than 1000 subjects with OSA, severity of OSA correlated with risk of mortality from stroke and other causes. In addition, self-reported snoring has been found to be an independent risk factor for stroke in women. AHI also appears to predict mortality in patients with a first-time stroke or TIA within 2 years.

The cause and effect of cerebrovascular disease and sleep-disordered breathing is controversial; as mentioned earlier, some studies demonstrate that OSA is a risk factor for stroke. However, some researchers suggest that some forms of sleep-disordered breathing, particularly central sleep apnea, may be caused by injury of brain respiratory centers or centrally mediated upper airway reflexes.

### Heart Failure

OSA is associated with an increased frequency of congestive heart failure. Likely contributors include OSA-induced hypertension, large negative swings in intrathoracic pressure, hypoxemia, and increased sympathetic activity. The prevalence of patients with heart failure referred to a clinical sleep laboratory who have sleep-disordered breathing is at least 40%. The effects of CPAP treatment on heart failure patients with OSA are currently controversial, with two interventional studies demonstrating improvement in left ventricular ejection fraction and one study that demonstrated no clear changes in cardiovascular function.

### Diabetes Mellitus Type 2

OSA is an often-observed comorbidity with diabetes type 2, possibly because of the common relationship to obesity. The Sleep Heart Health Study found that patients with AHI  $\geq$ 5 events per hour had a two times greater risk of having impaired glucose tolerance, even after adjusting for confounding variables. The glucose tolerance impairment in these subjects was correlated with the severity of oxygen desaturation. The Wisconsin Sleep Cohort found similar information, demonstrating that 15% of subjects with AHI >15 events per hour had type 2 diabetes. Although the exact cause-and-effect relationship is not completely clear, some suggestions have included OSA causing stimulation of the sympathetic nervous system, stimulation of the hypothalamic-pituitary-adrenal axis, and increase in cytokine release. A role for intermittent hypoxia in the interaction between diabetes type 2 and OSA has also been raised.

### Motor Vehicle Crashes

Although less of a medical risk factor, automobile crashes may be the most immediate source of danger from OSA. Patients with OSA may suffer from a 2-fold to a 7-fold increased risk of a motor vehicle accident when compared with the general population. One metaanalysis demonstrated that 800,000 drivers were involved with OSA-related motor vehicle accidents in 2000 with a cost of nearly \$16 billion and 1400 lives. Although it is unclear whether the severity of OSA is directly correlated with the risk of crashes, it is clear that treatment of OSA with positive air pressure (PAP) therapy reduces that risk.

## Treatment of Obstructive Sleep Apnea

### Medical Therapy

Not all patients demonstrate interest in or a preference for more aggressive therapies for OSA, particularly depending on the severity of the patient's symptoms. Obesity clearly is related to smaller airway size, promoting nocturnal airway collapse. Therefore in patients who are obese, weight loss may play a major role in the treatment of OSA. In some cases, self-motivating patients may be able to lose weight without much support; however, many patients have success in group programs or via a multidisciplinary team approach. In some cases, surgical approaches to weight loss such as gastric bypass surgery are appropriate options for those who fail more conservative therapies. Gastric bypass surgery has been shown in several studies to cause a significant decrease in AHI as weight loss occurs.

Another common conservative treatment of OSA is positional therapy because for many patients, sleep-disordered breathing may be significantly worse in the supine sleeping position. The cause of this positional predisposition is likely the effect of gravity on the tongue, causing closure against the posterior pharyngeal wall. One method of treatment would be to sleep with the head and trunk elevated (30–60 degrees to the horizontal), which has been shown to lessen airway opening pressure. Alternatively, the patient should avoid the supine position while lying horizontal. Methods to minimize sleeping on the back may include the use of a small backpack, sewing a pocket in the back of a T-shirt, which then would contain a tennis ball, or using a wedge pillow. Recently, electronic vibrotactile sleep positioning devices have shown success in preventing supine sleep, using vibration to induce the patient to change from the supine position. It is necessary to demonstrate that a person has positional OSA before implementing positional therapy.

Other methods of limiting OSA include avoidance of the use of tobacco, abstinence from alcohol or sedative-hypnotic medications before bedtime, and minimization of sleep deprivation. Cigarette smokers have a four to five times higher risk of at least moderate OSA compared with those who do not smoke, perhaps via upper airway edema. Alcohol may induce apneas in snorers and may increase the

frequency of apneas in preexisting apneics. There is some evidence, although limited and inconclusive, suggesting that benzodiazepines may have similar effects to alcohol. In addition, alcohol may worsen daytime sleepiness in patients with OSA. Acute sleep deprivation may increase the severity of sleep-disordered breathing. Medications such as rapid eye movement-suppressing tricyclic antidepressants and respiratory stimulants have not been effective in treating OSA. Improvement in nasal airflow with saline rinses, medications, or nostril-opening adhesive strips may also provide mild reduction in snoring and apnea severity. Supplemental oxygen reduces the degree of hypoxemia but does not reverse the obstructive events; therefore it should only be used as an adjunct to other therapies.

### Positive-Pressure Therapy

The use of air pressure to maintain airway patency was introduced in Australia in 1981 by Colin Sullivan. Now, after the evolution of masks and breathing circuits over the last 25 years, CPAP is the first-line treatment for OSA. CPAP acts as a pneumatic splint to maintain pharyngeal airway patency. The selection of the appropriate CPAP level has been classically done via an in-laboratory polysomnogram during which CPAP is titrated to the lowest possible pressure that eliminates snoring, respiratory-related arousals, and obstructive hypopneas and apneas. As this occurs, the patient's sleep architecture often improves, no longer fragmented by the repetitive airway collapse. Pressures set in the laboratory rarely need to be changed over time; some factors that may suggest the need for a pressure change include significant weight gain or loss, the return of snoring, or return of notable daytime symptoms that had been previously suppressed.

CPAP has been shown to improve daytime sleepiness, performance, and quality of life and to reduce automobile accidents. Studies often refer to CPAP use of more than 4 hours per night as being compliant; however, recent study has shown a dose-response relationship between improvement in symptoms and performance and time used. Patients should be encouraged to wear CPAP whenever sleeping. Compliance with PAP therapy is often difficult for patients. The three primary factors that impact tolerance to CPAP are mask fit, PAP level, and nasal congestion. Different mask styles may include nasal masks, oral/nasal masks, and nasal prong-style masks. Different patients will require different mask types; there is no one-type-fits-all mask. Although trial and error is often the method used to select mask style, some useful guidance may be offered by a patient's report of mouth breathing (need for a chin strap), nasal congestion (consider an oral/nasal mask), or claustrophobia (use less bulky nasal prong mask). If higher pressures lead to difficulty with tolerance or aerophobia, some consideration may be given to lowering the CPAP level for comfort, use of expiratory pressure adjustment (available on some CPAP machines), or switching to bilevel PAP therapy. Humidification of PAP therapy can decrease nasal congestion and increase compliance.

Unlike the constant single pressure of CPAP, bilevel PAP therapy provides two different positive pressures, a higher one on inspiration and a lower one on expiration. Overall, compliance is not better with bilevel PAP than CPAP; however, some patients who will not tolerate CPAP can tolerate bilevel PAP. A separate titration study night is often recommended when trying to initiate bilevel PAP therapy because the pressures required for treatment may be similar to but not exactly the same as those for CPAP.

AutoPAP, an autotitrating CPAP device, has been increasingly available and adjusts the PAP pressure via an internal algorithm to continuously eliminate respiratory events as the night goes on (during positional changes or sleep stage changes). The advantage of this device is that the pressure is only as high as necessary at any given time frame, potentially improving patient comfort and avoiding the need for an in-laboratory titration study. Similar to bilevel PAP, studies have not shown improved compliance with autoPAP, but some patients will tolerate this modality and not others. To function adequately, these devices require a low leak level, and thus a good mask fit is necessary. In addition, autoPAP only treats OSA; if the patient has a comorbid nocturnal breathing disorder, an in-laboratory titration is still recommended.

### Oral Appliances

When patients are unable to tolerate PAP therapy, one alternate option for treatment is using a custom-fit oral appliance. There are several types of appliances, but the two primary styles of devices are mandibular advancing (more common) and tongue retaining. The mandibular-advancing appliances are created to move the bottom jaw forward compared with the upper jaw, moving the tongue forward to increase the size of the retroglossal airway. Preferably, specially trained dentists will make the appliances by taking an impression of the upper and lower teeth and building the appliance based on the molds. The mandibular-advancing devices may be either adjustable or nonadjustable. There are several advantages to the use of an oral appliance, although the most notable is the size. Easy for travel and without need for electricity, the appliance is a good choice for a rustic camper or frequent business traveler. Patients who were claustrophobic with CPAP may be more open to this style of treatment. However, the oral appliances as a group tend to be most successful for patients who have mild or moderate OSA; in more severe cases of OSA, the reduction in severity from the use of the appliance may not improve the patient's symptoms or reduce cardiovascular risk. The appliances will work best in patients with a full set of teeth and with good jaw mobility; patients with poor dentition and with temporomandibular joint pain may not be good candidates. Tongue-retaining devices pull the tongue anteriorly in an attempt to reduce airway closure during the night but are less commonly used. Because the success rate for treating mild-to-moderate OSA with an oral appliance is 50% to 60%, patients should have a sleep study with the appliance in place to demonstrate effectiveness of the device.

## Surgery

Surgery is infrequently a cure for OSA, although often significant reductions in apnea severity can be observed. To increase the rate of a positive result, the presurgical evaluation should be oriented toward identifying the site of airway collapse (palate, base of tongue, or both). Although an external oronasal examination is helpful, often the use of fiberoptic nasopharyngolaryngoscopy and cephalometric radiography/CT scans may allow for more specific localization.

Tracheostomy was the first described surgical treatment for OSA and is nearly universally successful in the rare occasions that it is still performed. Its rarity is primarily related to patient disinterest combined with the knowledge that CPAP is an equally effective alternative. Tracheostomy may also be a temporary measure to maintain airway patency when performing other upper airway surgery.

Nasal reconstruction is rarely a sole intervention for OSA, although good nasal airflow may improve nocturnal respiration and increase the likelihood of CPAP tolerance. More frequently, this surgery may occur in combination with other upper airway surgeries.

Uvulopalatopharyngoplasty (UPPP) was first proposed in 1964 as a treatment for snoring. Over time this procedure has become quite popular, although the data supporting its use in all patients are variable. If the obstructive process is solely related to the retro-palatal area, this surgery may be quite effective. UPPP involves removal of a portion of the soft palate, the uvula, and residual tonsillar tissue. Although the procedure is described by some surgeons as simple, there is significant throat pain described by patients postoperatively. Studies have demonstrated a 20% to 50% reduction in respiratory events with this procedure.

Laser-assisted uvulopalatoplasty is an ambulatory procedure that also focuses on oropharyngeal obstructive processes; through use of a carbon dioxide laser, the surgeon may shorten or amputate the uvula and tighten the palate. Less successful than the UPPP, this procedure rarely brings the AHI into a normal range and should be used primarily for treating primary snoring without OSA.

Mandibular osteotomy with genioglossus advancement attempts to prevent collapse of the hypopharyngeal space during sleep. A hole is created in the mandible, and part of the tongue muscle is pulled forward; however, no additional space is anatomically created.

Maxillomandibular advancement osteotomy is a more advanced surgery to improve refractory base-of-tongue obstruction, often after other surgeries fail (some surgeons consider this a second-phase surgery to be performed after failure of a palatal surgery). In some patients with craniofacial disorders, such as mandibular deficiency, this surgery may be a first-line treatment. Movement of both the maxillary and mandibular

complex forward by at least 10 mm via fracture creates physical room for the tongue. An orthodontist is also frequently involved in the procedure to manage dental occlusion.

## Recent Interventions

Radiofrequency ablation delivers low-heat energy to an area of tissue, which can reduce volume and create scar tissue, particularly directed to the soft palate. This intervention has improved snoring via repeated treatment sessions, but the data demonstrating improvement in OSA have been limited.

Placement of palatal implants is a recently approved operation for snoring and OSA; by placing three polyester pieces into the soft palate and stiffening it, the frequency and volume of snoring have been reduced. The advantages to this system are low cost and low morbidity. However, although the data have demonstrated a small but statistically significant improvement in mild OSA, this intervention has not been shown to be curative for OSA of any severity.

One new nonsurgical option includes a disposable device applied over the nostrils. By use of a one-way valve, expiratory positive airway pressure is created, which may minimize the patient's sleep-disordered breathing during the night. Although seemingly a good alternative to PAP therapy, these devices have been unpredictable in which patients will be adequately treated, and patient response to using them has been mixed.

The most recently described and approved surgical therapy for OSA is electrical nerve stimulation of the hypoglossal nerve, which controls some of the upper airway dilator muscles. The stimulation is timed to inspiration and maintains elevated muscle tone and airway patency. In carefully selected patients (BMI <32, AHI between 20 and 50 per hour) the procedure produced greater than 50% reduction in AHI in 66% of patients and resolution of OSA in 29%, with results persisting after several years of use.

## A Brief Comment on Central Sleep Apnea

Although both are associated with stoppage of breathing, OSA should not be confused with central sleep apnea. Unlike the collapse of the airway, which prevents air movement in OSA, temporary loss of ventilatory effort is the cause of a central apnea. This disorder is rarer than OSA, comprising 4% to 10% of the sleep laboratory population. Central sleep apnea has several different causes, most commonly related to congestive heart failure although neurologic disorders, medications, and high altitude are alternative options. Unlike OSA, central sleep apnea does not appear to confer the same medical risks although sleep disruption and occasionally daytime sleepiness may occur.

## Summary

OSA is a common but underrecognized disorder caused by repetitive airway closure during sleep. Although it is not directly implicated in mortality, the disorder appears to significantly increase the likelihood of hypertension, coronary artery disease, and cerebrovascular disease. In addition, there

is a large impact on quality of life as a result of disrupted nocturnal sleep and production of excessive daytime sleepiness, including an increased risk of motor vehicle accidents. The primary treatments include weight loss, positional therapy, positive-pressure therapy, oral appliances, and surgical intervention.

## Chapter Review

### Questions

1. A 44-year-old man presents feeling tired during the daytime to the point where he reports drowsy driving. His spouse reports snoring and gasping episodes during the night, which have worsened over the last few years. The patient also reports frequent nocturia and morning headaches. You perform a physical examination. Which of the following physical characteristics is most likely?
  - A. Clubbed nails
  - B. Elevated BMI
  - C. Leg edema
  - D. Tachycardia
2. An 18-year-old man comes to the clinic with a report of heroic snoring and daytime sleepiness. He reports difficulty staying awake while working at his desk job, particularly after lunch. He underwent a sleep study at an outside institution, which demonstrated moderate OSA with an AHI of 25 events/h and a minimum oxygen saturation of 82%. On physical examination, he has a crowded airway (Mallampati IV) without enlarged tonsils. His BMI is 23. What is the most likely cause of his OSA?
  - A. Deviated nasal septum
  - B. Hard palate torus
  - C. Hypoglossia
  - D. Retrognathia
3. A patient comes to the clinic with complaints about disturbed nocturnal sleep. He awakens at night suddenly with a feeling of gasping and choking. He has been told that his snoring has been getting progressively worse over the last several years. He has a BMI of 42, blood pressure of 155/95 mm Hg, and a Mallampati class IV airway with a large, scalloped tongue. The most appropriate test for diagnosis of this patient's likely OSA is:
  - A. Actigraphy
  - B. ESS
  - C. Overnight oximetry
  - D. Polysomnography
4. The aforementioned patient is diagnosed with OSA. He tries CPAP but is not interested in using it long term. He asks you what the most effective surgical procedure is for elimination of severe OSA. Your answer is:
  - A. Genioglossus advancement
  - B. Laser-assisted uvulopalatoplasty
  - C. Tracheostomy
  - D. UPPP
5. A bus driver with gasping arousals and daytime sleepiness, including drowsy driving, undergoes a polysomnogram. She is diagnosed with OSA with an AHI of 43 events per hour and a minimal oxygen saturation of 70%. The first-line treatment for OSA of this severity is:
  - A. CPAP
  - B. Mandibular-advancing oral appliance
  - C. Positional therapy
  - D. UPPP

### Answers

1. B
2. D
3. D
4. C
5. A

## Interstitial Lung Diseases

ANDREW D. MIHALEK AND HILARY J. GOLDBERG

Interstitial lung disease (ILD) is the term given to a large group of generally unrelated pulmonary diseases. Historically these diseases were lumped together for their common clinical, rather than pathologic, presentations. The true prevalence of ILD is unknown but incidence is estimated to be 30 patients per 100,000 people. Patients suffering from any one of the numerous ILDs typically present with chronic cough, progressive shortness of breath, and pulmonary function tests (PFTs) that reflect a restrictive pattern. Some, but not all, of these diseases can also display characteristic radiographic findings (i.e., reticular, nodular, or reticulonodular patterns) in the lung interstitium. Similarities between the ILDs, however, generally end here as each individual disease under the ILD umbrella has a unique clinical course, prognosis, overall radiographic picture, and available treatment options.

Understanding the nuances that underlie each member of the ILD family is an important task for any generalist. Unfortunately, given the sheer number of diseases that can be classified as an ILD, an evolving understanding of their pathophysiology, and an ever-changing nomenclature system that has a proclivity for acronyms, clinician confusion surrounding this group of diseases abounds. This chapter will attempt to clarify some of the more common misunderstandings pertaining to the ILDs. The majority of content will be spent discussing ILDs that are without clear etiology (i.e., the idiopathic interstitial pneumonias or IIPs) with a particular emphasis placed on the most common of these, idiopathic pulmonary fibrosis (IPF). Discussions regarding the workup of IIP patients are applicable to all forms of ILD.

### Nomenclature

In response to the growing confusion surrounding inexact and overlapping terms for the ILDs, the American Thoracic Society (ATS) and European Respiratory Society (ERS) issued a joint consensus statement that included a succinct classification system for the ILDs. The consensus statement effectively discourages the use of vague terms such as “fibrosing alveolitis” and “bronchiolitis obliterans organizing pneumonia” and encourages the use of terms that embody histopathologic features of individual diseases. Specifically, the ATS/ERS statement attempts to move discussion away

from “interstitial lung diseases,” or diseases isolated to a specific anatomic compartment of the lung, toward that of the “diffuse parenchymal lung diseases” (DPLDs). This latter term implicates that this group of diseases involves not just the interstitium but also the peripheral airways, airspaces, and epithelial linings of the lung (of note, in common parlance and for the purposes of this chapter, *ILD* and *DPLD* still remain interchangeable).

The consensus statement further divided the DPLDs into four broad categories (Fig. 37.1):

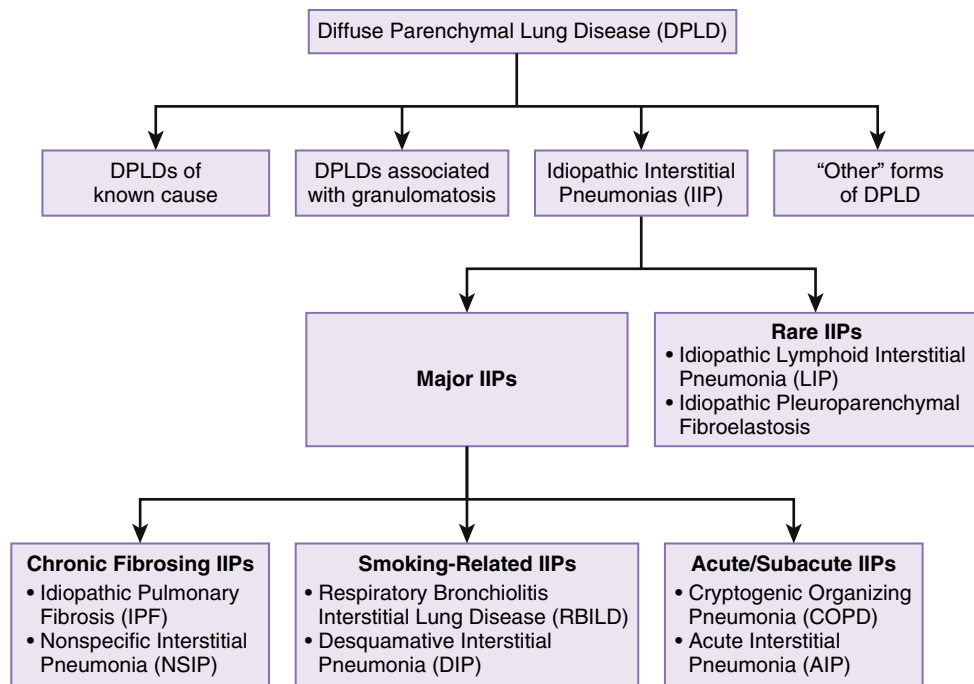

1. DPLDs without known cause (i.e., IIP)
2. DPLDs with known causes (i.e., environmental exposures as seen in pneumoconiosis or drug-induced ILD) or associations with other diseases (i.e., ILD associated with collagen vascular disease)
3. DPLD associated with granulomatous disease (i.e., sarcoidosis)
4. Other forms of DPLD that have distinct, well-defined clinicopathologic features (i.e., lymphangioleiomyomatosis and eosinophilic pneumonia)

The IIPs are by and large the most common group of ILDs encountered in the clinical setting. With that said, the practicing clinician should bear in mind that there has been a growing academic interest in the ILDs associated with collagen vascular disease (ILD-CVD). The association of rheumatoid arthritis and dermatomyositis with ILD has been known for many years. A greater appreciation for the complexity of this relationship has grown in light of epidemiologic data implicating underlying CVD in approximately 15% of ILD patients. Moreover, a full third of all patients affected by rheumatoid arthritis will showcase complications of ILD. Information regarding diagnostic biomarkers, novel immunosuppressive treatment regimens, and screening guidelines for patients with ILD-CVD are the subject of ongoing research efforts.

### The Idiopathic Interstitial Pneumonias

The original ATS/ERS consensus statement on IIP released in 2002 notes that IIP is “a heterogeneous group of nonneoplastic disorders resulting from damage to the lung parenchyma by varying patterns of inflammation and fibrosis.” In an attempt to integrate the growing body of information regarding the IIPs with the complexities surrounding

• **Fig. 37.1** Schematic of the classification system for diffuse parenchymal lung diseases devised by the American Thoracic Society and European Respiratory Society joint committee. There has been a growing movement to reclassify lymphangiomyomatosis, a disease involving the disordered growth of smooth muscle cells, as a true malignancy and remove it from this list. (Modified from Travis WD, Costabel U, Hansell DM, et al. An official American Thoracic Society/European Respiratory Society Statement: update of the international multidisciplinary classification of the idiopathic interstitial pneumonias. *Am J Respir Crit Care Med.* 2013;188(6):733–748.)

the clinical care decisions involving these patients, the ATS/ERS issued an updated classification system for the IIPs in 2013 (see Fig. 37.1). There are eight subtypes of IIP (separated into “major” and “rare” subcategories) distinguishable by clinical, radiographic, and histologic characteristics. All of the IIPs cause dyspnea and varying degrees of impairment in oxygen diffusion. The major IIPs are further subdivided into those that are stereotypically acute or subacute in their progression, have a more chronic course, and those closely associated with smoking-related injury.

Table 37.1 presents the common presentations and typical findings associated with each of the eight IIPs. Before digesting the contents of Table 37.1, keep in mind a few salient points. A full understanding of every single IIP can be a herculean task. Therefore the diseases are presented in descending order of prevalence. Although each IIP is showcased as a distinct entity, many of these diseases can overlap in presentation. Diagnosis is further complicated in severe and/or end-stage presentations because the terminal histologic findings of all the IIPs can ultimately resemble the histologic characterization of IPF, termed *usual interstitial pneumonia* (UIP).

## Workup and Diagnosis of Interstitial Lung Disease

Evaluating a patient for IIP (and all ILDs for that matter) is not unlike evaluating a patient for a rheumatologic

disease in that both involve the thorough collection and interpretation of diverse points of clinical data. Rarely is an IIP diagnosis made on a singular datum; it is the job of the experienced clinician to piece together a diagnosis that unites all findings.

The first step in any ILD evaluation involves taking a complete clinical history. Particular attention should be paid to signs and symptoms of collagen vascular disease (dry eyes, dry mouth, arthralgias, and myalgias) and potential occupational and environmental exposures (employees from ship yards, sandblasters, agricultural workers). Classically, the physical examination will reveal clubbing and bilateral crackles typically described as sounding like Velcro. Patients with severe disease may also display elements of air trapping with audible “squeaks” and wheezing. Objectively evaluating patient ambulatory efforts with a 6-minute walk test with pulse oximetry monitoring is an important tool for assessing the extent of functional impairment in suspected ILD patients.

Diagnostic evaluation of patients with a suspected ILD should be conducted in a step-wise and thoughtful manner. A complete set of PFTs is usually a fundamental first step in an ILD evaluation because testing is noninvasive and readily available in most clinical settings. PFTs typically show a restrictive pattern (Fig. 37.2) with decreased lung volumes as well as decreased diffusion capacity (DLCO). Given that approximately 20% of Americans are either active or former smokers, it is important to realize that coexisting obstructive lung diseases can “offset” findings of a restrictive disease on

**TABLE 37.1** A Comparison of the Idiopathic Interstitial Pneumonias

Idiopathic Interstitial Pneumonias	Clinical Characteristics	Demographics	Radiographic Characteristics	Pathologic Characteristics	Treatment Options
Idiopathic pulmonary fibrosis	Slow, progressive course Time from symptomatic presentation to diagnosis averages around 2 years	Elderly (50s–70s) Male predominance Former or active smokers	Basal and peripheral reticular opacities Subpleural Honeycombing Traction bronchiectasis	Diffuse nests (or foci) of fibroblasts and patchy fibrosis Frequent “honeycombing” fibrosis No evidence of granulomas, eosinophils, or inorganic dust Findings are termed usual interstitial pneumonia (UIP) and should be considered synonymous with IPF	Lung transplant for cure Nintedanib and pirfenidone to reduce decline in mild and moderate disease
Nonspecific interstitial pneumonia	Subacute, progressive course of symptoms similar to IPF (i.e., dry cough, SOB) More so than IPF, tends to be associated with constitutional symptoms	Middle-aged patients (40s–50s) No gender differences	Basal ground glass rather than reticular patterns Tends to be more centrally located (look for normal lung space between disease and pleura (i.e., “pleural sparing”))	Findings are variable (i.e., “nonspecific”) and may appear as different subtypes: 1. Cellular subtype: evidence of overt inflammation 2. Fibrosing subtype: dense fibrosis with underlying preserved architecture (i.e., not patchy) and without fibroblastic nests 3. Cellular-fibrosing subtype: combination of two	High doses of steroids for 3–6 months and then reassess In unrelenting or severe disease, additional immunosuppressive therapies are often added
Organizing pneumonia	Characterized as an “inflammatory pneumonia” with SOB, fevers, fatigue Should be on the differential for chronic, stable lung masses and in situations of “treatment failure” pneumonias Formerly known as bronchiolitis obliterans organizing pneumonia If insult is unknown (approximately 70% of the time), may be described as “cryptogenic organizing pneumonia”	Can affect all ages but generally seen most in middle-aged patients No sex or ethnic differences	Patchy, diffuse disease highlighted by ground glass opacities Tends to also present with overt consolidation in peribronchovascular regions	Profound overproliferation of granulation tissue in small airways resulting in intraluminal fibrosis Lung architecture is preserved Foamy macrophages generally present Paucity of fibrotic findings	Removal from insult (if known) Treatment with high-dose steroids for approximately 6–12 months if clinically significant If symptoms and PFT abnormalities not impressive, then can use conservative watchful waiting without steroids
Acute interstitial pneumonia	Rapid onset (i.e., 24 h) and progression of profound hypoxemia, often requiring mechanical ventilation Thought to be similar to, or an aggressive form of, acute respiratory distress syndrome No evidence of an inciting event (i.e., infection, surgery, trauma) as in ARDS Formerly known as Hamman-Rich syndrome	Can affect all ages without clear sex preference Average age of affliction is 50 years Most are nonsmokers	In acute phase, essentially the same findings as ARDS: bilateral, patchy consolidation In chronic phase, resembles findings in IPF	Similar to profound ARDS with hallmark findings of septal thickening from fibrosis, hyaline membrane deposition, and lack of granulomas or signs of infection (i.e., diffuse alveolar damage)	Similar to ARDS (i.e., lung protective strategies) Role for high-dose steroids is controversial and dictated by clinician experience

Respiratory bronchiolitis interstitial lung disease	Very, very rare (<3% of biopsied IIPs) Patients present with bland, nonspecific “annoying” symptoms such as a dry, nonhacking cough and mild dyspnea	Midlife smokers (40s–50s) Male to female ratio of 2:1	Diffuse, ground glass opacities with diffuse intraseptal nodules (generally symptoms are worse than appearance of CT scan) Similar to radiographic findings in DIP	Accumulation of macrophages around the bronchioles No evidence for “diffuse dispersion” of macrophages No fibrosis, fibroblastic nests, or honeycombing	Almost complete recovery with strict smoking cessation Can reoccur with just one cigarette
Desquamative interstitial pneumonia	Very, very rare (<3% of biopsied IIPs) Generally thought that 100% of people survive (with treatment)	Midlife smokers (40s–50s) No known gender or ethnic differences	Diffuse, ground glass opacities with diffuse intraseptal nodules (generally symptoms are worse than appearance of CT scan) Similar to radiographic findings in DIP	Uniform parenchymal involvement (not patchy) with increased numbers of diffusely distributed macrophages Mild evidence of active inflammation Lack of dense fibrosis, no honeycombing, no eosinophils	Smoking cessation results in recovery approximately 50% of the time Well-documented occurrences of disease progression despite smoking cessation Higher recovery rates demonstrated with glucocorticoid therapies
Idiopathic lymphoid interstitial pneumonia	Extremely rare (<1% of biopsied IIPs) Is one of the few lymph proliferative disorders of the lung; as such, has been considered a malignancy and not an IIP through the years Very little is known about the disease	Unclear and unknown for sporadic LIP Has close associations with Sjögren syndrome, HIV, and common variable immunodeficiency	Patchy, ground glass opacities Can often present with cystic lesions	Biopsy is absolutely required to confirm the diagnosis Has variable findings, but all have characteristic interstitial invasion by polyclonal lymphocytes, plasma cells, and histiocytes Polyclonality differentiates LIP from more typical lymphomas Infiltrates tend to appear along alveolar septa	No clear treatment options; no randomized control trials reported Steroids?
Idiopathic pleuroparenchymal fibroelastosis	Extremely rare (<1% of biopsied IIPs) Associated with recurrent respiratory infections and proclivity for pneumothorax	Midlife smokers (40s–50s) No known gender differences	Upper lobe volume loss on background of subpleural consolidation and traction bronchiectasis	Biopsy is absolutely required to confirm the diagnosis Intraalveolar fibrosis with elastin deposition	No clear treatment options; no randomized control trials reported

*AIP*, Acute interstitial pneumonia; *ARDS*, acute respiratory distress syndrome; *DIP*, desquamative interstitial pneumonia; *LIP*, lymphoid interstitial pneumonia; *IIP*, idiopathic interstitial pneumonia; *IPF*, idiopathic pulmonary fibrosis; *NSIP*, nonspecific interstitial pneumonia; *OP*, organizing pneumonia; *PFT*, pulmonary function test; *SOB*, shortness of breath; *RBILD*, respiratory bronchiolitis interstitial lung disease; *UIP*, usual interstitial pneumonia. Presented in this table is a summation of the clinical aspects of the eight known IIPs. Diseases are presented in descending order of commonality. Of note, perhaps with the exception of infectious etiologies that can cause organizing pneumonia, the histopathologic diagnosis of all these diseases can only occur in the absence of active infectious agents.

• **Fig. 37.2** A flow-volume loop showcasing the restrictive airflow pattern typically seen in patients with interstitial lung disease. PEF, Peak expiratory flow.

PFTs. In such circumstances, attention should be drawn to the DLCO, which will demonstrate reduced values (generally <50% of predicted) profoundly out of proportion to other PFT findings (i.e., normal vital capacity).

Although a full discussion of radiographic findings in IIP is far outside this review, a few important points should be made. To begin, although chest x-rays (CXRs) can demonstrate the same reticular and nodular patterns seen on CT, CXRs are notoriously insensitive and nonspecific. Therefore patients suspected of having an IIP should have a high-resolution CT (HRCT) scan with prone and supine images ordered. HRCT provides small (1 mm), high-resolution images of the lung parenchyma. Radiocontrast is generally not needed for HRCT unless there is a desire to simultaneously evaluate for thrombotic disease or mediastinal lymphadenopathy. Because some IIPs (particularly IPF) can arise in the lung bases and may be mistaken for atelectasis in supine films, specialized prone protocols are recommended for evaluating these patients.

Effectively ruling out nonpulmonary etiologies that can lead to dyspnea and interstitial radiographic patterns is also an essential task for establishing an ILD diagnosis. Congestive heart failure, pulmonary hypertension, hypersensitivity pneumonitis, viral infections, mycobacterium, indolent fungal infections, atypical bacterial infections, and malignancy (particularly bronchoalveolar carcinoma and lymphangitic metastasis) are common ILD mimics. Steps to effectively evaluate these diseases should be dictated by clinical suspicion and may necessitate further radiographic evaluations, appropriate testing of the cardiovascular system, and/or bronchoscopy in the appropriate clinical settings. Although not necessarily needed in all cases, an open lung biopsy should be pursued in any circumstance where a diagnosis is not clear (a more robust conversation regarding this issue will take place later in this chapter).

It should by now be clear to the reader that making an ILD diagnosis can be a daunting undertaking that runs the risk of producing confounding and contradictory pieces of clinical information. When a diagnosis is in doubt, or a

patient displays atypical features/presentations of their disease process, it is always prudent to refer to a health care facility with expertise in the diagnosis and management of ILD. Ideally such facilities will employ multidisciplinary teams that include pulmonologists, radiologists, pathologists, rheumatologists, and specialists in occupational medicine to effectively evaluate and make treatment recommendations for these patients.

## Idiopathic Pulmonary Fibrosis

IPF is the most common of the IIPs with an estimated prevalence of 14 to 43 people per 100,000. Age and gender are risk factors for IPF as the disease generally afflicts men in their 60s and 70s who have had a prior smoking history. A majority of IPF cases are spontaneous in presentation, although 10% to 15% will have genetic origins (we will focus on sporadic cases of IPF for the remainder of our discussion). The histopathologic findings consistent with IPF are termed *usual interstitial pneumonia* (see [Table 37.1](#)). Today, *IPF* and *UIP* are often used interchangeably.

Understanding of the pathophysiology that underlies IPF has changed rather dramatically over the past 10 years. Traditionally, IPF was thought to represent continued insult to the lung microenvironment that resulted in sustained inflammation and eventual fibrosis. As it became clear from clinical experience that typical efforts at immunosuppression failed to produce significant improvements in mortality, alternative pathophysiologic explanations were sought. Today, ideas pertaining to IPF development reflect a greater appreciation for the symphonic complexities of the immune system as it functions in the lung microenvironment. IPF development is thought to lie at the end point of a number of stress responses encountered by the lung that results not in active inflammation, per se, but in the remodeling of pulmonary endothelium, cell transformation, and aberrant fibroblast activity. Novel perspectives on IPF pathogenesis can hopefully be translated into novel therapeutic options in the near future.

Perhaps more so than the other IIPs, radiographic findings play an important role in establishing the diagnosis of UIP/IPF. In fact, clear evidence of subpleural (i.e., lung parenchyma just adjacent to the pleura), reticular changes in the peripheral bases of the lungs with accompanying honeycombing, traction bronchiectasis, and no infiltrates may be sufficient diagnostic evidence for IPF to avoid an open lung biopsy (the importance of this statement should not be lost upon the reader. As such, any diagnosis of IPF should effectively also be able to rule out the second most common IIP, nonspecific interstitial pneumonia [NSIP]). Information gathered from HRCT scans of the chest can be used to categorize patients as definitive UIP/IPF, possible UIP/IPF, or inconsistent with UIP/IPF ([Fig. 37.3](#)).

Differentiating between IPF and NSIP can often be difficult, but its necessity goes far beyond academic interests. For instance, NSIP carries a much better prognosis than IPF. Five-year mortality for patients suffering from NSIP is

• **Fig. 37.3** Representative chest CT images from patients with diffuse parenchymal lung disease: (A, B) Radiographic, diagnostic certainty for usual interstitial pneumonia (UIP) is considered in the presence of reticular abnormalities, honeycombing, and traction bronchiectasis with a basal predominant, subpleural distribution. (C) The midlobe, ground glass opacities with subpleural sparing seen in this patient with nonspecific interstitial pneumonia is inconsistent with UIP. (D) Upper lobe ground glass opacities, pleural thickening without honeycombing is also inconsistent with UIP but can be seen in chronic hypersensitivity pneumonitis.

approximately 10% whereas mortality from IPF within the same timeframe approaches 70%. Furthermore, the mainstay of treatment for NSIP is rooted in immunosuppression (i.e., corticosteroids, azathioprine, and/or mycophenolate) whereas aggressive immunosuppression seems to actually accelerate death in IPF patients (more on this later). If a firm diagnosis of IPF cannot be made from clinical or radiographic data alone or if there are atypical features of its presentations then, and really only then, is an open lung biopsy recommended by the ATS/ERS consensus task force. Biopsies from suspected IIP patients must have their results interpreted in the context of all other collected data points and, when available, should involve the expertise of a multidisciplinary group of clinicians before the solidification of a singular diagnosis.

Patients suffering from IPF typically demonstrate a downward progression in their pulmonary function resulting in death approximately 5 to 10 years following diagnosis. A progressive, relentless decline in lung function and quality of life, although highly variable, characterizes the clinical course of IPF. Complicating any one patient's progression is the possibility of suffering an acute IPF exacerbation. Acute exacerbations of IPF are predicated by almost any insult to the respiratory system including infections, lung biopsy, and microaspiration. Patients who recover from these exacerbations tend to have a "step off" in their lung function that generally never recovers to its preexacerbation baseline.

Systemic corticosteroids have traditionally served as the mainstay of treatment for IPF exacerbations, but evidence for their efficacy is lacking. Current professional consensus guidelines provide only weak recommendations (supported only by anecdotal evidence) for glucocorticoid use during acute exacerbations of IPF. Conservative, supportive measurements and treatment of any potential etiology remain the treatment strategy of choice.

Corticosteroids and other forms of immunosuppression have even less of a role as a maintenance therapy for IPF. Earlier (small) successes with aggressive immunosuppressive therapy during the 1980s seem to have clearly reflected misclassification of other IIPs (namely NSIP) as IPF. Misinterpretations of these trials have conferred much confusion in the management and role of immunosuppression in IPF patients. In 2012, after closing early on account of concerns over patient safety, results from the PANTHER-IPF trial (Prednisone, Azathioprine, and *N*-Acetylcysteine Study Evaluating Response in Idiopathic Pulmonary Fibrosis) showed that aggressive immunosuppression not only increased mortality but also increased the risk of hospitalization in IPF patients. The results of this trial would seem to imply that there is little room for immunosuppression in the management of IPF patients at the present time.

In contrast to the disappointments produced by the results of PANTHER-IPF, physicians taking care of patients

afflicted by IPF have very recently received new hope with the release of two new oral agents marketed directly to IPF patients. Nintedanib is a tyrosine kinase inhibitor, and pirfenidone is an antifibrotic agent that reduces activity of the transforming growth factor-beta. Both drugs have a myriad of effects on the cellular processes thought to lead to the proliferation of IPF (fibroblastic activity, vascular endothelial propagation, as well as platelet function). Trials leading to the approval of nintedanib and pirfenidone showed similar reductions in forced vital capacity (FVC) in patients suffering from IPF (slowing FVC decline by approximately 100 cc per year) but failed to demonstrate clear improvements in IPF mortality. Both drugs were studied in patients with mild-to-moderate disease, and decisions regarding which drug to start are tied to patient preference and provider experience. Although the effects of these drugs may be seemingly modest, it is important to emphasize that nintedanib and pirfenidone are the first drugs ever approved specifically for the management of IPF. How either pirfenidone or nintedanib could benefit patients suffering from other subtypes of IIP is currently under investigation. As noted earlier, besides lung transplantation, there are no curative treatment options for IPF.

## Chapter Review

### Questions

1. A 61-year-old man with a distant 40-pack-year smoking history as well as hyperlipidemia presents to his primary care physician with reports of progressive dyspnea on exertion and a dry cough for the past 2 years. Once an active man, able to walk an infinite distance on a flat surface, he now notes feeling short of breath with a flight of stairs and while playing with his grandchildren. His cough is nonproductive and is not associated with any environmental exposures. He is a former banker. On examination, he is noted to have an oxygen saturation of 98% on room air and 97% after walking 200 yards. He has fine crackles at the bases of his lungs and no clinical evidence of volume overload. His laboratory values are normal. PFTs show a reduced total lung capacity. A CT scan of the chest shows bibasilar, subpleural reticular findings at the bases without infiltrate or lymphadenopathy. The most appropriate course of action at the present time is which of the following?
  - A. Refer for lung biopsy because these findings represent an atypical presentation of an interstitial lung disease.
  - B. Start 40 mg of prednisone a day.
  - C. After alternative diagnoses such as heart failure and indolent infection are ruled out, consideration for lung transplant referral should be made.
  - D. Refer the patient for pulmonary rehabilitation.
2. A 38-year-old Caucasian woman reports to your office with reports of a chronic dry cough for the past 3 months. She denies fever, chills, and weight loss but states that she has had some joint discomfort as well as a painful, red rash on her legs. An examination reveals bilateral crackles. PFTs showcase a restrictive pattern and a CXR displays bilateral lymphadenopathy without parenchymal disease. The most appropriate course of action at the present time is which of the following?
  - A. Refer for lung biopsy because these findings represent an atypical presentation of an interstitial lung disease.
  - B. Start 40 mg of prednisone a day.
  - C. After alternative diagnoses such as heart failure and indolent infection are ruled out, consideration for lung transplant referral should be made.
  - D. Refer the patient for pulmonary rehabilitation.
3. A 45-year-old female patient from the Midwest of the United States has been undergoing a workup for chronic cough in your office over the past month. She does not report dyspnea on exertion or any constitutional symptoms. She does not have crackles on examination and can exert herself >1000 yards during a 6-minute walk test. She returns to your office to discuss the results of a recent HRCT scan of the chest that shows centralized interstitial changes with accompanying, well circumscribed 5 × 5-cm ground glass opacity in her right upper lobe. At this point, you should be comfortable informing her of which of the following?
  - A. Her presentation is consistent with a steroid responsive illness, and an open lung biopsy can be avoided.

Efforts at understanding the clinical implications and effects of IPF on patient well-being have improved our understanding of the human impact of this devastating disease. Resultantly, there has been a growing interest in symptomatic management and improving the quality of life in patients afflicted with this disease. Results from recently published trials have shown improved quality-of-life measures with pulmonary rehabilitation as well as with treatment of IPF-associated cough with thalidomide. Given the paucity of available treatment options for IPF patients at present, clinicians are recommended to refer patients with confirmed IPF as soon as possible for lung transplant evaluation.

### Conclusion

Whether termed *ILD* or *restrictive lung disease* or *DPLD*, it is clear that the ILDs are distinct, concerning disease entities that drastically affect patient lives and well-being. Many of these diseases present with vague, nonspecific symptoms. Having an ILD diagnosis at the forefront of clinical decision-making will allow for timely diagnosis and possible timely interventions.

- B. This is not a malignancy.
- C. Her findings are inconsistent with idiopathic pulmonary fibrosis.
- D. She will need pulmonary rehabilitation.

### Answers

- 1. C
- 2. B
- 3. C

## Pulmonary Function Tests

JEREMY B. RICHARDS AND DAVID H. ROBERTS

**P**ulmonary function tests (PFTs) include the measurement of velocity and volume of expiratory flow (spirometry), static volumes (lung volumes), diffusion of gases across the alveolar-capillary membrane (diffusion capacity), and respiratory muscle strength. PFTs can both identify patterns and quantify the severity of a variety of respiratory system diseases. The indications for performing PFTs may include diagnostic evaluation of symptoms, monitoring of disease stability or progression, assessing acute or long-term response to treatment, or providing preoperative pulmonary assessment.

### Technical Considerations

#### Spirometry: Measurement, Values, and Flow-Volume Loops

Spirometry is the determination of expiratory volume and flow rates. The primary spirometric values include the forced expiratory volume in 1 second ( $FEV_1$ ; the quantity of air in liters exhaled in 1 second), forced vital capacity (FVC; the total quantity of air exhaled in a maximum voluntary exhalation), and peak expiratory flow rate (PEFR; the maximum velocity of air during a forced exhalation in liters/second). The ratio of  $FEV_1/FVC$  differentiates obstructive (reduced ratio) and restrictive ventilatory (preserved or elevated ratio) deficits.

Spirometric measurements are effort dependent. To determine  $FEV_1$  and FVC, a subject is instructed to inhale maximally to total lung capacity (TLC) followed by a vigorous, maximal forced expiratory effort to residual volume (RV). The subject exhales into a mouthpiece attached to a flow meter through which expiratory flow rates are measured, and volume is integrated from the flow signal. Alternatively, expiratory volume may be measured by a volume-displacement spirometer, and flow is derived from the volume signal. Regardless of the method of assessing expiratory flow and volume, standard practice is to perform at least three acceptable expiratory efforts. To account for differences in effort, the accepted consensus standard for spirometry requires performance of at least two expiratory efforts of similar flow and volume characteristics. Specifically, the

largest  $FEV_1$  and FVC should not vary from the second largest  $FEV_1$  and FVC by  $>0.15$  L (or by  $>0.1$  L for a subject with an FVC of  $\leq 1.0$  L). More than three expiratory efforts may be performed if there is significant variation among efforts. There is no consensus on the maximum number of efforts that may be attempted; however, after 8 to 10 attempts, the yield of additional attempts is likely to be minimal. If two expiratory efforts in which the  $FEV_1$  and FVC vary by  $<0.2$  L cannot be achieved, the spirometry is termed as *lack reproducibility*. In addition to assessing reproducibility, spirometry should be assessed for acceptability. Consensus guidelines define an acceptable expiratory effort as an expiratory effort that lasts  $\geq 6$  seconds. Particularly in younger individuals, the FVC may be achieved in  $<6$  seconds, and a plateau in flow velocity of the expiratory effort of  $\geq 2$  seconds is considered by some as an alternative marker of acceptability.

Spirometry results are reported as both absolute values (i.e.,  $FEV_1 = 2.5$  L) as well as a percentage of what values would be predicted given certain individual characteristics (i.e.,  $FEV_1 = 90\%$  predicted). Predicted values for a given individual are derived from the person's height, race/ethnicity, age, and gender. Predictive equations have been derived from cross-sectional population studies; a number of equations are available in the literature. An American Thoracic Society (ATS) and European Respiratory Society (ERS) joint task force recommends using predictive equations derived from the 2005 National Health and Nutrition Examination Survey III cross-sectional study for individuals aged 8 to 80 years (Pelligrino et al., 2005). In subjects whose true height cannot be accurately measured (i.e., because of kyphoscoliosis or an inability to stand caused by neuromuscular disease), arm span can be used as a surrogate measure of height (Box 38.1). An individual's measured spirometric values can be compared with his or her predicted values to generate the percentage predicted value.

The percent predicted values for  $FEV_1$  and FVC can also be used to grade disease severity. Deficits are typically described as mild, moderate, moderately severe, severe, or very severe depending on the degree of deviation from the predicted values (Table 38.1).

### • BOX 38.1 Using Arm Span to Predict a Patient's Standing Height

Arm span: height ratio

Caucasian males: 1.019

Caucasian females: 0.999

African-American males: 1.044

African-American females: 1.035

Predictive equation:

$$\begin{aligned} \text{Height (cm)} &= 67.904868 + (\text{arm span})(0.664182) \\ &- (\text{Sex}^a)(2.816175) - (\text{race}^b)(4.05492) \\ &- (\text{Age in years})(0.070892) \end{aligned}$$

<sup>a</sup>For sex, male = 1 and female = 2.

<sup>b</sup>For race, Caucasian = 1 and African American = 2.

### TABLE 38.1 Using Confidence Intervals to Grade Severity of Deficits in Spirometry

#### For Both FEV<sub>1</sub> and FVC (Using Confidence Intervals)

Normal	<1 CI from predicted value
Mild deficit	≥1–1.75 CIs from predicted value
Moderate deficit	≥1.75–2.5 CIs from predicted value
Severe deficit	≥2.5 CIs from predicted value

#### For FEV<sub>1</sub> (Using Percentage Predicted)

Mild	>70% predicted
Moderate	60%–69% predicted
Moderately severe	50%–59% predicted
Severe	35%–49% predicted
Very severe	<35% predicted

CI, Confidence interval; FEV<sub>1</sub>, forced expiratory volume in 1 second; FVC, forced vital capacity.

In addition to being characterized numerically, the measurements obtained while testing spirometry (e.g., FVC, PEFR) are typically displayed as a flow-volume loop. The flow-volume loop displays the expiratory effort with volume (in liters) on the *x* axis and flow (in liters per second) on the *y* axis. The expiratory effort starts at the intersection of the axes and terminates when the loop again intersects the *x* axis (i.e., when flow again equals zero). The flow-volume loop typically displays the immediate posttest inspiration (below the *x* axis, when flow is negative). The shape of the flow-volume loop can be helpful in assessing the expiratory effort and the presence of certain disease states (see [Lung Volumes: Measurements and Values](#) later).

A less-than-maximal expiratory effort is present when the terminal aspect of the inspiratory portion of the flow-volume loop (the portion below the *x* axis, when flow is negative) intersects the *x* axis left of the *y* axis. This implies that the

• **Fig. 38.1** Flow-volume loop in a normal individual (A) and in an individual demonstrating submaximal expiratory effort (B). (From Miller MR, Hankinson J, Brusasco B, et al. Standardisation of spirometry. *Eur Respir J.* 2005;26:319-338.)

subject did not maximally inhale before the expiratory effort or there was an air leak during exhalation ([Fig. 38.1](#)). Other examples of less-than-maximal effort include a blunted peak flow or an abrupt drop to zero flow.

A classic finding of obstructive ventilatory disease is a coved appearance of the flow-volume loop. As discussed subsequently (see [Obstructive Ventilatory Deficits](#)), airway resistance is increased in obstructive ventilatory deficits because of narrowing of the airway lumen (i.e., bronchospasm in asthma or airway collapse in emphysema). The coved appearance of the flow-volume loop reflects this increased airway resistance as velocity of flow decreases precipitously compared with predicted values ([Fig. 38.2](#)). Airway resistance is decreased in patients with restrictive ventilatory deficits, while lung volumes are reduced overall (see [Restrictive Ventilatory Deficits](#) later), and the flow-volume loop may reflect this. PEFR may be higher than expected even though the FEV<sub>1</sub> and FVC may be reduced, and the FEV<sub>1</sub>/FVC ratio may be preserved or even elevated ([Fig. 38.3](#)). Finally, a fixed upper or central airway obstruction may cause a limitation on the upper maximum of flow velocity; the flow-volume loop reveals a decrease in PEFR with a plateau appearance, without reduction in overall FVC ([Fig. 38.4](#)). FEV<sub>1</sub> and FVC are not usually decreased in upper or central airway obstruction.

• **Fig. 38.2** Flow-volume loop in individuals with obstructive ventilatory deficits: asthma (A) and chronic obstructive pulmonary disease (B). (From Miller MR, Hankinson J, Brusasco B, et al. Standardisation of spirometry. *Eur Respir J.* 2005;26:319-338.)

### Lung Volumes: Measurement and Values

The lung volumes of most clinical interest include the TLC, which is the volume of air in the lungs after maximal inhalation; RV, which is the volume of air remaining in the lungs after maximal exhalation; and functional residual capacity (FRC; the volume of air in the lung after a normal tidal volume breath is exhaled). The various lung volumes and lung capacities are depicted in Fig. 38.5. In brief, lung volumes are the RV, expiratory reserve volume (ERV), tidal volume (VT), and inspiratory reserve volume (IRV). Lung capacities are the sum of two or more lung volumes. The lung capacities are the inspiratory reserve capacity (IRC = VT + IRV), vital capacity (VC = ERV + IRC), FRC = RV + ERV, and TLC = (RV + ERV + VT + IRV or VC + RV or FRC + IRC).

Lung volumes are typically measured by one of three techniques: helium dilution, nitrogen washout, or body plethysmography.

The nitrogen washout method determines lung volumes by comparing the initial concentration of nitrogen in the alveoli and the concentration after breathing 100% oxygen for up to 7 minutes (to wash out alveolar nitrogen). Although truncated protocols have been proposed (i.e., breathing 100% oxygen for 5 as opposed to 7 minutes), the nitrogen washout method of measuring lung volumes is time consuming compared with plethysmography.

Plethysmography is based on Boyle's law:  $P_1V_1 = k$ , where  $k$  is a fixed constant. Technically, lung volumes are measured by plethysmography in a sealed chamber in which the volume of air is known and constant (referred to as a *variable-pressure chamber*). Because people enter into and are sealed within this chamber during testing, the chamber is colloquially referred to as a *body box*. There is a mouthpiece within the chamber through which the subject breathes. When the respiratory cycle is at or near FRC, the mouthpiece is occluded by an automated shutter valve. The subject then pants (attempting to inhale and exhale against the closed mouthpiece). The change in pressure at the mouthpiece, the change in pressure in the plethysmograph, and the known fixed volume of gas in the plethysmograph can be used to calculate the quantity of air in the lungs at FRC. After determining the volume of air in the lungs at FRC, exhalation to RV followed by inhalation to TLC is performed to determine the values of ERV and IVC, respectively. Plethysmography may overestimate lung volumes. The most important example of this overestimation of lung volumes occurs in subjects with obstructive airways deficits and air trapping (see **Obstructive Ventilatory Deficits** later for definitions of air trapping and hyperinflation). When the shutter valve on the mouthpiece is closed and the subject pants, the assumption is that there is no flow of air (given the closed mouthpiece) and that changes in pressure reflect only changes in volume of the air in the lungs. However, particularly in patients with obstructive deficits, there may be flow between alveoli and extrathoracic airways. Air trapped in hyperinflated segments of lung may be liberated by the panting maneuver and flow to large airways; the pressure changes measured in the chamber are decreased by this intrathoracic airflow (because the pressure generated by panting leads to flow rather than compressed volume). Underestimating pressure changes leads to the volume of air in the lungs being overestimated.

Helium dilution is an alternative method of measuring lung volumes. The helium dilution method may be used when an individual is unable to perform plethysmography (caused by dyspnea, claustrophobia, inability to perform the panting maneuvers, etc.) or when obstructive airways disease is present and there is concern for overestimating lung volumes. Regardless of the method used to measure lung volumes, the values directly measured include FRC, ERV, and IVC. TLC and RV may be calculated in the following fashion:

$$RV = FRC - ERV$$

$$TLC = RV + IVC$$

**TABLE 38.2** Using Confidence Intervals to Grade Severity of Deficits in Total Lung Capacity: Difference of Predicted Minus Measured Value for Men and Women

	Men	Women
Normal: <1 CI from predicted value	<1.61 L	<1.08 L
Mild deficit: ≥1–1.5 CI from predicted value	1.61–2.41 L	1.08–1.61 L
Moderate deficit: ≥1.5–2 CI from predicted value	2.41–3.21 L	1.62–2.15 L
Severe deficit: ≥2 CI from predicted value	≥3.22 L	≥2.16 L

CI, Confidence interval.

As with spirometry (see earlier), lung volumes are reported as both measured values and as a percent predicted value. Predicted values are generated from large cross-sectional studies. Determinants of predicted lung volumes include height, gender, race/ethnicity, and age. Because of continued lung growth and changes in body habitus and height, age is particularly important in determining predicted values in children and adolescents, and separate prediction equations are used for these populations. For individuals aged ≥18 years, a set of reference equations has been endorsed by the ERS and appears to perform well in Caucasian, African-American, and Mexican-American populations. The ATS has adopted predictive equations for subjects 8 to 80 years old.

At least two measurements of lung volumes should be performed regardless of the method used, and, as noted previously, performing three separate measures of ERV and IVC is appropriate to account for effort-dependent variation. Lung volume measurements are considered to be reproducible if the TLC values are within 0.2 L of each other, and in that case the mean of the measured values is reported.

As with spirometry, 95% confidence intervals may be used to grade the severity of abnormalities in measured compared with predicted lung volumes (Table 38.2). Deviations from the predicted values for lung volumes can be quantified as mild, moderate, or severe in nature.

### Diffusion Capacity for Carbon Monoxide: Measurement and Correction Factors

The diffusing capacity for carbon monoxide (DLCO) is a test that quantifies the diffusing properties of the alveolar-capillary membrane. The DLCO provides information about the efficiency of gas exchange at the level of the alveolus and capillary.

The DLCO is typically measured by a single-breath method. When breathing through a mouthpiece, the subject takes a breath to RV from TLC, inhaling a mixture of

air that contains a known quantity of an insoluble gas (typically 10% of a gas such as helium, methane, argon, or neon) and 0.3% carbon monoxide (CO). The breath is then held for 10 seconds before exhaling. The first 0.75 to 1 L of the exhaled breath is discarded because it represents dead space of the tubing and upper airways (if the FVC is <2 L, then the first 0.5 L is discarded). The next 0.5 to 1 L of air is analyzed, and the quantity of the insoluble gas present in the exhaled air indicates the degree of dilution of the inhaled gas with the air already in the alveoli.

Exhaled CO is measured and corrected for dilution by gas already in the alveoli (using the known dilution of the insoluble gas). The difference between the amount of CO inhaled and the amount present in the exhaled gas (corrected for dilution) represents the uptake of CO across the alveolar-capillary membrane. By convention, DLCO is reported in units of mL/([min][mm Hg]), where mL indicates the volume of CO taken up across the alveolar-capillary membrane and mm Hg indicates the partial pressure of CO in the alveolus. Because the partial pressure of CO in the pulmonary capillaries is normally zero, the partial pressure of CO in the alveolus is essentially the driving pressure of CO across the alveolar-capillary membrane. To account for the length of time of the breath-hold maneuver to allow for transfer of CO across the alveolar-capillary membrane, units of time are present in the denominator. DLCO may be considered via the following equation:

$$\text{DLCO} = \frac{\text{total CO uptake}}{(\text{time} \times \text{partial pressure of CO } [P_{\text{ACO}}])}$$

The ERS prefers to report the amount of CO taken up across the alveolar membrane in millimoles and the partial pressure of CO in kilopascals (i.e., DLCO is reported as mmol/[(min)(kPa)]).

Correcting for a subject's hemoglobin (Hb) is a more clinically relevant adjustment of DLCO because CO binding to Hb is a requisite for CO uptake across the alveolar membrane. The calculation adjusting DLCO for Hb is expressed as follows:

$$\text{For men: DLCO (Hb)} = \text{DLCO} \times \frac{1.7 \text{ Hb}}{(10.22 + \text{Hb})}$$

$$\text{For women: DLCO (Hb)} = \text{DLCO} \times \frac{1.7 \text{ Hb}}{(9.38 + \text{Hb})}$$

The units of Hb in this equation are g/dL. These equations are relevant for Hb concentrations of  $\geq 7$  g/dL.

## Obstructive Ventilatory Deficits

### Definition and Characteristics

Obstructive ventilatory deficits are defined by a reduction of expiratory flow as measured by FEV<sub>1</sub> or PEF. Pathophysiologically, obstructive ventilatory deficits are caused by increased airways resistance. Increased airways resistance results

in impaired expiratory air flow. In the later stages of obstructive ventilatory diseases, incomplete exhalation caused by increased airways resistance and impaired flow may result in hyperinflation and intrinsic positive end-expiratory pressure.

There are a variety of pathologic processes that can cause obstructive ventilatory deficits, ranging from reversible air flow obstruction (i.e., asthma) to permanent changes in the lung parenchyma and airways (i.e., emphysema). Regardless of the underlying process, the primary manifestation of an obstructive ventilatory deficit is a decreased FEV<sub>1</sub> as measured by spirometry. Typically, FVC is relatively preserved in obstructive ventilatory diseases compared with the decrease in FEV<sub>1</sub>. The relative preservation of FVC occurs because the volume of air in the lungs is not decreased, and, given adequate time, a patient can exhale a relatively larger quantity of air during a complete expiratory effort than is possible in 1 second of exhalation.

In the setting of a decreased FEV<sub>1</sub> and a relatively preserved FVC, the FEV<sub>1</sub>/FVC ratio is decreased. This constellation of findings (decreased FEV<sub>1</sub> as compared with FVC and decreased FEV<sub>1</sub>/FVC) is the hallmark of obstructive ventilatory deficits.

As described earlier (see [Spirometry](#) and [Fig. 38.2](#)), the classic coved appearance of a flow-volume loop in a patient with an obstructive ventilatory deficit is caused by decreased expiratory flow rates. As depicted on a flow-volume loop, the overall volume of air exhaled may not be significantly decreased compared with predicted values. As the underlying disease process progresses, FVC may decrease (e.g., because of progressive air trapping in emphysema), and reduced FEV<sub>1</sub> and reduced FVC with a normal FEV<sub>1</sub>/FVC has been reported to occur in up to 10% of patients with a clinical diagnosis of chronic obstructive pulmonary disease (COPD) and normal TLC.

Lung volumes may be abnormal in certain obstructive ventilatory deficits. Particularly in emphysema, hyperinflation or air trapping may be present. Air trapping is defined by an increase in RV of >120% of predicted. Hyperinflation is defined as a TLC >120% of predicted and an RV >140% of predicted.

Lung volumes can occasionally be elevated without spirometric evidence of an obstructive deficit in normal subjects.

### Differential Diagnosis

Any process that increases airways resistance and reduces airflow velocity in a clinically significant manner can result in an obstructive ventilatory deficit. Differentiating between reversible and irreversible processes may be a useful way to approach obstructive ventilatory deficits. Bronchodilator responsiveness (discussed later) is helpful in determining the presence (or absence) of reversibility in most cases. Some pathologic processes may be partially reversible, thereby complicating determining the cause of obstruction.

An alternative approach to obstructive ventilatory deficits that may aid in understanding the causative pathophysiologic process is to consider the structural deficit

leading to airways obstruction. Specifically, abnormalities in the airway lumen, in the wall of the airway, or in the peribronchial structures may each result in an obstructive deficit.

Possible causes of an obstructive ventilatory deficit include COPD caused by emphysema and/or chronic bronchitis, asthma, congestive heart failure, bronchiectasis, tracheobronchomalacia, pneumonia, foreign body aspiration, or bronchiolitis.

### GOLD Criteria and Confidence Intervals

COPD is one of the most important and common causes of obstructive ventilatory deficits, and there are various methods for classifying severity of COPD. One of the most disseminated and widely used classification schemes is the GOLD criteria (global initiative for chronic obstructive lung disease).

The GOLD criteria are widely accessible and easy to use for diagnosing and grading the severity of COPD. They have increased both medical and public awareness about COPD ([www.goldcopd.com](http://www.goldcopd.com)). Although not a perfect tool for classification of severity, the GOLD criteria combine the degree of airflow obstruction (FEV<sub>1</sub> percent predicted), frequency of exacerbations, and symptom severity to provide a comprehensive assessment of the severity of COPD. The GOLD criteria are useful in considering treatment and predicting prognosis for a symptomatic patient with COPD (see [Table 34.1](#), [Chapter 34](#)).

### Bronchodilator Responsiveness

Assessing for bronchodilator responsiveness is commonly done during the evaluation of obstructive ventilatory deficits. Bronchodilator response can be assessed in one testing session by administering a short-acting medicine or over the course of two (or more) testing sessions with interval longitudinal treatment with a bronchodilator or bronchodilators. Bronchodilator responsiveness is defined as an increase in the percentage predicted FEV<sub>1</sub> and/or FVC of at least 12% and 0.2 L above baseline. Changes of <8% or <0.15 L are thought to be caused by test-to-test variability and not because of medication effect. Although not commonly measured as a marker of bronchodilator responsiveness, improvement in distance walked in the 6-minute-walk test is another very reproducible marker of the presence of bronchodilator responsiveness.

The drug, dose, and method of delivery of the bronchodilator for responsiveness assessment are not standardized. When testing bronchodilator responsiveness in one testing session, a short-acting inhaled medicine is appropriate. Inhaled albuterol (four puffs of a 90- $\mu$ g metered-dose inhaler) through a spacer is a typical regimen. An interval of 15 to 20 minutes between measuring baseline spirometry and postbronchodilator spirometry values allows time for any effect of the medicine to occur. If it is of particular clinical interest, a different short-acting medication (such as

ipratropium) can be used at the request of the ordering physician. Of note, one large study reported >50% bronchodilator responsiveness in patients with moderate to severe COPD when a combination of an inhaled anticholinergic plus an inhaled beta-agonist was administered in one testing session.

The clinical relevance of bronchodilator responsiveness (or the absence thereof) is unknown. Although some individuals may have a correlation between bronchodilator responsiveness and symptom improvement, others may experience significant subjective improvement after treatment with an inhaled bronchodilator despite the lack of improvement in FEV<sub>1</sub> or FVC. A possible explanation for this apparent discordance is that bronchodilators affect airway resistance and airway flow most at tidal volumes. FRC has been shown to decrease after bronchodilator therapy, which may partially explain an improved sense of dyspnea. Therefore assessing for changes in FEV<sub>1</sub> and FVC by forcibly exhaling from TLC (i.e., performing an FVC breath) may not adequately represent these changes at tidal volume breathing.

### How Pulmonary Function Tests Guide Treatment

The degree of decrease of the FEV<sub>1</sub> can guide treatment in patients with COPD. Treatment for other obstructive ventilatory deficits may also be driven by the measured FEV<sub>1</sub>; however, clinical management based on FEV<sub>1</sub> is most standardized for COPD.

For all patients with COPD, risk reduction is appropriate. Specifically, when applicable, encouragement of and assistance with smoking cessation is of the utmost importance. Appropriate vaccinations (influenza and pneumococcal vaccines) are suitable for all patients with COPD. For patients with mild disease (GOLD group A), short-acting bronchodilators on an as-needed basis are usually considered to be sufficient. Patients with moderate (GOLD group B) disease should receive long-acting bronchodilators (either a long-acting anticholinergic or long-acting beta-agonist) in addition to short-acting as-needed inhalers. Inhaled corticosteroids are added to the regimen of patients with severe disease (GOLD group C). Finally, very severe disease (GOLD group D) may necessitate combination treatment with a long-acting beta-agonist and/or anticholinergic, inhaled corticosteroids, and oxygen treatment depending on the patient's oxygen saturation. Lung volume reduction surgery may be offered to a very select group of patients with primarily apical bullous disease.

The value of continued patient education is important in improving patients' understanding of their disease. Pulmonary rehabilitation has been demonstrated to improve patients' quality of life, although there has not been a demonstrable effect on mortality. When to refer to pulmonary rehabilitation is unclear, but the GOLD criteria advocate early (i.e., GOLD group B, C, or D) referral.

The BODE score is a multifactorial index used to grade the severity of disease in patients with COPD. BODE is an acronym for *body* mass index, *airflow* obstruction (as measured by FEV<sub>1</sub>), symptoms of *dyspnea*, and *exercise* capacity (as measured by 6-minute walk). The BODE score has been shown to be more accurate than FEV<sub>1</sub> alone for predicting mortality in patients with COPD and can guide treatment.

## Restrictive Ventilatory Deficits

### Definition and Characteristics

Restrictive ventilatory deficits are defined by abnormally reduced lung volumes. Typically, confidence intervals around the percent predicted values of lung volumes determine the degree of restriction. In restrictive diseases, lung volumes are decreased below their expected values.

Spirometry has been shown to be sensitive in ruling out restrictive ventilatory deficits; in one large retrospective study, a normal FVC was associated with restrictive disease in <3% of cases. An abnormal FVC with a normal FEV<sub>1</sub>/FVC ratio, however, was present in subjects with normal lung volumes in >40% of cases. Therefore spirometric measurements of FVC can be considered relatively sensitive but not specific. Measuring lung volumes is necessary to confirm a restrictive ventilatory deficit when the FVC is abnormally low with a normal FEV<sub>1</sub>/FVC.

It is important to emphasize that airway resistance is not increased in restrictive ventilatory deficits caused by parenchymal diseases (such as fibrosis). In fact, PEFr may be increased compared with predicted values. This may be caused by the airways being in effect “tethered” open by fibrotic changes of the lung parenchyma. Not all restrictive disease is caused by pulmonary fibrotic changes, however, so an increase in PEFr, although suggestive, is not diagnostic of a restrictive ventilatory deficit.

### Differential Diagnosis

Restrictive ventilatory deficits can be caused by any process that results in decreased lung volumes. Fibrotic changes in the lung parenchyma can manifest as a restrictive deficit as the lung tissue becomes less compliant. The loss of compliance leads to lower lung volumes as a given inspiratory effort results in less inhaled volume.

Restrictive deficits can also occur from extrapulmonary processes. Pleural diseases, such as pleural effusions or pleural fibrosis, can limit lung expansion and result in low lung volumes and a restrictive ventilatory pattern. The lungs themselves may have normal elastic properties, but the extrinsic compression from diseased pleura may limit the volume that can be inhaled.

Chest wall pathology can similarly result in a restrictive deficit. Kyphosis and/or scoliosis may result in restrictive physiology because the muscles of respiration are placed at a mechanical disadvantage. With severe curvature of the vertebral column, the diaphragm and accessory muscles may

not be able to generate maximal inspiratory forces leading to decreased lung volumes. Chest wall trauma, including broken ribs or scarring (i.e., secondary to burns), may result in decreased mobility of the chest wall, extrinsic compression of the lungs, and a restrictive ventilatory deficit. Similarly, extreme obesity can cause a restrictive ventilatory deficit by a similar mechanism; extrinsic compression by excess adipose tissue can limit maximal expansion of the respiratory system.

Finally, neuromuscular diseases may cause a restrictive ventilatory deficit. Weakened or poorly functioning respiratory muscles (whether because of a myopathy and/or neuropathy) can limit a patient’s ability to ventilate, resulting in low lung volumes. One way of distinguishing neuromuscular disorders from other types of restrictive diseases is through the use of respiratory muscle forces (often reduced) as described subsequently. In addition, because the ability to exhale completely to RV is an effort-dependent process, RV may be elevated in neuromuscular weakness.

From the previous considerations, specific pathologic processes that may cause a restrictive ventilatory deficit include pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, medication/toxic pneumonitis, collagen-vascular diseases (i.e., scleroderma, systemic lupus erythematosus, rheumatoid arthritis), pneumothorax, pleural effusion, pleural fibrosis, severe morbid obesity, scoliosis, kyphosis, chest wall trauma or scarring, and ankylosing spondylitis. Possible neuromuscular causes of restrictive ventilatory deficits include Guillain-Barré, amyotrophic lateral sclerosis, myasthenia gravis, and muscular dystrophies.

### Grading Severity

As mentioned earlier, confidence intervals below the predicted values of lung volumes are used to identify and quantify the severity of a restrictive deficit (see [Table 38.2](#)). Unlike obstructive deficits (COPD in particular), the severity of restrictive ventilatory deficits does not necessarily guide treatment. Treating the underlying pathologic process causing the restrictive ventilatory deficit is appropriate.

## Reduced Diffusing Capacity for Carbon Monoxide

### Definition, Characteristics, and Physiology of Decreased Diffusing Capacity for Carbon Monoxide

Decreased DLCO indicates impaired diffusion of CO across the alveolar-capillary membrane into the bloodstream and is thought to correlate with impaired diffusion of oxygen across the alveolar-capillary membrane. However, CO uptake is dependent not only on diffusion across the alveolar-capillary membrane but also on binding to Hb. Therefore the term *diffusing capacity* is inaccurate in that it implies

**TABLE 38.3** Using Confidence Intervals to Grade Severity of Decreases in DLCO: Difference of Predicted Minus Measured Value for Men and Women

	Men	Women
Normal: <1 CI from predicted value	<7.99	<6.50
Mild deficit: ≥1–1.75 CI from predicted value	≥7.99–13.98	≥6.5–11.37
Moderate deficit: ≥1.75–2.5 CI from predicted value	13.99–19.97	11.38–16.24
Severe deficit: ≥2.5 CI from predicted value	≥19.98	≥16.25

Units are in mL/[(min)(mm Hg)].  
CI, Confidence interval; DLCO, diffusing capacity for carbon monoxide.

that the transfer of CO from the alveolus to the bloodstream is dependent on diffusion alone. As such, the term *transfer factor*, rather than DLCO, is used outside of the United States.

The DLCO may be conceptualized through the following equations:

$$DLCO = \text{total CO uptake} / (\text{time} \times P_{ACO})$$

or

$$DLCO = V_{CO} / (P_{ACO} - P_{CCO})$$

where  $V_{CO}$  is the uptake of CO (mL CO/min),  $P_{ACO}$  is the alveolar pressure of CO, and  $P_{CCO}$  is the average pulmonary capillary partial pressure of CO. The  $P_{CCO}$  is usually zero in nonsmokers.

As with measurements of spirometry and lung volume, confidence intervals are used to grade the severity of reductions in DLCO. Reductions in percent predicted of DLCO can also be used to grade severity. Table 38.3 delineates a schema for grading the severity of reductions in DLCO.

As described previously, the DLCO may be corrected for Hb level. This is a physiologically meaningful correction because CO uptake is directly dependent on blood Hb concentration. Decreases in DLCO corrected for Hb concentration (DLCO [Hb]) may be graded with confidence intervals.

### Clinical Utility and Meaning of Diffusing Capacity for Carbon Monoxide

The DLCO can provide useful information about the functional relationship of the alveoli and the pulmonary capillaries. By extension, the DLCO may provide some information about gas exchange in general. Given similarities of the mechanism of CO uptake (diffusing across the alveolar membrane and being taken up by Hb) to oxygen uptake, clinicians extrapolate the results of DLCO measurements to oxygen uptake. When DLCO is interpreted in this fashion, it at best provides a rough guide of actual oxygen diffusion and uptake.

### Differential Diagnosis

DLCO may be decreased or increased as compared with its predicted value. As with spirometry and lung volumes, the predicted value of DLCO is determined by equations that consider age, height, gender, and ethnicity/race. The grade of severity of the difference in the measured DLCO from the predicted DLCO is determined by confidence intervals (see Table 38.3).

DLCO may be increased by a number of processes. Increased CO uptake is primarily dependent on the increased availability of Hb for binding CO because the pressure gradient across the alveolar membrane is constant from test to test, and changes in the alveolar-capillary membrane only serve to decrease CO diffusion and subsequent uptake. Conditions that result in increased cardiac output through the pulmonary circulation can result in increased measured DLCO compared with its predicted value. Specifically, with exercise, cardiac output increases, pulmonary vascular resistance (PVR) decreases, and minute ventilation increases. These physiologic changes result in increased pulmonary capillary blood volume; therefore when measured immediately after exercise, DLCO is increased compared with its predicted value. Obesity is associated with an increased DLCO and, although the mechanism is unclear, it is thought to be related to increased cardiac output and increased pulmonary blood volume. When measured in the supine position, the DLCO may be modestly but not clinically significantly increased. This is thought to be caused by increasing the proportion of the lung that is well perfused (West zone 3). Polycythemic states may result in an increased DLCO as more Hb is available for CO binding. Similarly, intraalveolar hemorrhage may result in an increased DLCO even in cases where the alveolar-capillary membrane is abnormal, as CO binds to Hb in the alveoli without having to pass through the alveolar-capillary membrane. Finally, left-to-right intracardiac shunts may increase DLCO as a result of increased cardiac output and blood volume through the pulmonary circulation.

Decreased DLCO is typically caused by conditions in which the alveolar membrane is abnormal, cardiac output through the pulmonary circulation is decreased, or there is a decrease in Hb available for binding CO. Decreased DLCO may occur with restrictive lung deficits (i.e., pulmonary fibrosis) or obstructive ventilatory deficits (i.e., COPD). In these conditions, lung parenchymal changes lead to perturbations in pulmonary capillary perfusion, which in turn result in a decrease in the Hb available to bind CO and thereby decrease CO uptake.

When decreased DLCO is encountered in a patient with other PFT abnormalities (such as decreased lung volumes and/or decreased FEV<sub>1</sub>), a unifying diagnosis to explain all the abnormalities should be sought. For example, a patient with reduced lung volumes and a reduced DLCO may have idiopathic pulmonary fibrosis causing a restrictive ventilatory deficit (caused by parenchymal fibrosis and decreased lung compliance) and a decreased DLCO (caused by fibrotic

changes of the alveolar membrane and loss of alveolar surface area, leading to impaired diffusion of CO).

Decreased DLCO with otherwise normal PFTs is associated with a limited differential diagnosis. Conditions that affect the pulmonary circulation to reduce functional pulmonary capillary circulation may cause a decreased DLCO. Specifically, pulmonary vascular disease (including both pulmonary arterial hypertension and thromboembolic disease) is a possible explanation for a reduced DLCO and otherwise normal PFTs. Pulmonary hypertension results in elevated PVR and decreased blood volume in the pulmonary circulation with decreased Hb available for CO binding. Methemoglobinemia or carboxyhemoglobinemia can result in a decreased DLCO with otherwise normal PFTs because although there may be a normal quantity of Hb passing through the pulmonary circulation, Hb binding sites are already occupied. Furthermore, in carboxyhemoglobinemia, the partial pressure of CO in pulmonary blood is increased, which decreases the diffusion gradient for CO across the alveolar membrane. In methemoglobinemia, the binding sites for CO have undergone a conformational change and cannot bind CO. Anemia can also result in a reduced unadjusted DLCO, although the DLCO corrected for Hb concentration would be normal.

### Association of Diffusing Capacity for Carbon Monoxide With Functional Capacity

With worsening measured DLCO, patients' functional capacity decreases. As described previously, although CO and oxygen have similar properties of diffusion and Hb binding, there are important differences that make direct comparisons difficult; for this reason, the relationship between DLCO and function capacity is not linear.

One way DLCO represents functional capacity is its role as a marker of a patient's ability to tolerate surgery. Specifically, the percent predicted DLCO correlates with postoperative complications in lung resection surgeries. A predicted postoperative DLCO of <40% predicted has been associated with increased mortality in several studies, and a preoperative DLCO of <60% predicted has also been associated with increased mortality.

### Mixed Disorders: Interpreting Mixed Obstructive and Restrictive Deficits

Obstructive and restrictive ventilatory deficits may occur simultaneously. As previously described, the FEV<sub>1</sub>/FVC ratio is helpful in determining the presence of an obstructive versus restrictive deficit. A decreased FEV<sub>1</sub> and a decreased measured FEV<sub>1</sub>/FVC ratio compared with the predicted value indicate an obstructive ventilatory deficit. A decreased FEV<sub>1</sub> with a normal measured FEV<sub>1</sub>/FVC ratio suggests a restrictive deficit (although this must be confirmed by measuring lung volumes).

It is not possible by spirometry alone to diagnose a mixed obstructive and restrictive ventilatory disorder. However,

a decreased FEV<sub>1</sub>/FVC ratio in the setting of both a low FEV<sub>1</sub> and a low FVC is suggestive of a mixed obstructive and restrictive ventilatory deficit. If this pattern is observed, then lung volumes can be measured to confirm a diagnosis of a restrictive deficit (in addition to an obstructive deficit diagnosed by spirometry). Mixed deficits are commonly characterized by a normal FRC, decreased TLC, and increased RV. An increased RV is indicative of air trapping in the setting of an obstructive deficit, whereas a decreased TLC reflects the restrictive process.

The differential diagnosis of a mixed restrictive and obstructive ventilatory deficit is broad and can include any combination of restrictive and obstructive processes. Most commonly seen is the combination of a restrictive process (such as interstitial lung disease) and COPD. Less commonly, processes that are classically restrictive may have an obstructive component; examples include lymphangiomyomatosis, tuberous sclerosis, chronic hypersensitivity pneumonitis, sarcoidosis, and eosinophilic granulomatosis.

## Respiratory Muscle Forces: Maximal Inspiratory Pressure and Maximal Expiratory Pressure

### Definition

Maximal inspiratory pressure (MIP) and maximal expiratory pressure (MEP) are measurements of pressures generated by respiratory muscles. By extension, the MIP and MEP provide information about respiratory muscle strength and function.

MIP and MEP are particularly useful measurements in assessing patients with known or suspected neuromuscular disease, either inherent (Duchenne, amyotrophic lateral sclerosis) or acquired (myasthenia gravis, Guillain-Barré, or intensive care unit [ICU]-acquired weakness).

MIP can be used as a marker of readiness for extubation in mechanically ventilated patients. Specifically, a patient's ability to perform an adequate, coordinated maximal inspiratory effort can be used as one predictor of successful extubation. In this setting, the term *NIF* or *negative inspiratory force* is often used in place of MIP.

Normal measured values for MIP are approximately -70 to -100 cm H<sub>2</sub>O, and a normal measured MEP is approximately 100 to 150 cm H<sub>2</sub>O. As with other parameters of pulmonary function, predicted values for an individual patient's MIP and MEP may be generated by using reference equations. There is no consensus as to which reference equation is standard for determining predicted MIP or MEP. Regardless of the equation used, the measured MIP and MEP are displayed as both a measured value (in centimeters of H<sub>2</sub>O) and a percent predicted.

Low values for MIP may be related to submaximal subject effort. Performing the MIP maneuver can be uncomfortable for a subject, and early termination of inspiratory effort before generating a true maximal inspiratory effort is common.

## Differential Diagnosis

Respiratory muscle weakness as diagnosed by abnormal MIP and/or MEP can be caused by a variety of processes. Neuromuscular diseases are the most common causes of decreased MIP and MEP. Inherent or congenital neuromuscular processes that can lead to respiratory muscle weakness include muscular dystrophies (such as Duchenne), spinal cord processes (amyotrophic lateral sclerosis), or other primary neuromuscular pathologies.

Acquired neuromuscular diseases include Guillain-Barré, myasthenia gravis, and ICU-acquired weakness. Vasculitis, dermatomyositis, polymyositis, and Eaton-Lambert syndrome may all cause compromised neuromuscular function. Diaphragmatic dysfunction or paralysis may occur from a variety of causes; unilateral diaphragmatic paralysis is usually well tolerated clinically but may result in decreased MIP and MEP and occasionally symptoms of dyspnea. Bilateral diaphragmatic paralysis typically causes dyspnea, particularly in the supine position, and results in decreased MIP and MEP.

Central nervous system diseases such as viral encephalopathies (poliomyelitis, West Nile virus, etc.) may lead to depressed respiratory muscle function and decreased MIP and MEP. Spinal cord compression, particularly in the high cervical cord, can lead to decreased MIP and MEP by causing compromised phrenic nerve activity and diaphragmatic dysfunction.

Finally, toxic exposures or metabolic abnormalities may decrease MIP and MEP. Specifically, hypokalemia, hypophosphatemia, botulism, organophosphate poisoning, and heavy metal toxicities are all possible (but uncommon) causes of respiratory muscle compromise and decreased MIP and MEP.

## Clinical Utility: When to Order, How to Interpret, Further Testing

Measuring MIP and MEP in patients with unexplained dyspnea may be useful in identifying an underlying diagnosis, particularly when a neuromuscular process is suspected. When orthopnea is a component of shortness of breath and diaphragmatic dysfunction is a suspected clinical consideration, measuring respiratory muscle forces may be diagnostically helpful.

When the MIP and MEP are low, further workup can include an electroneurogram (ENG) and/or electromyogram. These tests are useful in determining a neuronal versus muscular contribution to respiratory muscle weakness. Phrenic nerve ENG may be performed to identify diaphragmatic dysfunction. The sniff test is a less sensitive test of diaphragmatic dysfunction; the patient is asked to rapidly inhale (i.e., sniff) while diaphragmatic movement (or the lack thereof) is monitored fluoroscopically.

Muscle biopsy in selected patients can be diagnostic for polymyositis, mitochondrial diseases, and myopathies.

## Advanced Pulmonary Function Tests

### Resistance and Compliance

The resistance of the airways to airflow (referred to as *airways resistance*) may be estimated when performing PFTs. Many assumptions are made in estimating airways resistance, and the clinical utility of this measured value in isolation is uncertain. However, measured airways resistance when correlated with the patient's symptoms and other measures of pulmonary function (such as spirometry) can serve to further characterize a patient's pulmonary physiology.

Airways resistance is caused by both the airways (affected by endobronchial obstruction, bronchospasm, and/or flow limitation) and the pulmonary parenchyma (specifically in the setting of noncompliant lungs). Typically, the majority of resistance to flow is from the airways rather than the pulmonary parenchyma. It is estimated that the airways account for approximately 80% of resistance. The measured resistance reported with PFTs is assumed to reflect the resistance of the airways, although in the setting of decreased lung compliance this may be an inaccurate assumption.

Resistance is defined as the change in pressure divided by flow:

$$\text{Resistance} = \text{Pressure difference (cm H}_2\text{O)}/\text{airflow (L/s)}$$

The pressure difference in this equation specifically refers to the difference between the mouth and the alveoli. Changes in pressure are measured via plethysmography as described earlier. Airflow at the mouth can be measured during PFTs, and resistance can be calculated. Resistance may be measured while the subject is panting or during tidal breathing.

In considering airways resistance, Poiseuille's law is informative; the resistance of a tube is dependent on viscosity of air flowing through it, the length of the tube, and the fourth power of the radius of the tube.

$$R = (8 \times \text{viscosity} \times \text{length})/(\pi \times \text{radius}^4)$$

Airways resistance may be quite variable between measurements, and the normal range for airways resistance is poorly defined.

Lung compliance is the ability of the lungs to stretch to accommodate volume. Compliance is defined as the change in volume divided by the change in pressure:

$$\text{Compliance} = \text{Volume difference}/\text{pressure difference}$$

Compliance is affected by numerous diseases. COPD results in parenchymal destruction, loss of the innate elastic recoil of the lungs, and increased compliance. Pulmonary fibrosis results in decreased distensibility of the pulmonary parenchyma and decreased compliance. As with airways resistance, the clinical utility of measured compliance in isolation is questionable. However, when correlated with a patient's clinical circumstances and other PFT results, compliance may provide useful corroborating information.

## Bronchoprovocation

Methacholine challenge is the most common method of performing bronchoprovocation. A methacholine challenge is used clinically to diagnose hyperreactivity of the airways in general and asthma specifically. Methacholine challenge is reserved for patients in whom the diagnosis of asthma is elusive despite prior investigations, such as spirometry performed prebronchodilator and postbronchodilator administration. Methacholine challenge is very sensitive but not specific. Patients with COPD, congestive heart failure, bronchitis, cystic fibrosis, and other conditions may have airways hyperreactivity and a positive methacholine challenge test.

Contraindications to methacholine challenge include an  $FEV_1 < 1$  L (or  $< 50\%$  predicted), a heart attack or stroke within the previous 3 months, uncontrolled hypertension ( $> 200/100$  mm Hg), and thoracic or abdominal aortic aneurysm.

There are different protocols for the administration of methacholine during testing. In all protocols, increasing concentrations of aerosolized methacholine are administered, followed by spirometry. One method of administering methacholine uses increasing concentrations of methacholine, with diluents at 0.0625, 0.25, 1, 4, and 16 mg/mL of methacholine. Five doses of each concentration of methacholine are administered before spirometry. Two acceptable efforts should be performed after each concentration of methacholine.

If  $FEV_1$  decreases by  $\geq 20\%$  from the baseline (diluent) level after a given concentration of methacholine, then no further doses should be given. Similarly, if the  $FEV_1$  does not decrease by  $\geq 20\%$  after the highest concentration of methacholine (16 mg/mL), no further doses of methacholine should be given.

The PC<sub>20</sub> is the concentration of methacholine that causes significant bronchoconstriction as defined by a decrease in  $FEV_1$  of  $\geq 20\%$ . If a decrease in  $FEV_1$  of  $\geq 20\%$

is not reached by 16 mg/mL of methacholine, then the PC<sub>20</sub> is reported as  $> 16$  mg/mL. A PC<sub>20</sub> of  $> 8$  mg/mL represents normal bronchial responsiveness. A PC<sub>20</sub> of 4 to 8 mg/mL is a borderline test, a PC<sub>20</sub> of 1 to 4 mg/mL indicates mild bronchial hyperresponsiveness, and a PC<sub>20</sub> of  $< 1.0$  mg/mL indicates moderate to severe bronchial hyperresponsiveness.

The results of the methacholine test alone do not determine whether a patient has asthma. Rather, the PC<sub>20</sub> must be correlated with the patient's clinical symptoms. Patients who smoke or who have allergic rhinitis are prone to have reactive airways and thereby a low PC<sub>20</sub>. Correlating clinical symptoms with PC<sub>20</sub> reduces false-positive methacholine challenges.

False-negative results are uncommon; as noted earlier, the methacholine challenge is sensitive for bronchial hyperreactivity. When the pretest probability of asthma is 30% to 70%, the negative predictive value of the methacholine challenge is 90%.

False-positive results are more likely to occur in patients with allergic rhinitis and in smokers with COPD. In addition, methacholine challenge may result in acute inspiratory vocal cord adduction without reactive airways disease, which causes a false-positive result.

Methacholine is not the only way to perform bronchoprovocation. Exercise can be used to induce bronchial hyperreactivity. There are various protocols for performing bronchoprovocatory exercise. Typically, 4 to 6 minutes of near-maximum exercise is performed on a treadmill or a cycle ergometer. The cool, dry air the patient breathes during the test is also thought to contribute to bronchial hyperreactivity.

## Acknowledgment

The authors and editors gratefully acknowledge and thank Mr. Richard Johnston for his thoughtful review of this chapter.

## Chapter Review

### Questions

1. A 63-year-old man presents to the clinic with a chief complaint of intermittent wheezing, chest tightness, and dyspnea that primarily occurs with exertion. He has smoked a pack of cigarettes daily for almost 40 years. The wheezing, chest tightness, and dyspnea with exertion have occurred intermittently over the years but became progressively more frequent approximately 2 years ago. He has no other associated symptoms or known past medical history. As part of his evaluation, he undergoes PFTs.

The most likely finding would be:

A.  $FEV_1/FVC < 0.7$  caused by obstructive airways disease

B. Decreased TLC caused by accumulation of mucus in his airways

C. Normal  $FEV_1$  and decreased FVC caused by goblet cell proliferation

D. Increased DLCO caused by increased cardiac output

E. Low  $FEV_1$  and FVC with a normal  $FEV_1/FVC$

2. A 65-year-old man presents to the clinic with dyspnea and dry cough. He has been feeling increasingly short of breath over the last 8 months, particularly with exertion. He doesn't recall any new exposures or recent illnesses. He has no other complaints. His examination reveals a heart rate of 115 beats per minute, a blood pressure of 110/60 mm Hg, a respiratory rate of 16 breaths per minute, and a

resting oxygen saturation of 89% on room air. His pulmonary examination is notable for bilateral diffuse dry crackles on inhalation. He undergoes PFTs.

The most likely finding would be:

- A. Low FEV<sub>1</sub>, FVC, and FEV<sub>1</sub>/FVC
  - B. Low FEV<sub>1</sub> with a normal FVC
  - C. Increased DLCO caused by increased cardiac output
  - D. Decreased TLC but normal RV
  - E. Low FEV<sub>1</sub> and FVC with a normal or elevated FEV<sub>1</sub>/FVC
3. A 23-year-old woman with a history of asthma presents to the emergency department with 2 days of worsening cough, wheezing, chest tightness, and dyspnea. She ran out of her inhalers a week ago and has been taking no medicine for her asthma during that time. Her peak flow rate on presentation is 150 L/min; her normal, baseline peak flow rate is 400 L/min. On examination her heart rate is 140 beats per minute, her blood pressure is 150/90 mm Hg, her respiratory rate is 24 breaths per minute, and her oxygen saturation is 94% on room air at rest. She is uncomfortable, appearing in severe respiratory distress. She has poor air movement with inspiratory and expiratory wheezing on pulmonary auscultation. She does not respond to nebulizer treatments and steroids and is ultimately intubated.
- Which of the following ventilatory parameters would you expect to find?
- A. Low compliance
  - B. Low peak inspiratory pressure with elevated plateau pressure
  - C. Elevated peak inspiratory pressure with normal airways resistance
  - D. Elevated peak inspiratory pressure with elevated airways resistance
  - E. A Pao<sub>2</sub>/Fio<sub>2</sub> of <100 mm Hg
4. A 51-year-old woman presents to your clinic with 2 years of progressive dyspnea on exertion. At first, she noticed

breathlessness with climbing multiple flights of stairs; over the past 6 months, however, she has become short of breath with minimal exertion such as grocery shopping or walking more than two blocks on a flat surface. She underwent spirometry and lung volume measurements a month ago, and the results of these studies were within normal limits. You recommend measuring her DLCO and DLCO corrected for Hb (DLCO [Hb]).

You would predict that DLCO testing will demonstrate:

- A. Normal DLCO, low DLCO (Hb)
  - B. Low DLCO, normal DLCO (Hb)
  - C. Normal DLCO, normal DLCO (Hb)
  - D. Low DLCO, low DLCO (Hb)
  - E. High DLCO, normal DLCO (Hb)
5. A 48-year-old man with a known history of advancing amyotrophic lateral sclerosis presents to the clinic for follow-up. His wife has noticed that he has been breathing more rapidly over the past few weeks, and the patient feels that he is subjectively working harder to breathe. He feels particularly short of breath when he lies down at night, and he awakens several times a night gasping for breath. These episodes are relieved when his wife helps him sit up. Which of these findings would support his restrictive physiology being caused by neuromuscular weakness and not caused by decreased lung compliance or chest wall stiffness?
- A. Decreased TLC and decreased RV
  - B. Decreased TLC and normal RV
  - C. Decreased TLC and normal FRC
  - D. Normal TLC and decreased RV
  - E. Normal TLC and normal FRC

## Chest X-Ray Refresher

CHRISTOPHER H. FANTA

In this chapter we will consider common radiographic patterns in pulmonary diseases, identify specific findings that can be helpful in diagnosis, and review certain topics covered elsewhere in the Pulmonary Medicine section of the *Brigham Intensive Review of Internal Medicine* book. Discussing the findings on your patient's chest radiograph with your local radiologist—with you providing clinical data and a grounding in internal medicine and the radiologist offering insights into the radiographic findings and potential causes for those findings—is one of the more enjoyable clinical interactions in medicine. I encourage you at any opportunity to review the actual chest images obtained on your patients rather than relying exclusively on the written reports, just as you might want to inspect your patient's actual electrocardiogram tracing when considering his or her cardiac status. Pattern recognition remains an important part of how we process medical information, and like any skill it improves with practice.

This chest x-ray refresher is organized as a game. For each of the three topics to be discussed, we offer four chest x-rays (CXRs) and four clinical histories. The order of each set is random. The exercise asks that you consider the clues in the history and the findings on CXR to match the history with the x-ray. In many instances, the combination will suggest a diagnosis or a limited differential of diagnostic possibilities. The three topics to be discussed are hemoptysis, chronic interstitial lung diseases, and obstructive lung diseases.

### Hemoptysis

After obtaining a history and performing a physical examination, the next step in the evaluation of the patient with hemoptysis is usually a CXR. Even episodes of minor hemoptysis warrant an initial CXR because serious illnesses (such as lung cancer, pneumonia, tuberculosis, and pulmonary embolism) can present with small amounts of expectorated blood. An abnormal CXR may point to the source of bleeding and to its cause. Further workup is often then directed at determining the cause of the radiographic abnormality. Diagnostic evaluation and treatment may vary

widely depending on CXR findings, as illustrated by our four examples (Figs. 39.1–39.4).

- Case 1: Expectoration of blood-streaked sputum preceded by chronic early morning cough in a 2-pack-per-day cigarette smoker; physical examination notable for clubbing and obvious weight loss
- Case 2: Several days of hemoptysis with progressive shortness of breath; dark-colored urine and serum creatinine of 2.5 mg/dL
- Case 3: Four weeks of cough with discolored sputum intermittently mixed with blood; fever, night sweats, and significant weight loss
- Case 4: Hemoptysis and pleuritic chest pain on the third postoperative day

The first chest film (see Fig. 39.1) has several areas of abnormality within the lung parenchyma. Abnormal opacities can be seen within the right upper lobe, right middle lobe (obscuring the normal sharp silhouette made by juxtaposition of the right heart border and aerated lung tissue in the right middle lobe), and the left midlung zone. Most striking is the abnormality in the right upper lobe. On close inspection, there are two distinct features to this area of opacities. First, in the right apex one can make out a ring of opacity surrounding aerated lung—a thick-walled lung cavity. The rim of this cavity is several millimeters thick (4–5 mm) and irregular along its inner margin. Second, the base of the opacities in the right upper lobe is curvilinear, making an upward bowing arc from hilum to lateral pleural surface. This linear opacity bears the characteristic shape of the minor fissure pulled cephalad by right upper lobe volume loss.

The differential diagnosis of a pulmonary cavity includes tuberculosis, bacterial lung abscess, lung cancer, and pulmonary vasculitis (e.g., granulomatosis with polyangiitis). The upper lobe location and associated volume loss are suggestive of mycobacterial disease such as tuberculosis. Which of the four clinical histories might fit with this x-ray appearance? Our choice is case history 3, the patient with subacute-to-chronic purulent sputum production with bloody sputum plus night sweats, fever, and weight loss. The CXR together with this brief history raises the suspicion of cavitary tuberculosis, with multifocal bronchogenic spread of infection in both lungs. Consider the initial evaluation and

• **Fig. 39.1** Hemoptysis: chest x-ray 1.

• **Fig. 39.3** Hemoptysis: chest x-ray 3.

• **Fig. 39.2** Hemoptysis: chest x-ray 2.

• **Fig. 39.4** Hemoptysis: chest x-ray 4.

treatment in this patient: have the patient wear a face mask; if hospitalized, request a negative-pressure isolation room; send sputum on at least three occasions for mycobacterial (acid-fast bacilli or AFB) culture and smear; and initiate antituberculous therapy with three or four drugs.

The second CXR in this series (see Fig. 39.2) has two major left-sided abnormalities notable as one inspects the normal contours of the hilar and mediastinal structures and of the diaphragms and pleural surfaces. There is a large, rounded opacity that at its top begins at the level of the arch of the aorta and then obliterates both the aortopulmonary

recess and the left hilar shadows. It looks like a large mass. In addition, the left hemidiaphragm is raised cephalad several centimeters above its usual position. A third finding of note is the hazy fanlike opacity with sharp medial border that extends “northeast” from the hilar area into the region of the left upper lobe. It is this appearance that is particularly worth remembering: the image of left upper lobe collapse. Unlike the right upper lobe, which collapses as an opacity that fills the right apex, the left upper lobe collapses anteriorly (its apex still tethered at the hilum), allowing aerated left lower lobe tissue to fill the left apex.

As in any lobar atelectasis, there must be displacement of other structures to compensate for the volume loss—cephalad movement of the ipsilateral diaphragm, shifting of mediastinal structures (sometimes including the heart) toward the side of collapse, and overexpansion of the remaining ipsilateral lobe(s) of the lung. In this example the left hemidiaphragm has shifted dramatically upward, perhaps in compensation for left upper lobe collapse, perhaps also because of phrenic nerve injury with hemidiaphragmatic paralysis.

What is the cause of left upper lobe collapse in this case? It is likely the result of proximal obstruction of the left upper lobe bronchus by the large medial mass. In a patient with hemoptysis, we would strongly suspect a neoplasm, probably a lung cancer. Case history 1 seems the best fit: a cigarette smoker with symptoms of chronic bronchitis (daily early morning cough) and weight loss, whose physical examination indicates (among other likely findings) clubbing of the digits. Evaluation of this patient with hemoptysis might include further imaging with chest CT, sputum for cytology, and probable bronchoscopy for endobronchial visualization of the airway obstruction and tissue sampling. Treatment will depend on the type of neoplasm and the anatomic extent of tumor involvement (both within and outside the thorax) but might include external beam radiation, chemotherapy, and possibly endobronchial approaches to opening the left upper lobe bronchus.

The third CXR to consider (see Fig. 39.3) has diffuse parenchymal opacities bilaterally, left more than right. Especially in the left lung, the appearance is that of diffuse “ground-glass” opacities. This ground-glass appearance is uniform in its texture, not so dense (like consolidation) that one cannot see aerated lung throughout, and not linear and nodular (like an interstitial process). It reminds one of the glass door of a shower stall made opaque by grinding the surface of the glass. The pathologic correlate of this radiographic pattern is partial or incomplete airspace filling, sometimes with edema fluid (e.g., congestive heart failure), sometimes with inflammatory material (e.g., pneumocystis pneumonia), and sometimes with blood (e.g., diffuse alveolar hemorrhage).

In our patient with hemoptysis, this radiograph raises a relatively limited differential diagnosis. Diffuse alveolar hemorrhage (in the absence of severe coagulopathy and/or platelet disorder) makes one think of a pulmonary vasculitis, and if we add in the “dark-colored urine and serum creatinine of 2.5 mg/dL” of case history 2, it specifically focuses us on pulmonary-renal hemorrhage syndromes. Diagnostic considerations include Goodpasture syndrome, granulomatosis with polyangiitis (Wegener’s granulomatosis), and collagen-vascular disorders, especially systemic lupus erythematosus. Bronchoscopy is useful to confirm the presence of alveolar bleeding; bronchoalveolar lavage fluid returns bloody without diminution on serial instillations of saline. To establish a specific diagnosis we may rely on serologic information, such as antiglomerular basement membrane antibody, antinuclear cytoplasmic antibody (ANCA), and

antinuclear antibody (ANA), or we may obtain tissue for histologic analysis via lung or kidney biopsy. In fact, in this patient the finding on CXR of free air under the right diaphragm (extra credit for all who noticed this finding!) suggests that a renal biopsy may have recently been performed. Treatment of hemoptysis in this patient is likely to involve high-dose systemic corticosteroids with potential addition of other modalities such as cyclophosphamide or rituximab (for granulomatosis with polyangiitis) or plasmapheresis (for Goodpasture syndrome).

By process of elimination we can match the fourth CXR in this series with case history 4, a patient with hemoptysis and pleuritic chest pain 3 days after a surgical procedure. Based on the history alone, the possibility of pulmonary embolism jumps to mind. Other potential causes might include pneumonia, perhaps upper airway bleeding following intubation, or postsurgical bleeding following thoracic surgery, but pulmonary embolism is the potentially fatal etiology that we will not want to miss. The CXR that we obtain (see Fig. 39.4) has opacity at the left base. There is blunting of the left costophrenic angle consistent with a small pleural effusion (a lateral chest film would be helpful here for confirmation) and loss of the normal silhouette along the medial portion of the left hemidiaphragm, perhaps caused by pleural effusion and perhaps caused by a component of subsegmental atelectasis causing the left hemidiaphragm to be raised up slightly and higher than the right hemidiaphragm (the reverse of normal).

A small pleural effusion and minor subsegmental atelectasis are common findings following cardiothoracic and upper abdominal surgery and are nonspecific, and that is the point here. The findings of pulmonary embolism on plain chest radiography are typically none (a normal chest film) or nonspecific (with pleural effusion and minor atelectasis being the most common abnormalities). Only very rarely in pulmonary embolism will one find the dramatic pleural-based, wedge-shaped consolidation with rounded apex (so-called Hampton hump; Fig. 39.5) that is characteristic of pulmonary infarction. Were one to wait to see this plain film manifestation of pulmonary embolism, one would miss a lot of pulmonary emboli!

For our last patient with hemoptysis, the evaluation will likely involve either a ventilation-perfusion lung scan or chest CT angiogram. If a diagnosis of pulmonary embolism is confirmed, then treatment of this patient with hemoptysis will be, paradoxically, anticoagulation.

## Chronic Interstitial Lung Diseases

Alveolar walls and their constituents (epithelial lining cells, macrophages, collagen, elastin and other matrix proteins, and pulmonary capillaries) make up the pulmonary interstitium. As discussed elsewhere in this volume, a broad collection of chronic inflammatory lung diseases affects primarily the pulmonary interstitium. Common categories include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pneumoconiosis, and others. The plain film radiographic

• **Fig. 39.5** Bilateral Hampton humps suggestive of pulmonary infarcts.

hallmarks of these interstitial pulmonary processes are linear and nodular opacities. As shown in the accompanying cartoon (Fig. 39.6), this pattern is made up of some combination of opaque lines of varying length and thickness and dots (nodules) of varying size. The combination of linear shadows and dots gives a lace-like pattern generally readily distinguishable from consolidation (dense white opacity) or ground-glass appearance (as discussed earlier). High-resolution chest CT (HRCT) imaging has proved very useful in distinguishing distinctive patterns of interstitial inflammation, helping further to identify specific diseases or disease patterns within this broad category. Obtaining an HRCT is

• **Fig. 39.8** Chronic interstitial lung disease: chest x-ray 2.

the appropriate next step in the radiographic evaluation of most instances of chronic interstitial lung disease.

Often the finding of diffuse linear and nodular opacities on chest film is nonspecific. A specific etiologic diagnosis will require additional history, further chest imaging such as HRCT, blood serologies, and perhaps lung biopsy (either bronchoscopic or thoracoscopic). However, on occasion, the history and characteristic CXR appearance will point to a specific diagnosis or limited group of diagnoses, as illustrated by the following examples (Figs. 39.7–39.10). Four brief case histories follow (to be matched to the four accompanying CXRs). Each of these four patients presented with

• **Fig. 39.9** Chronic interstitial lung disease: chest x-ray 3.

• **Fig. 39.10** Chronic interstitial lung disease: chest x-ray 4.

nonproductive cough and progressive dyspnea on exertion of several months' duration.

- Case 1: Inoperable gastric cancer
- Case 2: Worked as a stonecutter in a quarry for 20 years, now retired for 10 years
- Case 3: Prior episodes of erythema nodosum and uveitis
- Case 4: Worked cleaning and insulating boilers for 30 years

The first CXR in this series (see Fig. 39.7) has bilateral, predominantly upper lobe linear and nodular opacities, including many small nodules. Also present, and a clue to diagnosis, is the finding of enlarged hilar shadows bilaterally.

The lobulated appearance suggests enlarged hilar lymph nodes. Bilateral hilar adenopathy can often be confirmed on lateral CXR with the so-called “doughnut” or “bagel” sign: a ring of opacification surrounding the major bronchi at the distal end of the tracheal air column (Fig. 39.11, right panel). On the posteroanterior chest film, one can probably make out bilateral mediastinal adenopathy as well: an enlarged azygous node along the right margin of the inferior portion of the trachea and aortopulmonary adenopathy suggested by blunting of the normal recess between the aortic arch and the upper margin of the left main pulmonary artery.

The differential diagnosis for interstitial lung disease with bilateral hilar lymphadenopathy includes sarcoidosis, berylliosis, granulomatous (e.g., mycobacterial) infection, and lymphoma. A clinical history that would fit with this image is case history 3, a patient with persistent nonproductive cough, dyspnea on exertion, and a prior history of erythema nodosum and uveitis. These latter findings are among the more common extrapulmonary manifestations of sarcoidosis. In fact, given this history and CXR, many pulmonary physicians would make a presumptive diagnosis of sarcoidosis and not feel it necessary to obtain histologic confirmation (by bronchoscopic transbronchial lung biopsy, endobronchial ultrasound [EBUS]-guided bronchoscopic lymph node biopsy, or mediastinoscopy). Finally, the upper zone predominance of the interstitial opacities is worth noting. It is common in sarcoidosis and atypical for other frequently encountered chronic interstitial lung diseases, such as idiopathic pulmonary fibrosis.

Our next chest image (see Fig. 39.8) is full of abnormalities. One can see bilateral linear and nodular opacities, especially prominent at the right base. This finding alone is nonspecific and can be seen in myriad chronic interstitial lung diseases. However, as we look further, there are additional clues. The costophrenic recesses are blunted, and opacification extends up the lateral pleural borders bilaterally, indicative of loculated pleural effusion or pleural thickening. Perhaps you can make out (on this underpenetrated reproduction) dense white arcs paralleling each of the diaphragmatic shadows. The intensity of these white lines implies calcification, most likely calcification along the diaphragmatic pleura. A close-up of the diaphragms on this patient's lateral chest film brings out this finding more clearly (Fig. 39.12). Finally, there are nodular densities to be accounted for, in the left midlung zone laterally and in the right upper lobe. We will come back to these nodular opacities in a moment.

Chronic interstitial lung disease with pleural thickening and extensive pleural calcifications suggests a diagnosis of asbestosis. *Asbestosis* refers to the interstitial inflammation and fibrosis secondary to chronic inhalation of asbestos fibers. It typically develops only after many years of intense asbestos exposure and with a latency period of decades, appearing 20 to 30 years after exposure began. The exposure may have been work cleaning and insulating asbestos-lined boilers, as in case history 4. Pleural fibrosis and plaques, with or without calcification, are indicators of asbestos exposure. They are often asymptomatic and may or may

• **Fig. 39.11** Lateral chest films: normal (*left*) and bilateral hilar lymphadenopathy (*right*).

• **Fig. 39.12** Pleural calcifications along diaphragmatic pleura (close-up of lateral chest film).

not be accompanied by diffuse interstitial inflammation and fibrosis.

Now, what about the nodular opacities? On the left, I suspect a pleural plaque. When the plaque occurs along the anterior or posterior aspect of the pleura, surrounded by aerated lung and imaged *en face*, it can mimic an intraparenchymal nodule. On the other hand, the right upper lobe nodule proved to be a lung cancer. It reminds us that the most common cancer associated with asbestos exposure, especially when combined with cigarette smoking, is lung cancer. The pleural malignancy, mesothelioma, is more specifically associated with asbestos exposure, but it is far less common.

The next image (see [Fig. 39.9](#)) is classic, virtually pathognomonic, and now rare. It belongs in the category of interstitial diseases because of the presence of many small lung nodules throughout the lung parenchyma, but the major findings are elsewhere. There are large consolidated opacities in the upper lobes, bilaterally symmetric, and suspicious for malignancy. However, their size and shape have not changed over many months. And the appearance of the hila is distinctive; they are full and very radiopaque (whiter than usual). Perhaps on the left you can make out discrete, enlarged hilar lymph nodes as part of the hilar shadows. They are so radiopaque and distinct because they are calcified. Calcified hilar lymph nodes make one think of

granulomatous lung infections (e.g., tuberculosis, histoplasmosis, and coccidioidomycosis), chronic sarcoidosis, and silicosis. In a patient with many years of silica dust exposure (as a stonecutter in a quarry for 20 years, as in case history 2), one can make a diagnosis of silicosis based on this chest image. Sometimes calcification of the hilar nodes occurs only along their rim, giving a distinctive appearance referred to as *eggshell calcification*, seen in silicosis and occasionally sarcoidosis. [Fig. 39.13](#) offers a close-up view of a patient with eggshell calcification of right hilar and mediastinal lymph nodes caused by silicosis.

Multiple small silicotic nodules throughout the lungs can be asymptomatic, referred to as *simple silicosis*. This patient has more advanced disease, however. In the upper lobes, a dense conglomeration of silicotic nodules and inflammatory reaction has formed mass-like lesions, called *progressive massive fibrosis*. The symmetric involvement and upper lobe location have led to the description of an “angel’s wings” distribution of these opacities. Characteristically, in progressive massive fibrosis there may be progressive upper lobe scarring years after silica dust exposure has ceased.

The last of the four chest images in this series (see [Fig. 39.10](#)) must belong then with the patient with inoperable gastric cancer (case 1). Even knowing this history, one is strongly tempted to make a diagnosis of congestive heart failure. Besides linear and nodular opacities in the left lower lobe and a mixture of linear and nodular opacities combined with more confluent (airspace) opacities in the right lower lobe, there are probably small bilateral pleural effusions (although on both sides the film fails to include the lateral margins of the chest). In addition, if one had the opportunity to look at the x-ray close-up, one might be able to pick out Kerley B lines (thin, horizontal lines extending approximately 1 cm in length and ending laterally at the pleural margin) and a Kerley A line (thin, longer line, not oriented horizontally, that also indicates fluid in the interlobular septa). And then there is the circumstantial evidence of a cardiac pacemaker (with old, disconnected pacer wires still in place on the left).

• **Fig. 39.13** Pattern of eggshell calcification of hilar and mediastinal lymph nodes (close-up of right lung, medially, on posteroanterior chest film).

However, this patient does not have congestive heart failure. Of interest, the cardiac silhouette is normal in size. Additional history is that diuresis to the point of prerenal azotemia brought no improvement. As we expand our differential diagnosis of interstitial infiltrates with Kerley lines and pleural effusions, the history of inoperable gastric cancer becomes relevant. What is filling the interstitial spaces and especially the interlobular septa in this case is not edema fluid but malignant cells and associated desmoplastic reaction. This patient has lymphangitic carcinomatosis, the spread of malignancy (almost always adenocarcinoma) through lymphatic channels. Common primary cancers are lung and breast and also stomach, pancreas, and thyroid. A close-up image (Fig. 39.14) highlights the nodular component of the interstitial pattern in this case along with the Kerley A and B lines.

## Obstructive Lung Diseases

Obstructive lung diseases are grouped together based on their shared physiologic (rather than radiographic) pattern: airflow obstruction on the forced expiratory maneuver of spirometry. Common among the obstructive lung diseases are asthma, chronic bronchitis and emphysema (referred to collectively as *chronic obstructive pulmonary disease* [COPD]), bronchiolitis, diffuse bronchiectasis, and upper airway obstruction. In addition, other lung diseases may frequently manifest with airflow obstruction even though they are not primarily thought of in this category. Examples include congestive heart failure (remember wheezing due to heart failure, referred to as *cardiac asthma*), sarcoidosis (as many as one-quarter of patients with sarcoidosis will have primarily obstructive

• **Fig. 39.14** Linear and nodular opacities (arrows), including Kerley A and B lines (close-up of left paracardiac area on posteroanterior chest film).

• **Fig. 39.15** Patient with severe obstructive lung disease caused by chronic bronchitis.

rather than restrictive physiology), and the rare entity, discussed in [Chapter 37](#), called *lymphangioleiomyomatosis* (LAM).

When the primary abnormality is limited to the airways, the chest radiograph may be normal or reveal only hyperinflation. Consider this example, for instance, of a patient with severe COPD caused primarily by chronic bronchitis (Fig. 39.15). The chest film has only a minor, nonspecific increase of lung markings at the bases bilaterally. On close inspection, one can see a ring shadow in the left hilar region, representing a thickened bronchial wall cut in cross section. Despite the severity of airflow obstruction, the CXR has only few abnormalities.

Still, the CXR may provide valuable diagnostic clues in patients with chronic airflow obstruction, as illustrated by the next series of four CXRs (Figs. 39.16–39.19). Each of

• Fig. 39.16 Obstructive lung disease: chest x-ray 1.

• Fig. 39.18 Obstructive lung disease: chest x-ray 3.

• Fig. 39.17 Obstructive lung disease: chest x-ray 2.

• Fig. 39.19 Obstructive lung disease: chest x-ray 4.

these patients has cough, shortness of breath, and intermittent wheezing. In addition, the following histories were obtained:

- Case 1: The patient's father and older brother died in their 40s of emphysema.
- Case 2: The patient has had a chronic productive cough and recurrent sinusitis since childhood and now presents for evaluation of infertility.
- Case 3: The patient, a nonsmoker, had recurrent pneumothoraces in the past and a pleural effusion that was said to look milky when drained.
- Case 4: The patient complains of weight loss, chronic diarrhea, and sinusitis. Mucoid *Pseudomonas* has been grown from the sputum.

This first image (see Fig. 39.16) is quite striking: the lungs are large and very black (hyperlucent) and the diaphragms are flattened, lacking the normal rounded arc of their

silhouettes. The film is cut off at the lung apices, making it difficult to count rib numbers accurately, but it is clear that the diaphragms are positioned very low in the chest, probably at the level of the 11th or 12th ribs posteriorly (normal is at the 9th to 10th ribs). The pulmonary arteries centrally are brought into stark relief by the surrounding overinflated lung tissue. (An incidental note is made of an accessory [azygos] fissure in the right upper lung zone and a callus formed along the rib in the right lower lung zone.)

This pattern of hyperinflated and hyperlucent lungs is readily identified as that of emphysema, with destruction of alveolar tissue and consequent excessive lung compliance. However, this chest film holds additional clues as to etiology. The distribution of lucency is not uniform, apex to base. The blackest areas are at the lung bases. The cause is clear if we look for vascular markings: The blood vessels can be traced in the upper lung zones with almost none coursing inferiorly. These areas of hyperlucent lung tissue with absence of vascularity suggest bullae.

The location of these bullae at the lung bases is atypical. In most cigarette smokers with bullous emphysema, the bullae are located at the apices. The bibasilar location of the bullae in this example of emphysema suggests a specific etiology: alpha-1 antitrypsin deficiency. Consequently, we have no difficulty matching this CXR with a clinical history. It belongs to the patient with a strong family history of emphysema that developed at a relatively young age (case 1).

Confirmation of a suspicion of alpha-1 antitrypsin deficiency is easy; on a routine blood requisition form, request measurement of the alpha-1 antitrypsin level. Patients homozygous for an abnormal alpha-1 antitrypsin gene will have blood levels on the order of 10% to 15% of normal. Further specialized genetic or phenotypic testing can then be requested to identify the specific genetic abnormality, but the initial screening test simply involves a routine blood test.

Identification of the presence of alpha-1 antitrypsin deficiency as the cause of emphysema is important because alpha-1 antitrypsin infusions can be given weekly to decrease the progressive destruction of lung tissue caused by the deficiency and because family members can be advised to seek testing for the deficiency as well. Because the presence of alpha-1 antitrypsin deficiency goes largely undiagnosed, it has been recommended that all patients with COPD undergo testing once for this genetic abnormality.

The second CXR in this series (see Fig. 39.17) has evidence for hyperinflation (the diaphragms are flattened and at the level of the 11th ribs posteriorly), but it is not hyperlucent; just the opposite. It is hard to make out many details on this film, other than to say that it is not what we would expect in obstructive lung disease because of asthma or COPD. Close-up inspection helps somewhat (Fig. 39.20); it appears that the increased markings are caused by thickened walls of cystic spaces (and, incidentally, a very opaque linear shadow suggests a surgical clip, also seen at the left lung base). Potential etiologies of diffuse cystic lung disease that come to mind include emphysema, Langerhans cell histiocytosis, and LAM. Further evaluation is likely to include a chest CT scan, as shown in Fig. 39.21.

On the CT scan, loculated pneumothoraces are visible on the right and the myriad bilateral cystic spaces are dramatically demonstrated. The cyst walls are very thin, barely detectable in some instances, as is typical in emphysema and LAM. In this young nonsmoker with a history of recurrent pneumothoraces and chylous pleural effusion (case history 3), the likely diagnosis is LAM.

• **Fig. 39.20** Obstructive lung disease, chest x-ray 2: close-up view of right midlung zone.

• **Fig. 39.21** Chest CT scan with multiple thin-walled cysts and loculated right pneumothoraces.

LAM is a distinctive disorder characterized by neoplastic-like proliferation of abnormal smooth muscle–like cells along small airways and alveolar walls. It is part of a broader syndrome of abnormalities, tuberous sclerosis complex, for which genetic defects have been identified (mutations of a tuberous sclerosis gene, *TSC1* or *TSC2*). It occurs exclusively in women of childbearing age, suggesting a strong hormonal influence, and it commonly progresses to severe airflow obstruction and respiratory failure. Traditional therapies (oophorectomy and antiestrogen medications) have proved of limited benefit. In an exciting development, a recent randomized trial found that sirolimus slows the progression of airflow obstruction in LAM.

There is something very wrong with the next CXR (see Fig. 39.18)! It is either displayed in reverse (left side inverted to the right), or the patient has dextrocardia. If there were gas in the stomach, the location of gastric lucency (“stomach bubble”) under one of the diaphragms would indicate whether or not the dextrocardia were part of more generalized situs inversus.

Looking beyond this most striking finding, one can also note an abnormality of the lung parenchyma. The normal silhouette made by aerated lung tissue abutting the right ventricle (now on the right side of the film) has been lost. The heart margin is indistinct, and there are increased non-homogeneous opacities in the region of the adjacent lung tissue. The appearance suggests a possible pneumonia, but with additional information we find that the abnormality is unchanging and identical on prior chest films over a period of years. In a patient with symptoms of airway disease (chronic productive cough and intermittent wheezing), the possibility of bronchiectasis comes to mind. The radiographic opacities in bronchiectasis are caused by thickened airway walls and inflammation/infection in surrounding (peribronchial) lung tissue, often with associated atelectasis.

This combination of dextrocardia and bronchiectasis may trigger a synapse: primary ciliary dyskinesia (Kartagener syndrome). Manes Kartagener described patients with situs inversus, bronchiectasis, and chronic sinusitis; men with this syndrome have immotile or dysmotile sperm and consequent infertility. The pathogenesis of this syndrome has been explicated: abnormal ciliary function underlies all its manifestations. As a result, alternative names for this syndrome are used, including immotile cilia syndrome and, more precisely, primary ciliary dyskinesia. Primary ciliary dyskinesia is inherited as an autosomal recessive disorder. In some examples of this molecularly heterogeneous syndrome, an ultrastructural abnormality can be identified on electron microscopy of ciliated epithelial cells (obtained on nasal or bronchial biopsy) or of the tails of sperm. Absence of the dynein arm connecting adjacent microtubule doublets in the spoke-and-wheel architecture of cilia is the classic finding.

Confirmation of a diagnosis of primary ciliary dyskinesia has traditionally been made by electron microscopic examination of cilia on nasal or bronchial mucosal biopsies (or, in men, on evaluation of sperm motility and structure). Measurement of nasal nitric oxide (NO) is by a screening tool available in specialized centers, because patients with primary ciliary dyskinesia have a very low nasal NO concentration compared with persons with bronchiectasis of other etiologies. With recognition of the genetic basis for the many protein abnormalities causing functional as well as structural impairment of normal ciliary action, genetic testing is becoming a cost-effective method of diagnosis in certain centers.

The history that best matches this x-ray is case 2, a patient with a chronic productive cough and recurrent

sinusitis since childhood, now presenting for evaluation of infertility. The breast shadows seen on this CXR suggest that the patient is a woman. Some women with primary ciliary dyskinesia have infertility, presumably caused by ciliary dysfunction in the fallopian tubes.

By way of “full disclosure,” although this patient has airway disease and we have included bronchiectasis in our discussion of obstructive lung diseases, it is possible that this patient will not have significant airflow obstruction on pulmonary function testing. Localized bronchiectasis may have little impact on lung function, or it may manifest as restriction because of lung destruction, consolidation, and/or atelectasis.

The final CXR (see Fig. 39.19) is one of our most striking. Like the second film in this series (see Fig. 39.17), it has the unusual combination of hyperinflation and widespread parenchymal opacities. On closer inspection, these opacities have some distinctive features. First, they are distributed more in the upper lobes than in the lower lobes. Second, they appear generally aligned in the same orientation as the bronchovascular bundles, radiating out from the hila in “northwesterly” (in the right upper lobe) and “northeasterly” (in the left upper lobe) directions. Third, on close inspection one can make out cysts within these opacities, some of which are oval and share the same general orientation described previously. In fact, these are bronchi with cystic dilatation: cystic bronchiectasis. You have likely made a diagnosis already, based on the history (case 4) of weight loss, chronic diarrhea, and sinusitis, with mucoid *Pseudomonas* grown on sputum culture. This is an example of cystic fibrosis. Its upper lobe predominance puts it in a relatively small group of chronic lung diseases manifesting bilateral upper more than lower lobe opacities, including sarcoidosis, ankylosing spondylitis, and tuberculosis (and other chronic granulomatous infections).

Cystic fibrosis is recognized with increasing frequency among adults, not only because children with the disease are living longer (average age of survival is now projected into the mid-to-late 30s) but because variant forms of cystic fibrosis exist that can first manifest in adulthood. Often, chest disease (bronchiectasis) is the dominant manifestation of adult-onset cystic fibrosis. Diagnosis can be established by specialized genetic testing (with more than 100 abnormal alleles now identified in the cystic fibrosis transmembrane conductance regulator gene) or by the traditional sweat chloride test (sweat chloride level >60 meq/L).

## Mechanical Ventilation

JOSHUA A. ENGLERT

Patients receive mechanical ventilation for a variety of reasons. The general practitioner should understand the broad categories for initiation of mechanical ventilation as well as be able to determine when a patient can be liberated from a ventilator. The majority of this chapter focuses on the common modes of ventilation, the difference between pressure-cycled and volume-cycled breath delivery, and how these different modes are monitored. A brief discussion of the use of noninvasive positive-pressure ventilation is also included.

### Indications for Mechanical Ventilation

Patients may require mechanical ventilatory support for a variety of reasons (Box 40.1). These can be broadly categorized as impaired oxygenation (low partial pressure of oxygen [ $\text{PaO}_2$ ]), impaired alveolar ventilation (increased partial pressure of carbon dioxide [ $\text{PaCO}_2$ ]), or both. In addition, some patients with insufficient protective reflexes require intubation for airway protection even if both oxygenation and ventilation are adequate. Although there is no absolute threshold of supplemental oxygen to determine when mechanical ventilation is indicated, if a patient cannot maintain a  $\text{PaO}_2 > 60$  mm Hg or an oxygen saturation  $> 90\%$  despite high levels of supplemental oxygen, it is appropriate to consider initiating mechanical ventilation regardless of the  $\text{PaCO}_2$ . Pathophysiologic mechanisms of hypoxemia include increased shunt, ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) mismatch, hypoventilation, and low inspired fraction of oxygen. Only shunt and  $\dot{V}/\dot{Q}$  mismatch result in a widened alveolar-arterial (Aa) gradient. Common causes of hypoxemic respiratory failure include acute respiratory distress syndrome (ARDS), cardiogenic pulmonary edema, and pneumonia.

Inadequate alveolar ventilation causes progressive hypercarbia and an elevated  $\text{PaCO}_2$ . In this situation, hypoxemia is caused by a decrease in the alveolar oxygen concentration and not an increased Aa difference. Ventilatory failure can result from inadequate respiratory drive, mechanical impairment of the chest wall, neuromuscular disease, or increased airway resistance. Hypoventilation and respiratory failure may result from an overdose of drugs (e.g., opiates) that impair central nervous system (CNS) respiratory centers.

Mechanical restriction of the chest wall can be the result of severe kyphoscoliosis or morbid obesity, although this is usually a more chronic process. Patients with neuromuscular weakness (e.g., Guillain-Barré syndrome, amyotrophic lateral sclerosis) may not be able to maintain adequate alveolar ventilation especially in the setting of increased demand on the respiratory system as frequently occurs in the setting of acute metabolic acidosis due to sepsis or acute kidney injury. Perhaps most commonly, patients with exacerbations of underlying obstructive lung disease can present with ventilatory failure requiring mechanical ventilation. Patients with severe asthma can develop acute respiratory failure caused by a sudden, marked increase in airway resistance, and patients with chronic obstructive pulmonary disease can present with acute chronic respiratory failure caused by concurrent illnesses such as a viral upper respiratory tract infection or bacterial bronchitis.

As noted previously, some patients require endotracheal intubation not for support of oxygenation or ventilation but because of a need to “protect the airway.” The loss of protective airway reflexes is an indication for endotracheal intubation to prevent aspiration of gastric or oral secretions into the lower respiratory tract. In addition, some patients with massive hemoptysis or hematemesis may require endotracheal intubation despite having intact airway reflexes to prevent the aspiration of large amounts of blood into the lower respiratory tract.

### Role of Respiratory System Mechanics

Patients are supported with mechanical ventilation for a variety of reasons, often in complex clinical scenarios with multiple etiologies for respiratory failure. Measuring a patient’s airway resistance and respiratory system compliance can be a helpful way to tease out the underlying pathophysiologic process (or processes). Similarly, these parameters can be used to assess response to therapy or to help understand sudden changes in a patient’s respiratory status while being supported with mechanical ventilation.

Compliance is a measure of distensibility, the change in volume that occurs in response to a change in pressure. Although we often refer to compliance of the lung, this value actually reflects the distensibility of the respiratory

system as a whole, including the lungs and the chest wall. Airway resistance opposes the flow of gas; the more resistance, the greater the driving force required to move air. Airway resistance is predominantly dependent on the caliber (radius) of the airways. Once again, for patients on a ventilator, airway resistance not only encompasses the trachea, main stem bronchi, smaller bronchi, and bronchioles, but also the endotracheal tube and the tubing connecting the patient to the ventilator.

To move air into the chest, the ventilator must overcome both the compliance of the respiratory system and the airway resistance. The peak inspiratory pressure (PIP) reflects the force required to overcome both components. If airflow is eliminated, there is no airway resistance, and the remaining pressure (i.e., plateau pressure) is a reflection of what is needed to overcome compliance alone. The plateau pressure is measured by performing an inspiratory pause during which all airflow is stopped and the lung volume is held steady (Fig. 40.1).

Knowing the tidal volume delivered by the ventilator ( $\Delta V$ ) and the resultant pressures ( $\Delta P$ ) enables calculation of the respiratory system compliance ( $\Delta V/\Delta P$ ). The  $\Delta V$  is measured as the tidal volume (in milliliters) and the  $\Delta P$  as the difference between the plateau pressure (in centimeters  $H_2O$ ) and the positive end-expiratory pressure (PEEP). Based on Ohm's law ( $V = IR$ ), the equation for airway resistance is  $R = \Delta P/\text{flow}$ . In this case, the change in pressure is the difference between the PIP and the pressure when flow is halted with an inspiratory pause (i.e., plateau pressure). The flow (measured in liters per second) is a value that is set by the clinician on the ventilator. It is usually reported

in liters per minute and needs to be converted to liters per second before any calculations.

$$\text{Compliance} = \Delta V/\Delta P = V_t/(\text{Plateau} - \text{PEEP})$$

$$\text{Resistance} = \Delta P/\text{flow} = (\text{PIP} - \text{Plateau})/\text{flow}$$

Normal airway resistance, while on a ventilator, is usually  $<5$  cm  $H_2O/L/s$ . Normal respiratory system compliance is  $>50$  mL/cm  $H_2O$ .

Determination of airway resistance and respiratory system compliance is useful in making an initial diagnosis but perhaps even more helpful as a way of assessing an acute change in a patient. If a patient suddenly has an increased PIP, it is important to determine if this is because of a fall in compliance, an increase in resistance, or both. A sudden fall in compliance may be caused by a pneumothorax or because of migration of the endotracheal tube into the right main stem, resulting in delivery of the same tidal volume to only one lung instead of two. Increased airway resistance can have a variety of causes including acute bronchospasm, kinking of ventilator tubing, or secretions in the endotracheal tube. Another common reason for a sudden increase in PIP is patient agitation resulting in dyssynchrony with the ventilator and patient exhalation while the ventilator delivers a breath. A more complete list of common causes of increased resistance and decreased compliance is included in Table 40.1.

## Modes of Ventilation

There are several different modes of ventilation that determine the way breaths are initiated and the pattern of breath delivery over time (Table 40.2). The most commonly used modes are assist control (AC) and pressure support. For both modes, the PEEP and the fraction of inspired oxygen ( $FiO_2$ ) are set by the clinician, and the major differences are in how each breath is initiated and the pattern of breath delivery over time.

In AC ventilation, the patient triggers the ventilator to deliver a fully supported breath. In this mode, a minimum respiratory rate is set, and if the patient breathes at a rate above that level, each additional breath is fully supported. Therefore the patient's actual respiratory rate will only match the set respiratory rate if he or she is not

### • BOX 40.1 Potential Indications for Invasive Mechanical Ventilation

- Severe hypoxemia ( $PaO_2 < 60$  mm Hg or  $O_2$  saturation  $< 90\%$ ) despite high concentrations of supplemental oxygen
- Respiratory acidosis with a  $pH < \pm 7.25$  (or progressive respiratory acidosis unlikely to improve rapidly)
- Insufficient reserve to maintain ventilation in the setting of increased work of breathing
- Respiratory and/or cardiopulmonary arrest
- Inability to protect airway
- Failure of noninvasive positive-pressure ventilation

• **Fig. 40.1** Pressure-time curve from a volume-cycled breath. The peak inspiratory pressure (PIP) is determined by the resistance of the airways, the compliance of the respiratory system, and the inspiratory flow rate. In contrast, the plateau pressure is determined by pausing at the end of inspiration and solely reflects the compliance of the respiratory system. The baseline pressure is the set positive end-expiratory pressure (PEEP).

spontaneously initiating breaths. In the AC mode, breaths can either be volume targeted, which refers to the fact that the ventilator cycles between inspiration and exhalation once a set tidal volume has been delivered, or pressure targeted, in which the ventilator cycles between inspiration and exhalation once a set pressure has been reached. The term *volume targeted* is often used interchangeably with *volume cycled*, and the same is true for *pressure-targeted* and *pressure-cycled* ventilation.

Frequently, clinicians use the term *AC ventilation* to refer to AC volume-cycled ventilation. In this mode, inspiration ends once the set  $V_t$  has been reached and the independent variables set by the clinician are the  $V_t$  and flow rate along with the respiratory rate, PEEP, and  $FiO_2$ . The PIP and plateau pressure are dependent variables that are the result of the  $V_t$ , respiratory system compliance, and airway resistance. In this mode, the minute ventilation, which is the product of the tidal volume and the respiratory rate ( $V_t \times RR$ ), is guaranteed.

**TABLE 40.1 Causes of Increased Peak Inspiratory Pressures**

Increased resistance	Bronchospasm Kinked ventilator tubing Secretions in airways, endotracheal tube, or ventilator tubing Patient biting the endotracheal tube Airway edema
Decreased compliance	Right main stem intubation Large mucous plug → lobar collapse Pneumothorax Worsening airspace disease: ARDS, pneumonia Pulmonary edema
Agitation	Dyssynchrony with the ventilator

ARDS, Acute respiratory distress syndrome.

When AC ventilation is used for pressure-targeted breaths, the term *pressure control ventilation* (PCV) is frequently used. In this mode, the independent variable is the inspiratory pressure specified by the clinician, and the tidal volume is the dependent variable determined by the intrinsic properties of the respiratory system. With a pressure-targeted AC mode (i.e., PCV), the volume delivered with each breath (and therefore the total minute ventilation) is not assured, given that it depends on the lung compliance and the airway resistance.

There are no data demonstrating superiority of either pressure-targeted or volume-targeted breath delivery with respect to mortality or liberation from the ventilator. They can both achieve adequate oxygenation and ventilation in most scenarios. The main advantage of volume-targeted ventilation is that a minimum minute ventilation can be guaranteed because both a tidal volume and a minimum respiratory rate are set by the clinician. Volume-targeted breath delivery also makes it easier to assure low tidal volumes are maintained in conditions such as ARDS. Pressure-targeted ventilation, on the other hand, has the advantage of being able to limit airway pressures, but tidal volume can vary with changes in the mechanical properties of the lungs and airways. It also allows variability in flow rates and patterns that may result in greater patient comfort. It is difficult, however, to predict which ventilator settings will be most comfortable for an individual patient because significant variability occurs.

In contrast to AC ventilation, pressure support ventilation (PSV) is a spontaneous mode and used only when a patient is awake enough to initiate breaths. In this mode, the independent variable that must be set is the inspiratory pressure, which is triggered by and delivered with each patient-initiated breath. Each breath is terminated when the flow diminishes to a preset percentage of the peak inspiratory flow rate, usually 25%. Although the positive pressure decreases the patient's work of breathing, the patient

**TABLE 40.2 Modes of Ventilation**

Mode	Clinical Use	Independent Variables (Set by the Clinician)	Dependent Variables (Determined by Intrinsic Properties of the Lung)
Volume AC	Full ventilatory support	Minimum respiratory rate, tidal volume	Peak inspiratory pressure, plateau pressure
PCV	Full ventilatory support	Minimum respiratory rate, inspiratory time or inspiratory to expiratory (I:E) ratio, peak inspiratory pressure	Tidal volume, minute ventilation
PSV	Weaning or partial ventilatory support	Peak inspiratory pressure	Respiratory rate, tidal volume, minute ventilation
SIMV	Full or partial ventilatory support	Respiratory rate, tidal volume (for fully supported breaths), peak inspiratory pressure (for patient-triggered breaths in patients also receiving PSV)	Minute ventilation, peak inspiratory pressure, plateau pressure

AC, Assist control; PCV, pressure assist ventilation; PSV, pressure support ventilation; SIMV, synchronized intermittent mandatory ventilation.

determines the flow rate, inspiratory time, tidal volume, and respiratory rate. Many clinicians believe that this mode is more comfortable for patients who are awake and alert, and it is commonly used when a patient is clinically improving and moving toward extubation. The disadvantage of this mode is that the minute ventilation is not guaranteed, and it is not suited for a patient with waxing and waning respiratory drive (e.g., patients who are deeply sedated or who have suffered CNS injury). PSV may also be inappropriate when, despite an intact CNS drive to breathe, the patient lacks sufficient muscular strength to reliably generate adequate tidal volumes (e.g., with neuromuscular disorders).

There are several other, less commonly used ventilator modes including airway pressure release ventilation, bilevel ventilation, and volume-targeted pressure-cycled ventilation. These advanced modes are beyond the scope of this chapter.

## Discontinuation of Mechanical Ventilation

The longer a patient is intubated, the greater the risk of complications associated with mechanical ventilation including nosocomial infection, deconditioning, and prolonged sedation. Although mechanical ventilation is often life saving, it also has the potential to cause lung injury known as *ventilator-induced/associated lung injury*. Therefore it is imperative to try to extubate patients as soon as safely possible. Traditionally, it was felt that patients with respiratory failure required gradual weaning from mechanical ventilation until they could breathe spontaneously. More recently the term *weaning* has fallen out of favor because it has become clear that most patients with respiratory failure rapidly regain the ability to breathe spontaneously, and it is the job of the clinician to determine when this occurs so that mechanical ventilation can be discontinued. To this end, patients should be assessed on a regular basis for extubation readiness. Previously, various weaning parameters were used to predict extubation readiness, and there is a substantial literature examining the use of many different parameters including the rapid shallow breathing index. Most of the data related to the use of weaning parameters were from retrospective studies and, overall the data suggest that these are not predictive of successful extubation.

When a patient has improved to a point where they can maintain adequate oxygenation ( $\text{SaO}_2 >90\%$  on  $\text{FiO}_2 \leq 40\%$ ) and ventilation ( $\text{pH} >7.3$ ), it is reasonable to consider extubation. In most situations, a patient should also be hemodynamically stable and not comatose. Patients who meet these criteria should undergo a spontaneous breathing trial (SBT) during which they breathe with minimal ventilator support or on a T-piece for 30 to 120 minutes. The amount of ventilator support used during an SBT varies by provider and institution. Some clinicians use low levels of PSV (0–5 cm  $\text{H}_2\text{O}$ ), continuous positive airway pressure (CPAP) (0–5 cm  $\text{H}_2\text{O}$ ), or both. If patients tolerate this trial without deterioration of gas exchange or hemodynamic instability, extubation can be considered. Patients

being assessed for extubation should also have an adequate cough and the ability to safely clear respiratory secretions. If a patient fails a spontaneous trial, additional workup should be pursued, including repeat measurement of respiratory mechanics, to determine the reason(s) for failure so that they can be reversed when possible.

Practices that promote regular assessments of a patient's readiness to breathe independently have been shown to decrease the duration of mechanical ventilation. Most often, these have involved the use of protocols that allow respiratory therapists and nurses to evaluate a patient's ability to breathe spontaneously at least daily, without the need for a physician order (provided specified safety parameters are met). In a randomized controlled trial of 300 mechanically ventilated patients, a daily spontaneous breathing trial resulted in fewer days of mechanical ventilation, fewer complications, and lower cost. The daily interruption of sedative drugs is also suggested as a means of hastening a patient's readiness to breathe spontaneously, and in a randomized controlled trial of 128 patients at a single center, this practice reduced both the duration of mechanical ventilator and intensive care unit (ICU) length of stay.

## Noninvasive Positive Pressure Ventilation

Not all patients require endotracheal intubation to receive mechanical ventilatory support. Noninvasive positive-pressure ventilation (NIPPV) provides positive-pressure ventilation via a variety of interfaces, typically a tightly fitting mask or nasal plugs, without the need for endotracheal intubation. The use of NIPPV can be beneficial both for hypoxemia and hypercarbia in specific clinical scenarios.

The simplest mode of noninvasive ventilation is CPAP. CPAP is most commonly used in the home setting for the treatment of obstructive sleep apnea. When used for sleep apnea, CPAP mainly acts by splinting the upper airway open. However, CPAP also has a role in acute illness in the ICU. CPAP has effects similar to PEEP in that it can recruit alveoli and thus improve oxygenation. CPAP may be particularly useful for acutely decompensated heart failure because it also has beneficial hemodynamic effects.

Bilevel positive airway pressure (BiPAP) can be thought of as a noninvasive version of pressure support ventilation. With BiPAP, the physician specifies a low pressure that is applied during expiration (i.e., expiratory positive airway pressure [EPAP]), and a high pressure that helps support inspiration (i.e., inspiratory positive airway pressure [IPAP]). The EPAP is analogous to PEEP during PSV, and the IPAP is equivalent to PEEP plus the level of pressure support. BiPAP has the same benefits as CPAP, but in addition BiPAP can be used to improve ventilation and decrease the work of breathing. Because of these features, BiPAP is indicated for the treatment of hypercapnic respiratory failure in patients with obstructive lung disease and neuromuscular weakness. Despite its benefits, NIPPV is not appropriate in all situations. Specifically,

patients who have copious secretions are not good candidates because the secretions cannot be cleared around the mask. Similarly, patients with poor mental status may be at a higher risk of aspiration without a secure airway. If NIPPV is used in a patient who is somnolent because of hypercapnia, he or she should be observed for a rapid improvement in blood gas parameters and mental status. If mental status remains poor, a more secure airway should be obtained.

## Summary

Mechanical ventilation is used when a patient develops hypoxemia, hypercarbia, or both. Ventilator settings are chosen to improve oxygenation as well as to maintain

ventilation. The different modes of ventilation and the different types of breath delivery (pressure-cycled vs. volume-cycled) are simply different ways to achieve ventilation. When a pressure-cycled mode is used, the clinician needs to monitor volumes because they are a reflection of the patient's airway resistance and respiratory system compliance. Conversely, when ventilation is maintained with a volume-cycled mode, the pressures (PIP and plateau) will be a reflection of the patient's respiratory system mechanics. When patients begin to recover from respiratory failure, they should be assessed for extubation readiness with a daily spontaneous breathing trial. Finally, patients with acute respiratory failure caused by cardiogenic pulmonary edema and obstructive lung disease may benefit from NIPPV.

## Chapter Review

### Questions

1. A 22-year-old college student with asthma presents to the emergency department with a severe flare. She had a recent upper respiratory infection and then progressive shortness of breath and wheezing. She has been using her albuterol inhaler 12 to 16 times per day. On examination, she is intubated because of extreme work of breathing and appears agitated with heart rate 135 beats per minute, blood pressure 95/47 mm Hg. There are no audible wheezes, but she is tachycardic with cool extremities. The patient's initial ventilator settings are assist control ventilation (volume-targeted):  $V_t$  450 mL, respiratory rate 16 breaths per minute,  $F_{iO_2}$  40%, PEEP 10 cm H<sub>2</sub>O. She is overbreathing at 19, and her peak airway pressures (PIPs) are 48 to 54 cm H<sub>2</sub>O. The patient is given intravenous glucocorticoids and continuous albuterol treatments. She is fully sedated with fentanyl and midazolam, although she still seems to be interacting with the ventilator and continues to have high PIPs. In addition to dyssynchrony, what do you think is contributing to the patient's high PIPs?
  - A. Increased auto-PEEP, high airway resistance, and high lung compliance
  - B. Increased auto-PEEP alone
  - C. Low airway resistance and low lung compliance
  - D. Increased auto-PEEP, high airway resistance, and low lung compliance
  - E. Low airway resistance alone
2. To adequately ventilate the patient, the next step with the patient's ventilator settings would include:
  - A.  $\downarrow V_t$  and  $\downarrow$  inspiratory flow rate
  - B.  $\uparrow V_t$  and  $\uparrow$  respiratory rate
  - C.  $\downarrow V_t$  and  $\uparrow$  inspiratory flow rate
  - D.  $\downarrow V_t$  and  $\uparrow$  expiratory flow rate
  - E.  $\uparrow$  respiratory rate and  $\uparrow$  inspiratory flow rate
3. A 62-year-old man with a history of alcohol abuse, hypertension, and chronic pancreatitis is admitted to the ICU with sepsis from cholangitis. He develops progressive hypoxemia and requires endotracheal intubation for respiratory failure. Repeat chest x-ray shows worsening bilateral airspace opacities. Physical examination is notable for bilateral crackles. Initial ventilator settings are assist control volume-targeted ventilation with a respiratory rate of 12 breaths per minute, tidal volume of 500 mL, PEEP of 5 cm H<sub>2</sub>O, and  $F_{iO_2}$  of 100%. The inspiratory flow is 60 L/min. Arterial blood gas on these settings reveals a pH of 7.32, PaCO<sub>2</sub> of 46 mm Hg, and a PaO<sub>2</sub> of 65 mm Hg. The ventilator is alarming because his PIP is elevated to 40 cm H<sub>2</sub>O with a  $P_{plat}$  35 cm H<sub>2</sub>O. Which of the following is the primary physiologic derangement and the most likely cause?
  - A. Low compliance, mucous plugging
  - B. Low compliance, ARDS
  - C. Increased resistance, mucous plugging
  - D. Increased resistance, pneumothorax
4. The patient is placed on low tidal ventilation, and his PEEP is increased. His oxygenation improves, and gradually over the course of the next several days his  $F_{iO_2}$  is decreased to 0.4, and his PEEP is weaned to 5 cm H<sub>2</sub>O. What is the best strategy to determine when mechanical ventilation can be discontinued?
  - A. Change to PSV using a pressure that maintains the current minute ventilation.
  - B. Change to synchronized intermittent mandatory ventilation so the patient can start to do some of the work of breathing.
  - C. Daily spontaneous breathing trial
  - D. Change to PSV during the day but rest on AC overnight.
  - E. Daily spontaneous breathing trial paired with interruption of sedation

### Answers

## Sepsis Syndrome

JOSHUA A. ENGLERT AND REBECCA MARLENE BARON

Sepsis is a clinical syndrome characterized by life-threatening organ dysfunction as a result of a dysregulated response to infection. According to current paradigms, sepsis arises because of the infection of a normally sterile body compartment. Infection leads to activation of the innate immune system to produce a systemic inflammatory response. This response is a necessary component of the body's defense against infection under normal conditions, but it is believed that the lack of regulation of this response is central to the sepsis syndrome. As discussed in more detail later, this dysregulated inflammatory state can lead to tissue injury and dysfunction in organs not involved in the original infectious insult. Although sepsis remains a condition with exceedingly high morbidity and mortality, recent management and treatment strategies applied early in the course of sepsis have demonstrated exciting improvements in overall outcomes.

### Definitions

In 2016 the consensus definition of sepsis was updated by an international panel of experts. Before this update (from 2001 to 2015), the definition of sepsis was based upon the conceptual framework that patients progressed from the systemic inflammatory response syndrome (SIRS; [Box 41.1](#)) to sepsis to severe sepsis to septic shock. SIRS is defined as two or more of the following: (1) fever or hypothermia, (2) tachypnea, (3) tachycardia, and (4) leukocytosis or leukopenia; it can be caused by both infectious etiologies and noninfectious causes. According to the

#### • **BOX 41.1** The Systemic Inflammatory Response Syndrome

Defined as two or more of the following criteria:

1. Temperature  $>100.4^{\circ}\text{F}$  or  $<96.8^{\circ}\text{F}$
2. Heart rate  $>90$  beats per minute
3. White blood cell count  $>12 \times 10^3$  cells/ $\mu\text{L}$  or  $<4 \times 10^3$  cells/ $\mu\text{L}$  or  $>10\%$  bands
4. Respiratory rate  $>20$  breaths per minute or  $\text{Paco}_2$   $<32$  mm Hg

$\text{Paco}_2$ , Partial pressure of carbon dioxide.

2001 consensus definition, sepsis was defined as evidence of SIRS in the presence of an infection; sepsis accompanied by organ hypoperfusion or dysfunction ([Box 41.2](#)) was termed *severe sepsis*; and septic shock occurred when sepsis was accompanied by hypotension (defined as an absolute systolic blood pressure of  $<90$  mm Hg or of 40 mm Hg less than the patient's baseline despite fluid resuscitation). There are several notable changes within the 2016 definitions. The most notable change is that the use of SIRS criteria has been eliminated from the definition because of concerns over the lack of specificity. Currently, sepsis is defined as life-threatening organ dysfunction caused by a dysregulated response to infection. Organ dysfunction is now defined by an increase of at least 2 points on the sequential organ failure assessment (SOFA) score (see SOFA score components in [Box 41.2](#)). Given that organ dysfunction is now incorporated into the definition of sepsis, the use of the term *severe sepsis* was thought to be redundant and was removed from the recommended classification of sepsis severity. Furthermore, septic shock is now defined as including vasopressor dependency (despite adequate fluid resuscitation) and a blood lactate level  $>2$  mmol/L. In addition, the 2016 consensus conference put forth the "quick" or qSOFA score to

#### • **BOX 41.2** Definition of Severe Sepsis

Severe sepsis is sepsis with evidence of organ hypoperfusion or organ dysfunction as defined by the following criteria:

##### Organ Hypoperfusion

Oliguria

Signs of abnormal peripheral circulation (e.g., mottled skin)

Altered mental status

Increased serum lactate levels

##### Organ Dysfunction

Pulmonary:  $\text{PaO}_2/\text{FiO}_2$   $<300$  mm Hg

Cardiovascular: systolic blood pressure  $<90$  mm Hg or mean arterial pressure  $<65$  mm Hg

Renal: urine output  $<0.5$  mL/kg/h despite adequate volume resuscitation

Gastrointestinal: hyperbilirubinemia

$\text{FiO}_2$ , Fraction of inspired oxygen;  $\text{PaO}_2$ , partial pressure of oxygen.

try to identify those patients in the outpatient, emergency department (ED), or ward settings with a worse predicted outcome from sepsis, that is, those patients with at least two of the following: (1) respiratory rate  $\geq 22$  per minute; (2) altered mental status (based on a Glasgow Coma Scale score of  $\leq 13$ ); and (3) systolic blood pressure  $\leq 100$  mm Hg. Of note, the qSOFA score has not yet undergone prospective validation. Furthermore, although the 2016 consensus definitions were put forth by a panel of international experts, it is important to note that these new definitions remain somewhat controversial, and not all professional societies have endorsed their use at this time.

## Epidemiology

Sepsis affects approximately 750,000 people in the United States annually and is associated with a mortality rate of 40% to 70% in its most severe form. The incidence continues to increase as the American population ages and as increasingly complex treatments are applied for conditions such as cancer and organ transplantation requiring significant immunosuppression of the host. The majority of cases occur in patients with significant comorbidities. Significant risk factors include increasing age, immunosuppression, and chronic illnesses (such as chronic obstructive pulmonary disease or diabetes mellitus). Although there are no universally agreed upon biomarkers of sepsis available for routine clinical use, various risk stratification tools, including the Acute Physiology and Chronic Health Evaluation III score and the SOFA score, can be used to quantify the severity of illness and estimate the risk of death from sepsis.

## Clinical Presentation and Diagnosis

The clinical manifestations of sepsis can vary greatly from one patient to another. Not infrequently, this variability in presentation contributes to diagnostic uncertainty in cases of sepsis, especially early in the course of illness. Difficulty in early recognition of sepsis has hampered the identification of patients who might benefit from early aggressive management as described later. All too often patients are identified further into the course of the inflammatory “storm,” by which time rescue strategies to restore adequate tissue perfusion and oxygen delivery are likely not as effective. There is no single specific diagnostic test for sepsis; rather, the diagnosis hinges on physical findings and laboratory values that point toward organ dysfunction. Moreover, early localization of the primary source of infection is critical for optimal therapy. Thus the clinician must be on the lookout for signs and symptoms attributable to the primary infection as well as to those that might reflect the inflammatory response to infection. It is equally important to keep an open mind in the diagnostic process because many patients who present with signs or symptoms of sepsis or septic shock may have alternative or concomitant diagnoses (e.g., cardiogenic or hemorrhagic shock) that explain their presentation.

As noted earlier, the four components of SIRS (see [Box 41.1](#)) were common but not requisite in sepsis, which played a role in elimination of the SIRS criteria from the 2016 consensus definition. One example of the variability in the clinical presentation is that elderly patients with sepsis often present without fever. Other common findings on physical examination include delirium, confusion, and tachypnea that might represent nonspecific effects of a variety of different possible sources of infection. Thus it is also important to search for manifestations of the primary infectious insult that might point to the primary site of infection. For example, patients with sepsis caused by pneumonia may present with fever, a productive cough, evidence of lung consolidation on percussion and auscultation of the chest, and the presence of an infiltrate on chest radiography. Sepsis originating from an infection of the urinary tract can present with dysuria, urinary frequency or incontinence, suprapubic tenderness on physical examination, and the presence of pyuria on examination of a urine specimen. An abdominal source of infection might manifest itself with nausea, vomiting, diarrhea, and/or the presence of rebound or guarding on physical examination. The wide variability in clinical presentation requires vigilance on the part of the providers caring for patients with sepsis.

Laboratory abnormalities in septic patients can sometimes help point toward a source of sepsis (e.g., elevated bilirubin and alkaline phosphatase levels in cholecystitis or cholangitis), but more often reveal nonspecific indices of infection and inflammation and possibly end-organ dysfunction (see SOFA score [Table 41.1](#), [Box 41.2](#)), including a leukocytosis with a left shift and thrombocytopenia. Patients can develop an anion gap acidosis resulting from the accumulation of lactic acid in the setting of organ hypoperfusion. In fact, an elevated lactate level (e.g.,  $>2$  mmol/L) has now been included in the 2016 consensus conference definition of septic shock and even before 2016, an elevated lactate level was viewed by many as a possible marker that should heighten suspicion for the presence of sepsis, even though the lactate level can be elevated from other causes of tissue hypoperfusion (e.g., ischemic bowel). Unfortunately, once the lactate level is elevated in sepsis, end-organ hypoperfusion and damage may already have occurred. This end-organ effect has been referred to as the *multiple organ dysfunction syndrome*, and laboratory evidence of renal and hepatic insufficiency are often hallmarks of this syndrome. In addition, coagulopathy can occur because of the development of disseminated intravascular coagulation. Hyperglycemia is a common finding among patients with underlying diabetes, and, even in patients without previously diagnosed underlying diabetes, elevated glucose levels are often seen during critical illness, likely as a result of a stress response.

In patients with suspected infection who do not manifest focal signs, symptoms, physical findings, or laboratory data pointing at the source of sepsis, a continued search must be pursued while the patient is treated with broad-spectrum antibiotics and stabilized. Cultures of blood, urine, and

From Vincent JL, Moreno R, Takala J, et al. The SOFA (sepsis related organ failure assessment) score to describe organ dysfunction/failure. On behalf of the Working Group on Sepsis-Related Problems of the European Society of Intensive Care Medicine. *Intensive Care Med.* 1996;22(7):707-710.

sputum should be obtained on presentation. Samples of fluid from other potential sources of infection should also be sent for culture as the clinical scenario dictates (e.g., spinal fluid if meningitis is suspected, or ascitic fluid if spontaneous bacterial peritonitis is a concern). If the patient's condition deteriorates on empiric antibiotic therapy without a known source of infection and/or the initial microbiological workup is negative, a more aggressive workup may be indicated including early consideration of additional imaging by CT. More invasive testing is often necessary in critically ill patients to identify (or exclude) possible sources of infection. For example, if a patient with suspected bacterial pneumonia worsens on broad-spectrum antibacterial agents, bronchoscopy with bronchoalveolar lavage to culture the pathogenic organism may be helpful.

## Pathophysiology

As described previously, sepsis can develop following microbial infection of a normally sterile cavity leading to physiologic and biochemical derangements that cause organ dysfunction. The response to a particular infection varies greatly from one individual to another. For example, it is

not uncommon for an elderly patient to present with a urinary tract infection and subsequent bacteremia as a result of translocation of the organisms into the bloodstream. Some of these patients will have a fulminant course complicated by septic shock and organ dysfunction. In contrast, other patients will remain normotensive and asymptomatic despite the circulating microbes. The predisposition of some patients to developing sepsis is likely related to a combination of genetic and environmental factors. Immune suppression, either drug-induced or caused by comorbid conditions such as malignancy or cirrhosis, weakens the host response to infection and predisposes patients toward the development of sepsis. It is likely that genetic variation also plays an important role in the response to infection, as demonstrated by studies that have shown possible differences in the risk of sepsis among individuals with polymorphisms in various genes.

The site and microbiology of the antecedent infection play a key role in the pathogenesis of this syndrome. The microbiology of sepsis has shifted over time. Before 1990 intraabdominal infections were the most common. Recently, studies have shown that pulmonary infection (i.e., pneumonia) is the most frequent source, accounting for

approximately 40% of sepsis cases. Moreover, although a large percentage of sepsis cases had traditionally been attributed to infection with gram-negative bacterial organisms, recent years have seen an increase in numbers of infections attributed to gram-positive bacteria and infections with nonbacterial organisms such as fungi or viruses. The increasing prevalence of infections with fungi and viruses has been associated with an increase in numbers of immunocompromised hosts as a result of chemotherapy treatments for cancer or immune suppression for organ transplantation or rheumatologic disease.

The host response to infection is another key determinant in the pathophysiology of sepsis. It begins when immune cells recognize and bind to pathogen-associated molecular patterns (PAMPs) on invading microorganisms. Microbe recognition by the host results in the release of numerous proinflammatory cytokines that further recruit neutrophils and other immune cells to the infected site. Cytokines that are thought to be important to the proinflammatory response include, but are not limited to, tumor necrosis factor (TNF)- $\alpha$ , and interleukin (IL)-1 $\beta$ . The proinflammatory response can help to limit the inciting infection but can also lead to injury of tissues not involved in the initial infection. This injury can lead to the release of damage-associated molecular patterns (DAMPs) from damaged or dying cells that can propagate further organ dysfunction. Examples of DAMPs include extracellular high-mobility group B-1, mitochondrial DNA, and extracellular ATP. Following the production of proinflammatory cytokines, it has been proposed that the host can develop a compensatory response through production of antiinflammatory cytokines such that a period of relative immune compromise or immunoparalysis for the host can develop later in the septic response.

Other key components of the host response to sepsis include activation of the coagulation and neuroendocrine systems. Endothelial damage leads to expression of tissue factor and subsequent activation of the clotting cascade, followed by the formation of thrombin. Some experts hypothesize that this process may play a role in containing invading pathogens. Deficiency of several fibrinolytic proteins, including protein C, further enhances the procoagulant milieu. To this end, recombinant human activated protein C (rhAPC) was previously used as a treatment for patients with severe sepsis and a high risk of death, but a randomized trial of rhAPC versus placebo (PROWESS-SHOCK trial) failed to demonstrate a benefit, and rhAPC was ultimately removed from the market. The stress response also results in the development of peripheral insulin resistance and hyperglycemia, as well as an activation of the hypothalamic-pituitary axis and secretion of a number of key hormones including adrenocorticotrophic hormone (ACTH) and vasopressin. Insufficient production of these hormones during sepsis has led to the concept that critical illness might result in states of relative adrenal insufficiency and vasopressin deficiency, respectively. Management strategies that have arisen in

response to the appreciation of these pathophysiologic processes are discussed in more detail subsequently.

As described earlier, sepsis is defined as life-threatening organ dysfunction in response to infection, but the mechanisms of organ dysfunction remain unknown. Tissue hypoperfusion as a result of hypotension and vasodilatation likely plays an important role. Moreover, significant interest has arisen in the concept of microcirculatory dysfunction as an important contributor to this process. Inflammation and a local activation of clotting mechanisms are needed to combat infection as described previously, but if left unchecked these processes can lead to progressive organ dysfunction. Thrombosis of the microvasculature can lead to shunting of blood flow away from vital organs and result in impaired local oxygen delivery to the tissues. As an alternative or perhaps coexisting phenomenon, inability of the tissues to use delivered oxygen as a result of the development of mitochondrial dysfunction has been proposed as a possible mechanism of organ dysfunction.

## Management

### Early Management

The prompt recognition and treatment of sepsis is necessary to correct metabolic derangements, optimize oxygen delivery, and prevent the development of organ dysfunction. The initial approach to the patient involves stabilization with a focus on maintaining adequate circulation, securing the airway (if necessary), and ensuring adequate oxygenation and ventilation. Endotracheal intubation and support with mechanical ventilation is necessary for those patients who are unable to protect their airway or for those that present with an inability to sustain adequate oxygenation or ventilation. Assessment of the blood pressure, pulse, and signs of perfusion as described earlier is important to ensure adequate circulation. Obtaining early intravenous access with large-bore peripheral catheters and/or central venous catheters is critical for the facilitation of aggressive volume resuscitation and administration of medications.

### Source Control

A key component in the management of patients with sepsis is controlling the source of the infection. This requires the early administration of broad-spectrum antibiotics as well as drainage or removal of any sources of infection. Examples of infectious sources requiring removal/drainage include infected venous catheters, soft tissue abscesses, and empyema (Table 41.2). It is recommended that broad-spectrum antibiotics to cover all suspected sources of infection be administered as soon as possible and ideally within the first hour of presentation; each hour of delay in antibiotic treatment has been associated with an increased mortality rate. If cultures reveal a specific organism, the antibiotic regimen

can be tailored accordingly. Recommended duration of antibiotic therapy varies greatly depending on the initial source and severity of infection.

### Initial Resuscitation

Early optimization of tissue perfusion and oxygen delivery is a critical step in the management strategy of septic patients. In a landmark randomized, single-center trial, Rivers and colleagues demonstrated a 16% absolute reduction in in-hospital mortality using a protocolized resuscitative strategy (i.e., early goal-directed therapy [EGDT]) targeted to achieve specific goals in a number of parameters (e.g., central venous pressure, mean arterial pressure, and central venous oxygen saturation). One important way in which this trial was unique compared with previous studies is that the resuscitative strategy was applied within the ED during the first 6 hours of the patient's care. Analysis of the study revealed that all subjects received about 13 L of fluid within the first 72 hours of their course, but the subjects randomized to EGDT received significantly more fluids in the first 6 hours of their course. This feature was thought to be an important contributor to the beneficial outcome. In addition to focusing on early administration of intravenous fluids, the EGDT protocol also used red blood cell transfusions and inotropes to maximize tissue oxygen delivery. Over the years, debate has persisted as to which components of the EGDT protocol were responsible for the mortality benefit demonstrated in the initial trial. Recently in 2014 to 2015, three large, multicenter trials (ProCESS, ARISE, and ProMISE) failed to find a difference between protocolized care for septic patients in the ED compared with usual care. Of note, mortality in the usual care group has declined substantially since 2001, suggesting that usual care may have evolved over time. Most intensivists agree that early recognition of sepsis, early antibiotic administration, and early-targeted volume resuscitation remain critical when caring for septic patients. Resuscitation goals remain the subject of debate, but studies have suggested that monitoring lactate clearance is a useful marker of organ perfusion during the initial resuscitation and is a more practical parameter from

a monitoring standpoint (compared with central venous oxygen saturation) in not requiring central access for its measurement.

Numerous trials support the most recent consensus guidelines that recommend crystalloids as the first-line choice for fluid resuscitation in sepsis. Within the initial resuscitation phase, it is recommended that volume expansion be administered in rapidly infused boluses as opposed to continuous infusion. This allows the clinician to monitor the physiologic response to each bolus and to assess whether organ perfusion is improving. If resuscitation efforts fail to normalize the mean arterial blood pressure or restore organ perfusion, vasopressor therapy is indicated. The choice of vasopressor in sepsis has also been examined in multiple clinical trials. Most trials have not shown significant differences in outcomes with the use of different vasopressor agents although the use of dopamine is associated with increased rates of arrhythmia compared with other agents. Consensus conference guidelines recommend norepinephrine as a first-line agent and vasopressin as an adjuvant pressor in patients who remain hypotensive despite norepinephrine administration. Another option is to try to limit use of higher doses of norepinephrine that might have adverse consequences on tissue perfusion.

### Corticosteroids

One recurring controversy in the management of septic patients is the use of corticosteroids. Given that the activation of inflammatory pathways plays a key role in the pathophysiology of sepsis, it seems logical that inhibiting these pathways could prevent the development of end-organ damage. However, several trials of high-dose steroids in septic patients have demonstrated that this strategy did not improve outcomes. Although high-dose steroids are not effective for treating sepsis, there were data to suggest that low-dose steroids (e.g., hydrocortisone, 50 mg intravenously every 6 hours) might be beneficial in a subset of patients with relative adrenal insufficiency. In a randomized, placebo-controlled trial by Annane et al. of hydrocortisone and fludrocortisone in 300 patients with hypotension, despite use of fluids and vasopressors, 28-day mortality was significantly lower in a subgroup of patients who did not respond to an ACTH stimulation test with an increase in cortisol of at least 9 µg/dL (termed *nonresponders*). Of note, there was no significant difference in the primary end point (i.e., 28-day mortality) when all patients (responders and nonresponders) were included in the analysis. This study led to increased use of corticosteroid treatment for septic patients with no response to a 250-µg ACTH stimulation test. More recently, a larger trial of corticosteroids (hydrocortisone alone without addition of fludrocortisone) in patients with septic shock demonstrated no significant difference in 28-day mortality in the entire study population, nor in the nonresponder subgroup of patients who did not have an appropriate increase in

**TABLE 41.2** Examples of Sources of Infection Requiring Intervention in Addition to Antibiotic Therapy

Source of Infection	Procedure
Soft tissue abscess	Surgical or percutaneous drainage
Empyema	Chest tube placement or surgical evacuation
Cholangitis	ERCP with biliary decompression
Catheter- or device-related bacteremia	Remove the infected catheter/device
Septic arthritis	Arthrocentesis ± debridement
Endocarditis/valvular abscess	Consider valvular replacement

ERCP, Endoscopic retrograde cholangiopancreatography.

serum cortisol following stimulation with ACTH (CORTICUS trial). Notably this population of patients was less sick overall than the group included in the trial by Annane et al., in that the CORTICUS trial included patients who had restored adequate perfusion parameters with fluids and vasopressors. Hydrocortisone treatment led to faster reversal of shock in patients in whom shock was ultimately reversed, but there was also a suggestion of increased rates of infection with steroid administration. Thus although significant debate still exists regarding the role of low-dose steroids in septic shock, the most recent consensus guidelines have suggested that low-dose hydrocortisone be considered only for patients who remain hypotensive after fluid and vasopressor administration and that use of an ACTH stimulation test does not predict who might benefit from low-dose steroids.

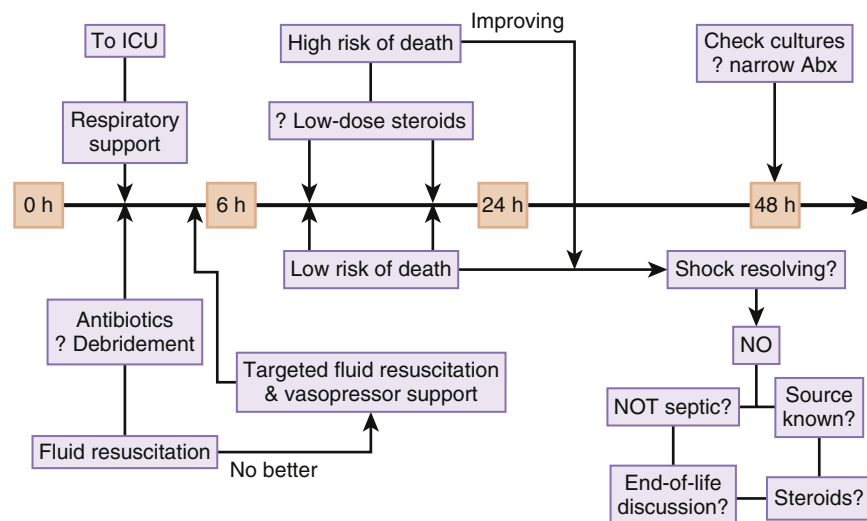

### Glucose Control

Given the high frequency of hyperglycemia in critically ill patients, there have been many studies examining whether restoration of euglycemia improves outcomes from sepsis. One notable study of patients in a surgical intensive care unit (ICU) showed improved mortality when intensive insulin therapy was used to lower glucose levels to the range of 80 to 110 mg/dL. A subsequent study of all patients in a medical ICU (i.e., patients with sepsis as well as other diagnoses and who were assumed to require at least 3 days of ICU-level care) showed no improvement in overall mortality with intensive insulin therapy. Although subgroup analysis revealed a benefit of intensive insulin therapy for patients who required a medical ICU stay of longer than 3 days, the subgroup of patients in the ICU for <3 days exhibited an increased mortality rate. In 2009
